Abstract

Pre-mRNA splicing is an essential step in the process of gene expression in eukaryotes and consists of the removal of introns and the linking of exons to generate mature mRNAs. This is a highly regulated mechanism that allows the alternative usage of exons, the retention of intronic sequences and the generation of exonic sequences of variable length. Most human genes undergo splicing events, and disruptions of this process have been associated with a variety of diseases, including cancer. Hepatocellular carcinoma (HCC) is a molecularly heterogeneous type of tumor that usually develops in a cirrhotic liver. Alterations in pre-mRNA splicing of some genes have been observed in liver cancer, and although still scarce, the available data suggest that splicing defects may have a role in hepatocarcinogenesis. Here we briefly review the general mechanisms that regulate pre-mRNA splicing, and discuss some examples that illustrate how this process is impaired in liver tumorigenesis, and may contribute to HCC development. We believe that a more thorough examination of pre-mRNA splicing is still needed to accurately draw the molecular portrait of liver cancer. This will surely contribute to a better understanding of the disease and to the development of new effective therapies.

Key words: Cell signalling; Hepatocarcinogenesis; Pre-mRNA splicing; Splicing factors; Targeted anticancer therapy

Peer reviewer: Thérèse Tuohy, MS, PhD, High Risk Cancer Clinics, Huntsman Cancer Institute, University of Utah, Salt Lake City, UT 84112, United States

INTRODUCTION

Hepatocellular carcinoma (HCC) is a deadly disease, and is currently ranked as the fifth most common cancer worldwide[1]. Most cases of HCC emerge on a background of chronic liver injury and inflammation induced by viral infection (hepatitis B and C viruses), chronic alcohol abuse, exposure to hepatotoxins (such as aflatoxin B), and genetic or metabolic conditions (such as haemochromatosis, 1-antitrypsin deficiency, obesity or diabetes)[2]. The end-stage of chronic liver disease is liver cirrhosis, characterised at the histological level by the massive deposition of extracellular matrix in fibrous septa that surround regenerative nodules. In these regenerative

nodules, partially dedifferentiated hepatocytes are driven by a pro-inflammatory milieu to divide in an attempt to restore the lost functional mass, frequently giving rise to foci of dysplastic cells[3,4]. Accumulating evidence indicates that this microenvironment favours the development of mutations and genetic alterations that are at the origin of the malignant transformation of the liver[5-7]. In view of this, chronic hepatitis and cirrhosis are considered as pre-neoplastic conditions. Nevertheless, a small but sizeable proportion of HCCs develop in normal liver tissues, in the absence of any known risk factor for liver cancer. The mechanisms leading to cancer in this small but sizeable minority of HCC cases are not known[1].

HCCs are complex tumors from the molecular point of view[8,9]. Over the past decade many efforts have been made to identify the molecular alterations that take place during the development of HCC. High throughput array-based techniques evaluating gene expression profiles have provided valuable clues for the identification of key molecular pathways driving the neoplastic conversion of the liver[10-12]. Such studies have significantly contributed to the definition of accurate prognostic genetic signatures, and to the identification of relevant therapeutic targets, some of which are currently being validated in the clinical setting[13-15]. However, conventional microarray approaches are not robust enough to detect the subtle differences in the transcriptome that arise through alternative splicing mechanisms, and therefore potentially relevant alterations involved in the carcinogenic process can be missed[16,17]. Indeed, a large proportion of the diversity within the transcriptome is generated by alternative splicing, a mechanism through which multiple mRNAs and structurally different proteins can be produced from a single gene and that may affect more than 70% of human genes[18,19]. The protein products generated by alternative splicing can have different or even antagonistic biological roles, and therefore their relative levels may impact significantly on cell function. Alterations in mRNA splicing are important cause of disease, as illustrated by the fact that single-point mutations affecting splicing represent at least 15% of all disease-causing point mutations[20]. The relationship between alternative splicing and cancer has also been clearly established, cancer-specific splice variants and cancer-associated changes in the relative levels of spliced isoforms of genes with an established role in carcinogenesis have been observed[21-25]. Moreover, in some cases the pro-tumorigenic effects of these changes have been directly demonstrated, and the mechanisms leading to the appearance of these tumor-associated alterations in normal mRNA splicing are now being elucidated[24,25]. Together these findings attest to the importance of dysregulated pre-mRNA splicing in cancer. However, compared to other types of tumors, less information is available on the disruption of normal splicing in liver cancer and its biological significance. Here we discuss representative cases that illustrate the importance that perturbations in this process may have from the early stages of hepatocarcinogenesis.

OVERVIEW OF THE BASIC MECHANISMS OF PRE-MRNA SPLICING AND ITS REGULATION

Most eukaryotic pre-mRNAs contain noncoding sequences (introns) that need to be removed to generate the correct concatenation of exonic sequences[18,19]. Introns represent more than 90% of the length of pre-mRNAs, and the spliceosome, a complex nuclear machine, needs to accurately identify specific nucleotide sequences at intron-exon boundaries to carry out intron excision and exon joining. The spliceosome is composed of five types of small nuclear ribonucleoproteins (snRNPs), plus a large number of ancillary proteins. This complex is able to recognize a 5' donor splice site beginning with a GU dinucleotide, and a 3' acceptor site ending with an AG dinucleotide at the boundaries of introns, as well as the so-called branching sequence that precedes the 3' acceptor site. The 5' splice site is recognized by the U1 snRNP, while the branching sequence and the 3' acceptor site are recognized and bound by the U2 snRNP and the auxiliary factor U2AF, respectively (Figure 1A)[21]. Subsequent interaction with the U4, U6 and U5 snRNPs leads to the formation of the catalytically active complex that carries out the trans-esterification reactions, resulting in the cleavage and religation of the mRNA chain.

The accurate excision of introns requires the recognition of the above-mentioned consensus sequences that identify the splice sites[26]. Deviations from these consensus sequences generate weak sites that have less affinity for their respective snRNPs, resulting in less efficient exon recognition and therefore allowing the alternative selection of exons[21,24]. In these cases an additional class of sequence elements present both in introns and exons may come into play and modulate the selection of splice sites by the spliceosome machinery. These sequences, known as splicing enhancers and silencers, are short conserved elements of about 10 nucleotides that can enhance or repress exon recognition. The specific binding of a wide range of splicing regulatory proteins, such as SR proteins and heterogeneous nuclear ribonucleoproteins (hnRNP), to these elements in pre-mRNAs influences (positively or negatively) the placement of the spliceosome on the appropriate splice sites (Figure 1B). This mechanism allows the facultative use of weak splice sites and mediates the generation of alternatively spliced mRNAs[19,24]. Nevertheless, many if not all exons contain exonic splicing enhancers that tend to be clustered around splice sites, and these elements are of particular high density within constitutive exons. As discussed by Jensen *et al*[26], this suggests that enhancers are important for the control of constitutive exon splicing, even in the presence of consensus splice sites. Exonic splicing silencers also help to define exon boundaries, and strongly affect splicing when there are cryptic or multiple splice sites of similar strength. These elements are thought to play a more prominent role in the control of alternative splicing[26,27]. Figure 2 summarizes

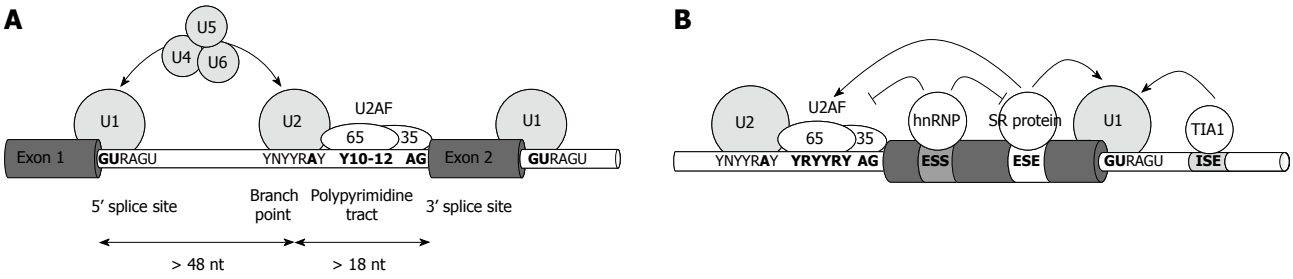

Figure 1 Splicing consensus sequences and interactions with small nuclear ribonucleoproteins (snRNPs), SR proteins and heterogeneous nuclear ribonucleoproteins (hnRNPs). A: Arrangement of donor and acceptor sites in a eukaryotic gene and interaction with snRNPs during splicing. Core elements necessary for pre-mRNA splicing include the 5' and 3' splice sites and a branch point sequence and a polypyrimidine-rich tract located upstream of the 3' splice site. The splicing factor U2AF (U2 auxiliary factor) consists of two subunits which bind to the 3' splice site and the polypyrimidine tract. U2AF promotes the binding of U2 snRNA in the U2 snRNP complex to the branch site. The U1 snRNP particle binds to the upstream and downstream 5' splice sites through base pairing of the U1 snRNA. The additional assembly of the snRNPs U4, U5 and U6 is required for the constitution of the spliceosome and the removal of introns; B: Interaction of splicing regulatory proteins with exonic and intronic target sequences. SR (Ser-Arg) proteins bind to exonic splicing enhancers (ESEs) to stimulate the binding of U2AF to a weak 3' splice site, which here is interrupted by purines (R). They also stimulate the binding of the U1 snRNP to the downstream 5' splice site. SR proteins antagonise the negative effect on splicing of hnRNPs bound to exonic splicing silencers (ESSs). In many cases, U-rich sequences situated immediately downstream of 5' splice sites known as intronic splicing enhancers (ISEs) are bound by factors such as T cell-restricted intracellular antigen 1 (TIA1) to facilitate U1 binding.

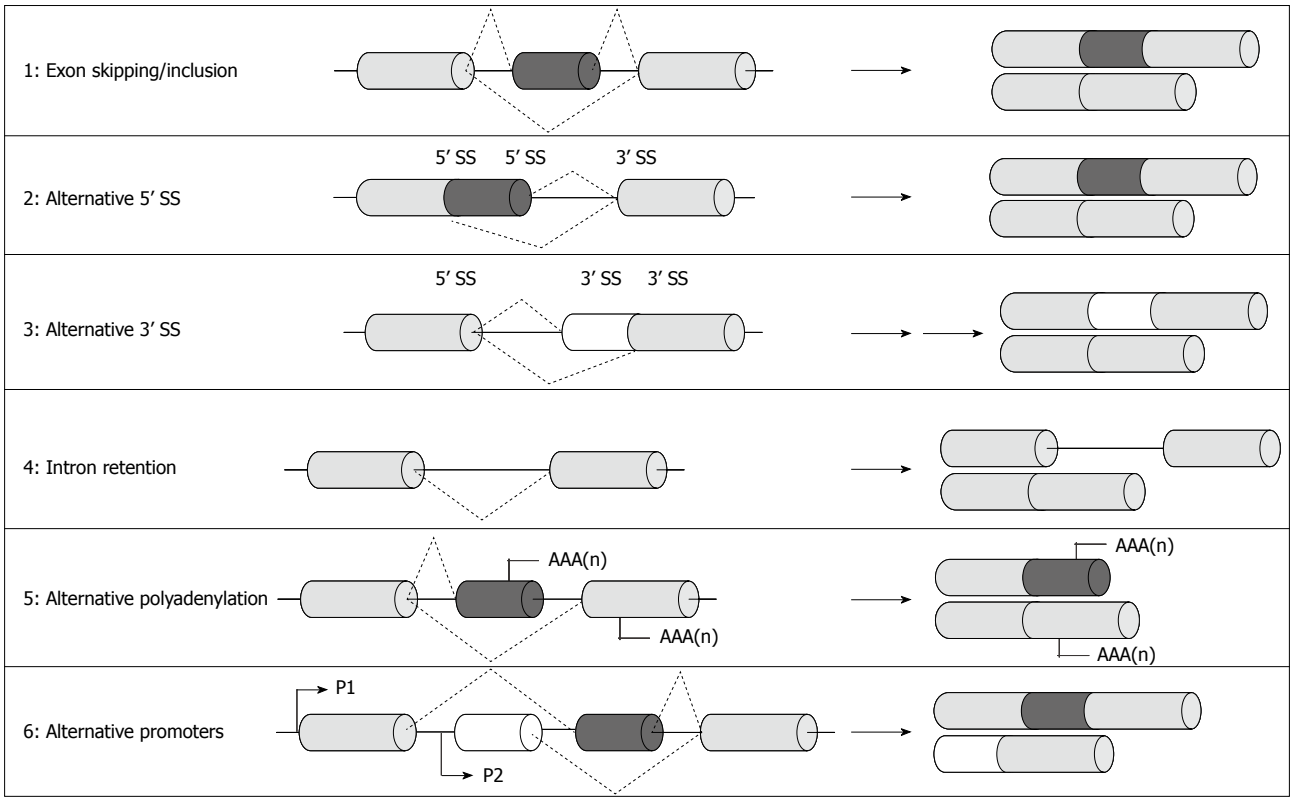

Figure 2 Different modes of alternative splicing. After pre-mRNA processing a single gene can encode multiple mRNA isoforms that possess distinct coding and regulatory sequences. Alternative splicing isoforms can result from: 1: The skipping or inclusion of alternative exons; 2: The selection of alternative 5'; or 3: 3' splice sites (SS); 4: The inclusion of introns; 5: The selection of different polyadenylation sites [AAA(n)]; and 6: The transcriptional initiation at an alternative promoter associated with the inclusion of specific exons.

the different alternative splicing events observed, these include: (1) exon skipping (cassette exons), in which the exon can be spliced from the transcript together with its flanking introns; (2) alternative 5' and (3) 3' splice site selection, where two or more splice sites can be recognised in an exon; (4) intron retention, in which an intron can remain in the mature mRNA; (5) alternative polyadenylation signals, which allows the generation of isoforms with 3' untranslated regions (UTRs) of different length; and (6) the alternative usage of promoters, with the generation of isoforms with promoter associated exons[18,19].

SR proteins are highly conserved RNA-binding proteins that facilitate splice site recognition and promote the inclusion of exons in the mature mRNA. The SR protein family members mostly interact with exonic splicing enhancers (ESE), stabilising the interaction of snRNPs and other factors at splice sites. Among other factors this family includes the ASF/SF2, 9G8, SC35, SRp30c, SRp20,

SRp40 and SRp46 proteins[27]. In contrast to the SR proteins the hnRNPs, such as hnRNPA1 and hnRNP I, have been mainly implicated in exon skipping. hnRNPA1 binds to exonic splicing silencers (ESS) and is able to prevent the binding of SR proteins to their specific sites in the exonic region, while hnRNPI competes with the U2AF auxiliary factor for its binding sequence close to the 3' splice site[24,28]. Variations in the expression levels of these splicing factors are known to affect the selection of splice sites, and therefore are thought to significantly influence the relative levels of splice variants among different tissues and also between normal and transformed cells[23,24].

Interestingly, accumulating evidence points also to the influence of extracellular stimuli on the regulation of alternative splicing[28,29]. In this respect, the activity of splicing factors is known to be affected by their phosphorylation status[30]. For instance SR proteins can be extensively phosphorylated on Ser residues, and their phosphorylation status affects protein-protein and protein-RNA interactions[28,30]. Moreover, extracellular signals can also impinge on the subcellular localisation of splicing factors, and consequently modulate their ability to interact with pre-mRNAs. This has been shown for different members of the SR protein family[29], and also for the splicing factor Slu7[31]. Several kinases and phosphatases responsible for the post-translational modification of splicing factors have been identified, and these include for instance the SR protein kinases (SRPKs), Clk/Sty, CDC-2 related protein kinase-7, and more recently, Akt and Fas-activated Ser/Thr kinase (FASTK)[28,29,32,33]. Among the phosphatases able to dephosphorylate splicing factors of the SR family we can cite PP1 and PP2A[29]. Less is known regarding the extracellular signalling pathways that control the activity of splicing factors, however, recent experimental efforts are beginning to pay off and relevant pathways are being delineated[29]. For example, insulin treatment has been shown to increase SRp40 phosphorylation and to stimulate protein kinase CβII alternative splicing *via* Akt2 activation[34]. Similarly, growth factors like the epidermal growth factor (EGF) have been demonstrated to modulate the splicing of the surface antigen CD44 in HeLa cells through the activation of Ras/mitogen-activated protein kinase (MAPK) cascade[35]. More recently, the activation of the EGF receptor (EGFR) was also shown to regulate the alternative splicing of the tumor suppressor genes *Krüppel-like zinc finger transcription factor 6* (*KLF6*) and *p73* in HCC cells. Although this will be discussed later in more detail, alternative splicing of *KLF6* pre-mRNA triggered by EGFR stimulation involved the Ras/phosphatidylinositol 3-kinase (PI3K)/Akt cascade, while that of *p73* specifically depended on c-Jun N-terminal kinase (JNK) activation[36,37]. Complex interactions between intracellular signalling pathways in the control of alternative splicing are also emerging. Such as the case of the antagonistic effect of JNK signalling on PI3K-mediated splicing regulation of the fibronectin gene in response to extracellular stimuli[38]. Taken together, these observations underscore the dynamic nature of alternative splicing, and also the high sensitivity to environmental signals displayed by this fundamental mechanism of gene expression regulation.

MECHANISMS AND SIGNIFICANCE OF ALTERATIONS IN PRE-MRNA SPLICING IN HEPATOCARCINOGENESIS

As previously mentioned, alterations in pre-mRNA splicing patterns, including changes in the normal tissular patterns of alternative splicing and the appearance of tumor-specific aberrantly spliced mRNAs, are increasingly being reported and implicated in cancer[39,40]. The mechanisms responsible for these alterations observed in cancer cells are still not well known. Nevertheless, some of these mechanisms are currently being elucidated and include: (1) mutations that create or disrupt splice sites or splicing enhancers or silencers[21]; (2) the abnormal expression of splicing factors[22,23,41,42]; and (3) the activation of cell signalling pathways that affect the activity of the splicing machinery[21,29]. In spite of recent advancements a major challenge in the field is still to discriminate whether these changes in alternative splicing can be the cause or are the consequence of human diseases. This is especially difficult in neoplastic diseases like HCC, if we take into account the multiple and heterogeneous genetic alterations that occur along the multi-step process of hepatocarcinogenesis, and the profound effects that the tumor microenvironment may have on transformed cells. Nevertheless, in some cases direct evidence has been provided on the oncogenic potential of liver cancer-associated splice variants and on the mechanisms involved in their generation. Interestingly, some cancer-associated isoforms have already been detected at pre-neoplastic stages, suggesting their potential early contribution to liver malignisation. Below we discuss some examples that are summarised in Table 1.

One interesting case of dysregulated alternative splicing occurring early during human hepatocarcinogenesis was reported by Saito *et al*[43]. These authors described the overexpression of a splice variant of DNA methyltransferase 3b (*DNMT3b*), namely *DNMT3b4*, in liver tissues showing chronic hepatitis and cirrhosis, as well as in HCC tissue samples. In contrast to *DNMT3b3*, the major variant in normal liver tissues, the *DNMT3b4* splice variant lacks the conserved methyltransferase motifs IX and X in exon 21, and probably also lacks this enzymatic activity. An elevation of the ratio of *DNMT3b4* to *DNMT3b3* mRNA was significantly correlated with the degree of DNA hypomethylation on pericentromeric satellite regions in precancerous conditions and HCC[43]. Hypomethylation of pericentromeric satellite regions may induce chromosomal instability, and is considered an early event during hepatocarcinogenesis. The authors hypothesised that the protein product of *DNMT3b4* transcript might compete with the active variant DNMT3b3, behaving as a dominant negative isoform. They confirmed this possibility by transfecting HEK293 epithelial cells, which express the DNMT3b3 active variant, with a DNMT3b4 expres-

Table 1 Examples of genes with altered splicing in liver carcinogenesis

Gene	Function	Selected ref.
DNMT3b4	DNA methyltransferase	[43,44]
MDM2	E3 ubiquitin ligase	[47]
Aurora kinase B Sv2	Serine/Threonine kinase	[45,46]
Hugl-1	Tumor suppressor	[49]
Tensin 2var3	Focal adhesion	[48]
Cadherin 17	Cell surface adhesion	[55]
MAD1 (β)	Spindle-assembly checkpoint	[50]
KLF6	Tumor suppressor	[36]
SVH	Unknown	[52]
p73	Tumor suppressor	[37,72]

sion vector and observed satellite DNA demethylation[43]. Furthermore, subsequent observations demonstrated that DNMT3b4 transfection resulted in enhanced growth rate and increased expression of transformation-related genes, even before chromosomal alterations appeared, underscoring the profound biological consequences of this altered splicing event[44].

Other examples of aberrantly-spliced genes detected in the preneoplastic cirrhotic liver include the serine/threonine kinase aurora kinase B (*AURKB*), and the E3 ubiquitin ligase and p53-antagonistic protein *MDM2*. AURKB, which is expressed in normal liver tissue, had been shown to be overexpressed in HCC correlating with tumor recurrence and a poor prognosis[45]. It was subsequently observed that over 60% of metastatic liver cancer tissues expressed the *AURKB* splice variant 2 (*AURKB Sv2*), which was also present in about 16% of the cirrhotic tissues tested regardless of their aetiology, but was absent in the normal liver parenchyma[46]. Interestingly, *AURKB Sv2* variant-positive HCC samples were mostly obtained from younger patients, and correlated with a poor outcome and short disease-free period[46]. From a mechanistic point of view the contribution of AURKB Sv2 to hepatocarcinogenesis is not known. This splice variant lacks parts of the kinase domain, and it could compete with the full length AURKB in a dominant negative manner, but experimental data on this aspect are not available yet. Regarding *MDM2*, two splice variants with tumorigenic potential, which are absent in the normal liver tissue, were found in alcoholic and autoimmune liver cirrhosis. However, for still unknown reasons these variants were not detected in hepatitis C virus (HCV)-infected cirrhotic samples[47].

As previously mentioned, the experimental demonstration of the pro-oncogenic effects of the splice variants found in transformed tissues is important to establish a cause and effect relationship. This is commonly done by expressing the splice variant under evaluation in cultured cell lines, as presented above for DNMT3b4, and more recently also by the generation of transgenic animals with targeted expression of the spliceoform in question. Although these approaches can be limited by the generally unphysiological expression levels obtained, relevant mechanistic information may be drawn from these studies. For instance, Yam *et al*[48] found that the Tensin 2 splice variant 3 (*TENSIN 2sv3*) was overexpressed in 46% of HCC tissues and most HCC cell lines examined, and that the expression of this variant correlated with a more aggressive tumor phenotype and other pathological features of poor prognosis. Tensins constitute a new family of focal adhesion proteins that link the extracellular matrix to the actin cytoskeleton and to intracellular signalling pathways. To directly assess the consequences of *TENSIN 2sv3* overexpression, the authors generated stable clones in a HCC cell line with low *TENSIN 2sv3* expression. These clones displayed increased growth, invasive properties, and tumorigenicity in an orthotopic model of HCC[48]. Together these findings identified a novel determinant in the metastatic behaviour of HCC which is generated by alternative splicing. Another cytoskeletal protein recently shown to be aberrantly spliced in HCC is the product of the *Hugl-1* gene, a tumor suppressor mainly expressed in the cytoplasm and involved in the regulation of cell polarity. Lu *et al*[49] found that 32.5% of HCCs displayed aberrant spliced variants of this gene that lacked a conserved repeat motif involved in protein-protein interactions. The presence of these Hugl-1 variants correlated with poor differentiation and large tumor size, and their overexpression in HCC cells resulted in enhanced invasion and tumorigenicity when injected into nude mice. Similar findings were recently reported for the *mitotic arrest deficient 1* (*MAD1*) gene. Sze *et al*[50] identified a novel *MAD1* splice variant in human HCC samples which they named *MAD1β*, while the original wild-type isoform was renamed *MAD1α*. MAD1α is a key protein in the mitotic checkpoint complex that monitors the status of kinetochore-microtubule attachment and the formation of the connections to the mitotic spindle. Defective mitotic checkpoint leads to DNA aneuploidy and chromosomal instability, which are features of HCCs[51]. MAD1β was overexpressed in 24% of the HCC tissue samples compared to the surrounding parenchyma, and interestingly more than 50% of the cases expressed MAD1β both in the tumoral and nontumoral tissue. MAD1β lacks the exon 4 of MAD1α, and is localised to the cytoplasm instead of the cell nucleus. MAD1β overexpression also affected the subcellular location and protein levels of other key components of the mitotic checkpoint such as MAD2. Functional studies overexpressing MAD1β in HCC cell lines demonstrated that the presence of this splice variant resulted in severe chromosome aberrations, thus demonstrating that MAD1β induces mitotic checkpoint incompetence[50]. Finally, there are also examples in which the specific targeting and downregulation of an aberrant splice variant found in HCC cells and tissues results in reduced tumorigenesis. This is the case of the "specific Splicing Variant involved in Hepatocarcinogenesis" (*SVH*) gene, an armadillo repeat domain containing gene of still unknown biological function that can produce four splice variants (*SVH-A, -B, -C* and *-D*). Only the splice variant *SVH-B* was upregulated in HCC tissues and hepatoma cell lines, and only the overexpression of this variant in non-transformed liver cell lines resulted in accelerated cell growth and tumorigenicity in nude mice[52]. Interestingly, the specific inhibition of *SVH-B* with antisense oligode-

oxynucleotides reduced HCC cell growth and survival[52]. This observation also suggests the possibility of specifically targeting aberrantly spliced mRNAs to quell liver cancer, as will be discussed later.

The observations described above illustrate the oncogenic potential of aberrantly spliced isoforms in HCC tissues. However, for all these cases no information is so far available regarding the molecular events involved in their generation[43,48-50,52]. In fact, the mechanisms that lead to the appearance of aberrantly-spliced genes in hepatocarcinogenesis have been so far elucidated for a limited number of genes. Among them we find *Cadherin 17* (*CDH17*), also known as liver-intestine cadherin (LI-Cadherin), a non-classic member of the cadherin family of cell-cell adhesion proteins overexpressed in about 90% of HCCs[53,54]. CDH17 expression was shown to confer tumorigenic potential to premalignant liver progenitor cells[53]. Interestingly, it was later found that 50% of HCC samples, and 30% of peritumoral tissues, also expressed a CDH17 splice variant lacking exon 7[55]. The expression of this splice variant was strongly associated with decreased overall survival of the patients[55]. While the reason why overexpression of this splice variant may have a pathogenic role remains speculative, the mechanisms behind its generation have been characterised. Wang *et al*[55] detected a base change at position 651 in exon 6, and another single nucleotide polymorphism (SNP) in a putative branch point at intron 6 position 35 (IVS6+35) was also found. The mutation at position 651 in exon 6 could affect exon 7 inclusion by generating an ESS, or by disrupting an ESE located in exon 6[21]. GG and AG polymorphisms were identified in 73% of the patients at IVS6+35, and in the same patients TT and CT polymorphisms were also observed at 651 (exon 6), in the control group normal livers showed the wild-type phenotype 651 CC, IVS6+35 AA. The functional role of these two SNPs was confirmed in a minigene assay, in which the presence of 651 T and IVS6+35 G SNPs resulted in exon 7 skipping[55]. It was later observed that the 651 T IVS+35 G haplotype, specially 651 TT and IVS6+35 GG homozygotes, seemed to be strongly associated with HCC, and therefore could be considered as a genetic susceptibility factor for HCC development in a Chinese population[56].

While point mutations in splice or regulatory sites are perhaps the most common alterations leading to aberrant splicing in cancer, the role of signalling pathways is gaining recognition. This is very well illustrated by the study of fibronectin alternative splicing regulation. Fibronectin is a glycoprotein found in blood, body fluids and tissues that plays a key role in cell adhesion and migration. Fibronectin has a domain structure consisting of three internally homologous repeats, termed type Ⅰ, Ⅱ and Ⅲ domains. There are two type Ⅲ domains that can be alternatively spliced, and incorporated or not in the mature transcript, the extra domains A and B, denominated EDA and EDB[57]. In addition, the so-called type Ⅲ connecting segment (ⅢCS) can also be alternatively spliced, generating in total up to 20 fibronectin isoforms in humans[57]. Fibronectin is biologically classified in two forms, namely plasma and cellular fibronectin, and only cellular fibronectin contains the EDA and EDB sequences. Plasma fibronectin is secreted by the hepatocytes, but these cells, as other normal adult cells, express limited amounts of EDA-containing fibronectin, which is expressed by foetal hepatocytes[57]. Several functions have been described for the EDA domain, including cell adhesion, wound healing, matrix assembly, matrix metalloproteinase expression, cell differentiation and tissue injury and inflammation[57]. Alternative splicing of the EDA exon is controlled by a bipartite element comprising an ESE and an ESS[29,57]. Srebrow and co-workers[38,58,59] have characterised the effect of extracellular matrix components and growth factors like EGF, hepatocyte growth factor and fibroblast growth factors, on fibronectin splicing. These authors observed that extracellular matrix components such as laminin and collagen Ⅳ downregulated EDA inclusion, while growth factors promoted the inclusion of EDA in fibronectin mRNA[38,59]. The signalling pathways connecting the cell surface with the nuclear splicing machinery controlling fibronectin splicing were also investigated. Exposure to a laminin-rich basement membrane resulted in JNK activation and sustained extracellular signal-regulated kinase (ERK) dephosphorylation, and these events were mechanistically linked to the described downregulation of EDA inclusion[38]. On the other hand, growth factor-activated Ras-PI3K-mediated signalling was shown to alter the phosphorylation levels of the SR proteins SF2/ASF and 9G8, and direct evidence was also provided on the importance of these events in mitogen-stimulated EDA inclusion[32,38].

All the mechanistic observations on the modulation of fibronectin splicing described above were carried out in mammary epithelial cells, however, they can be highly relevant to the alterations of fibronectin splicing found in liver disease. Indeed, EDA and EDB containing variants have been detected in the rodent liver during acute and chronic injury, and during liver regeneration after partial hepatectomy[60-63]. In models of liver injury, EDA-containing fibronectin was mainly produced by sinusoidal endothelial cells, while extracellular matrix-producing cells expressed EDB fibronectin[60,63]. In contrast, in human chronic hepatitis and in liver fibrosis EDA-containing fibronectin was detected not only in non-parenchymal cells, but also in hepatocytes[63,64]. Moreover, both EDA- and EDB-containing fibronectin variants were detected in human HCC tissues, and were localised to hepatoma cells[62,65]. The molecular mechanisms involved in fibronectin alternative splicing in liver injury and transformation are currently unknown. However, the pro-inflammatory milieu characteristic of chronic liver injury and HCC activates the same intracellular pathways that promote fibronectin splicing in mammary epithelial cells. Therefore, it is likely that cytokines and growth factors upregulated during hepatocarcinogenesis promote the alternative splicing of fibronectin in the liver. In support of this is the positive effect of transforming growth factor-β (TGFβ) on EDA inclusion observed in isolated mouse liver endothelial cells, or that of TGF and EGF found in human HCC cells in culture[58,59,62]. The expression of EDA-containing fibronectin during liver injury has been shown to contribute to the activation of ECM-

producing cells[60]. This effect, together with its ability to stimulate cell cycle progression and cellular migration observed in other cell types[57], suggests its likely involvement in the neoplastic conversion of the liver.

Together with fibronectin, other relevant examples of genes for which extracellular signals are known to affect their normal alternative splicing are the tumor suppressor genes *KLF6* and *p73*. As previously mentioned KLF6 is a ubiquitously expressed Krüppel-like zinc finger transcription factor, and tumor suppressor gene that is functionally inactivated in a number of cancers including HCC[66]. The *KLF6* pre-mRNA can give rise to three alternative splice variants, and at least one of them acts as a dominant-negative protein that antagonises the full length KLF6. This variant, named KLF6 SV1, lacks the three zinc finger DNA binding domains but retains the activation domain that mediates protein-protein interactions essential for the biological activity of this family of transcription factors. KLF6 SV1 is overexpressed in several human cancers, correlating with poorer outcome and reduced survival[67]. Increased *KLF6* alternative splicing, expressed as the ratio of *KLF6 SV1* to full length *KLF6*, was observed in 76% of the HCC samples examined[36]. While full length KLF6 overexpression in HCC cells inhibited growth and promoted cell differentiation[68], the overexpression of KLF6 SV1 partially restored the decreased cell proliferation induced by inhibition of the Ras pathway[36]. Mechanistically, the first cause that was identified for the generation of KLF6 SV1 in cancer cells was the presence of a SNP in intron 1 of the *KLF6* gene. This SNP abrogates a binding site for the splicing factor ASF/SF2 and generates a binding site for the SR protein SRp40, provoking the use of two cryptic splice sites in exon 2[66]. The presence of this SNP in association with HCC development has not been tested so far. However, it was known that *KLF6* could still be alternatively spliced into *KLF6 SV1* in normal and cancerous tissues without this SNP[66]. One relevant mechanism for the generation of KLF6 SV1 in HCC cells was recently outlined by Yea *et al*[36]. It involved the oncogenic activation of the Ras/PI3K/Akt pathway and the splice regulatory protein ASF/SF2. Interestingly, upstream of Ras the authors identified the EGFR tyrosine kinase activity as a signal that could trigger KLF6 SV1 generation. These findings may be of special relevance for the biology of HCC, they link a signalling pathway hyperactive in liver cancer[69] to the functional inactivation of a tumor suppressor gene through dysregulated alternative splicing.

p73 is another tumor suppressor gene which is frequently altered in different cancers, including HCC[70]. This gene is structurally related to *p53*, sharing common transcriptional targets that promote cell cycle arrest, apoptosis and limit anchorage-independent cell growth[70]. However, at variance with *p53*, no inactivating mutations have been described for *p73* in cancer cells. Inhibition of p73 tumor suppressive activity derives from the coexpression of N-terminally truncated isoforms. Two of these isoforms are known as ΔEx2p73 and ΔEx2/3p73, and are splice variants of the full length *p73* pre-mRNA that lack the transactivation domain, but retain the DNA binding domain and a C-terminal oligomerisation domain. ΔEx2p73 and ΔEx2/3p73 behave as dominant negative inhibitors of both p53 and p73, and are not expressed in normal tissues, but are frequently up-regulated in HCC[37,71-73]. Forced expression of these variants induces malignant transformation in fibroblasts and chemotherapy resistance in cancer cells[74,75]. Moreover, transgenic mice overexpressing human ΔEx2/3p73 in hepatocytes spontaneously developed HCC, attesting to the *in vivo* oncogenicity of aberrantly spliced p73 variants for liver cells[76]. The mechanisms regulating the generation of protumorigenic p73 variants are not known, however, a recent study by Castillo *et al*[37] identified a signalling pathway that promoted the generation of ΔEx2p73 in liver cells. It was observed that the stimulation of the EGFR by its ligand amphiregulin (AR) in an autocrine manner triggered the splicing of p73 into its ΔEx2p73 variant[37]. AR expression is undetectable in the healthy liver, but it is upregulated during injury and inflammation, contributing to tissue repair but also to the progression of liver disease[77-79]. Overexpression of AR is detected in liver tumors, and significantly participates in the maintenance of the neoplastic phenotype of HCC cells[79]. Interestingly, the expression of AR significantly correlated with the presence of ΔEx2p73 transcripts not only in tumor tissues, but also in cirrhotic livers. Furthermore, this correlation was also observed in the non-neoplastic normal parenchymal tissue of livers that developed HCC in the absence of any risk factor for this neoplasia[37]. These findings suggest that AR-mediated dysregulation of *p73* pre-mRNA splicing can be an early event during hepatocarcinogenesis, including those cases in which cancer develops in a tissue not chronically injured. Mechanistically it was demonstrated that downstream of the EGFR the activation of JNK1 resulted in the downregulation of the splicing factor Slu7 in HCC cells[37]. Slu7 is involved in the correct selection of the 3' splice site during the second step of splicing, and it has been demonstrated that Slu7 knockdown results in exon skipping of endogenous genes[80]. Inhibition of Slu7 expression by AR/EGFR/JNK1 signalling involved the activation of the transcription factor Elk-1, a previously recognised repressor of *Slu7* transcription[80]. Of importance, the expression of Slu7 was also found to be significantly decreased in chronic liver disease and HCC. Together, these observations identify a cancer-related extracellularly triggered signalling pathway that culminates in the transcriptional knockdown of a splicing factor, and the consequent generation of an oncogenic splice variant.

As mentioned before, abnormally expressed splicing factors can induce the production of mRNA isoforms nonexistent or present in low amounts in normal cells. Increasing evidence points to the significant contribution of this phenomenon to malignant progression, as recently demonstrated by the oncogenic consequences of SF2/ASF overexpression[41,81], or the contribution to the cancerous phenotype of hnRNP proteins upregulation[42]. However, a decrease in the expression of splice factors is less frequently observed in cancer cells, although some cases have been reported[23]. For instance reduced expression of

U2AF was found in pancreatic cancer[82], and siRNA-mediated inhibition of its expression in HeLa cells increased the level of the oncogenic CDC25B phosphatase[83]. In view of this, the downregulation of Slu7 gene expression in the cirrhotic liver may have mechanistic implications for the progression towards HCC.

POTENTIAL THERAPEUTIC INTERVENTIONS TARGETING SPLICING DEFECTS

The appreciation that dysregulated splicing may influence the development of human disease makes this process a potential therapeutic target. Different strategies are currently being explored to correct or inhibit pathological splicing events. They may be grouped in two major categories: molecules that can change alternative splicing and antisense strategies[39,84-86].

High throughput screens and individual studies on specific molecules have identified a number of compounds that can change splice site selection. For instance two different natural products with broad anticancer activity, pladienolide and spliceostatin A, have been recently reported to bind and interfere with the essential splicing protein SF3b, a core component of the U2 snRNP, inhibiting the splicing of a number of transcripts resulting in growth inhibition[87,88].

Targeting the expression and the post-translational modifications of splice modulators have also been attempted with promising results. As mentioned before, there are several kinases that phosphorylate the SR proteins in their arginine/serine domains (RS), affecting their intracellular localisation and their interaction with other splice factors and the pre-mRNAs. These kinases include topoisomerase I (Topo I) and members of the Clk/Sty and SRPK families[84,85]. Several antineoplastic compounds that target Topo I, such as diospyrin and indole derivatives like NB-506, can modify splice site selection. NB-506 inhibited the phosphorylation of SF2/ASF and altered the splicing pattern of several target genes including the apoptosis regulator Bcl-X in tumor cells[89]. The Clk1 kinase inhibitor TG003 also interferes with SF2/ASF-dependent splicing and can suppress alternative splicing in reporter genes[90]. The specific targeting of SRPK1 may be of special relevance, given its prominent role in cancer cells. Downregulation of SRPK1 expression by siRNA was reported to inhibit cancer cell proliferation and increase the sensitivity to chemotherapeutics[91], therefore the inhibition of this kinase may be an effective pharmacological strategy. Another approach to modify the activity of splice modulators is to target protein phosphatases (PPs). PP1 can bind directly to a conserved motif in the RNA-recognition region of at least nine splicing-regulatory proteins[84]. Modulation of PP1 activity shows a strong influence on alternative splicing, as illustrated by the lipid ceramide which activates PP1 and promotes the alternative splicing of the apoptosis regulator Bcl-X into its pro-apoptotic variant Bcl-Xs[92]. Activation of PP1 expression and upregulation of Bcl-Xs levels have also been demonstrated to occur in response to S-adenosylmethionine (AdoMet) and 5'-methylthioadenosine (MTA) treatment in HCC cells[93]. Interestingly, these two naturally occurring compounds show antitumoral effects in HCC and can induce growth inhibition and apoptosis in liver cancer cells, while normal hepatocytes are spared from this effect[94,95]. The reasons why AdoMet and MTA promote PP1 expression and Bcl-Xs upregulation only in HCC cells are still unknown, but this fact represents an advantage over other experimental approaches in which splicing can be altered both in normal and cancerous cells.

The selective modulation of splicing reactions is a big challenge, and the specific target of one splicing event is difficult to achieve with the above-mentioned compounds. This can be addressed with antisense oligonucleotides that can complementarily bind to a target site in pre-mRNAs and regulate the splicing process. Antisense oligonucleotides can block cryptic splicing sites created by a mutation, and redirect splicing back to the correct splice site. They can be used to induce exon skipping, and can also be targeted to regulatory sequence elements within exons and introns, like ESEs and ESSs[86]. These antisense oligonucleotides must be stable in biological fluids, and also need to be efficiently delivered inside target cells. To achieve the desired stability, chemical modifications are introduced that prevent degradation. To increase cellular delivery, formulations coupling oligonucleotides to arginine-rich cell penetrating peptides have been devised[39]. Moreover, intracellular delivery of antisense oligonucleotides to correct splicing defects has also been attained using adenoviral vectors[96]. The new generation antisense oligonucleotides include: phosphoroamidate morpholino oligomers, peptide nucleic acids (PNA), and locked nucleic acids (LNA)[86]. Morpholino oligonucleotides have been used to inhibit splicing silencers and to activate otherwise repressed exons. This has been shown for instance for the α exon of fibroblast growth factor receptor 1 (FGFR1), which is excluded in glioblastoma cells[97]. PNAs are oligonucleotide analogs in which the nucleobases are bound to a polyamide backbone that is highly stable *in vivo*[98]. They have been tested in cultured cells and *in vivo* with promising results, inducing the splicing of Bcl-X and promoting apoptosis in cancer cells[99]. LNA antisense oligonucleotides contain a methylene bridge that connects the 2'-oxygen of the ribose with the 4'-carbon. This modification increases the serum stability of oligonucleotides, prevents their degradation by RnaseH, and imparts high specificity toward their target sequences[100]. LNAs have been successfully used to modulate the splicing of tumor necrosis factor receptor 2 (TNFR2) in the liver, switching the endogenous expression of the membrane bound functional form of TNFR2 to a soluble secreted form lacking exon 7 (Δ7TNFR2). The secreted form acted as a decoy receptor for TNF-α, and mice were protected from liver damage in a model of acute inflammation and injury[101]. LNAs have also been used to target and promote the degradation of specific oncogenic splice forms. This has been shown recently by Emmrich and co-workers[102], who designed LNA antisense oligo-

nucleotides directed against the *ΔEx2p73* and *ΔEx2/3p73* oncogenic isoforms of the tumor suppressor p73, which as previously described are upregulated in HCC. Specificity was obtained by targeting the splice junction of each exon deletion variant. This strategy reduced tumorigenic p73 transcripts, without affecting wild-type p73, and inhibited malignant melanoma growth. Additional examples illustrating the potential of antisense oligonucleotide-based strategies to correct splicing defects have been recently reviewed in detail by Khoo and Krainer[103]. Among other cases, these authors describe how the splicing of liver apolipoprotein B 100 (APOB100), a key player in the development of atherosclerosis, can be engineered without affecting the expression of the intestinal isoform APOB48, involved in fat absorption from the gut. Specific targeting of *APOB100* pre-mRNA with antisense oligonucleotides induced the skipping of exon 27, leading to the generation of a shorter variant that has been associated with reduced cholesterol and LDL levels[103].

Also within these targeted strategies, a recent report by Alló and co-workers demonstrated that small interfering RNAs (siRNAs) targeting gene sequences surrounding an alternative exon (the flanking introns) can modulate its alternative splicing, resulting in exon inclusion[104]. It was found that upon siRNA transfection there was an increase in the levels of facultative heterochromatin in the vicinity of the siRNA target sites. The authors proposed that the condensed chromatin structure slows down Pol II elongation and facilitates the inclusion process. Regardless of the mechanistic details underlying this phenomenon, these findings open the door to the application of siRNA technology to correct splicing defects.

Although further studies are needed, together these observations demonstrate that targeting the splicing machinery is feasible and can also be achieved *in vivo*. Moreover, the application of antisense-based therapeutic strategies may be especially effective to treat liver diseases, as suggested by the preferential accumulation of antisense oligonucleotides in this organ when administered to mice[105].

HCC is a molecularly complex type of tumor, however, the identification of key splicing defects that may be corrected or interfered with targeted molecules as outlined above could help to develop new therapeutic strategies. These strategies may be used in combination with other targeted therapies, or with conventional chemotherapeutic approaches.

CONCLUSION

The detection of splicing aberrations from early stages of hepatocarcinogenesis together with the validation of their functional significance, suggests the likely implication of splicing defects in the oncogenic transformation of the liver. The realisation of this is just a start point for future research aimed at the development of effective therapeutic interventions in a deadly disease like HCC. There are different fronts in which action is needed. For instance, a thorough knowledge of the splicing alterations in pre-neoplastic and transformed liver tissue is still lacking. The use of improved splice-sensitive microarray platforms, and the implementation of new technologies like deep sequencing of transcriptome (RNA-seq), that allows both known transcript quantification and novel transcript discovery, are likely to yield valuable information on all splicing events[106,107]. These approaches will allow the identification of new splicing defects with potential pathological significance, and the generation of splicing signatures that may have prognostic value. The characterisation of functional splice regulatory elements in the genome that can be targeted by RNA binding proteins is also a challenge. New methods combining immunoprecipitation of RNA-protein complexes with high-throughput sequencing of reverse transcribed tags are currently being devised[19,106]. From the therapeutic perspective, it is possible that alterations in pre-mRNA splicing resulting from hyperactive intracellular signalling pathways could be reversed in part by the emerging targeted therapies that block these pathways[6,15,36,37]. However, when aberrant splicing is the consequence of genetic mutations that affect splicing reactions, and are not due only to the dysregulation of signalling pathways that impinge on pre-mRNA splicing, different approaches must be used. In these cases that involve structural changes due to mutations, the inhibition of hyperactive signalling pathways may not be effective, and the antisense oligonucleotides described above can be applied. Nevertheless, some aspects such as their potential off-target effects and their efficient delivery to the target tissues still need to be further elaborated[86]. In summary, the integration of pre-mRNA processing alterations in the molecular portrait of liver cancer will surely contribute to the understanding of the disease and the development of new effective therapies.

Abstract

Nowadays, the number of cases in which malignant colorectal polyps are removed is increasing due to colorectal cancer screening programmes. Cancerous polyps are classified into non-invasive high grade neoplasia (NHGN), when the cancer has not reached the muscularis mucosa, and malignant polyps, classed as T1, when they have invaded the submucosa. NHGN is considered cured with polypectomy, while the prognosis for malignant polyps depends on various morphological and histological factors. The prognostic factors include, sessile or pedunculated morphology of the polyp, whether partial or *en bloc* resection is carried out, the degree of differentiation of the carcinoma, vascular or lymphatic involvement, and whether the polypectomy resection margin is tumor free. A malignant polyp at T1 is considered cured with polypectomy if it is a pedunculated polyp (Ip of the Paris classification), it has been completely resected, it is not poorly differentiated, the resection edge is not affected by the tumor and there is no vascular or lymphatic involvement. The sessile malignant polyp (Is of the Paris classification) at T1 is considered not cured with polypectomy. Only in some cases (e.g. older people with high surgical risk) local excision (polypectomy or endoscopic submucosal dissection or conventional endoscopic mucosal resection) is considered the definitive treatment.

INTRODUCTION

Adenomatous polyps are tumors of benign neoplastic epithelium with variable potential for malignancy. The adenoma-carcinoma sequence is well known and it is accepted that more than 95% of colorectal cancers arise from adenomas. The World Health Organisation (WHO) classifies adenomas into tubular (less than 20% villous architecture), tubulovillous and villous[1], with approximately 87% of adenomas being tubular, 8% tubulovillous and 5% villous. Only 5% of adenomas are in danger of becoming malignant. The probability of high grade dysplasia and of carcinomatous transformation increases with polyp size, especially when they are larger than 1 cm, they have a villous component, there are many polyps or the age at diagnosis is more than 60 years. The neoplasia is considered to be advanced when polyps are 1 cm or more in diameter, there is a villous component or a high degree of dysplasia. More than 25% of advanced polyps[2] and colon cancers are located in the area

proximal to the splenic flexure[3]. Mixed polyps also have the ability to become malignant, as does hyperplastic polyposis syndrome.

EPIDEMIOLOGY

The prevalence of cancerous polyps in series of endoscopically removed polyps is between 0.2% and 11%[4-7]. Nowadays, the number of cases in which malignant polyps are removed is increasing due to screening programmes. In an asymptomatic population of people over 50 years old who underwent direct colonoscopy, there was a 0.8% prevalence of adenocarcinoma of which 50% were carcinoma "*in situ*" or in stage I [8,9]. During screening programmes, adenocarcinomas have been detected in between 3% and 4.6% of those who undergo colonoscopy following a positive immunological faecal occult blood test result[1,10]. In 2006, Rubio *et al*[11] reported 10 patients with hyperplastic polyposis coli syndrome and a review of the literature showed that 50% (74/147) of patients with hyperplastic polyposis coli syndrome developed colorectal cancer (CRC).

HISTOLOGY

Carcinoma "*in situ*", intramucosal carcinoma, high-grade dysplasia or intraepithelial neoplasia is the stage at which there is no involvement of *the muscularis mucosa*. In general, this tumor stage does not cause metastasis. It is classified as pTis or Stage 0 in the TNM staging system. These terms are defined as non-invasive high grade neoplasia (NHGN) in the Vienna classification[12]. Carcinoma *in situ* or high-grade dysplasia or intraepithelial neoplasia corresponds to a carcinoma that is restricted to the epithelial layer without invasion into the lamina propria. Intramucosal carcinoma is a carcinoma characterised by invasion into the lamina propria.

When the carcinoma spreads to the submucosa, the polyp is considered to have become malignant, being able to spread to lymph nodes or distant sites. The tumors that affect the submucosa are classified as T1 and correspond to Stage I of the TNM staging system. This term is defined as submucosal carcinoma in the classification of Vienna[12] or malignant polyp.

The term pseudoinvasion refers to the presence of glandular epithelium of the mucosa beneath the muscularis mucosa in colonic polyps. These lesions have no malignant potential and should be treated in a similar way to adenomas[13]. However, this phenomenon can be mistaken for invasive carcinoma by an inexperienced pathologist. Pseudoinvasion usually occurs in large polyps (> 1 cm), especially those with long stalks, and is most commonly found in polyps of the sigmoid colon. Islands of adenomatous epithelium are displaced through the muscularis mucosa and are found within the submucosa of the stalk. The displaced glandular tissue usually has rounded, not infiltrative, contours, carries with it a small amount of lamina propria, and is cytologically identical to the overlying adenomatous component. Haemorrhage and haemosiderin deposition are commonly seen and are a clue to diagnosis. In addition, inflammation and granulation tissue can be found. Cystic dilatation of the displaced glands with mucin distention is also not uncommon in pseudoinvasion because mucin produced by the entrapped glands has no means of reaching the lumen. Occasionally, rupture of dilated glands occurs with acellular mucin extravasation and there is a subsequent inflammatory response. Distinction from mucinous (colloid) carcinoma is important and can be difficult. Specifically, in mucinous carcinoma, the mucin pools contain malignant cells, a feature lacking in pseudoinvasion. For these reasons it is highly recommended that level sections and second opinions are obtained in cases of polyps with potential pseudoinvasion[14].

All adenomas have some degree of dysplasia, be it high or low. However, low and high grade dysplasias are artificial subdivisions of a spectrum; there is no definition of "high-grade". Indeed, the WHO book on tumors of the digestive system, does not contain a list of criteria for high-grade dysplasia in adenomas[15,16]. However, in general, high-grade dysplasia entails more substantial changes and includes carcinoma "*in situ*". Among these changes we consider architectural alteration, often resembling the glandular arrangement of adenomas and cytologic abnormalities, principally cellular and nuclear pleomorphism, nuclear hyperchromatism, loss of nuclear polarity, and marked stratification of nuclei. Other authors have considered as features of high grade dysplasia: loss of normal glandular architecture, hyperchromatic cells with multilayered irregular nuclei and loss of mucin, high nuclear/cytoplasmic ratio, marked nuclear atypia with prominent nuclei and focal cribriform patterns. Not all these features are necessarily present to the same degree in all dysplastic epithelia, while low-grade dysplasia manifests these same changes but to a lesser degree[15,16].

PROGNOSTIC FACTORS

Many factors have been associated with a higher probability of residual disease or recurrent carcinoma.

Morphology

Morphology is described as polypoid (pedunculated or sessile) and nonpolypoid (flat or ulcerated) subtypes according to the Paris classification[17]. The endoscopist should be alert to some features that are suggestive of possible malignancy. These features include the size, the presence of depressed ulceration, irregular contours, deformity, a short and immobile stalk and the inability to elevate a sessile polyp when a submucosal bleb is formed. Nonpolypoid colorectal neoplasms have a greater association with carcinoma (NHGN or submucosal invasive carcinomas) compared with polypoid neoplasms, irrespective of size[7]. Attempts at diagnosis in such suspicious lesions, as well as in flat or depressed lesions, can be carried out using chromoendoscopy and magnification techniques that can highlight abnormalities of glandular cytoarchitecture, while also revealing information concerning the extent of submucosal invasion[18,19]. Kudo *et al*[20] developed

Table 1 Pit pattern classification

Type of lesion	Description
Type 1	Round pits
Type 2	Stellar or papillary pits
Type 3 L	Large tubular or roundish pits
Type 3 S	Small tubular or roundish pits
Type 4	Branch-like or gyrus-like pits
Type 5	Non-structural pits

Evaluation of the fine surface structure (pit pattern) of the mucosa. Lesions with type 1 and 2 pit patterns are nontumorous epithelial tissue, that is normal, inflammatory, or hyperplastic tissue. Tumorous lesions have type 3 S, 3 L, 4 and/or 5 pit patterns. Lesion 3 L and 4 are typical of the protruded type of tumor, whereas type 3 S and 5 are typical of the depressed type of tumor.

the pit pattern classification for colon polyps with six classes of surface pattern depicted by magnifying endoscopy after indigo-carmine dye (Table 1). Class 5 of this pit pattern classification or an unstructured surface has been shown to correlate well with a diagnosis of malignancy, and can provide important additional information prior to endoscopic treatment. However, endoscopic ultrasound using high frequency transendoscopic miniprobes currently appears to be the most accurate method for defining submucosal or further bowel wall invasion, enabling direct referral for surgical intervention in those cases with deeper infiltration who are at the greatest risk of lymphatic spread[21].

Type of resection

When *en-bloc* removal of a polyp is performed, it is possible to assess the depth of infiltration of the tumor cells and whether the margin is affected. Pedunculated malignant polyps are easily removed using a loop snare. However, this technique frequently results in piecemeal removal when applied to sessile and flat malignant polyps. Nevertheless, around one-third of malignant polyps are removed in this way[22]. *En-bloc* removal is advantageous because it allows full histological evaluation of the complete resection and is associated with lower recurrence rates than piecemeal removal[23]. Endoscopic submucosal dissection (ESD) has been found to be particularly useful for the removal of sessile or flat adenomatous lesions. It has an advantage over other endoscopic techniques in that it allows *en-bloc* removal of large (> 2 cm) colonic lesions. In ESD an electrosurgical cutting device is used to carefully dissect the deeper layers of the submucosa to remove neoplastic lesions in the mucosa. In a meta-analysis it was found that ESD *en-bloc* resection is achieved in 84.9% of lesions, and clear vertical and lateral margins are achieved in 75.3% of cases[24].

Polypectomy resection margin

It is essential that the pathologist identifies the stalk or the depth of the diathermy burn. The risk of relapse ranges from 0% to 2% in malignant polyps with a margin of resection greater than 1 mm. When the resection margin is also involved, or is less than 1 mm, the percentage of relapse ranges between 21% and 33%[25]. Most authors believe that a resection margin of $\geqslant$ 2 mm is safe and that in such cases the probability of residual disease or recurrent carcinoma is low[4,5,25,26]. However, whether the requisite distance from cancer to margin of resection should be > 1, > 2, or > 3 mm or only a clear margin of excision is still under debate.

Stage of differentiation

Four grades were considered. Grade 1 corresponded to a well-differentiated intestinal-type adenocarcinoma and is composed of well-formed glands with open lumina or with more than 95% glandular differentiation. Grade 2 was moderately differentiated intestinal-type adenocarcinoma containing solid nests showing only focal glands or with 50%-95% glandular differentiation. In the case of Grade 3, the carcinoma is poorly differentiated intestinal-type, signet ring cell or mucinous adenocarcinoma, composed of hyperchromatic cells arranged into solid sheets and forming absorptive glands. These tumors have between 5% and 50% glandular differentiation. Undifferentiated tumors which have less than 5% glandular differentiation correspond to Grade 4. Medullary carcinomas with high microsatellite instability are classified as undifferentiated carcinomas. The prognosis correlates with the histological grade[27]. Grade 3 of differentiation is seen in 5.7% to 9.2% of patients with polyps and the risk of residual lesions or relapse in these cases is of the order of 36%-38%[25]. In most cases, grade 3 differentiation is associated with invasive adenocarcinoma cells $\leqslant$ 1 mm from a clearly visualized margin.

Level of invasion of adenocarcinoma into the polyp

Haggitt *et al*[28] assigned anatomic regions (levels) of invasion to each malignant polyp. In this study, level 1 described invasive adenocarcinoma limited to the polyp head; level 2 included neck involvement; level 3 corresponded to adenocarcinoma cells in the stalk; and level 4 to invasion, adenocarcinoma cells infiltrating the submucosa at the level of the adjacent bowel wall (Figure 1). In this system, invasive adenocarcinoma in a sessile polyp by definition had level 4 invasion. However, precise histological evaluation of Haggitt's level may be difficult, especially the differentiation between Haggitt's level 1 *vs* 2, and 2 *vs* 3. Properly marked and orientated specimens are essential. Some authors conclude that only patients with level 4 invasion require resection[29]. More recently, some authors have proposed an additional histological classification system based on the grade of cell differentiation at the lesion margins and on the size and depth of invasion of the submucosa. Accordingly, the degree of submucosal invasion has been classified into three types based on the depth of invasion. When less than one-third of the submucosa is invaded the stage is sm1, and if more than two-thirds is invaded the stage is sm3, while stage sm2 is intermediate with invasion of cancer into the middle third. Sm1 is when the depth of invasion is less $\leqslant$ 1 mm or 1000 μm from the muscularis mucosae[17]. It has been shown that penetration of cancerous cells into the lower third of the

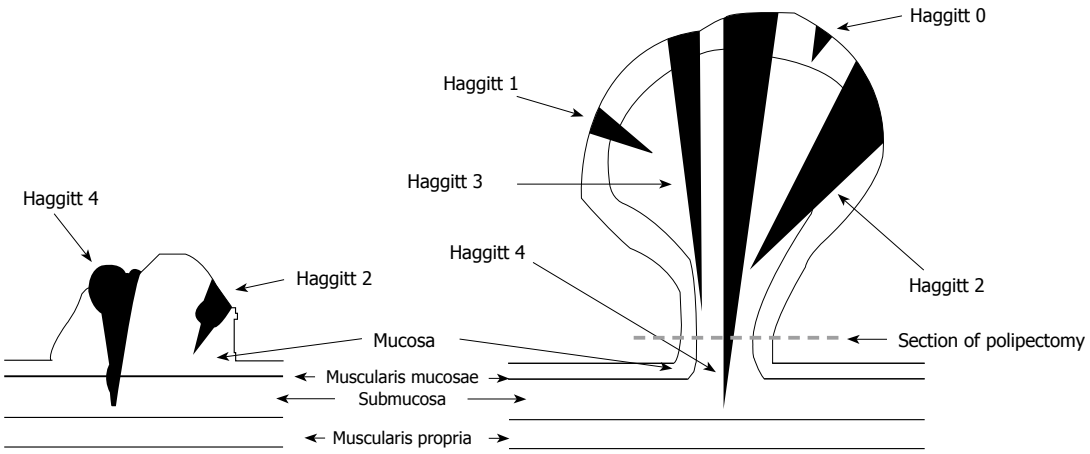

Figure 1 The Haggitt classification. Haggitt 0: Limited to the mucosa without invasion of submucosa; Haggitt 1: Invasion of submucosa but limited to the head of the polyp; Haggitt 2: Invasion extending into the neck of the polyp; Haggitt 3: Invasion into any part of the stalk; Haggitt 4: Invasion beyond the stalk but above the muscularis propria.

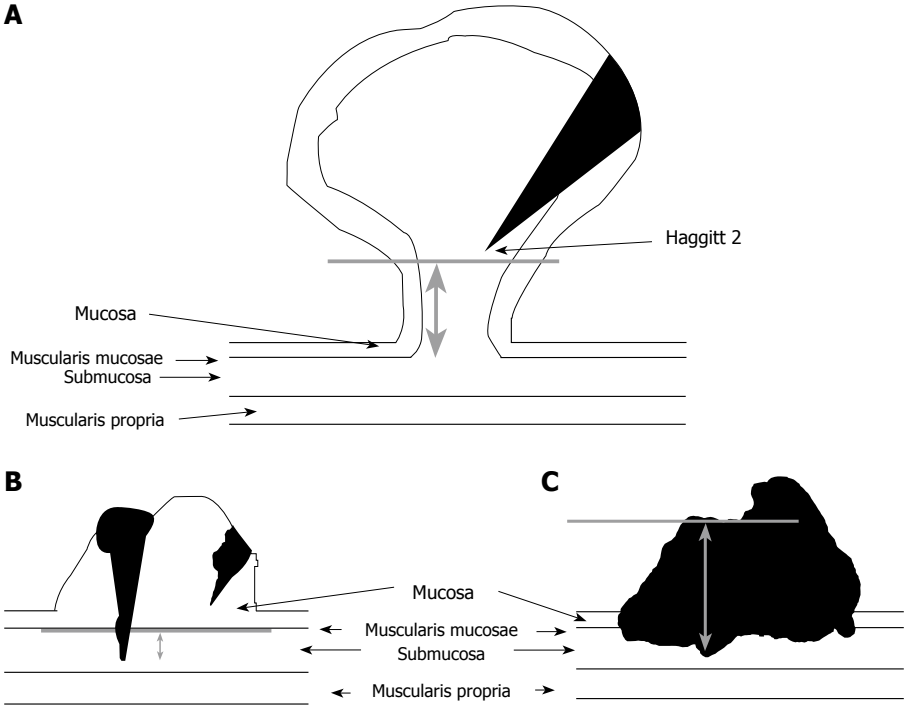

Figure 2 Kitajima's classification. The method used for measurement of submucosal invasion (SM) depth. A: For pedunculated submucosal invasive colorectal carcinoma, level 2 according to Haggitt's classification was used as the baseline (grey line), and SM depth was measured as the vertical distance from this line to the deepest portion of invasion; B: For nonpedunculated, when the muscularis mucosae could be identified in HE stained specimens, the muscularis mucosae was used as baseline (grey line) and the vertical distance from this line to the deepest portion of invasion represented with bidirectional arrow grey; C: For nonpedunculated, when the muscularis mucosae could not be identified due to carcinomatous invasion, the superficial aspect of the invasive carcinoma was used as baseline (grey line), and the vertical distance from this line to the deepest portion of invasion was determined (bidirectional arrow grey).

submucosa (sm3) of sessile lesions is associated with a greater risk of lymphatic spread than only mild penetration[27-32]. Research based on large patient series has shown a 1%-3% risk for lymph node metastases in sm1 cancers, 8% in sm2 cancers and 23% in sm3 cancers[31].

However, two problems exist in measuring submucosal invasion (SM) depth; how to measure SM depth in a lesion whose muscularis mucosae could not be identified, and how to determine SM depth in tumors demonstrating morphological differences. To solve the first problem, when the muscularis mucosae could not be identified due to carcinomatous invasion, Kitajima *et al*[33] (Figure 2) in a Japanese collaborative study defined the superficial aspect of submucosal invasive colorectal carcinoma (pedunculated, nonpedunculated with muscularis mucosae identified and nonpedunculated without muscularis mucosae identified) and measured SM depth from this baseline to the deepest portion of invasion. For pedunculated, submucosal invasive colorectal carcinoma, the level 2 proposed by Haggitt was used as baseline (neck of the adenoma or junction between adenoma and stalk). In these cases the rate of lymph node metastasis was 0% when stalk invasion was < 3 mm or 3000 μm. For nonpedunculated, the muscularis mucosae was used as baseline and the vertical distance from this line to the deepest portion of invasion represented SM depth. In nonpedunculated polyps without muscularis mucosae identified, the superficial aspect was used as baseline and the vertical distance from this line to the deepest portion of invasion was determined. The rate of lymph node metastasis was 0% if SM depth was < 1 mm or 1000 μm for nonpedunculated polyps[33].

Lymphatic invasion

The presence or absence of lymphatic invasion by cancer is defined as tumor cells within a true endothelial-lined channel in the absence of red blood cells[34]. The risk of lymphatic spread from a malignant polyp has been estimated by histological study of resected specimens. Since lymphatics do not penetrate much beyond the muscularis mucosae, focal cancer that has not invaded through this layer appears to present little or no risk of lymph node spread[35]. A plexus of lymphatic channels is normally found in the superficial submucosa and within the muscularis mucosa, with rare extensions into the lamina propria (mucosa) limited to the region at the base of the crypts. The near absence of lymphatics within the mucosa has been proposed as the reason for the observed lack of malignant potential (lymph node metastasis) observed in polyps showing only intramucosal carcinoma. However, this theory has been challenged by studies using more sensitive techniques to detect lymphatic vessels. Studies using the relatively new antibody D2-40 (Dako, Carpenteria, CA, USA), which stains lymphatic but not blood vessel endothelium, have shown that lymphatics undergo proliferation and are present in the stalk and mucosa of adenomas and early invasive cancers. In malignant polyps, lymphatic channels are often present near nests of infiltrating tumors[36,37]. From a practical point of view, detecting lymphatic invasion by expert pathologists using light microscopy is difficult. There are no recognised guidelines for establishing the presence of lymphatic invasion (for example, the number of sections or immunostains needed to identify lymphatic vessels). For example, in a study in which five pathologists assessed the lymphatic invasion of 140 malignant polyps, they agreed (4 out of 5 observers) on only 17 cases. The intra- and inter-observer variability in the interpretation of samples received among even the most expert histopathologists can be high and often leads to diagnostic uncertainties which inevitably results in a more cautious therapeutic approach being taken[38]. True lymphatic invasion is rare, although retraction of tissue creating an artificial space around tumor cells is common in paraffin sections. The use of immunohistochemistry for D2-40 may help identify lymphatic channels. However, its use is not yet routine, and technical issues such as loss of a suspicious focus in level sections limits the usefulness of special stains in this setting. The presence of lymphatic invasion in a malignant polyp has been proposed by some researchers as an indication for colectomy. However, few malignant polyps with lymphatic invasion have been reported, and most of them have had positive margins, Grade 3 invasive adenocarcinoma (as defined above), or both[5]. Approximately 12% to 16% of all polyps have lymphatic invasion, and in these cases, the risk of relapse or residual lesions ranges between 17% and 39%.

Vascular invasion

The presence or absence of venous invasion is defined as cancer in an endothelial-lined channel surrounded by a smooth muscle wall[36]. However, it is difficult to recognise venous invasion. Vascular markers, such as CD31, CD34 and factor Ⅷ may help in assessing vascular invasion. These markers strongly stain blood vessel endothelium, and, to a lesser extent, lymphatic endothelium[14]. The prevalence of venous invasion in malignant polyps varies greatly from one study to another, ranging from 3.5% to 39%[38]. Often venous invasion is associated with lymphatic invasion and/or tumors which have a resection margin of less than 2 mm and/or are poorly differentiated. In contrast to the majority of studies, Talbot *et al*[39] observed that venous invasion was not associated with poorer prognosis.

Favourable and unfavourable histology and the risk of residual disease or recurrent carcinoma

Favourable histology is defined as Grade 1 or 2 differentiated adenocarcinoma in which carcinoma cells are at least 2 mm from a clearly visualised margin, resection is carried out *en bloc* and there is an absence of vascular or lymphatic invasion.

The definition of unfavourable histology is when the distance between the invasive tumor and the cauterized biopsy margin < 2 mm or 2000 μm, there is piecemeal removal or tumor within the cauterized region constitutes a positive margin or a poorly differentiated tumor (Grade 3) or there is lymphatic or vascular invasion. In these cases, surgical resection is indicated because of the increased risk of lymph node metastasis or residual disease[14]. On the other hand, in the absence of unfavourable features, polypectomy is considered curative. Specimens that do not lend themselves to proper analysis for any reason (piecemeal removal or poor orientation) sometimes result in a default decision to resect.

In 1995, Volk *et al*[5] reviewed 20 studies in which 858 malignant polyps were analysed. They observed that in 89 patients (10%), there was residual disease or recurrent carcinoma. However, there were relapses or tumors in the area of the resection in only 8 (1%) patients with favourable histological criteria. Subsequent studies have also reported an incidence of less than 1%[38,40]. Only one study described an incidence higher than 5% in malignant polyps with favourable histology[41] and the study itself has been widely criticised and excluded from subsequent reviews[5]. By contrast, in malignant polyps with unfavourable histology, the risk of relapse or residual lesions ranges between 10% and 39%[5,14,31,40].

TREATMENT

Prior to removal of the polyp, it is difficult to know whether the polyp is malignant or not. Some features, as we have mentioned earlier, can give some indication of the degree of malignancy (Figure 3). In these cases, it is advisable to perform tattooing in order to mark the base of the resected polyp. Tattooing helps the surgeon or endoscopist to locate the base of the polyp. Regardless of the morphological characteristics, a polyp is normally removed when detected. Polypectomy should be per-

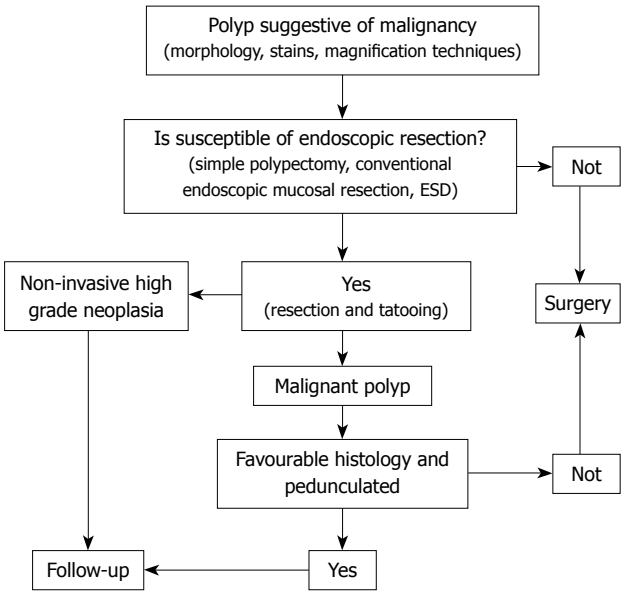

Figure 3 Diagnostic and therapeutic algorithm of malignant polyps.

formed *en bloc*, since this is essential to establish and define favourable or unfavourable histological criteria. In just a few cases, only polyp biopsies are performed. This may be due to a lack of coagulation data, the polyp being difficult to remove at that point in time, or the patient being on antiplatelet drugs or anticoagulants.

NHGN regardless of their morphology, are considered to be cured with polypectomy[42].

The indication for a malignant polyp with sessile morphology, regardless of favourable histological criteria, is surgery[1], especially in patients younger than 50 years old, who tend to present fewer surgical complications[39]. ESD has emerged as a possible technique to successfully resect malignant colonic polyps *en bloc*[24,43]. This approach is indicated for polyps larger than 2-3 cm, involving more than one-third of the colon circumference or two haustral folds, or with a flat/depressed morphology. The technique makes it possible to treat large (> 2 cm) sessile and flat polyps enabling pathological evaluation and cure in most patients. ESD is better than conventional endoscopic mucosal resection because it has higher *en bloc* resection and curative rates despite the longer procedure time and higher perforation associated with ESD[44]. Also, ESD can be an alternative to surgery for older patients and for those suffering from associated conditions that contraindicate surgery. In addition, this type of resection should be considered for malignant polyps with sessile morphology, and hence, with surgical indication, regardless of histological criteria.

Surgical treatment is also recommended for malignant polyps with pedunculated morphology which have unfavourable histological criteria (partial polyp resection, poorly differentiated carcinoma, vascular or lymphatic invasion, margin of resection < 2 mm or depth of submucosal invasion is ⩾ 3 mm from muscularis mucosae[1,33]. On the other hand, for malignant polyps with pedunculated morphology but with favourable histological criteria, polypectomy is considered to be curative.

However, until now many pathology reports did not report histological criteria. For example, at the University of Minnesota between 1987 and 2000, in 83% of patients angiolymphatic vessel invasion was not reported, in 69% the depth of invasion by cancer cells was not reported and in 22% the degree of tumor differentiation was not stated[45]. Besides the agreement among experienced pathologists was poor with respect to histological grade of differentiated carcinoma and angiolymphatic vessel invasion[45].

In recent years, various serum markers have been identified in an effort to establish which patients could benefit from surgical treatment and from a stricter follow up. These markers include metalloproteinase 7[46], vascular adhesion proteins[47], vascular endothelial growth factors[48] and cytokeratins[49]. The majority of markers have been studied in patients operated on for colon cancer with infiltration of the muscularis propria (equivalent to or higher than T2), so these results cannot readily be extrapolated to malignant colorectal polyps.

An exception to these guidelines is patients with malignant polyps, with sessile or flat morphology, that are located in the rectum. The occurence of distant metastases is correlated to T-stage and, after radical resection of T1 tumors, the 5-year rate of metastases is about 10%[50], similar to malignant polyps in other locations. An adequate preoperative evaluation of the patient's general health is essential before deciding the modality of treatment for the individual T1 rectum cancer patient. About 50% of local recurrences following local resection are curable if the patients are included in an intensive follow-up programme. T1 rectal cancer should be classified into at least two subgroups (low and high risk). The most widely accepted criteria for classifying low-risk T1 cancer are tumor diameter < 3 cm or tumor infiltration no deeper than the middle layer of the submucosa. Some authors differ as to whether T1 sm2 cancer should be classified as low-risk or high-risk cancer. Between the low risk criteria are tumor diameter < 3 cm, high or intermediate differentiation, infiltration no deeper than the middle layer of the submucosa (sm1 or sm2) and no sign of lymphovascular infiltration[51]. Low risk T1 cancers should be treated with local resection (ESD or conventional endoscopic submucosal resection or transanal endoscopic microsurgery). Also, local resection of high-risk T1 cancers may offer the best treatment for older patients (> 80 years) and for patients with comorbidity[51].

Transanal endoscopic microsurgery (TEM) is a minimally invasive surgical technique that allows the surgeon to operate on problems in the mid and upper rectum without having to make an incision through the abdomen. TEM is a safe technique with few complications. The local recurrence rate varies widely, less than 10% in patients with low-risk. The ideal patient for local excision with TEM therefore has a small T1 cancer with low-risk, located between 5 and 10 cm from the anal verge (5-15 cm up on the posterior rectal wall)[51].

FOLLOW-UP

In cases of NHGN and malignant polyp with pedunculated morphology and favourable histological criteria, it is recommended that a colonoscopy be carried out three months after taking the biopsy[1,52]. If this is normal, a further check up is advised after one year, three years and five years[48]. Some authors suggest that if the results within three months are negative, subsequent monitoring should be the same as that offered to patients with non-malignant adenomas, since there is no evidence that such patients are at a higher risk of metachronous polyps or cancers than those patients with benign adenomas[42,53]. However, recent studies estimate that 11.8% of patients who have undergone polypectomy will develop a metachronic advanced adenoma and 0.6% an invasive carcinoma. Associated risk factors include age, number of polyps (5 or more), size (greater than 1 cm), villous architecture, proximal location, and being male. The odds ratio increases progressively according to the number of adenomas, it being 1.39 for those who have had 2 adenomas and 3.87 for those who have had 5 or more. Smoking, body mass index, family history of CRC, and degree of dysplasia were not found to be associated with higher risks of advanced adenoma or cancer[54].

There have been reports of cases of malignant pedunculated polyps with unfavourable histological criteria which, despite no findings of residual carcinoma in the intestine wall or lymph node involvement, are found on follow up to have distant metastasis, even five years after surgery[4,5]. These data force us to consider the monitoring of such patients using serum levels of carcinoembryonic antigen and imaging techniques such as computerised tomography which would enable early detection of recurrence.

Published series of malignant colorectal polyps usually include fewer than 100 cases, and most of these are retrospective studies. Given this, it would be interesting for new prospective studies to be carried out to evaluate the progress of such patients and to establish the most suitable treatment and follow up regimens for them.

CONCLUSION

The prevalence of malignant polyps in series of endoscopically removed polyps is between 0.2% and 11%. Currently the number of cases in which malignant polyps are removed is increasing due to screening programmes. Carcinoma "*in situ*", intramucosal carcinoma, high-grade dysplasia or intraepithelial carcinoma is the stage at which there is no involvement of the muscularis mucosa. These terms are defined as non-invasive high grade neoplasia in the Vienna classification. When the carcinoma spreads to the submucosa, the polyp is considered to have become malignant, being able to spread to lymph nodes or distant sites. This term is defined as submucosal carcinoma in the classification of Vienna. The definition of unfavourable histology is when the distance between the invasive tumor and the cauterized biopsy margin < 2 mm, there is piecemeal removal or tumor within the cauterized region constitutes a positive margin or a poorly differentiated tumor (grade 3) or there is lymphatic or vascular invasion. In these cases, surgical resection is indicated because of the increased risk of lymph node metastasis or residual disease. Also, the indication for a malignant polyp with sessile morphology, regardless of favourable histological criteria, is surgery. In cases of non-invasive high grade neoplasia and submucosal carcinoma with pedunculated morphology and favourable histological criteria, it is recommended that a colonoscopy be carried out three months after taking the biopsy and if this is normal, a further check up is advised after one year, three years and five years.

Abstract

Heme oxygenase (HO)-1 is the inducible isoform of the first and rate-limiting enzyme of heme degradation. HO-1 not only protects against oxidative stress and apoptosis, but has received a great deal of attention in recent years because of its potent anti-inflammatory functions. Studies with HO-1 knockout animal models have led to major advances in the understanding of how HO-1 might regulate inflammatory immune responses, although little is known on the underlying mechanisms. Due to its beneficial effects the targeted induction of this enzyme is considered to have major therapeutic potential for the treatment of inflammatory disorders. This review discusses current knowledge on the mechanisms that mediate anti-inflammatory protection by HO-1. More specifically, the article deals with the role of HO-1 in the pathophysiology of viral hepatitis, inflammatory bowel disease, and pancreatitis. The effects of specific HO-1 modulation as a potential therapeutic strategy in experimental cell culture and animal models of these gastrointestinal disorders are summarized. In conclusion, targeted regulation of HO-1 holds major promise for future clinical interventions in inflammatory diseases of the gastrointestinal tract.

Key words: Antioxidant; Heme oxygenase; Hepatitis; Immunity; Inflammation; Inflammatory bowel disease; Oxidative stress; Pancreatitis

INTRODUCTION

Heme oxygenase (HO), which was initially described more than 40 years ago, enzymatically degrades heme and produces equimolar amounts of carbon monoxide (CO), biliverdin, and iron[1] (Figure 1). In a coupled reaction, biliverdin is converted into bilirubin (BR) *via* biliverdin reductase[2]. Two distinct isozymes of HO, HO-1 and HO-2, have been identified and represent the products of two different genes with distinct tissue- and cell-specific expression patterns[3-5]. The constitutive isoform HO-2 is preferentially expressed in brain and testis[6], and is essentially not regulated by metabolic or receptor-mediated

stimuli[4,7]. In contrast, the inducible HO isozyme, HO-1, which exhibits low basal expression levels in most cells and tissues, is markedly upregulated not only by its substrate heme, but also by other oxidative stress stimuli, such as UV-light and lipopolysaccharide (LPS) or directly by reactive oxygen species, such as hydrogen peroxide. In addition, heavy metals, sulfhydryl-reactive reagents, and hypoxia are potent inducers of HO-1[8-10]. Thus, although HO-1 does not directly catalyze an antioxidant reaction, its induction is generally considered an adaptive cytoprotective response against the toxicity of oxidative stress[11-13]. In the current review, we focus our attention on recent findings that show the emerging anti-inflammatory and immunomodulatory role of HO-1 and its products. In particular, we highlight recent advances in the understanding how HO-1 might modulate the inflammatory immune response and the potential role of HO-1 for therapeutic applications in inflammatory conditions of various organs in the gastrointestinal tract.

HO-1 GENE DEFICIENCY CAUSES PROINFLAMMATORY PHENOTYPICAL ALTERATIONS

A potential link between HO-1 and inflammatory disease has been shown by Willis *et al*[14] in an animal model of carragenin-induced pleurisy, in which specific upregulation of HO enzyme activity attenuated a complement-dependent inflammation. Mice that are deficient for HO-1 not only develop chronic inflammation, but are also highly vulnerable to experimental sepsis induced by the classical proinflammatory mediator endotoxin[15]. In addition, innate and adaptive immune reactions are severely affected in these knockout mice[16-18]. In contrast, HO-2 knockout mice appear to have an intact immune regulation, but exhibit defects in their central and autonomous nervous system[19]. The phenotype of the only known human case of genetic HO-1 deficiency is very similar to that observed in HO-1 knockout mice. This HO-1 deficient patient, a Japanese boy who died at the age of six years, was initially diagnosed with anemia and a chronic inflammatory disorder[20,21].

ANTI-INFLAMMATORY EFFECTS OF HO-1 IN MONONUCLEAR PHAGOCYTES AND ENDOTHELIAL CELLS

Although HO-1 is expressed in all tissues and cells, the immunomodulatory functions of HO-1 appear to be primarily dependent on HO-1 functions in mononuclear phagocytes and endothelial cells. In the following, we describe pertinent findings that illustrate the anti-inflammatory role of HO-1 in these two cell types.

Mononuclear phagocytes

Mononuclear phagocytes, such as monocytes and macrophages, are cells with a common bone marrow lineage and have versatile functions in the innate and adaptive immune system[22,23]. As an example, macrophages ingest and kill invading microorganisms as a first line of defence and are activated by various immunological stimuli, such as microbial products or cytokines. In response to these stimuli, macrophages are able to initiate and enhance the inflammatory immune response[23]. It has been known for many years that tissue macrophages, such as Kupffer cells and spleen macrophages, are cell types in which HO-1 is highly expressed under normal conditions[24,25]. Several studies have been performed with cultured mononuclear cells from rodents. Here, HO-1 is upregulated in response to LPS[25-27], which attenuates the expression of various proinflammatory genes, such as cyclooxygenase-2, tumor necrosis factor-α, interleukin (IL)-1, and IL-6[18,28-31]. The cell-specific antiinflammatory function of HO-1 in mononuclear phagocytes was recently confirmed in a conditional HO-1 knockout mouse model. The cell-specific lack of HO-1 in mononuclear cells caused a major defect of interferon-β expression. In addition, a pathological immune response in an experimental infection with Sendai virus and in autoimmune encephalomyelitis in these animals was observed[32]. Interestingly, others have shown that HO-1 is also important for the appropriate function of human and mouse dendritic cells. It has been shown that pharmacological induction of HO-1 attenuates maturation and cell-specific functions of dendritic cells[33,34]. Moreover, HO-1 expression in mononuclear cells has been demonstrated to be essential for the functionality of regulatory T cells[17].

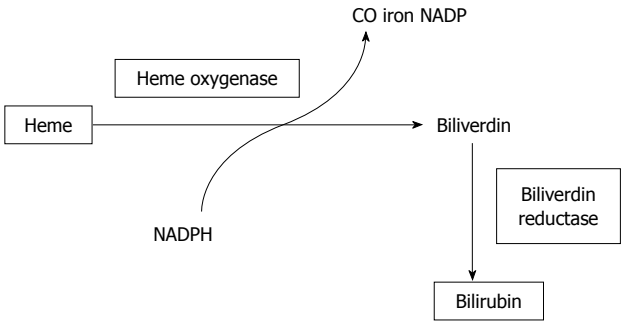

Figure 1 The heme oxygenase enzyme reaction. Heme is enzymatically degraded to yield carbon monoxide (CO), iron, and biliverdin, which is converted into bilirubin in a coupled reaction.

Endothelial cells

The endothelium plays a central role in the regulation of inflammatory reactions, because it serves as a barrier between the peripheral blood stream and inflamed tissues. More specifically, endothelial monolayers regulate the recruitment and transmigration of immunologically active blood cells, such as polymorphonuclear leukocytes (neutrophils) or T lymphocytes, to the site of an inflammation[28,35,36]. Hayashi and colleagues[37] have reported that HO-1 regulates cell-cell interactions between polymorphonuclear leukocytes and endothelial cells. These authors showed in an *in vivo* rat model that the increased

enzyme activity of HO in the endothelium of microvessels downregulated the adhesion of leukocytes during experimental oxidative stress[37]. Accordingly, others have demonstrated that the activity of endothelial HO-1 specifically modulates leukocyte recruitment into organs with an experimental inflammation[38]. Independently, in a streptozocin-induced rat model of experimental diabetes, overexpression of HO-1 has been shown to attenuate oxidative stress-dependent endothelial cell damage[39]. Similar findings in the endothelium have recently been reported for knockout mice, in which genetic deficiency of HO-1 caused major pathological alterations of the endothelial monolayer[40]. Specifically, endothelial cells from HO-1 deficient mice were shown to be more susceptible to apoptosis and denudation from the extracellular matrix. Moreover, independent groups have shown that antiinflammatory endothelial protection of HO-1 might be mediated *via* its ability to downregulate the tumor necrosis factor-α-induced expression of various adhesion molecules[41-43]. It is also remarkable that histopathological studies in the autopsy of a human patient with genetic HO-1 deficiency revealed major endothelial cell damage[21].

HOW DOES HO-1 MEDIATE ITS ANTIINFLAMMATORY FUNCTIONS

The mechanisms of how HO-1 may counteract inflammatory reactions are not understood in detail. An accumulating body of evidence, however, indicates that the HO substrate heme is a compound with major proinflammatory properties and that the HO products BR and CO have potent antiinflammatory functions.

Heme as a proinflammatory compound

The tetrapyrrole heme has contradictory biological properties. On the one hand, heme is important for oxygen and mitochondrial electron transport as the prosthetic group of various hemoproteins such as hemoglobin, myoglobin, and cytochromes[44,45]. On the other hand, heme can be toxic as it can cause oxidative stress in its "free" non-protein bound form. The prooxidant properties of heme have been shown in various animal and cell culture models[46,47]. Due to the critical role of intracellular heme levels, enzymatic synthesis and degradation of this compound is tightly controlled[48-50]. More recently, heme has also been recognized to exhibit potent proinflammatory properties[18,51]. As an example, Jeney *et al*[52] have demonstrated that heme-dependent oxidation of low-density lipoproteins is involved in inflammation-mediated tissue damage. In this report, the proinflammatory effects of heme have also been shown to be correlated with specific clinical conditions, such as atherosclerosis and hemolytic anemia[52]. Independently, others have demonstrated that intravenous administration of heme caused experimental inflammation *in vivo* with a major influx of leukocytes[38]. Heme-dependent toxicity has also been associated with its proinflammatory effects in an animal model of experimental cerebral malaria, in which heme-dependent detrimental effects were markedly more pronounced in HO-1 knockout mice[53]. Recent findings might shed light on the mechanisms that could be involved in the proinflammatory effects of heme. Figueiredo and colleagues have demonstrated that initiation of heme-dependent inflammation was mediated *via* specific interaction of heme with the central pattern recognition receptor toll-like receptor-4, in a cell culture model of mononuclear cells and in mice[54]. The role of HO-1 in maintaining intracellular heme homeostasis has been reviewed elsewhere[18,47,48,51].

Bilirubin

The role of bilirubin (BR) as a beneficial compound with potent antioxidant and antiinflammatory effects has only been appreciated in recent years[55,56]. Protection against an experimental inflammation has been shown for HO-derived BR in an animal model[37]. Moreover, it has been observed in a murine asthma model that BR specifically reduces leukocyte transmigration to the site of an experimental inflammation *via* interaction with the adhesion molecule vascular cell adhesion molecule-1[57]. More recently, it has been reported in a mouse model of sepsis that a single bolus of BR markedly blocked the toxicity of endotoxin[58]. Epidemiological studies have indicated that moderately increased concentrations of serum BR (e.g. in Gilbert's disease) are associated with a lower risk of developing cardiovascular disease[59,60] and colorectal carcinoma[61]. In conclusion, the generation of BR by HO-1 might, in part, explain the antiinflammatory effects of this enzyme.

CO

Although CO is generally considered a toxic gas, various physiological functions of CO as a major signaling molecule have been recognized in recent years[3,62,63]. In particular, HO-1-derived CO has been shown to be involved in the regulation of apoptosis, neurotransmission, coagulation, vasodilation, and inflammation. In a pioneering report on the potential protective effects of this gas, administration of exogenous CO has been shown to block the LPS-induced production of proinflammatory cytokines *via* modulation of p38 MAP kinase[29]. Similar to the signaling gas NO, CO upregulates the production of cGMP *via* activation of soluble guanyl cyclase. This mechanism has also been implicated in other functions of CO, such as vasodilation and blockage of smooth muscle cell proliferation. A remarkable development with major potential for future therapeutic applications has been the introduction of CO-releasing molecules (CORMs). CORMs are compounds that can be administered intravenously and are intended to deliver CO to its target site without the toxicity of gaseous CO[64]. Further details on CO and CORMs are given in specific reviews[63,65,66].

HO-derived iron

Iron, as the third product of HO, is an essential com-

Table 1 HO-1 and inflammatory disorders of the gastrointestinal tract

Disorder	Mechanism of protection by HO-1	Experimental model	Ref.
Viral hepatitis (HBV, HCV)	HBV: repression of HBV replication	*In vivo*: transgenic mice; *in vitro*: human HepG2 hepatoma cells	[74]
	HCV: repression of HCV replication	*In vitro*: human Huh-7 hepatoma cells	[78-80]
		In vitro: human Huh-5-15 hepatoma cells	[81]
Inflammatory bowel disease	HO-1-derived biliverdin inhibits inflammatory activity	*In vivo*: colitis in dextran sodium sulfate-treated mice	[89]
	Inhibition of IRF8 activation	*In vivo*: colitis in IL-10-/- mice	[90]
	HO-1 mediates protection of 5-aminosalicylic acid	*In vivo*: colitis in trinitrobenzene sulfonic acid-treated rats	[91]
	Inhibition of NF-κB activation	*In vivo*: colitis in trinitrobenzene sulfonic acid-treated mice	[92]
	Inhibition of interleukin-17	*In vivo*: colitis in dextran sodium sulfate-treated mice	[93]
Pancreatitis	Homing of hemin-treated macrophages in pancreas before onset of inflammation	*In vivo*: acute pancreatitis in choline-deficient diet-fed mice	[101]

HO: Heme oxygenase; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

pound for redox-dependent enzyme reactions and bioenergetics. Iron, however, might cause the formation of toxic reactive oxygen species, if not appropriately contained by specific intracellular protective mechanisms. A key role in the protection against the toxicity of HO-1-derived iron is played by the intracellular iron storage protein ferritin[67,68]. This protection has been demonstrated in various cell culture models, in which the synthesis of HO-1 and ferritin was coordinately upregulated and prevented iron-mediated cell toxicity[12,47,69]. Remarkably, genetic deficiency of HO-1 in mice[70] and humans[20,21] is associated with a major pathological iron overload in the liver and kidney.

In summary, the HO products BR and CO have anti-inflammatory potential, which could be relevant for therapeutic interventions.

TARGETING HO-1 IN INFLAMMATORY DISORDERS OF THE GASTROINTESTINAL TRACT

HO-1 and chronic viral hepatitis

Chronic viral hepatitis mainly consists of viral hepatitis B and C, and is a major cause of liver cirrhosis and end-stage liver disease worldwide. These disorders are characterized by chronic self-perpetuating inflammation of the liver for at least six months. For example, chronic hepatitis C virus (HCV) infection affects 4 million US citizens, a third of whom will progress to liver cirrhosis and primary hepatocellular carcinoma if left untreated[71-73]. Treatment with interferon and ribavirin is effective in only 50% of patients, because many patients either have contraindications to these therapies or have failed to respond to this treatment, indicating a need for alternative or supplementary therapeutic strategies. In the following, we will focus on links between HO-1 and chronic viral hepatitis and their potential therapeutic use. Research on hepatitis B virus (HBV) and HCV infections has been prevented by a lack of appropriate animal and cell culture models to study these infections[73].

As regards HO-1 and HBV infection, Protzer and colleagues have reported that HO-1 has antiviral activity in a transgenic mouse model of chronic HBV infection. In this animal model, specific induction of HO-1 by cobalt-protoporphyrin-IX significantly reduced the levels of the viral HBV core protein. Moreover, these authors have shown that the antiviral effects of HO-1 are mediated *via* reduction of HBV core protein stability in cell cultures of stably transfected hepatoma cells[74] (Table 1).

Several reports suggest that HO-1 might serve as a specific therapeutic target for the treatment of chronic HCV infection, although the results are somewhat contradictory. On the one hand, Schmidt and colleagues have presented evidence that HCV specifically downregulates gene expression of HO-1, but not that of other antioxidant genes, such as manganese superoxide dismutase and catalase[75]. In cell cultures of hepatoma cells, inhibition of HO-1 by HCV appeared to be specifically regulated *via* the HCV-core protein[75,76]. On the other hand, it has been demonstrated that HCV leads to an increased expression of HO-1 in hepatoma cell lines, possibly *via* interactions with the HO-1 repressor, Bach1[77]. Clearly, further studies are necessary to reconcile these conflicting results.

In contrast, findings from independent reports have indicated that targeted overexpression of HO-1 had antiviral effects on HCV replication (Table 1). The group of Bonkovsky has demonstrated that upregulation of HO-1 either by a pharmacological approach or, more recently, by a microRNA-based strategy repressed HCV replication in human Huh-7 hepatoma cells[78,79]. Accordingly, Zhu *et al*[80] have shown that targeted overexpression of HO-1 led to a significant inhibition of HCV replication without affecting other parameters of cell viability in human hepatoma cells, which stably replicate subgenomic selectable HCV RNAs[80]. These studies have recently been extended by others, who have shown that the HO-1 product biliverdin interfered with HCV replication *via* direct modulation of the antiviral interferon-α response in two human hepatoma replicon cell lines[81] (Table 1).

Due to the limited success rate of current therapies for chronic viral hepatitis, it is conceivable that targeted modulation of HO-1 might be an innovative comple-

mentary strategy for the treatment of these infectious diseases.

HO-1 and inflammatory bowel disease

Inflammatory bowel disease (IBD) is a group of chronic inflammatory disorders, which is primarily represented by ulcerative colitis and Crohn's disease. The etiology of IBD is not well understood and a complex interplay of genetic, immunological and environmental factors appears to play a role in the initiation and perpetuation of IBD[82]. The onset of IBD is characterized by an autoimmune inflammatory reaction that causes excessive production of pro-inflammatory cytokines and reactive oxygen species, which in turn damage the intestinal mucosa[83]. A number of experimental animal models of IBD have been established, in which IBD develops either spontaneously, such as in various knockout mouse models, or after treatment with specific chemical compounds, such as trinitrobenzene sulfonic acid[84]. These models are widely used to investigate potential therapeutic strategies for the treatment of IBD. HO-1 regulation has been studied in a variety of these animal models and in biopsies from human IBD patients.

In a trinitrobenzene sulfonic acid-induced model of experimental colitis, it has been demonstrated that HO-1 is prominently upregulated in various cell types of the inflamed colon[85]. These findings correspond with observations from an independent study, in which increased HO-1 expression has been observed in mucosa biopsies of a murine colitis model. Importantly, in this study, HO-1 expression has also been shown to be increased in inflamed mucosa of human IBD patients[86]. Similar findings have been reported by Takagi *et al*[87] for a Japanese population. Indirect evidence that HO-1 might play a role in the pathogenesis of IBD has been demonstrated in knockout mice for the Nrf2 gene, which is the major transcriptional regulator of HO-1. Nrf2-deficient mice were more susceptible to develop an experimental colitis in response to dextran sodium sulphate when compared with their wild-type counterparts[88].

As regards the potential therapeutic role of HO-1 in IBD, important insights have been presented in independent reports on HO products (Table 1). In a dextran sodium sulphate-induced colitis model, HO-1-dependent protection against inflammation has been attributed to the beneficial effects of biliverdin[89]. By contrast, others have indicated that CO might provide anti-inflammatory protection in mice with genetic IL-10 deficiency, which develop a chronic colitis-like disease. In these mice it is also shown that the immunosuppressive effects of CO were recapitulated by pharmacological induction of HO-1[90]. Interestingly, upregulation of HO-1 might also play a role in the antiinflammatory protective effects of some established current standard therapies of IBD. As an example, Horváth *et al*[91] have shown that 5-amino salicylic acid (5-ASA), which is one of the pharmacological standard therapies of IBD, might, at least in part, mediate its antiinflammatory effects *via* upregulation of HO-1 in a trinitrobenzene sulfonic acid-induced rat colitis model. In addition, others have demonstrated that the fungal metabolite gliotoxin and the HO-1 substrate heme mediate antiinflammatory effects in independent experimental colitis models *via* specific induction of HO-1, respectively[92,93] (Table 1).

Finally, it is important to point out that targeted HO-1 induction does not provide anti-inflammatory protection in an experimental animal model of dextran sulphate sodium-induced colitis, when HO-1 was induced after the onset of IBD[86]. Therefore, it seems questionable whether HO-1 induction is useful for treatment of established IBD, but rather might be useful as a preventive measure.

HO-1 and pancreatitis

Pancreatitis is an inflammatory disorder that is clinically categorized into acute and chronic pancreatitis[94]. The clinical stages of pancreatitis range from a transient self-limiting inflammatory reaction to a fulminant disease with necrotic lesions. Severe acute pancreatitis, which might have multiple local and systemic complications, is associated with high mortality[87]. In general, acute pancreatitis is caused by alcohol abuse and gallstones. More recently, however, genetics and obesity have been identified as independent risk factors. The pathogenesis of pancreatitis is not well understood, but it is known that proinflammatory pancreas-independent factors, such as exposure to endotoxin, can trigger the onset of the disease. Oxidative stress has repeatedly been implicated in the pathogenesis of pancreatitis[95,96]. Although the exact role of oxidative stress during the course of the disease is not well understood, antioxidant enzymes and vitamins have been shown to improve the clinical consequences of pancreatitis[97]. Other therapeutic strategies for the treatment of pancreatitis include inactivation of pancreatic enzymes and blockage of platelet factor activating receptor[94,97,98].

HO-1 is upregulated in animal models of experimental pancreatitis in a cell-specific manner[99,100]. In particular, it has been demonstrated that HO-1 gene expression in the inflamed pancreas is primarily upregulated in peripheral macrophages, which migrate into areas of inflammation[101] (Table 1). In the latter report, the authors have also asked whether HO-1 induction might protect against pancreatitis. The major finding of this study, in which experimental pancreatitis was induced with a choline-deficient diet, indicated that administration of heme decreased pancreatitis-associated lethality in mice. Moreover, administration of heme increased the pancreatic tissue secretion of chemokines, which was responsible for the infiltration of HO-1 expressing peritoneal macrophages into the pancreas. It is important to note, however, that heme-dependent HO-1 induction after the onset of pancreatitis failed to reduce the severity of the disease. This finding is similar to what has been observed in IBD, as mentioned above. Thus, although HO-1 induction might not be useful for the treatment of established pancreatitis, it might help to prevent the onset of pancreatitis in a clinical setting, in which pancreatitis is likely to develop. In a model of pancreas transplantation, in which pancreatitis develops as a consequence

of ischemia-reperfusion injury, pharmacological induction of HO-1 has been shown to be protective against pancreatitis[102] (Table 1). Similar observations have also been reported in an independent study, in which pretreatment with cobalt-protoporphyrin-IX prevented the microcirculatory dysfunction after pancreas ischemia-reperfusion injury in rat[103]. More recently, the CO donor CORM-2 has been shown to protect against acute pancreatitis in rats[104].

Finally, specific induction of HO-1 might also be applicable for treatment of chronic pancreatitis. In a recent report, Schwer *et al*[105] have shown that HO-1 induction by curcumin inhibited pancreatic stellate cell proliferation, which plays a major role in the pathogenesis of pancreatic fibrosis in chronic pancreatitis. This protection was abolished by blockage of HO activity, either by an enzyme inhibitor or by knockdown of HO-1 with a specific siRNA (Table 1).

CONCLUSION

Targeted overexpression of HO-1 has major potential for the treatment of inflammatory disorders of the gastrointestinal tract. Current knowledge on the applications of HO-1 as a therapeutic target, however, still seems precocious and critical questions remain to be answered before clinical interventions might be available.

Abstract

AIM: To investigate our learning curves of orthotopic liver transplantation (OLT) in rats and the most important factor for successful surgery.

METHODS: We describe the surgical procedures for our rat OLT model, and determined the operator learning curves. The various factors that contributed to successful surgery were determined. The most important surgical factors were evaluated between successful and unsuccessful surgeries.

RESULTS: Learning curve data indicated that 50 cases were required for operator training to start a study. Operative time, blood loss, warm ischemic time, anhepatic phase, unstable systemic hemodynamic state, and body temperature after surgery significantly affected surgery success by univariate analysis, while the anhepatic phase was the most critical factor for success by multivariate analysis.

CONCLUSION: OLT in rats is the only liver transplantation model that provides clinically relevant and reliable results. Shortened anhepatic phase is key to success in this model.

Key words: Animal model; Liver transplantation; Microsurgery; Rat; Reperfusion injury; Ultra-microsurgery

INTRODUCTION

Orthotopic liver transplantation (OLT) has become the treatment of choice for end-stage liver disease. Split OLT shows great promise for narrowing the gap between the number of patients waiting for an OLT and the number of available deceased organ donors. Living-donor OLT also addresses the severe problem of donor shortage and should ensure donor safety. However, further investigation into small-for-size grafts and small-for-size graft syndrome associated with split and living-donor OLT is needed prior to full acceptance in the clinical practice of OLT. Murine organ transplantation models, such as cardiac, lung, and kidney grafts, have been reported[1-5] and are commonly used by transplant immunity investigators. However, OLT in mice is technically very difficult, even without reconstruction of the hepatic artery (HA). Furthermore, a validated model of murine OLT is unavailable. In contrast, OLT in rats is technically accessible, producing more clinically relevant and reliable data. Hence, a comprehensive model of OLT in rats is particularly useful.

OLT in rats was first reported in 1973 using hand-suture techniques[6], while a modified model without HA reconstruction and temporal shunt of the porto-jugular veno-venous bypass was documented in 1975[7]. However, these models were not widely used due to the prolonged surgery time and technical demand. With the cuff method being introduced in 1973[8], OLT in rats without HA reconstruction became globally accepted. The pros and cons of each model were recently reported[9-23], and a combination of hand-suture and cuff methods are deemed to be key factors for successful OLT[24].

The development of clinically relevant OLT models in rats[9-23] has advanced clinical knowledge in liver transplantation[24-26]. Therefore, we will describe detailed surgical procedures of innovative OLT in rats based on two decades of experience at our centers. We will present the learning curves and important factors associated with successful OLT in rats.

MATERIALS AND METHODS

Materials

Animals: Lewis rats (RT-1[l], 8-10 wk) were used as recipients. As donors, Lewis rats were used for syngeneic grafts. As a large vessel diameter is necessary for the anastomosis, male rats of 230-250 g body weight were most suitable. Rats > 300 g were avoided because of the large amount of intra-abdominal fat, making the surgical procedures more difficult.

Adequate hydration, achieved with solution injections, is important for successful surgery, particularly prior to the anhepatic phase and after allograft recirculation[27]. We used male rats because the penile vein was easily accessible for repeated intravenous injections.

The use of animals was institutionally approved in accordance with The National Institutes of Health Guide for the Care and Use of Laboratory Animals.

General instruments: Cotton swabs with optimal stiffness (cotton tipped applicators; Hardwood Products Company, Guilford, ME, USA) and soft clay (Color Mounting Clay; Hampton Research, Aliso Viejo, CA, USA) were prepared. A cylindrical warmer (Mantello, Ambulatory Surgical Warmer, medium; Kent Scientific Co., Torrington, CT, USA) was used immediately after surgery.

General anesthesia was performed with a rodent anesthesia machine (VetEquip Inc., Pleasanton, CA, USA), including an evacuation canister and induction chamber.

Agents and solutions: Chemical agents used were: heparin (heparin lithium salt, 100 unit/mg; MP Biomedicals, Cleveland, OH, USA); Cephalexin hydrate (MP Biomedicals); buprenorphine 300 μg/mL (Reckitt Benckiser Pharmaceuticals Inc., Richmond, VA, USA); bicarbonate, 8.4% Sodium Bicarbonate Injection USP, 1 mEq/mL, 84 mg/mL (Hospira Inc., Lake Forest, IL, USA), and microfibrillar collagen, Avitene (C. R. Bard, Inc., Murray Hill, NJ, USA). The solutions used were: Lactated Ringer's Injection USP and Ringer's Injection USP (B. Braun Medical Inc., Irvine, CA, USA); 0.9% Sodium Chloride Injection USP (Hospira Inc.).

Surgical instruments: Basic instruments required for small animal surgery were similar to those described in previous reports[27,28]. For the anastomosis of vessels with a diameter under 0.5-1.0 mm, the instruments used were as previously described[27-29].

We have preferentially used instruments from Takasago Medical Industry Co. (Tokyo, 113-0033, Japan), Kent Scientific Co., Roboz Surgical Instrument Co., Inc. (Gaithersburg, MD, USA), and Southpointe Surgical Supply Inc. (Coral Springs, FL, USA).

Sutures used were thin silk threads (Silk Suture 7-0; Braintree Scientific Inc., Braintree, MA, USA), monofilament nylon suture (10-0 Ethilon, BV130-3, 2820G; Ethicon, Inc., Somerville, NJ, USA), monofilament polypropylene sutures (7-0 Prolene, BV-1, 8304H-X, and 8-0 Prolene, BV130-5, 8732H; Ethicon, Inc.), and absorbable thread (5-0 Coated Vicryl Plus; Ethicon, Inc.). Micro-clips (Microclip size: M, ML, and L, Horizon Ligation System; Teleflex Medical, Durham, NC, USA) and applying forceps (Microclip applicators; Teleflex Medical) were prepared.

Microscopes: A surgical loupe (2.0-3.0 × magnification) or a microscope (5-6.25 × magnification) is sufficient for microsurgery. We used a surgical microscope at 5-20 × magnification (Surgical Scope M680, Type 10445496; Leica Microsystems Inc., Bannockburn, IL, USA) for hepatic artery reconstruction at high magnifications (12.5-20 × magnification).

Micro-tubes and catheters: The micro-tubes used were polyurethane micro-tubes (Polyurethane Catheters, Straight Tip, Hydrocoat, 2 French, 20 gauge; Access Technologies, Skoki, IL, USA).

The peripheral catheters used were 14 gauge (14G Cathlon i.v. catheter; Johnson & Johnson Medical, Inc., Arlington, TX 76004-3130, USA) and 24 gauge (24 G Surflo Flush; Terumo Co., Tokyo, Japan).

Preparation of the stent tube for biliary duct and cuffs for portal vein and infra-hepatic inferior vena cava

Stent tubes for biliary duct (BD) reconstruction were made using 24 gauge peripheral catheters or 2 French polyurethane micro-tubes. A total length of 7-8 mm is sufficient.

The portal vein (PV) cuff was made using a 14 gauge peripheral catheter. First, 2-3 mm of the main body and 2 mm of the extension were made (Figure 1A).

The infra-hepatic inferior vena cava (IHIVC) cuff was similarly made using a conventional sterilized tube with a minimum inner diameter of 2.0-2.5 mm and a thin wall. The total cuff length should be 5-6 mm, with 3-4 mm main body and 2 mm extension.

Anesthesia

All operative procedures were performed under general anesthesia using isoflurane accompanied by oxygen, and inhalational anesthesia was induced and maintained. Isoflurane accompanied by oxygen flow at 5 L/min was used in the introduction phase and was reduced to 0.5-2.0 L/min in the maintenance phase.

After the introduction of anesthesia, the abdominal wall was shaved using electric clippers. The feet were fixed to the surgical table. Before skin incision, 2.0-2.5 mL/rat of lactated Ringer's solution was injected intravenously (penile vein) using a 27 gauge fine needle.

Donor operation

Laparotomy: The abdominal wall was prepped with betadine. A long midline skin incision was made extending from the xiphoid process to the pubis, followed by a transverse incision. Tractions on bilateral subcostal borders and the lower abdominal walls provided maximal exposure of the abdominal cavity. Liver damage should be avoided during laparotomy. Warm saline was arbitrarily dripped onto the intraperitoneal organs to prevent drying during laparotomy.

Preparation for graft harvest: The gastrointestinal tract was moistened with warm saline and positioned to the outside of the left abdominal cavity and coated with gauze. The liver was handled delicately by blunt and soft items such as a cotton swab.

The falciform and triangular ligaments were cut, and the left inferior phrenic vein was located. This vein was skeletonized carefully and ligated with silk to prevent massive hemorrhage after liver reperfusion. The transparent membranes around the liver which fix each lobe to the surrounding organs were cut, and the PV branch communicating to the paraesophageal vessels was ligated with silk thread.

The retroperitoneum on the IHIVC was dissected, and the IHIVC was skeletonized. The right renal vein and artery were carefully isolated, ligated with silk thread, and divided close to the renal hilum. The fat tissue around the right adrenal gland was dissected. From this side, the back of the IHIVC was skeletonized from the connective tissues and the right renal artery. The IHIVC was then tunneled using blunt micro-forceps. Both lumbar and right adrenal veins were ligated. The lower lumbar vein and left adrenal vein were ligated with silk thread, and the junction of the left renal vein and the IHIVC were skeletonized.

The hepatoduodenal ligament was cut and the extrahepatic BD was mobilized completely. Rats have no gallbladder. The BD was cut at the level of the pancreas. A biliary stent tube was inserted and fixed with silk thread. Bile was usually observed coming out of the stent tube during the donor operation.

All branches of the PV trunk were ligated by silk thread. Complete isolation and skeletonization of the PV trunk is required for the cuff method. Excess attached tissues tend to cause stenosis in the cuff.

The proper hepatic artery (PHA) and the gastroduodenal artery (GDA) were dissected. The GDA was ligated with silk thread. The PHA was further dissected toward the hepatic hilum and was isolated from the PV. The common hepatic artery (CHA) was similarly dissected from

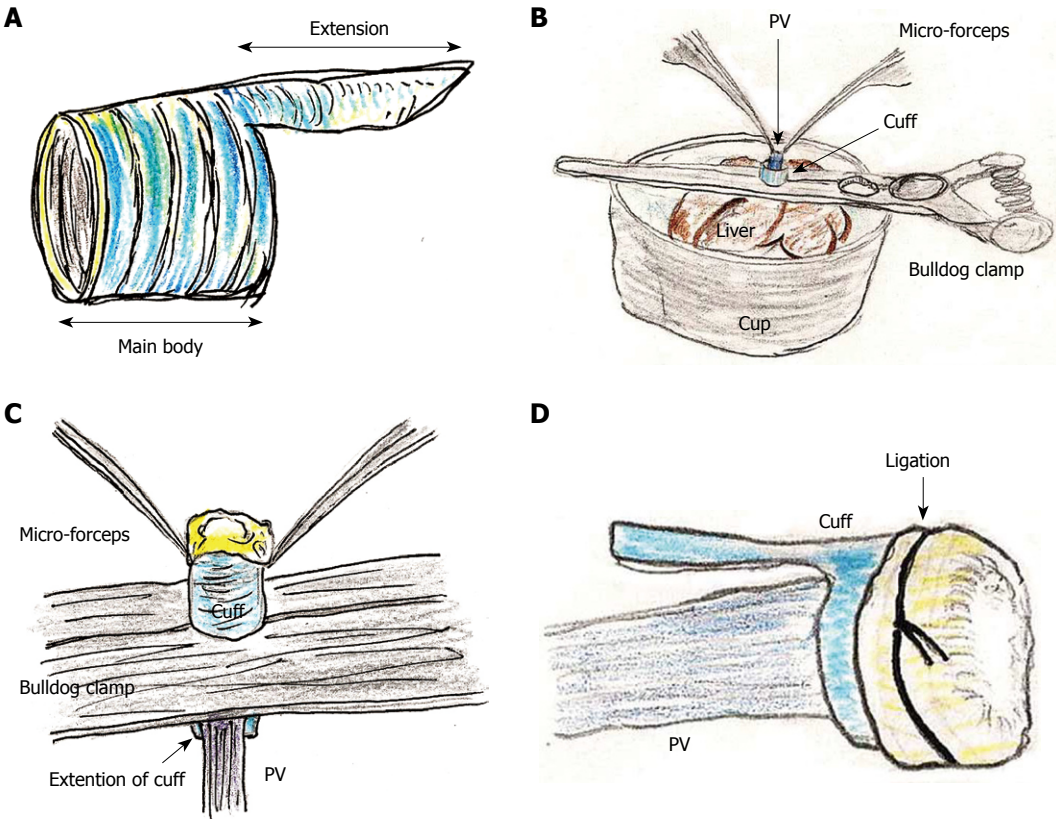

Figure 1 Portal vein (PV) cuff attachment. A: Cuff body with encircled chases and extension are made; B: PV trunk is induced through PV cuff. Cuff extension and PV trunk are grasped with a straight large-sized bulldog clamp. Cuff is set on the cup; C: Wall of PV trunk completely reversed using micro-forceps; D: Reversed PV wall is fixed to chase on cuff by ligation of silk thread.

the connective tissue around the celiac and superior mesenteric arteries.

Graft harvest: Heparinization (500 units/rat) was administered intravenously. One minute after heparin injection, the CHA was ligated at the aorta. Next, the IHIVC was clamped at an upper point of the right renal vein using a micro-clamp. The mesenteric branches of the PV trunk were clamped using micro-clamps, and one of superior mesenteric branches was opened using the cut-down method. A 24 gauge peripheral catheter was subsequently inserted into the PV trunk. After confirmation of the tip position in the PV trunk, 10 mL of cold Ringer's solution (4℃) was injected to start the hypothermic perfusion of the donor liver. A thoracotomy was performed immediately, and the thoracic supra-hepatic inferior vena cava (SHIVC) was divided. The IHIVC clamp was maintained during the cold perfusion and after the cuff attachment. The cold flush was slowly continued without high pressure, and the PV was clamped using a micro-clamp at the hepatic hilus.

After the cold wash-out, liver procurement was performed in the order of the PV trunk, diaphragm, remnant ligaments behind the SHIVC, hepatic inferior vena cava (HIVC), IHIVC, and the renal vessels. Note that the IVIHC was cut in a branch patch-fashion using the IHIVC and the left renal vein for an easy insertion of the IHIVC cuff (Figure 2A). The PV trunk was also cut in a branch patch-fashion using the portal vein trunk and the splenic vein (Figure 3A). Finally, the whole liver was harvested and immediately placed into cold Ringer's solution (4℃).

Back table benching of donor liver graft

All procedures should be performed on crushed ice. Cold Ringer's solution (4℃) was used as the preservation solution.

Plasty of the SHIVC: The anterior wall of the SHIVC was cut as near to the diaphragm as possible, leaving enough margin for the suture. The anterior diaphragm was completely trimmed. The posterior wall of the SHIVC was carefully detected, and the bilateral edge of the white tendon was removed. Stay sutures using polypropylene sutures were then made on the bilateral edges of the SHIVC. The bilateral stay sutures were held separately with curved bulldog clamps, and retention was achieved using the stay sutures. A key technique for SHIVC plasty involves leaving enough margin in the wall for retention with stay sutures (Figure 4A). Figure 4B illustrates the corresponding liver anatomy including the three lobes (right, left, and caudate lobes) arranged into seven segments including the right median, left median, left lateral, right superior, right inferior, superior caudate and inferior caudate segments[30,31].

Attachment of cuffs: Any fat tissue on the wall of the PV was completely removed, particularly in the portion

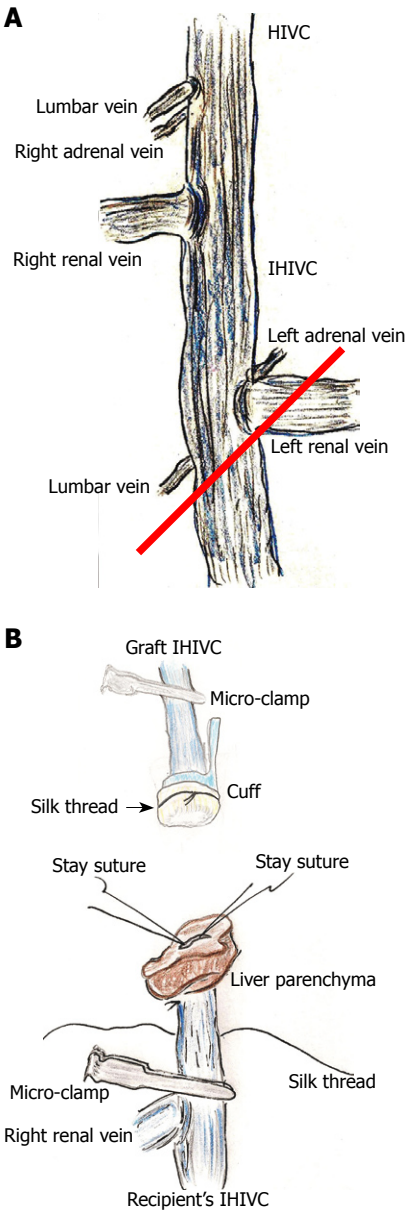

Figure 2 Infra-hepatic inferior vena cava (IHIVC) branches and reconstruction. A: Right adrenal and lumbar veins flow directly into IHIVC at point of lowest edge of right inferior segment. Left adrenal and the lower lumbar veins flow into the IHIVC at the junction of the left renal vein and the IHIVC. In donor operation for IHIVC reconstruction using the cuff method, IVIHC is cut in a branch patch-fashion (red line); B: Inner side of recipient's IHIVC is easily detected by adherent liver parenchyma. Stay sutures are made bilaterally on posterior wall, and anterior wall has some allowance for cuff insertion. Stay sutures are held by a bulldog clamp and are pulled to the cranial side. Silk thread is set behind the recipient's IHIVC beforehand. Confirmation of quality of graft IHIVC is confirmed using saline flush. Cuff is led towards the recipient's IHIVC, and cuff is inserted into IHIVC.

of the cuff, to prevent considerable cuff stenosis. The PV trunk was induced through the PV cuff. The cuff extension and the PV trunk were grasped with a large straight bulldog clamp. The cuff was set on the cup/glass using the verge of the preservation cup/glass and a long bulldog clamp (Figure 1B). The wall of the PV trunk was completely reversed using micro-forceps (Figure 1C). The reversed PV wall was fixed onto the cuff with a silk ligation (Figure 1D). A clip on the hilar PV trunk was maintained during this procedure.

The IHIVC cuff was also attached using a similar procedure to that for the PV cuff. A clip on the distal side was maintained during the procedure. After attachment of the cuffs to the PV and the IHIVC, the patency of the cuffs and the closure of branches up to the clamp points were checked using a flush of Ringer's solution through a 24 gauge catheter or dull-tip injector.

Recipient operation

Anesthesia: The induction of anesthesia and the injection of lactated Ringer's solution were the same as for the donor operation. However, shaving was omitted or performed only over as small an area as possible to maintain body temperature after surgery.

Laparotomy: The skin incision was made only by long midline incision. Too great a volume of saline on the intraperitoneal organs causes a low body temperature after recipient surgery. As such, only warm saline was used when necessary. Temporary retention of the abdominal wall by retractors was performed sparingly to prevent limitation of thoracic movements. Direct touch was possible in the recipient operation as the native liver was not used as a graft. The gastrointestinal tract was kept moistened with warm saline.

Preparation before anhepatic phase: The procedures used to mobilize the whole liver were basically the same as for the donor operation. The cut-off point of the BD was the hepatic hilus, and the BD was isolated to the upper side of the pancreas. The GDA was ligated at the point of the root. The CHA was not dissected up to the root, but the PHA was isolated sufficiently from the PV. The PHA was ligated at the hepatic hilus. Dissection of the hepatic hilus was performed more clearly than in the donor operation to provide enough length and good mobility of the BD, PHA, and PV.

The PV trunk should be isolated to provide enough length for cuff insertion. Skeletonization of the PV trunk was the same as for the donor operation, except for the splenic vein. The PV trunk was mobilized by ligating the PV branches, as for the donor operation.

For the IHIVC procedures, the portion from the HIVC to the right renal vein was completely isolated with preservation of the renal vessels. The right adrenal and lumbar veins were ligated. After cutting the dorsal membrane of the HIVC, the connective tissues at the boundary line between the SHIVC and the diaphragm were carefully dissected to provide satisfactory extensibility of the SHIVC.

Removal of native liver: A total of 2.0-2.5 mL of lactated Ringer's solution was administered intravenously. The vascular clamps at the proximal sides were applied in the order of IHIVC and PV, starting the anhepatic phase. Anesthesia was stopped. The hilar PV was ligated. SHIVC was clamped partly including the diaphragm. The SHIVC was cut at the liver parenchyma. The PV

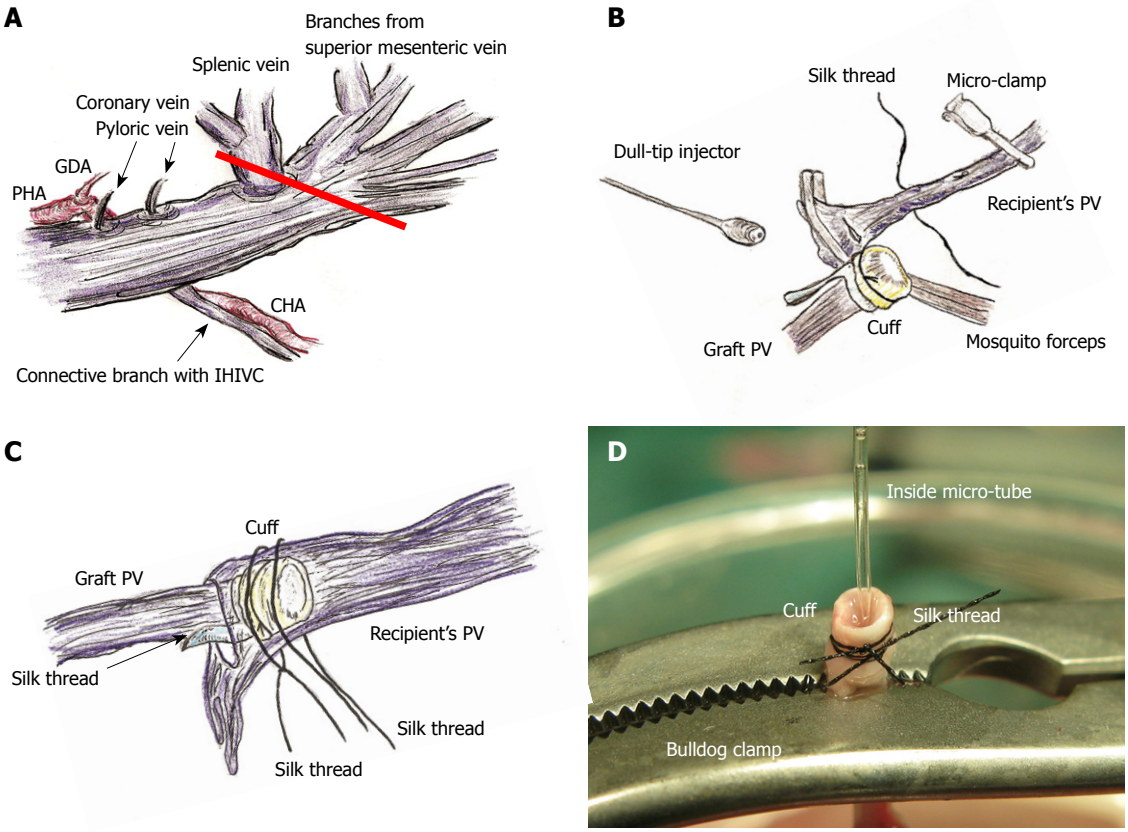

Figure 3 PV preparation and reconstruction. A: The splenic vein and coronary vein flow into PV trunk at the left or posterior sides of the PV. The pyloric vein flows into PV trunk at the left side of PV. The posterior side of PV trunk has a branch that connects with the IHIVC. The common hepatic artery (CHA) is located at the back of PV trunk, and the proper hepatic artery (PHA) and gastroduodenal artery branches are located at the left side of PV trunk. The PV trunk and these arteries are encased together in a thin sheath. The PV trunk is cut in a branch patch-fashion using PV trunk and splenic vein in the donor operation (red line); B: Retention of recipient PV is performed using mosquito forceps. Silk thread is set behind the recipient's PV trunk beforehand. The natural form of the PV is confirmed using saline flush. The cuff is led onto recipient's PV. The PV is opened using the cut-down method at the point nearest the hepatic hilus, and patency of the inner side is confirmed by saline flush; C: Cuff is inserted into recipient's PV avoiding any torsion; D: At the back table a bulldog clamp holds PV trunk, micro-tube, and cuff extension. Because of the micro-tube inside, detection of the inner side is simple. GDA: Gastroduodenal artery.

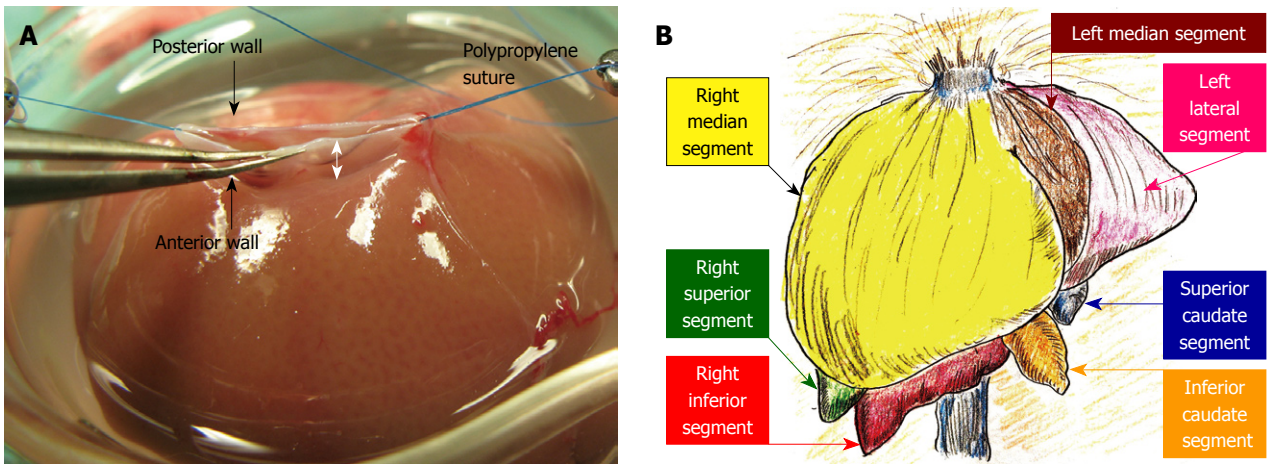

Figure 4 Hepatic segments and hepatic vein flows. A: The hepatic vein itself has no extra-hepatic margins for suture. The most important techniques for SHIVC plasty are (1) ensuring enough margin of the wall, and (2) retention using stay sutures. In particular, sufficient margin of the SHIVC wall (white arrow) is indispensable for confirmation of optimal out-flow; B: The liver comprises 3 lobes, which are subdivided into 7 segments. In basic anatomy, the left median segment is joined with the right median segment, and an incomplete lobulation is often detected in those segments.

was divided close to the hilum. The HIVC in the right inferior segment was cut at the upper point at 3-5 mm from the border line of the IHIVC and the HIVC. The native hepatectomy was completed.

Allograft implantation: The presence of bleeding points should be carefully checked using a cotton swab because secure hemostasis is very difficult after liver insertion. Placement of the graft liver is important, and should be

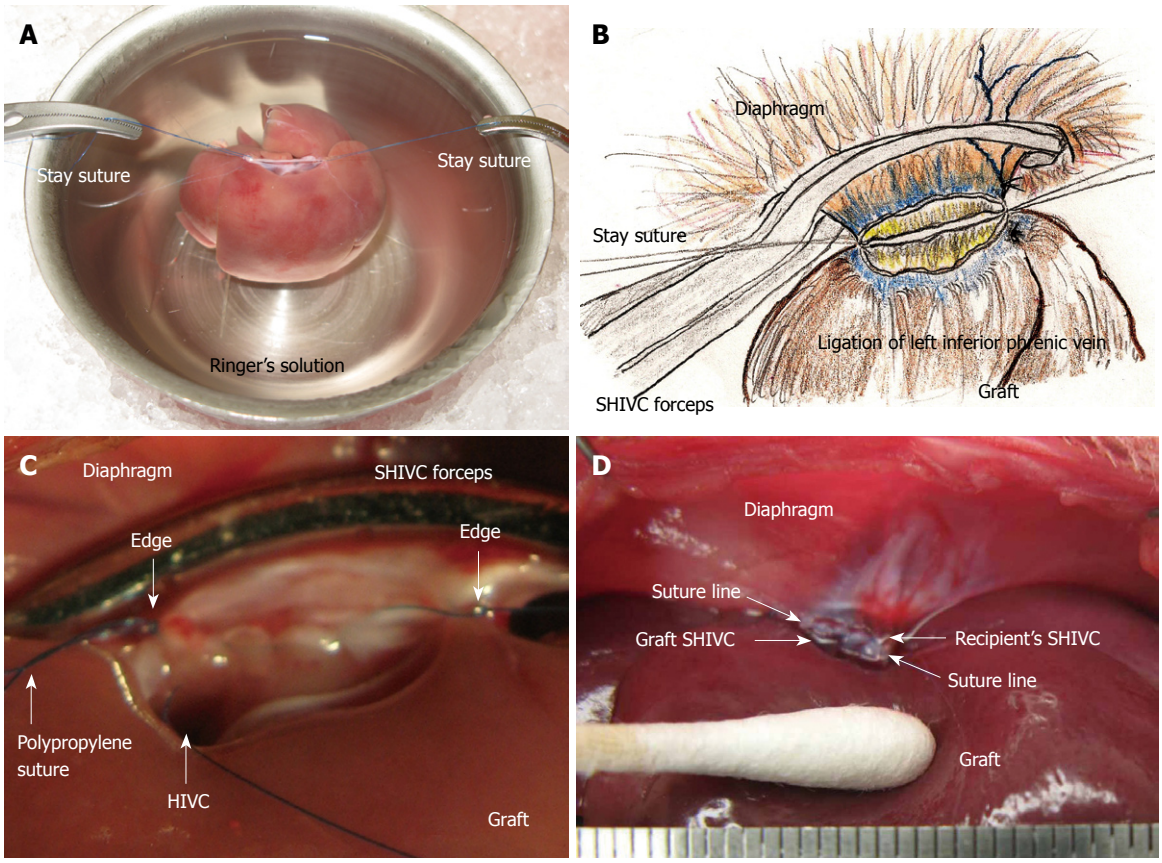

Figure 5 Supra-hepatic inferior vena cava (SHIVC) reconstruction. A: Note that an out-flow block can make the model unusable, and points of stay sutures without the axis torsion should be checked again before allograft implantation; B: The stay suture is placed bilaterally after careful consideration of the setup. The posterior wall straightens and the anterior wall is set as an arch; C: Finding after suture of the posterior wall is shown. HIVC is confirmed to enter into the right lobe. Too tight a ligation causes stenosis of the HIVC and disturbance of the flow. Ligations with stay sutures on both sides should be completed, although not too tightly; D: Completed SHIVC reconstruction is shown.

performed based on the anatomical characteristics of the graft liver. Note that an out-flow block can make the model unusable, and the points of the stay sutures without the axis torsion should be checked again before the allograft implantation (Figure 5A).

SHIVC reconstruction: A 5 or 10 mL syringe is deployed under the back of the recipient at the point of the SHIVC. In some cases, the movement of the thorax stops; however, the heart rate remains stable. A retractor is used for the retention of the costal bows if the respiratory movement is satisfactory. Forceps are used to grasp the diaphragm and expose the ventral surface, then to pull caudally. The forceps are fixed by soft clay at an adequate point for easy and stable sutures, and sutures are placed bilaterally. The posterior wall becomes straight and the anterior wall is set as an arch (Figure 5B). The left side is ligated, and the posterior wall is sutured from the left side using 5-6 stitches of continuous sutures. The last suture is ligated with a stay suture from the right side, avoiding over-tightening (Figure 5C). The anterior wall is then sutured from the right side using 15-20 stitches of continuous suture. The SHIVC cavity is filled with saline containing heparin by using an L-shaped injector before the complete closure. The anterior suture is then finished, and this thread is ligated not too tightly with the stay suture from the left side (Figure 5D). The back syringe and clay fixation are removed, and the retractors are released.

PV reconstruction: Retention of the recipient PV from the right side was achieved with mosquito forceps, and the forceps are fixed with soft clay. Note that too strong a retention makes it difficult to insert the cuff, despite increasing the PV length. The recipient PV was encircled beforehand with silk thread, and one knot is made for cuff fixation. The cuff was led onto the recipient PV. The PV was opened using the cut-down method at the nearest point of the hepatic hilus, and the inner side of the PV was confirmed with a saline flush (Figure 3B). The cuff was inserted into the recipient PV, avoiding any torsion of the PV (Figure 3C).

Allograft recirculation: The clamps were released in the order of the SHIVC, then the PV, and the allograft recirculation then starts. The anhepatic phase ceases. Cardiac and respiratory movements were allowed to recover, particularly in the case of a whole liver graft, and anesthesia is resumed.

IHIVC reconstruction: The inner side of the IHIVC was easily detected by the adherent liver parenchyma. Stay sutures were made bilaterally on the posterior wall, and the anterior wall had some allowances for the cuff inser-

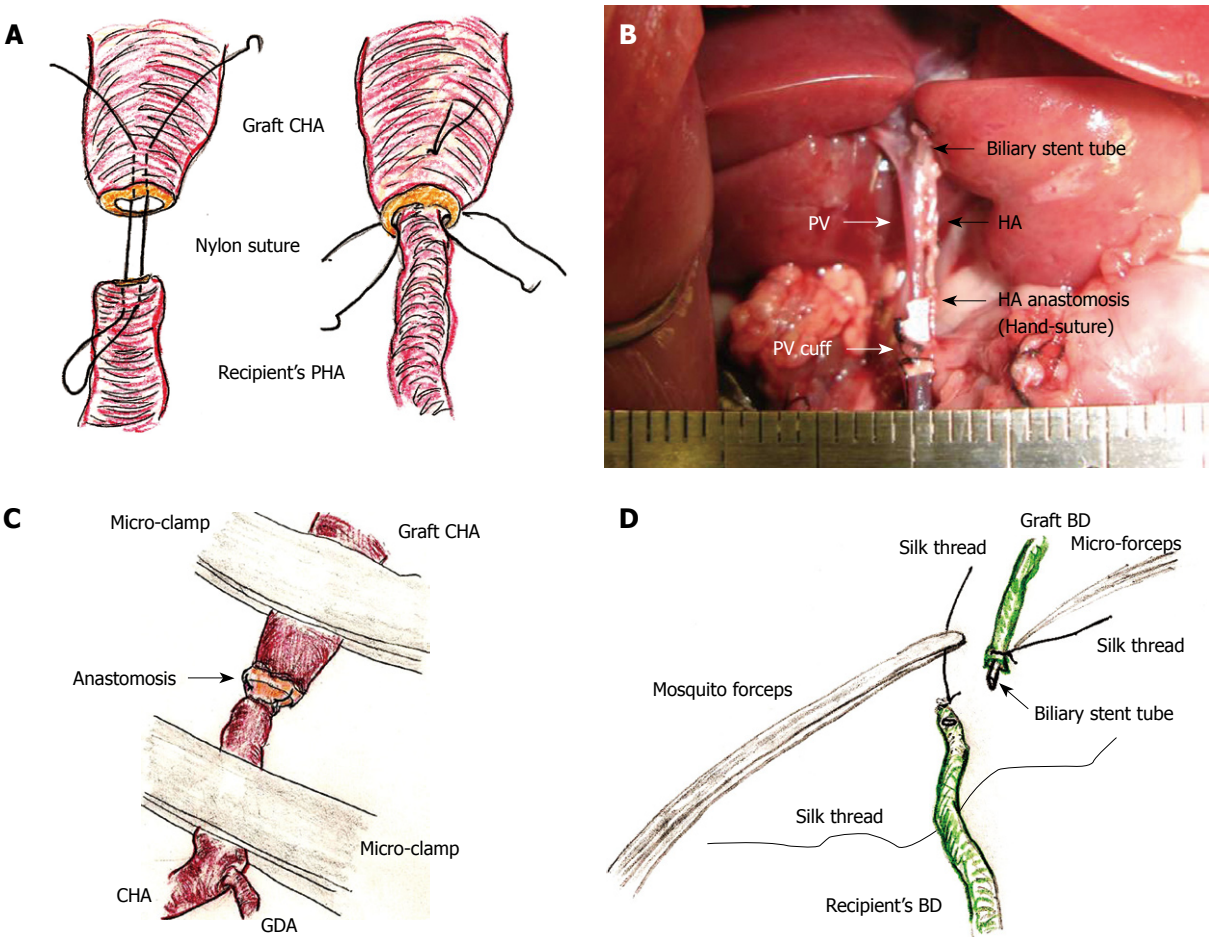

Figure 6 Hepatic artery (HA) and biliary duct (BD) reconstruction. A: An initial suture is made through the whole layer of the CHA from the outside to the inside, and a thrusting is then performed through the whole layer of the PHA from the inside to the outside. Subsequently, reverse thrusting from the PHA to the CHA is performed with the same thread. The recipient's PHA is then led into the graft CHA. One or two superficial stitches can be added if bleeding occurs; B: The diameter of the recipient's PHA is approximately 0.2 mm. Complete ultra-microsurgery allows the use of end-to-end anastomosis in HA reconstruction; C: Intermittent and alternate clamping of the HA also achieves hemostasis; D: The previously ligated silk thread of the recipient's BD is held using mosquito forceps. The recipient's BD is encircled beforehand with silk thread. The biliary stent tube is led into the recipient's BD. The recipient's BD is open using the cut-down method, and the stent tube is inserted.

tion. Stay sutures were held with a bulldog clamp and were pulled to the cranial side. The recipients' IHIVC is encircled beforehand with silk thread (Figure 2B), and one knot is made for cuff fixation. The inner side of the graft IHIVC was filled with saline. The cuff was led onto the IHIVC of the recipient liver. The cuff was inserted into the IHIVC, avoiding any IHIVC torsion. Fixation of the cuff to the IHIVC was performed. The IHIVC clamps were released in the order of the donor, then the recipient. Congestion of the right kidney and dilatation of the IHIVC were immediately resolved, and the liver color improved.

After IHIVC reflow, 2.0-2.5 mL of lactated Ringer's solution was injected *via* the penile vein. If required, a total of 0.3-1.0 mEq of bicarbonate can be injected simultaneously to offset metabolic acidosis.

HA reconstruction: An atraumatic small-sized clamp was placed on the recipient's PHA. A clamp was not needed on the graft CHA, as there was usually no backflow. The connective tissues were completely removed. A sharp cut surface is made at the ends of the recipient's PHA and graft CHA. An initial nylon suture was threaded through the whole layer of the CHA from the outside to the inside, and a thrusting was carried out through the whole layer of the PHA from the inside to the outside. A reverse thrusting from the PHA to the CHA is then carried out using the same thread. Next, due to the difference in vessel diameter, the recipient PHA was fed into the graft CHA, and the vessel clamp was released. One or two superficial stitches were added if bleeding occurred. This completed the "vest and pant" method (Figure 6A). Graft color was slightly improved after HA reconstruction.

In contrast, complete ultra-microsurgery allows the use of end-to-end anastomosis (Figure 6B). First, the sharp surfaces were joined as the vessel diameter in the graft CHA and the recipient CHA are similar. Next, three or four stitches were made through the whole layer using interrupted nylon sutures. Although additional superficial sutures are possible if bleeding occurs, the initial use of a cotton-like hemostatic agent with subtle compression is better. Intermittent and alternant clamping on the graft CHA and the recipient's CHA also achieves hemostasis (Figure 6C).

Biliary reconstruction: The previously ligated silk thread of the recipient's BD was held using mosquito forceps, and the mosquito forceps were fixed to a clay holder. The recipient's BD was encircled with silk thread and one knot was made beforehand. The biliary stent tube was led into the recipient's BD. The recipient's BD was opened using the cut-down method (Figure 6D), and the stent tube was inserted. The stent tube was then fixed with ligation of silk thread, and one edge of the ligated silk thread was also reserved for the donor operation. To prevent removal of the biliary stent tube, the preserved silk threads in the donor and the recipient were ligated together.

Abdominal closure: The intraperitoneal cavity and organs were washed with warm saline, and the point of BD anastomosis was covered with the greater omentum to prevent biliary complications. The peritoneum and fascia were closed with continuous sutures using absorbable thread, and the skin layer was closed separately using the same method.

Postoperative care and observation

The recipient was warmed on a hot pad immediately after surgery. A total of 2.0-2.5 mL of lactated Ringer's solution or maintenance solution was injected *via* the penile vein. An analgesic agent (0.1 mg/kg) was routinely given intramuscularly every 8 h for 3-5 d after surgery. Use of antibiotics was normally not required, although can be administered intravenously (30 mg/kg) if required.

Each transplanted recipient was allowed to recover in an individual cage to prevent injury by cage mates. Survival checks were made every 2 h until 48 h after surgery.

Statistical analysis

Data are presented as mean ± SD. Univariate and multivariate analyses were used for the between-group comparisons as follows: Mann-Whitney *U* test and χ^2 test for unpaired variables between two groups, Kaplan-Meier method (the log-rank) for survival rates, and logistic regression analysis for factors important for surgery success. Statistical calculations were performed using SPSS Software Version 16.0 (SPSS Inc., Chicago, IL, USA). $P < 0.05$ was considered statistically significant.

RESULTS

Learning curves

We examined the learning curves of some surgeons at our institutions. A success rate ⩾ 0.80 in whole liver transplantation was considered enough to learn the basic procedures for this model.

The importance of learning curves in producing reliable data using the rat OLT model has been previously reported[17]. In our experience, we observed that 30 cases are required for an initial successful OLT, and that 50 cases are required to be technically proficient for reproducible outcomes of OLT in rats. The survival curves of the first 50 cases from one surgeon can be seen in Figure 7.

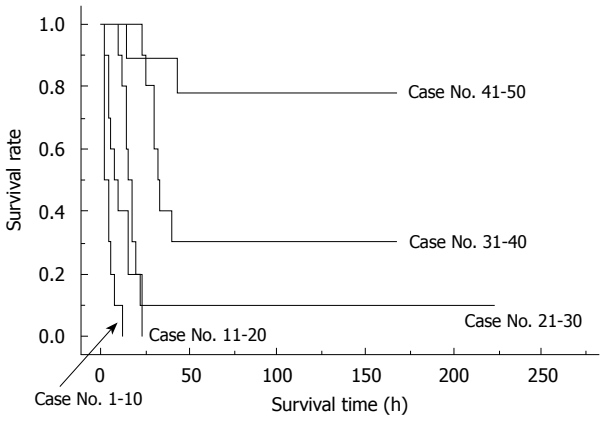

Figure 7 Learning curve in a surgeon. The initial 50 trial surgeries by one surgeon are shown. Learning curves of each surgeon showed similar patterns. Whole liver grafts were used in all cases. Preservation solution and cold ischemic time are unified as Ringer's solution for 2 h.

Critical factors for successful surgery

To determine the factors that were important for successful surgery, body weight (g), age difference between donor and recipient (d), abstinence before surgery, anesthesia method, operative time (min), blood loss (g), cold ischemic time (range: 0.5-4 h), organ preservation solution, warm ischemic time (the time from liver insertion to allograft recirculation; min), anhepatic phase (the time from portal clamp to allograft recirculation; min), unstable systemic hemodynamic state (the time from clamping of the IHIVC to IHIVC reflow), HA reconstruction, and body temperature immediately after surgery (℃) were collected in 100 OLT cases with whole liver grafts. The surgical timetable can be seen in Figure 8. The survival observation time was at least three days after surgery, and three day survivors were considered confirmation of successful surgery, as surgical and technical problems resulted in early deaths in the OLT model[17].

By univariate analyses, we found that operative time, blood loss, warm ischemic time, duration of anhepatic phase, unstable systemic hemodynamic state, and body temperature had a significant impact on the successful outcome of OLT in rats. Body weight, the age difference between donor and recipient, abstinence before surgery, anesthesia method, cold ischemic time, preservation solution, and hepatic artery reconstruction on the other hand, showed no difference (Table 1). When the univariate variables that showed a statistical significance were subjected to multivariate analysis, only the duration of anhepatic phase remained statistically significant in determining the successful outcome of an OLT in rats (Table 1). Furthermore, we compared the survival rates between the following groups: (1) anhepatic phase > 20 min; (2) anhepatic phase 15-20 min; and (3) anhepatic phase < 15 min. OLT recipients with an anhepatic phase > 20 min had a poor survival outcome, while those with an anhepatic phase of 15-20 min often died due to surgical issues. In contrast, recipients of an OLT with an anhepatic phase < 15 min all survived (Figure 9).

DISCUSSION

The cuff method cannot be used in SHIVC reconstruction. The setting for the hepatic venous flow after allograft implantation should be carefully considered, as the initial setting impacts on all subsequent procedures. An important consideration for the SHIVC setting is that it is different from humans, as the HIVC flows into the right lobes. Bilateral retention using accurate stay sutures at both edges is indispensable from the start of the procedure. With respect to operative time, a running suture of the anterior wall is faster than an interrupted suture. The thread used in the running suture should be ligated at both edges with some allowance to prevent stenosis, although if too loose a ligation causes bleeding after allograft recirculation. The clamp for the SHIVC needs an optimal bite on the thoracic side, as a shallow bite totally disturbs the SHIVC suture and slows down the surgery, although too deep a bite results in cardiac and respiratory arrest. SHIVC reconstruction should be completed using only thin SHIVC walls, and never include the liver or diaphragm in order to prevent out-flow block and thrombosis. As for hepatic

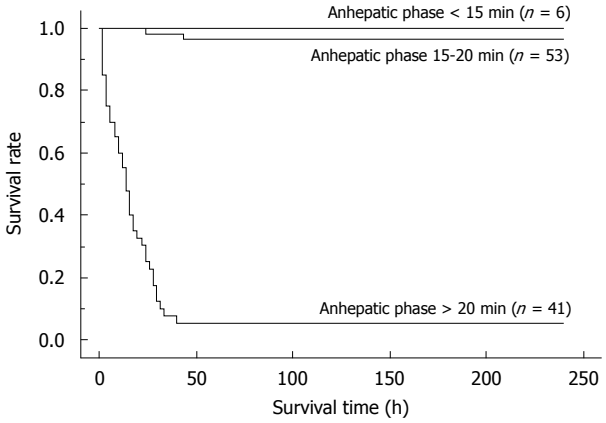

Figure 9 The differences in survival rates based on the anhepatic phase length. Recipients with a long anhepatic phase had poor survival rates, while recipients with an anhepatic phase of 15-20 min often died due to surgical issues. In contrast, recipients with an anhepatic phase < 15 min all survived. Whole liver grafts were used in all cases. All cases were accompanied by HA reconstruction. Preservation solution and cold ischemic time are unified as the Ringer's solution for 2 h. Anhepatic phase < 15 min *vs* anhepatic phase 15-20 min: $P = 0.0830$; Anhepatic phase < 15 min *vs* anhepatic phase > 20 min: $P < 0.0001$.

vein reconstruction, in contrast to humans, rats have no extra-hepatic margins in each hepatic vein. Thus, there is no choice except for anastomosis of the SHIVC to the SHIVC. A twist of the SHIVC causes out-flow block, and out-flow complications destroy the experimental setup. Even when attempting rapid surgery due to the limitation of the anhepatic phase, all IHIVC reconstruction procedures, including adequate initial setting, smooth hand-suture, and optimal ligation, should be perfectly completed.

The cuff procedures of PV are often difficult due to its thin wall and small diameter, while the IHIVC cuff procedures are comparatively easy due to its larger diameter. In some cases of small PV, we performed the following procedure: The PV trunk is clamped using the micro-clamp near the hepatic hilus to prevent air embolism, and a soft micro-tube is inserted into the portal venous trunk from the point of the wash-out injection. Next, another micro-clamp is placed on the PV trunk and the micro-tube. At the back table, a bulldog clamp holds the PV trunk, micro-tube, and cuff extension. Due to the micro-tube inside, detection of the inner side of the vessel is very easy, even in thin and small PV cases (Figure 3D). However, care must be taken to avoid air embolism and injury of the PV trunk during this procedure. The same procedure can also be applied for the attachment of the IHIVC cuff if required.

We consider that the cuffs may cause the occlusion of blood flow in long-term survivors, although based on our experience, the cuff method produces no survival problems up to 14 d recovery. Since the PV is thin and small, kinking of the trunk, torsion of the axis, and incorrect insertion can easily occur. Our studies clearly demonstrate that shortening the anhepatic phase to less than 15 min is critical during both PV reconstruction and SHIVC reconstruction. Although we and others use a hand-suture even for PV reconstruction[15], we consider the cuff method indispensable for keeping the anhepatic phase < 15 min and for obtaining reliable data. Based on the results of the present study, we perform the late phase of the recipient operation on a hot pad to prevent hypothermia. Furthermore, we currently keep transplanted rats covered with a cylindrical warmer to reduce heat loss immediately after surgery.

The importance of training for liver transplantation was previously reported[17,18]. In the first study, 65 rat OLTs were performed by a single investigator for training. The first 39 OLT were required to master the technique, and included 23 recipients that died in the first 24 h due to technical deficits and 16 OLT to learn the technique. In our experience, 20 OLTs are required to obtain an overnight survivor, while 40 OLTs are required to obtain a one week survivor. Thus, we suggest that 40-50 OLTs per surgeon are necessary for complete learning, while more OLTs are required for an amateur microsurgeon or non-surgeon. As previously reported[17,18] surgical issues can occur, even in long-term survivors, and we consider a reliable sampling rate for assays of approximately 0.6-0.9, even when experienced microsurgeons perform the surgery. Strict elimination of unsuitable rats at the sampling time point is also important for reliable data in this model. Although a large amount of time and labor is required for even a small number of reliable samples, this model produces valuable results.

A previous study investigating the regenerative capacity of individual lobes after hepatectomy in a murine hepatectomy model demonstrated that the caudate lobes work as well as the remnant liver, especially after a 75% hepatectomy[32]. Furthermore, successful survivals were reported in recipients receiving 20% grafts without HA reconstruction[33]. The 30% graft is achieved using the caudate segments, while the 10% graft is possible in this model by using the caudate lobe. However, we did not use the caudate lobe for creating 70% or 40% grafts, as the caudate lobe showed reduced regenerative capacity in the 30% and 60% hepatectomy model compared with other lobes[32]. Based on the behavior of the caudate lobe in large hepatic remnants, we performed a 60% graft without right superior, right inferior, superior caudate, and inferior caudate segments. The set-up of 20% and 30% grafts is well established in our model for studies of small-for-size grafts.

The 40% graft is clinically important in liver regeneration due to split and pediatric grafts from cadaveric donors for the donor shortage in the United States and the shift to left-lobe grafts in a living-donor for donor safety in Japan. It should be noted that when using our experimental model, there are distinct differences between basic anatomy and surgical anatomy. In basic anatomy, the left median segment is aggregated with the right median segment, and an incomplete lobulation is often detected in those segments (Figure 4B). However, dominating vessels of the left median segment make a common channel with those of the left lateral segment (Figure 4D). Thus, the left median segment should be handled together with the left lateral segment with respect to in-flow and

out-flow in surgery. No-margin hepatectomy by the clip method causes the SHIVC/HIVC twist, especially during removal of the right median segment. The hepatic margin in the clip method prevents the SHIVC/HIVC twist and common channel injury. The parenchymal margin has no hepatic circulation (these areas are insignificant as a functional volume), and we currently use right median and left median segments as a 40% graft accompanied by the margin method. Although removal of the right median segment requires several micro-clips, the left lateral segment can usually be treated with only one micro-clip. Thus, for procedure simplicity, we recommend right median and left median segments as a 40% graft using the clip method of hepatectomy accompanied by a margin, although a 40% graft of the left median and left lateral segments without margin is ideal based on surgical anatomy. This simple and useful method with margin areas prevents unintended injury of the common channel, avoids twisting of the SHIVC/HIVC, and allows easy application to incomplete lobulation. However, the percentage of the actual graft weight to the recipient's native liver cannot be calculated due to margin weight. Therefore, we estimated the percentages of each segment in 100 rats. A previous detailed report in a rat hepatectomy model used a ligation method with a hepatic margin[30], and we recommend the clip method with a hepatic margin in the rat S-OLT model.

With regard to another feature of the hepatic venous flow in rats, the hepatic veins of the right superior, right inferior, superior caudate, and inferior caudate segments flow directly into the HIVC (Figure 4D). Note that we never opened the IHIVC clamp during the wash-out procedure in the donor operation, as this can cause incomplete wash-out due to drainage from the PV to the HVC *via* these direct pathways.

Co-instantaneous reconstruction of the HA is ideal for studies focused on liver regeneration, although the omission of HA reconstruction is fine for studies focused on transplant immunity. HA reconstruction requires the most skillful ultra-microsurgery (approximately 0.1-0.3 mm vessel diameter), and extended anesthesia and operative times. For the surgeon, both finely-honed concentration and non-nervous distraction are required in microsurgery and ultra-microsurgery. If a microscope is employed, we recommend limiting its use to reconstructive procedures only to avoid fatigue. In particular, ultra-microsurgery is introduced only at limited times, while continuous microsurgery during all steps is inadvisable due to the likely loss of mental focus. If possible, preparation of the surgical equipment is better than repeating surgery in the same day to obtain enough samples[27,28].

In summary, although the rat OLT model with HA reconstruction is difficult and complicated, the model without HA reconstruction is well established[9-23]. Moreover, the model with HA reconstruction provides clinically relevant data.

COMMENTS

Background

Due to the clinical situation of liver donor shortage and donor safety, the main focus of the liver regeneration field is on patients with small-for-size liver syndrome and liver reperfusion injury. The development of clinically relevant rat orthotopic liver transplantation (OLT) models has advanced the clinical liver regeneration field. However, pseudo models of fake OLT/S-OLT, such as temporal clamp or simple hepatectomy, are still used experimentally for assessing reperfusion injury and/or small-for-size syndrome after liver transplantation due to the technical demands of the rat OLT/S-OLT model.

Research frontiers

The cold ischemic time (CIT) is a critical factor in producing reliable data using the OLT model, and also plays an important role in the mechanism of true reperfusion injury and small-for-size syndrome. Data from pseudo models that omit CIT are clinically irrelevant, and should not be translated into the actual OLT field. Clinical OLT is made possible by the phenomena of immunological tolerance even after allograft transplantation and the ability of the liver to regenerate even after initial insufficient volume. As such, these factors form the prominent focus of studies attempting to further develop the OLT field. Murine organ transplantation models, such as cardiac, lung, and kidney grafts, are well established, and are commonly used by transplant immunity investigators. New insights into the mechanisms of graft injury after OLT have also been established from experiments in small animal models. Mice are particularly suitable for laboratory assays due to the growing availability of gene-altered or knock-out animals and the development of specific agents and antibodies. However, murine OLT is the most technically difficult animal transplantation model, even when reconstruction of the hepatic artery (HA) is omitted. Furthermore, a validated model of OLT in mice is unavailable, and the authors consider that the rat OLT model produces more clinically relevant and reliable data. Hence, there is a requirement for a complete rat OLT model, including S-OLT, particularly in the field of liver regeneration.

Innovations and breakthroughs

OLT in rats is the only liver transplantation model that provides clinically relevant and reliable results. Shortened anhepatic phase is an important key to success in this model.

Applications

In summary, although the rat OLT/S-OLT with HA reconstruction model is difficult and complicated, only this model provides clinically relevant data. The authors have established this model and hope that their surgical guide will also help young researchers with an interest in the liver transplantation field.

Peer review

The article itself is well written and describes the different techniques and requirements for a successful outcome in animal liver transplantation. The illustrations are excellent and clearly portray the techniques.

Abstract

AIM: To investigate efficacy and safety of cetuximab combined with two chemotherapy regimens in patients with unresectable metastatic colorectal cancer (mCRC).

METHODS: Randomized patients received cetuximab with 5-fluorouracil (5-FU), folinic acid (FA) and oxaliplatin (FOLFOX) 6 (arm A, *n* = 74) or 5-FU, FA and irinotecan (FOLFIRI) (arm B, *n* = 77). *KRAS* mutation status was determined retrospectively in a subset of tumors (*n* = 117).

RESULTS: No significant difference was found between treatment arms A and B in the progression-free survival (PFS) rate at 9 mo, 45% *vs* 34%; median PFS, 8.6 mo *vs* 8.3 mo [hazard ratio (HR) = 1.06]; overall response rate (ORR) 43% *vs* 45% [odds ratio (OR) = 0.93] and median overall survival (OS), 17.4 mo *vs* 18.9 mo (HR = 0.98). Patients with *KRAS* wild-type tumors demonstrated improved PFS (HR = 0.55, *P* = 0.0051), OS, (HR = 0.62, *P* = 0.0296) and ORR (53% *vs* 36%) and in arm A, improved PFS (HR = 0.49, *P* = 0.0196), OS (HR = 0.48, *P* = 0.0201) and ORR (56%

vs 30%), compared with patients with *KRAS* mutated tumors. In arm B no significant differences were found in efficacy by *KRAS* mutation status. Treatment in arms A and B was generally well tolerated.

CONCLUSION: This study confirms that combinations of cetuximab with FOLFOX6 or FOLFIRI are effective and significantly improve clinical outcome in *KRAS* wild-type compared with *KRAS* mutated mCRC.

Key words: Cetuximab; 5-fluorouracil folinic acid and oxaliplatin; 5-fluorouracil folinic acid and irinotecan; *KRAS*; Metastatic colorectal cancer

INTRODUCTION

Colorectal cancer (CRC) accounted for 529 000 deaths worldwide in 2002[1]. Up to 25% of CRC patients present with metastatic disease (mCRC) with five-year survival rates of approximately 10% reported[2,3]. The standard treatment for unresectable mCRC has been to administer first-line 5-fluorouracil (5-FU) with folinic acid (FA)[2,4,5], with improvements in clinical outcome being demonstrated for infusional 5-FU/FA combined with oxaliplatin (FOLFOX)[6,7] or irinotecan (FOLFIRI)[8,9]. However safety profiles differ, with grade 3/4 neutropenia and neurotoxicity more common with FOLFOX, and grade 3/4 mucositis and nausea/vomiting more common with FOLFIRI.

Cetuximab [Erbitux, developed by Merck KGaA Darmstadt, Germany (under license from Imclone, NY USA)] is an immunoglobulin G1 monoclonal antibody that specifically targets the epidermal growth factor receptor (EGFR), competitively inhibiting ligand binding and ligand-dependent downstream signaling[10,11]. Cetuximab first gained approval for use in Europe and the United States in the treatment of EGFR-expressing mCRC following failure of irinotecan-containing regimens[12]. More recently, the randomized CRYSTAL study demonstrated improved progression-free survival (PFS) in EGFR-expressing mCRC patients receiving FOLFIRI plus cetuximab compared with FOLFIRI alone[13]. In addition, the phase Ⅱ OPUS trial reported a trend towards improved overall response rate (ORR) in EGFR-expressing mCRC patients receiving FOLFOX4 plus cetuximab compared with FOLFOX4 alone[14].

An accumulating body of data from studies of chemorefractory mCRC patients receiving cetuximab as monotherapy or in combination with chemotherapy suggests that clinical responses are confined to those patients whose tumors do not harbor mutations in codons 12 or 13 of the *KRAS* gene (*KRAS* wild-type)[15-19]. The *KRAS* gene encodes a GDP/GTP binding protein which, following ligand binding to receptor tyrosine kinases including EGFR, activates downstream intracellular signaling cascades promoting cellular growth and proliferation[20,21]. *KRAS* mutations (in codons 12 or 13) occur in 40%-50% of CRCs and circumvent the cellular requirement for receptor activation of the KRAS protein[20,21]. Metastatic colorectal tumors harboring *KRAS* mutations are therefore hypothesized to be refractory to EGFR-targeting monoclonal antibodies. Data from retrospective analyses of the CRYSTAL and OPUS studies confirmed that the efficacy of cetuximab in combination with FOLFIRI or FOLFOX was restricted to patients with *KRAS* wild-type tumors[13,14], indicating tumor *KRAS* mutation status to be a predictive biomarker for the efficacy of cetuximab in combination with chemotherapy.

In the current Central European Co-operative Oncology Group (CECOG)-sponsored randomized phase Ⅱ trial, the efficacy and safety of cetuximab in combination with either FOLFOX6 or FOLFIRI was investigated first-line in patients with mCRC. In addition, a retrospective subgroup analysis of clinical outcome according to tumor *KRAS* mutation status was performed.

MATERIALS AND METHODS

Main patient eligibility criteria

Patients (≥ 18 years old) with histologically confirmed adenocarcinoma of the colon or rectum, with metastatic disease unsuitable for resection with curative-intent, an Eastern Co-operative Oncology Group (ECOG) performance status < 2, and adequate organ function were eligible for inclusion.

Exclusion criteria included: previous chemotherapy for metastatic disease; prior EGFR-targeted therapy; adjuvant chemotherapy with oxaliplatin or irinotecan (5-FU-based adjuvant chemotherapy was allowed provided the chemotherapy treatment-free interval was > 6 mo). Patients with brain metastases; concurrent malignancy and those with a previous malignancy within the last 5 years (excluding non melanoma skin cancer and in situ carcinoma of cervix); coronary artery disease or a history of myocardial infarction within 12 mo of study entry; pre-existing neuropathy > grade 1; intestinal occlusion or a history of inflammatory bowel disease; a ≥ grade 3 allergic reaction to study treatment components; those

undergoing surgery (excluding biopsy) or irradiation within 4 wk of study entry were also excluded, as were pregnant or lactating patients.

The study was approved by independent ethics committees at each center and was conducted in accordance with the principles of the Declaration of Helsinki and the Note for Guidance on Good Clinical Practice. All patients provided written informed consent.

Study design

This was a two-arm randomized multicenter, open-label, parallel-group phase Ⅱ study involving 28 participating centers across 13 countries (CECOG/CORE1.2.001). Eligible patients were centrally randomized 1:1, using a minimization technique, stratifying patients according to study site, the number of organs involved and prior neo-adjuvant/adjuvant therapy. Patients received cetuximab (400 mg/m^2 initial infusion day 1, then 250 mg/m^2 weekly), then either in arm A: oxaliplatin (day 1, 100 mg/m^2) with FA [400 mg/m^2 (racemic) or 200 mg/m^2 (L-form)] plus 5-FU (400 mg/m^2 bolus plus 2400 mg/m^2 as a 46-h continuous infusion) every 2 wk (FOLFOX6), or in arm B: irinotecan (180 mg/m^2) with the 5-FU/FA regimen described (FOLFIRI). Patients received 6 mo of combination therapy, after which cetuximab was continued. Study treatment was discontinued in the case of progressive disease (PD). Patient follow-up was every 12 wk until treatment end or clinical cut-off date. The primary endpoint was PFS at 9 mo, secondary endpoints included ORR, PFS at 3, 6 and 12 mo, overall survival and safety.

Dose modifications

Dose reductions, treatment delays and the omission of a maximum of two consecutive doses of cetuximab were permitted in cases of grade 3 skin reactions. Two dose reductions for irinotecan or oxaliplatin were permitted after which the drug was discontinued (in either case cetuximab could be continued). Dose reductions were permanent.

Assessments

Computed tomography or magnetic resonance imaging of chest, abdomen and pelvis was performed at baseline and weeks 6, 12, and every 12 wk thereafter during treatment, and at the end of the study or upon PD. PFS rate was defined as the percentage of patients in each arm alive and free of tumor progression at analysis from the time of randomization, using response evaluation criteria in solid tumors (RECIST). Tumor response was evaluated according to RECIST guidelines. Survival was defined as time from randomization until death (patients lost to follow-up were censored at the time they were last determined to be alive). Adverse events (AEs) were assessed at treatment visits using National Cancer Institute Common Terminology Criteria for Adverse Events (version 3) and coded using the Medical Dictionary for Regulatory Activities (MedDRA; version 10.1).

Tumor DNA was extracted and purified from formalin-fixed paraffin-embedded tissues as previously described[14]. The presence of *KRAS* mutations in codons 12 and 13 was determined by allele-specific real time polymerase chain reaction assays using validated methodology (DxS Ltd Manchester UK)[22,23]. EGFR expression was determined using the DAKO EGFR pharmDx™ test. Tumor *KRAS* mutation status and EGFR expression were assessed centrally by one pathologist.

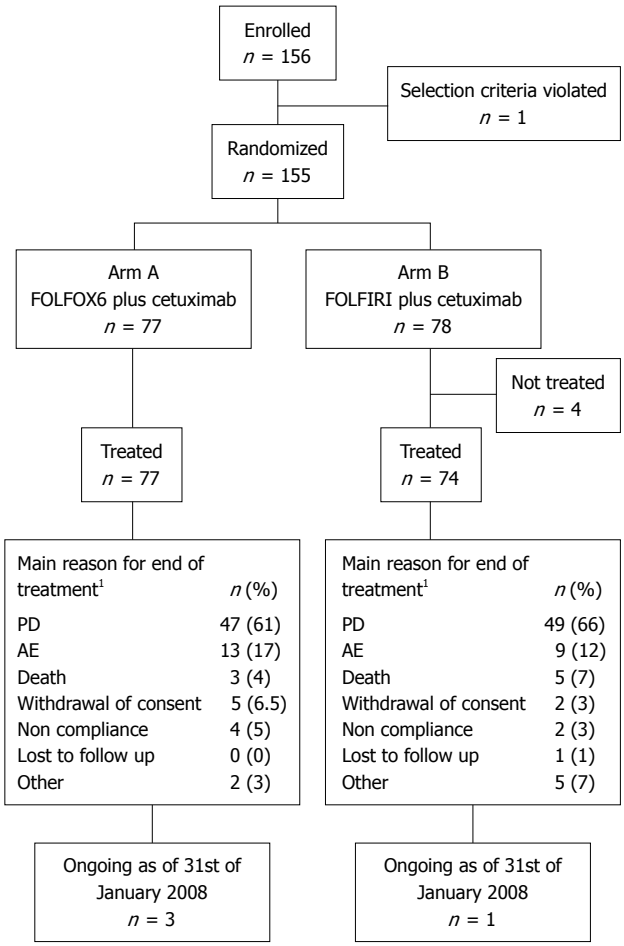

Figure 1 Disposition of patients as of clinical cut-off date January 2008. The intention to treat (ITT) population comprised 77 patients randomized to FOLFOX6 plus cetuximab and 74 randomized to FOLFIRI plus cetuximab. [1]Values based on all treated patients (*n* = 151). FOLFOX: 5-fluorouracil (5-FU) folinic acid (FA) and oxaliplatin; FOLFIRI: 5-FU FA and irinotecan; PD: Progressive disease; AE: Adverse event.

Statistical analysis

The primary objective of the study was to estimate the difference in 9-mo PFS rates between the treatment arms. In accordance with the objective of this phase Ⅱ study, the planned sample size was fixed to 2 × 75 patients to achieve appropriate precision for the estimate of the difference in 9-mo PFS rates. With 75 patients in each treatment arm evaluable for 9-mo PFS, the two-sided 95% confidence intervals (CI) for the difference in PFS rates had a range of not more than ± 16% assuming a low number of censored cases (up to 5%) and PFS rates in both treatment arms being approximately 50%-60%.

Statistical analyses were performed on data accrued up until the clinical cut-off date (January 31, 2008). The efficacy analyses were performed on the intention to treat

[1]Metastases detected within 1 mo of tumor diagnosis; [2]Patients with >1 metastasis per organ site, the organ site was counted once only; [3]Three patients included with rectal cancer received neoadjuvant therapy; [a]Value determined from 76 patients. Patients receiving FOLFOX6 plus cetuximab (arm A) and those receiving FOLFIRI plus cetuximab (arm B). ITT: Intention to treat; FOLFOX: 5-fluorouracil (5-FU) folinic acid (FA) and oxaliplatin; FOLFIRI: 5-FU FA and irinotecan; ECOG: Eastern Cooperative Oncology Group; PS: Performance status; Q1-Q3: Interquartile range; mCRC: Metastatic colorectal cancer.

(ITT) population defined as all randomized patients who received at least one dose of study medication, which was the same as the safety population. Time to event data were analyzed using the Kaplan-Meier method[24]. Standard errors were calculated using Greenwoods formula[25] and the hazard ratio (HR) for PFS between both treatment groups and corresponding 95% CIs was calculated using an unadjusted Cox proportional hazard model. Differences in survival were tested using the logrank test. Estimates of ORR in each treatment group, odds ratios and associated 95% CIs were calculated using the Cochran-Mantel-Haenszel procedure.

The study was initiated and patient recruitment finished (2006) before the evidence from a randomized trial that *KRAS* tumor mutation was associated with clinical outcome in patients treated with cetuximab in combination with chemotherapy was first presented[26]. Subsequently a retrospective analysis of efficacy and safety was performed in the subgroup of patients with available tumor material that was evaluable for *KRAS* mutation status (wild-type *vs* mutant). Exploratory Cox proportional hazard models and logistic regression models were used to investigate the impact of *KRAS* mutation status on PFS, overall survival and ORR across the treatment groups adjusted for other significant confounding factors. A significance level of 0.2 was used to enter a factor into the model and a significance level of 0.10 was used for removing a factor from the model. Following an update of survival time, all information available by December 16th 2008 was considered for survival analyses. All calculations

were performed with SAS release 8.2 (SAS Institute, Cary, NC USA).

RESULTS

Patient demographics

Patients were enrolled between July 2005 and July 2006; patient disposition is shown in Figure 1. Four patients randomized to receive cetuximab plus FOLFIRI withdrew their consent prior to treatment, with 151 patients subsequently receiving treatment. Reasons for discontinuing the study treatment were similar for both treatment arms.

Patient characteristics at baseline were generally well balanced between treatment groups (Table 1). *KRAS* mutation status was evaluable in 117/151 (77%) patient tumors; of these, *KRAS* mutations were detected in 55/117 (47%) patient tumors. Baseline characteristics of the *KRAS* subpopulation were representative of those of the ITT population (Table 1).

[1]Median time and rates are based on Kaplan-Meier estimates; [2]Hazard ratio and corresponding 95% CI based on unadjusted Cox proportional hazard model: hazard rate FOLFIRI plus cetuximab divided by hazard rate FOLFOX6 plus cetuximab. CR: Complete response; NE: Not evaluable; PD: Progressive disease; PFS: Progression-free survival; PR: Partial response; SD: Stable disease.

Treatment compliance

Patient exposure to cetuximab and chemotherapy was similar for both treatment arms (Table 2). The proportion of dose reductions and treatment delays for cetuximab was slightly higher in arm A than arm B. Treatment delays were more commonly due to diarrhea in the FOLFIRI arm and to neuropathy in the FOLFOX6 arm. In treatment arm A, median exposure to cetuximab in patients with *KRAS* wild-type patients was 35.4 wk and *KRAS* mutant tumors 23.3 wk, compared with 24.5 and 32.4 wk, respectively, in arm B. Exposure to chemotherapy in each treatment arm by *KRAS* mutation status was similar to

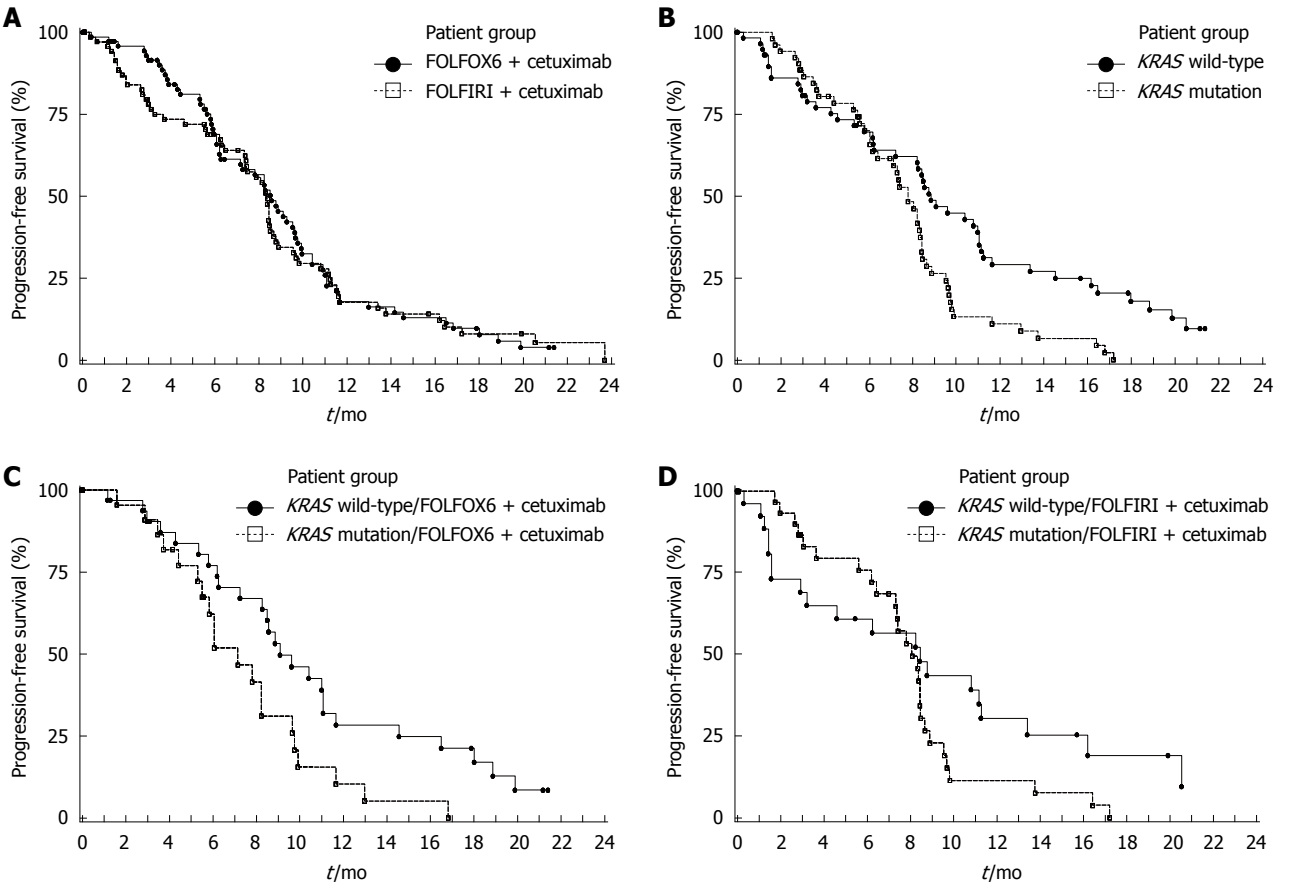

Figure 2 Kaplan Meier estimates for progression-free survival. A: By treatment group in the ITT population, FOLFOX6 plus cetuximab (*n* = 77) *vs* FOLFIRI plus cetuximab (*n* = 74); B: By *KRAS* mutation status in the *KRAS* population, *KRAS* wild-type (*n* = 62) *vs KRAS* mutation (*n* = 55); C: By tumor *KRAS* mutation status in patients receiving FOLFOX6 plus cetuximab, *KRAS* wild-type (*n* = 34) *vs KRAS* mutation (*n* = 23); D: By tumor *KRAS* mutation status in patients receiving FOLFIRI plus cetuximab, *KRAS* wild-type (*n* = 28) *vs KRAS* mutation (*n* = 32).

that for the safety population. The proportion of patients experiencing dose reductions, delays in treatment, and treatment discontinuations for cetuximab or chemotherapy in each treatment arm by *KRAS* mutation status was not markedly different and was comparable with that found in the safety population.

Efficacy

Efficacy data for the ITT population are summarized in Table 3. The 9-mo PFS rate was 11% higher in arm A than arm B (45% *vs* 34%); however, the 95% CI for the difference was -6% to 28%, indicating no significant difference. The risk of disease progression (Figure 2A), death (Figure 3A) and the ORR were also similar between treatment arms.

The influence of tumor *KRAS* mutation status on clinical outcome is summarized in Table 4. The 9-mo PFS rate was higher and the risk of disease progression was significantly reduced in patients with *KRAS* wild-type tumors compared with those with *KRAS* mutations (Figure 2B). A significant improvement in survival (Figure 3B) and an increase in ORR were also demonstrated in patients with *KRAS* wild-type tumors compared with *KRAS* mutated tumors. In multivariate analyses of the *KRAS* evaluable population using Cox proportional hazard models (baseline characteristics and acne-like rash), only *KRAS* tumor mutation status (wild-type *vs* mutant) was identified as a significant prognostic indicator for prolonged PFS (HR = 0.55, $P = 0.006$), while *KRAS* mutation status (wild type *vs* mutant, HR = 0.51, $P = 0.003$), prior adjuvant/neoadjuvant therapy (no *vs* yes, HR = 0.32, $P < 0.001$) and acne-like rash during the first 6 wk (grade 2-3 *vs* grade 0-1, HR = 0.47, $P = 0.004$) were significant independent prognostic indicators for prolonged overall survival.

In treatment arm A, the 9-mo PFS rate in patients with *KRAS* wild-type tumors was higher and the PFS time was significantly longer compared with patients with *KRAS* mutated tumors (Table 4, Figure 2C). In arm B, the 9-mo PFS rate was also higher in *KRAS* wild-type patients, although the PFS time was not significantly different compared with patients with *KRAS* mutated tumors (Figure 2D, Table 4). Similarly, in treatment arm A, survival time was significantly higher in patients with *KRAS* wild-type tumors compared with tumors with *KRAS* mutations (Figure 3C, Table 4). In arm B survival time was not significantly different according to tumor *KRAS* mutation status (Figure 3D, Table 4). In both treatment arms the ORR was higher in patients with *KRAS* wild-type tumors compared with *KRAS* mutated tumors (Table 4).

In treatment arm A *vs* B; median PFS was 8.2 *vs* 8.4 mo

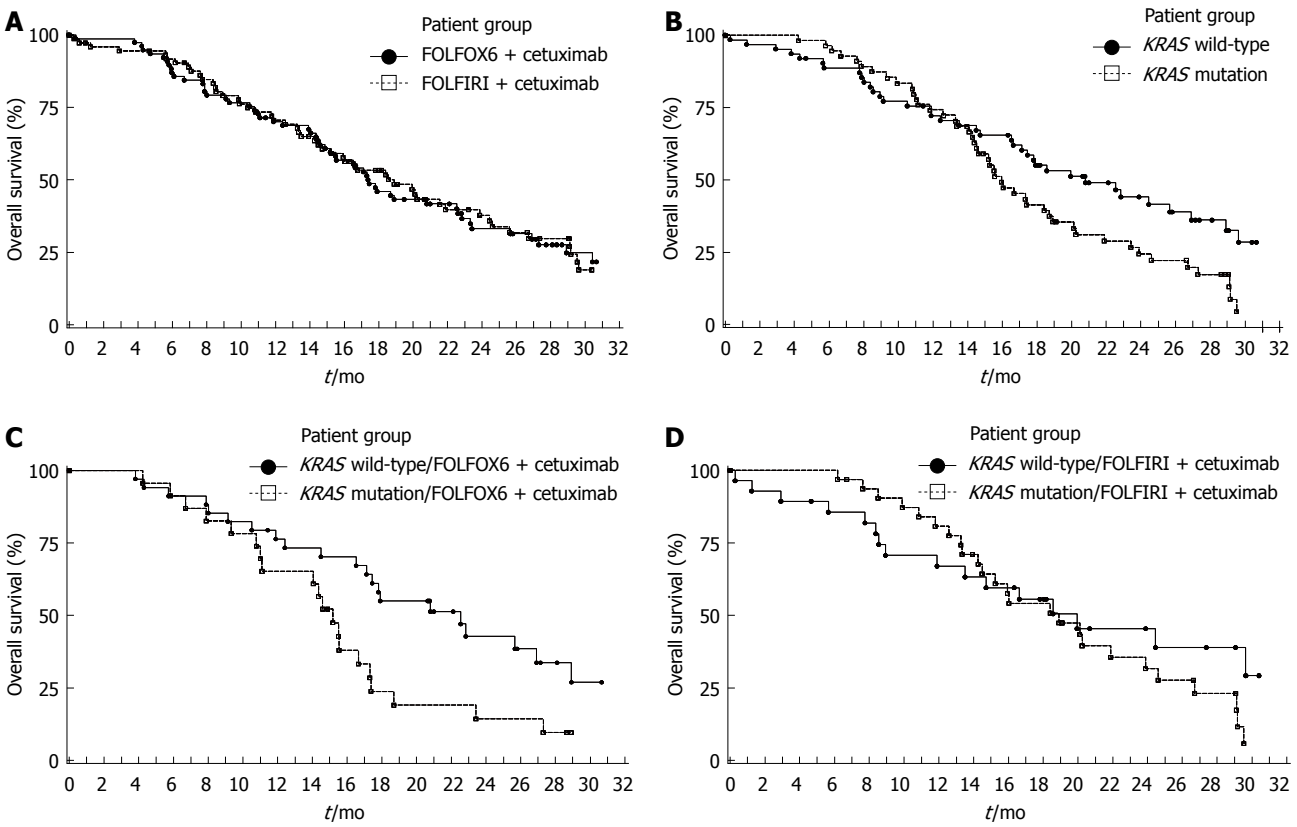

Figure 3 Kaplan Meier estimates for survival. A: By treatment group in the ITT population, FOLFOX6 plus cetuximab (*n* = 77) *vs* FOLFIRI plus cetuximab (*n* = 74); B: By tumor *KRAS* mutation status, KRAS wild-type (*n* = 62) *vs KRAS* mutation (*n* = 55); C: By *KRAS* mutation status in patients receiving FOLFOX6 plus cetuximab, *KRAS* wild-type (*n* = 34) *vs KRAS* mutation (*n* = 23); D: By tumor *KRAS* mutation status in patients receiving FOLFIRI plus cetuximab, *KRAS* wild-type (*n* = 28) *vs KRAS* mutation (*n* = 32).

in patients with EGFR-detectable tumors (*n* = 43 *vs n* = 46), and 11.0 mo *vs* 8.1 mo in patients with EGFR-undetectable tumors (*n* = 17 *vs n* = 12). Median OS was also comparable by EGFR tumor status between the treatment groups. In arm A *vs* arm B; median OS was 15.5 mo *vs* 21.6 mo in patients with EGFR-detectable tumors and 23.3 mo *vs* 17.6 mo in patients with EGFR-undetectable tumors.

Adverse events

The number of patients experiencing serious AEs was balanced between the treatment groups (27% in arm A *vs* 28% in arm B). The frequencies of the most common treatment emergent AEs (TEAE) in arm A *vs* arm B were: neutropenia (47% *vs* 36%); nausea (40% *vs* 26%); diarrhea (44% *vs* 58%); rash (36% *vs* 34%); vomiting, (26% *vs* 23%); stomatitis (22% *vs* 18%); dermatitis acneiform (21% *vs* 23%); anorexia (22% *vs* 20%), pyrexia (22% *vs* 20%). Peripheral neuropathy was reported only in arm A (13%).

Grade 3/4 TEAEs related to study treatment (Table 5) were slightly higher in arm A than in arm B. Grade 4 neutropenia occurred more frequently in patients in arm A than in patients in arm B. The incidence of the special AEs, acne-like rash and infusion-related reactions (composite categories), was not significantly different between the treatment groups (Table 5).

Fifty-four deaths (70%) were reported for patients in arm A and 50 deaths (68%) in arm B. Ten deaths (13%) occurred on-treatment or within 60 d after the last dose in arm A and six (8%) in arm B. None of these deaths were assessed as being due primarily to treatment. Progressive disease and death related to disease complications were the most common reasons for death in both treatment groups.

The frequencies of serious AEs by *KRAS* tumor mutation status and treatment group were similar across the 4 groups (29%-31%). The only noteworthy finding was the relatively low incidence of related grade 3/4 AEs in *KRAS* wild-type patients treated with FOLFIRI plus cetuximab (36%) in comparison to the other 3 groups (56%-71%), mainly due to a lower incidence of neutropenia (Table 5). However, the low sample size in the subgroup analysis should be taken into account, when considering this finding.

DISCUSSION

No significant differences in efficacy were found for cetuximab combined with FOLFOX6 or FOLFIRI in the first-line treatment of mCRC. Efficacy data in the current study are comparable with those reported from the corresponding arms of the CRYSTAL (median PFS of 8.9 mo, median overall survival of 19.9 mo and an ORR of 47%)[13] and OPUS studies (median PFS value of 7.2 mo and an ORR of 46%)[14].

[1]Median time and rates are based on Kaplan Meier estimates; [2]Hazard ratio and corresponding 95% CI based on unadjusted Cox proportional hazard model: Hazard rate *KRAS* mutation divided by *KRAS* wild-type. na: Not available; ORR: Objective response rate.

frequency (47%) was similar to that previously reported for mCRC[13,14,27]. Across the treatment groups, PFS and overall survival were significantly improved and there was an increased chance of a tumor response in patients with *KRAS* wild-type tumors compared with *KRAS* mutant tumors; differences in PFS and survival appeared to increase over time. Multivariate analysis also confirmed that tumor *KRAS* mutation status is a prognostic marker for PFS and overall survival after adjustment by other independent predictors such as acne-like rash in the first 6 wk.

Patients with *KRAS* wild-type tumors receiving cetuximab plus FOLFOX6 demonstrated significantly improved PFS and overall survival and an increased chance of tumor response compared with patients with *KRAS* mutated tumors. Similar findings were reported in the OPUS study in patients receiving cetuximab plus FOLFOX4, where patients with *KRAS* wild-type tumors had a reduced risk of disease progression (HR 0.45, $P = 0.0009$) and a higher response rate (61% *vs* 37%) compared with those with tumor mutations[14]. However in the present study for patients receiving FOLFIRI plus cetuximab, no significant benefit was apparent with regard to PFS, survival or ORR according to *KRAS* tumor mutation status. This contrasts somewhat with the CRYSTAL study, where a significant clinical benefit was associated with the addition of cetuximab to FOLFIRI in patients with *KRAS* wild-type tumors, but not in patients with *KRAS* mutant tumors[13]. This non-significance may be due to the comparatively small sample size in the *KRAS* subgroup analysis in the present study compared with the CRYSTAL study[13]. It should also be noted that the difference in the predictive power of *KRAS* tumor mutation status in patients receiving FOLFOX with cetuximab compared with those receiving FOLFIRI with cetuximab described here is consistent with the *KRAS* analysis from CRYSTAL and OPUS studies[13,14,26]. Furthermore, FOLFIRI and cetuximab were given until disease progression in the CRYSTAL study, whereas FOLFIRI was given for 6 mo and cetuximab until progression in the present study. Within this context it is noteworthy that the PFS curves cross after 6 mo in the FOLFIRI subgroup.

In the absence of chemotherapy-alone control arms, the present study was not able to accurately assess the influence of *KRAS* mutation status on clinical outcome for cetuximab or chemotherapy-alone as individual treatment components. The influence of *KRAS* tumor mutation status on patients treated with 5-FU-based chemotherapy remains controversial. The MRC FOCUS study of mCRC patients randomized to receive first-line 5-FU, 5-FU plus irinotecan or 5-FU plus oxaliplatin, reported that patients whose tumors harbored *KRAS* tumor mutations displayed significantly worse survival than those with *KRAS* wild-

[a]Grade 3/4 adverse events occurring in ⩾ 5% of patients in either treatment group in each population are reported; [b]Safety population: 77 patients received FOLFOX6 plus cetuximab in arm A, 74 patients received FOLFIRI plus cetuximab in arm B; [c-e]Composite categories. Skin reactions include the terms: acne*, acne pustular*, cellulitis, dermatitis acneiform*, dry skin*, erysipelas, erythema*, face edema, folliculitis*, hair growth abnormal, hypertrichosis, nail bed infection, nail disorder, nail infection, paronychia, pruritus*, rash*. Of these, all terms marked with an asterisk constituted the acne-like rash subset of the skin reaction category. Infusion-related reactions refer to special adverse-event categories, including the MedDRA preferred terms: acute myocardial infarction, acute respiratory failure, anaphylactic reaction, **anaphylactic shock, **anaphylactoid reaction, **anaphylactoid shock, **angina pectoris, apnea, bronchial obstruction, bronchospasm, cardiac failure, cardiopulmonary failure, chills, clonus, convulsion, cyanosis, drug hypersensitivity, **dyspnea, dyspnea at rest, dyspnea exacerbated, dyspnea exertional, epilepsy, hyperpyrexia, hypersensitivity, **hypotension, **hypoxia, infusion-related reaction, loss of consciousness, myocardial infarction, myocardial ischemia, orthopnea, pyrexia, respiratory distress, respiratory failure, shock, sudden death, syncope. A double asterisk refers to those included regardless of when they occurred, all other terms were included only if the onset of the adverse event occurred on the same day as the first administration of cetuximab; [g]Patients with *KRAS* wild-type tumors: 34 in arm A, 28 in arm B; [f]Patients whose tumors harbored *KRAS* mutations: 23 in arm A, 32 in arm B. AE: Adverse event.

type tumors (HR = 1.24, P = 0.08)[28]. In contrast, in patients treated in the FOLFIRI-alone arm in the CRYSTAL trail, *KRAS* mutation status was not associated with clinical outcome. Furthermore, in the large PETACC-3 trial of stage Ⅱ and Ⅲ colon cancer patients treated with adjuvant chemotherapy, *KRAS* tumor mutation status was found not to be of prognostic value[29]. The data from the present study lends support to the findings from retrospective analyses of randomized trials that demonstrated a lack of efficacy of cetuximab (either in combination with chemotherapy or best supportive care) in the treatment of mCRC patients with *KRAS* mutant tumors[13,14,19], adding to the view that *KRAS* tumor mutation status is predictive of resistance to EGFR-targeted antibodies.

No marked difference in efficacy between the treatment groups for patients with EGFR-undetectable and EGFR-detectable tumors was found. Whilst this result should be treated with caution given the low numbers of EGFR-undetectable patients, the efficacy of cetuximab in combination with chemotherapy in EGFR-undetectable tumors has been reported previously[30,31].

The combination of FOLFIRI with cetuximab was generally better tolerated than FOLFOX6 plus cetuximab with regard to grade 3/4 related AEs, and the frequency of study withdrawal being slightly higher in the latter group. The observed chemotherapy toxicity profiles are similar to those previously reported[32]. AEs associated with cetuximab were typically acne-like skin rash, which was observed with both chemotherapy combinations. *KRAS* tumor mutation status did not appear to markedly influence the toxicity profiles of either treatment regimen as would be expected and as previously reported[26].

In summary, this CECOG study shows that combinations of cetuximab with either FOLFOX6 or FOLFIRI have similar efficacy and acceptable toxicity profiles, in the first-line treatment of patients with unresectable mCRC. Analyses of tumor *KRAS* mutational status demonstrated cetuximab in combination with chemotherapy to have an increased treatment effect on tumor response, overall survival and PFS in patients with *KRAS*-wild-type tumors compared with those with *KRAS* mutated tumors. Whether there is a stronger predictive effect of *KRAS* mutation status in patients treated with cetuximab plus FOLFOX6 compared with cetuximab plus FOLFIRI requires further investigation.

ACKNOWLEDGMENTS

We would like to thank all patients participating in this trial and their families. We also acknowledge the following colleagues from centers in the participating countries for enrolling patients: Austria: Professor Felix Keil, LKH-Leoben, Abt. f. COMMENTS

Background

The standard first-line treatment for patients with metastatic colorectal cancer (mCRC) is a combination of 5-fluorouracil (5-FU) and folinic acid (FA) with either irinotecan or oxaliplatin. The addition of cetuximab, one of a new class of drug known as biological therapeutics, to both these regimens has led to an increase in efficacy in some studies. This is even more pronounced in patients who do not carry a mutation in the *KRAS* gene (some 60% of the CRC population). No direct comparison has been made between the efficacy of these two regimens and the current study was undertaken to address this.

Research frontiers

Cetuximab is one of a number of biological therapies which have the potential to improve the outcome of patients with mCRC. However, as with all treatments, some patients respond well to this therapy while others do not. The current research hotspot is to identify key biomarkers which will predict the treatment to which patients are more likely to respond. The *KRAS* gene is one such biomarker and many others are under investigation.

Innovations and breakthroughs

A number of studies have produced encouraging results for combinations of cetuximab with various regimens containing 5-FU, FA and irinotecan or 5-FU, FA and oxaliplatin for the first-line treatment of mCRC. The current CECOG study was important in that it directly compared cetuximab combined with 5-FU FA and irinotecan (FOLFIRI) and 5-FU FA and oxaliplatin (FOLFOX) and showed that there was no statistical difference in efficacy between the two regimens in this setting. Efficacy data in the current study are also comparable with those reported from the corresponding arms of the CRYSTAL (cetuximab plus FOLFIRI) and OPUS studies (cetuximab plus FOLFOX). Of further interest is the retrospective analysis of *KRAS* data, which demonstrated that the 9-mo PFS rate was higher and the risk of disease progression was significantly reduced in patients receiving cetuximab in combination with chemotherapy who had *KRAS* wild-type tumors compared with those with *KRAS* mutations.

Applications

The results of this study suggest that cetuximab plus FOLFIRI and cetuximab plus FOLFOX are equally effective in treating patients with mCRC. The data consolidate the view that cetuximab in combination with standard chemotherapy should be tailored to patients with *KRAS* wild-type mCRC. Whether there is a stronger predictive effect of *KRAS* mutation status in patients treated with cetuximab plus FOLFOX6 compared with cetuximab plus FOLFIRI requires further investigation.

Peer review

This is a well written manuscript which describes the effect of cetuximab combined with FOLFOX6 or FOLFIRI. The authors report that in general, in patients with *KRAS* wild-type tumors the treatment was more effective compared with patients with *KRAS* mutated tumors.

Abstract

AIM: To establish the diagnostic performance of several serological tests, individually and in combination, for diagnosing celiac disease (CD) in patients with different pretest probabilities, and to explore potential serological algorithms to reduce the necessity for biopsy.

METHODS: We prospectively performed duodenal biopsy and serology in 679 adults who had either high risk (n = 161) or low risk (n = 518) for CD. Blood samples were tested using six assays (enzyme-linked immunosorbent assay) that detected antibodies to tissue transglutaminase (tTG) and deamidated gliadin peptide (DGP).

RESULTS: CD prevalence was 39.1% in the high-risk population and 3.3% in the low-risk group. In high-risk patients, all individual assays had a high diagnostic efficacy [area under receiving operator characteristic curves (AU ROC): 0.968 to 0.999]. In contrast, assays had a lower diagnostic efficacy (AU ROC: 0.835 to 0.972) in the low-risk group. Using assay combinations, it would be possible to reach or rule out diagnosis of CD without biopsy in 92% of cases in both pretest populations. We observed that the new DGP/tTG Screen assay resulted in a surplus compared to more conventional assays in any clinical situation.

CONCLUSION: The DGP/tTG Screen assay could be considered as the best initial test for CD. Combinations of two tests, including a DGP/tTG Screen, might be able to diagnose CD accurately in different clinical scenarios making biopsy avoidable in a high proportion of subjects.

INTRODUCTION

The current criterion for diagnosing celiac disease (CD) is mainly based on the presence of a characteristic enteropathy in an intestinal biopsy and evidence that these changes are gluten-triggered[1,2]. While intestinal biopsy is still considered necessary for diagnosing CD, the presence of positive CD-specific serology tests associated with enteropathy are the most commonly used surrogate markers for gluten dependency of damage[3,4]. The assessment of intestinal biopsies requires a certain level of expertise and skill, and the diagnostic accuracy can be affected by variability in sample quality and subjective interpretation[5]. Thus, while pathologists specialized in gastroenterology might have difficulties interpreting mild forms of damage; general pathologists might be susceptible to misdiagnosis, especially if a severe villous atrophy is not present[6,7].

Serological tests have been used for more than 20 years as valuable markers for screening candidates for the need of a duodenal biopsy. Clinical research has demonstrated very high sensitivity and specificity in the detection of IgA antibodies to human tissue transglutaminase [anti-tissue transglutaminase (a-tTG) and anti-endomysial antibodies (EmA)], which are now widely used for identifying patients who might require biopsy, or as a non-invasive confirmation of the CD enteropathy[6-10]. More recently, a new generation of promising assays detecting the presence of deamidated synthetic peptides of gliadin (a-DGP) have shown very high diagnostic performance equivalent to conventional tests[11,12].

As the difficulties in histological diagnosis of CD in clinical practice have been well documented[4,13,14], the appropriate use of simpler and more accurate tools would add reliability to the diagnosis of a condition with high comorbidity and mortality[15]. A new diagnostic standard based on serology alone, which could accurately detect patients in any clinical setting, has been previously suggested[16]. Thus, based on the very high positive predictive values (PPVs) of reliable serological tests, some authors have proposed that intestinal biopsy could no longer be mandatory for the diagnosis of CD in some patients[16-19].

The utility of serological tests finding the search for a new reliable and accurate diagnostic standard for CD requires additional analysis[20]. To obtain the best serological algorithm, studies need to evaluate as many tests and combinations of tests as possible. Furthermore, they should assess a diversity of patient populations, taking in consideration different relevant aspects, such as the disease prevalence and the magnitude of intestinal mucosal damage[10,21-23]. Our aims in this prospective study were threefold: (1) to determine the diagnostic effectiveness of a complete panel of CD-specific serological tests as compared against CD enteropathy in two groups of patients with different risk characteristics; (2) to analyze the performance of individual tests and two-test combinations; and (3) to explore the performance of serology-based algorithms that can potentially obviate the need for intestinal biopsies for diagnosis. The gold standard used in the study to confirm the CD diagnosis was the presence of enteropathy in duodenal biopsies, as assessed by expert gastrointestinal (GI) pathologist.

MATERIALS AND METHODS

Study design

This is a prospective, cross-sectional study on the predictive performance of a set of CD-related antibodies in the diagnosis of CD in two patient populations with different pretest probabilities for having the disorder. All study patients underwent an intestinal biopsy, regardless of the clinical, laboratory and endoscopic findings. For the serological tests, all serum samples were obtained from study subjects before the endoscopy. Endoscopy and biopsies were performed at the endoscopy units of two tertiary care institutions: the "Dr. Carlos Bonorino Udaondo" Gastroenterology Hospital in Buenos Aires and the Endoscopy Service at the HIGA "San Martín" Hospital of La Plata, Buenos Aires Province, Argentina.

Subjects

Between December 2004 and December 2006, we enrolled and performed intestinal biopsies in 679 adult subjects who underwent upper GI endoscopy. Based on their pretest probability of having CD, subjects were categorized as having either high or low risk for the disorder.

High-risk group: During the study period, 161 consecutive adults with suspected but undiagnosed intestinal disorders were enrolled in the study upon their first visit to the Small Bowel Diseases clinic at "Dr. Carlos Bonorino Udaondo" Gastroenterology Hospital. Inclusion criteria required that patients (1) were referred to the clinic because of a suspected small bowel disorder (diarrhea, weight loss, chronic iron-deficiency anemia, malabsorption signs, *etc.*), (2) had no previously known diagnosis of a GI disorder and (3) signed the informed consent. Patients with CD serology performed before the endoscopy, a previous diagnosis of CD, prior treatment with a gluten-free diet, or a former diagnosis of dermatitis herpetiformis, were

excluded from the study. Some data from this population was reported in a prior study[12]. Here, we report the results of a new test in the same population and the analysis of a combination of tests addressing our aims.

Low-risk group: We randomly selected 518 subjects from patients who had been referred for routine upper GI endoscopy because of nonspecific symptoms not primarily related to CD (heartburn, regurgitation, epigastric pain, non-ulcer dyspepsia, *etc*.). Exclusion criteria were the same as those for the high risk group. The first two patients appointed daily for the Endoscopy Unit who fulfilled the inclusion/exclusion criteria were invited to enroll in the study.

Study endpoints

The CD enteropathy was diagnosed based on currently accepted histological criterion: the presence of a type Ⅲ a or more severe enteropathy according to the Marsh's modified classification[24,25]. The final diagnosis of CD was supported by additional presence of positive anti-tTG antibodies or EmA. In addition, the clinical and/or histological response to a gluten-free diet was assessed when possible, and the typical CD-related HLA DQ was tested in some seronegative patients with enteropathy.

Endoscopic procedure and small bowel histology

All endoscopic procedures were performed by experienced endoscopists who were blinded to the clinical and laboratory data. At least three biopsy samples were obtained from a subject's descendent duodenum at different levels distal to the papilla. Morphological and quantitative assessments (intraepithelial lymphocyte -IEL-density) were performed by one experienced pathologist from one center (A.C.). Morphology was categorized according to the modified Marsh classification[25].

Celiac disease-specific serology

Serum samples were kept frozen at -20℃ until the assay was performed in only one center. The CD-related tests and cut-offs were: (1) a-tTG IgA by enzyme-linked immunosorbent assay (QUANTA Lite™, h-tTG IgA, Inova Diagnostic Inc., San Diego, CA, USA); cut-off at 20 units (U)/mL; (2) IgA and (3) IgG antibodies reacting with deamidated gliadin-derived peptides (IgA and IgG a-DGP), (QUANTA Lite™ DGP IgA or IgA. Inova Diagnostic Inc., San Diego, CA); cut-off: 20 U/mL; (4) IgA + IgG isotypes of a-DGP in a single assay (DGP Dual) (cut-off at 20 U/mL); (5) detection of IgA + IgG isotypes of both a-DGP and a-tTG in a single assay (DGP/tTG Screen) (QUANTA Lite™, h-DGP/tTG Screen. Inova Diagnostic. Cut-off: 20 U/mL); (6) IgA antiactin antibodies (AAA) (QUANTA Lite™ F-Actin IgA. Inova Diagnostic Inc., San Diego, CA; cut-off at 25 U/mL); and (7) total serum IgA by radial immunodiffusion (Diffu-Plate, Biocientífica S.A., BA, Argentina) only for cases with enteropathy but negative IgA serology tests. IgA endomysial antibody (IgA EmA) by immunofluorescence on primate esophagus substrates (INOVA Diagnostics Inc., San Diego, CA) was used only in cases with discrepancies between histology and serology. The characteristics of the tests have been reported in previous studies[11,12]. Positive tests were checked in duplicate assays.

Statistical analysis

Based on data distribution, descriptive data are reported as either mean and standard deviation (SD) or median and range. The diagnostic performance of individual serological tests was determined by calculating the sensitivity, specificity, 95% confidence intervals (95% CI), positive and negative predictive values (PPVs and NPVs), and likelihood ratios using cut-offs provided by the manufacturer and at cut-off values that would give a PPV of 100%. Data were analyzed using MedCalc® version 9.3.8.0 (MedCalc Software; Broekstraat, Mariakerke, Belgium). The area under the receiving operator characteristic curve (AU ROC) and corresponding 95% CIs were determined using MedCalc. When assessing the performance of different assay combinations, a particular combination was considered positive if both tests produced concentrations above the cut-off. Comparisons were performed using the Student's *t* test, Mann-Whitney *U* test, χ^2 test, or Fisher's exact test, as appropriate.

To explore the effectiveness of serology for predicting CD in a theoretical context of reducing the necessity of intestinal biopsy, we compared different algorithms for individual assays and two-assay combinations, in both the high-risk and low-risk groups. For individual assays, we devised an algorithm in which only patients with positive serology results would receive biopsy. For combinations of two tests, we explored an algorithm where a patient would receive a biopsy if only one of the assays was positive while the other was negative. For each algorithm, we estimated the number of true positives, false positives, false negatives, and the proportion (%) of biopsies correctly avoided.

RESULTS

Subject characteristics and CD diagnosis

The demographics and some clinical and histological features of the subjects in both groups are presented in Table 1. Compared to those with a high probability of having CD, subjects with low-risk for the disease had a significantly higher mean body mass index (BMI) ($P < 0.0001$). The prevalence of CD correlated with the pretest probability of the disease. Sixty-three (39.1%) of the 161 patients in the high-risk group were diagnosed with CD. In contrast, 17 (3.3%) of the 518 subjects undergoing routine upper GI endoscopy at the two endoscopic units (low-risk group) had a diagnosis of CD. As expected, newly diagnosed CD patients in the high-risk group had a significantly more severe clinical picture and greater degree of histological damage (*P* values between < 0.001 to < 0.0001) compared to those diagnosed in the low-risk group (Table 1).

Table 1 Demographic, clinical, and histological characteristics of subjects categorized by their pretest probability of having CD and from newly diagnosed CD patients from each subgroup

Characteristic	High pretest	Low pretest	*P* value
No. of subjects enrolled (F/M)	161 (131/30)	518 (351/167)

Atypical CD	11	10	< 0.0010
Silent CD	0	6	< 0.0001

CD: Celiac disease.

Performance of serological tests

Individual assays in high-risk group: Some of the data collected from patients in the high-risk group in this study were reported in a previous publication[12]. Data reported here, however, includes results of the newly developed assay (DGP/tTG Screen), explores the value of combinations of two assays, and analyzes the performance of tests using theoretical cut-offs with an absolute (100%) PPV. All newly diagnosed CD patients in the high-risk group had at least one positive serology result.

Table 2 shows that sensitivities for the different assays ranged from 95.2% (for IgA a-tTG) to 100% (for the DGP/tTG Screen), except for the AAA assay (87.3%), which had the worst performance. The IgG a-DGP test had an optimal specificity and PPV (100%). Very high values of AU ROC curves were seen for all individual assays (0.968 to 0.999). Table 2 also shows the performance of assays if the cut-off values had been set to values that would give a PPV of 100%. In most assays, a slight deterioration of the sensitivity was associated with almost absolute specificity. Two assays require further consideration: the IgG a-DGP tests, which had a 100% PPV at the manufacturer's cut-off level (20 U/mL); and the AAA assay, which reached the optimal PPV at a 64 U/mL cut-off, resulting in poor sensitivity (52.4%).

Individual assays in the low-risk group: Table 2 shows the statistical performance of individual assays in the low-risk population. Using the cut-offs provided by the manufacturer, all assays had lower diagnostic efficacy compared with their performance in the high-risk group. (The AU ROC ranged from 0.835 for AAA to 0.972 for the DGP/tTG Screen). The IgA a-DGP and DGP/tTG Screen tests had high sensitivity (82.3%), and all assays had very high specificity (ranging from 88.2% to 99.0%). The PPVs were overall quite low, ranging from 17.6% for AAA to 70.6% for IgG a-DGP. The PPVs for both, the widely used a-tTG (at a cut-off value of 20 U/mL) (50.0%) and the sensitive DGP/tTG Screen (19.2%) were frustratingly low. Once again, the performance of the assays was also determined using cut-off values that would produce a 100% PPV (Table 2). The sensitivity at a 100% PPV cut-off was also disappointing for all assays. For example, the cut-off for the IgA a-tTG would be 139 U/mL, consistent with a sensitivity of 35.3%. The DGP/tTG Screen was the most sensitive test (64.7%) at this cut-off value.

Two-assay combinations in both groups

Table 3 shows the performance of some of the assay combinations in the high-risk group. As expected, the combination tests were more specific, but less sensitive, than individual tests. Furthermore, combinations had excellent AU ROC curves (0.962 to 0.984). Most of these combinations had PPVs of 100% when both assays were positive. Considering the association of two assays in the low-risk group (Table 3), the best sensitivity (82.3%) was achieved by the a-tTG plus the DGP/tTG Screen with an almost absolute specificity (99.0%) and the best NPV and AU ROC curve.

Seronegative patients with mild enteropathy and type Ⅰ damage

In the low-risk group, three patients had mild enteropathy (both with type Ⅲa villous atrophy) but a negative CD-specific serology (one case was positive for AAA and negative for the haplotype DQ2 or DQ8). She had a positive clinical response to the gluten-free diet. The remaining two cases died during the follow-up period: one from an acute myocardial infarction and the other as result of an esophageal malignancy discovered at the time of the endoscopy.

Five other patients had histological features characterized as type I of Marsh's modified classification (IELs count > 30%) and, based on the inclusion criteria, were not categorized as having a CD diagnosis. Two of these patients had a positive serology (IgA a-DGP, IgA a-tTG).

Exploring the value of tests aiming to reduce the necessity of intestinal biopsy

Based on the serology findings, we explored the diagnostic algorithms that might reduce the number of patients required to undergo the invasive diagnostic duodenal biopsy. The algorithm for the use of individual assays would avoid biopsies for patients with negative serology and require biopsy only for those with positive serology. For the theoretical algorithm using combination assays, patients

The statistical performance of tests if concentrations are above the cutoff. PPV: Positive predictive value; NPV: Negative predictive value; tTG: Tissue transglutaminase; DGP: Deamidated gliadin peptide; AAA: IgA antiactin antibodies; AU ROC: Area under the ROC curve.

would not have a biopsy if both assays were congruent (either both positive or both negatives), but would have a biopsy only if the two serology results disagree (one positive and the other negative).

Table 4 shows the performance of the algorithm for single assays. In the high-risk group, the percentage of cases that would not require biopsy ranged from 56.5% to 62.7%, and the single use of DGP/tTG Screen would not miss any CD case. In the low-risk group, the use of single assays would avoid biopsy in most cases (90.3% to 96.7%). However, a substantial number of CD diagnoses (three to eight cases) would be missed, mainly because three CD patients were negative for all serology tests.

The simultaneous combination of two assays for the high-risk group would allow significant reduction in the percentage of intestinal biopsies (92.0% to 98.7%) with no case missed for any of the following four pairs of tests (a-tTG + IgG a-DGP, a-tTG + IgA a-DGP, a-tTG + DGP Dual and a-tTG + DGP/tTG Screen) (Table 5). The use of assay combinations in the low-risk group would result in a similarly high proportion of biopsies avoided (92.1% to 99.0%), but three to five CD cases would be missed.

DISCUSSION

Small bowel histology is still considered the gold standard for diagnosing CD, notwithstanding the fact that the morphological features are not specific, and that other conditions can produce similar findings[1,2]. The possibility of a noninvasive diagnostic algorithm for CD has been explored before[16-19], but no definitive standard has been established yet. Our first aim was to assess the diagnostic performance of serological tests in two patient groups

The statistical performance of the 10 combinations assessed is reported, considering a result to be positive if both tests of the combination have concentrations above the cutoff.

Table 4 Performance of individual assays in both risk populations in the theoretical analysis aiming to avoid duodenal biopsy when serology is negative

Individual serology tests	High-risk		Low-risk	
	Biopsy avoided (%)	Missed CD cases (*n*)	Biopsy avoided (%)	Missed CD cases (*n*)
IgA a-tTG	61.5	3	95.4	4
IgA a-DGP	57.1	1	93.6	3
IgG a-DGP	62.7	3	96.7	5
DGP Dual	61.5	2	96.0	4
DGP/tTG Screen	56.5	0	91.3	3
AAA	62.7	8	90.3	8

with different risk levels of having CD. In this context, we postulated that different assays might perform differently in populations with low pre-test risk for the disease compared to those with high-risk. We hypothesized that this could change the selection of the best serological algorithm to be used in case finding among disorders with increased prevalence of CD (e.g. chronic anemia, osteoporosis, irritable bowel syndrome, *etc.*) or for screening the general population. Notably, the use of serological tests for the selection process of cases in clinical situations with low pretest probabilities has been mostly based on the performance of assays assessed in cohort studies with post-test probabilities greater than 95%.

Considering the high-risk group, we confirmed that all the individual serological assays had very high diagnostic efficacy. Interestingly, our present study shows the DGP/tTG Screen test is the only assay with optimal sensitivity, and only the IgG a-DGP test had 100% specificity and PPV at the cut-off provided by the manufacturer. If the cut-off values were set to obtain 100% PPV, the sensitivity would be minimally reduced for the IgA a-DGP and the DGP/tTG Screen, but more profoundly affected for IgA a-tTG, IgG a-DGP and DGP Dual. The sensitivity for AAA would be reduced from 87.3% to 52.4% with the 100% PPV cut-off, making its use non recommendable in the diagnostic work-up. Therefore, our results highlight the value of the new DGP/tTG Screen, which was the most sensitive assay in detecting CD among subjects with high-risk for the disorder at both cut-offs: the value set by the manufacturers and at a 100% PPV. As far as we know, this is the second study showing the efficacy of the newly developed DGP/tTG Screen test for CD[26].

As we expected, the serological tests did not perform as well in the low-risk group. The sensitivity of individual tests varied between 52.9% and 82.3%, and the highest were again the DGP/tTG Screen and the IgA a-DGP assays. The specificity was high, ranging from 88.2% to 99.0%. As expected, the NPVs were excellent (98.3% to 99.4%) and the PPVs were disappointingly low for all the assays, ranging from 17.6% for the IgA AAA test to 70.6% for the IgG a-DGP. The commonly used IgA a-tTG assay had an unacceptable PPV of 50.0%. Once again, we assessed the performance of individual assays at cut-off values that would result in a 100% PPV. Sensitivity dropped

Table 5 Performance of combinations of two assays in both risk populations exploring the potential avoidance of duodenal biopsy if the procedure is only performed in +/- cases

Combination of two tests	High risk		Low risk	
	Biopsy avoided (%)	Missed CD cases (*n*)	Biopsy avoided (%)	Missed CD cases (*n*)
IgA a-tTG + IgA a-DGP	93.2	0	96.7	4
IgA a-tTG + IgG a-DGP	95.6	0	94.4	3
IgA a-tTG + DGP Dual	95.0	0	96.1	4
IgA-tTG + DGP/tTG Screen	92.0	0	94.4	3
IgA aDGP + DGP/tTG Screen	95.0	2	92.1	3
IgG a-DGP + IgA a-DGP	94.4	1	95.0	3
IgA a-DGP + DGP Dual	94.4	1	95.2	3
IgG a-DGP + DGP Dual	98.7	2	99.0	4
IgG a-DGP + DGP/tTG Screen	93.8	0	93.6	3
DGP Dual + DGP/tTG Screen	93.8	0	93.8	5

significantly to unacceptable values, with the highest being the DGP/tTG Screen at 64.7%. Notably, the sensitivity of the commonly used IgA a-tTG was 35.3%. Overall, these observations for patients with a low-risk for CD (with a prevalence that is intermediate between those disorders at risk and that of the general population) suggest the possibility of underdiagnosis using the most commonly employed serological algorithms. Interestingly, the sensitivity of the assays in the low-risk group was affected by the fact that three of the 17 new patients with villous atrophy (17%) had a minor damage (type IIIa) and were negative for all tests. These cases were considered as having a CD-like enteropathy. We confirmed former observations that a minor degree of damage is frequently detected in patients diagnosed from populations with low pretest probability[27]. Furthermore, our observations on the behavior of serological tests in this group are consistent with former findings showing that CD patients with a minor histological damage might have seronegative results[21,22,25]. However, confirmation of a definitive diagnosis of CD in seronegative cases (and even more in cases with lesser degree of histological damage) requires additional features indicative of gluten dependency that often are difficult to meet. This was the case with the small group identified in this study. Interestingly, one patient had a positive clinical response to the GFD, but was negative for the HLA-DQ2 and DQ8 investigated in the β1 chain. The other two cases died some time after the biopsy without having performed a GFD, one due to a myocardial infarct, and the other due to an esophageal malignancy diagnosed at the time of endoscopy. We estimate that the lack of the specific HLA alleles in the first case minimized the possibility of the patient having a gluten-triggered enteropathy[28]. However, although the inclusion of these three not well defined cases has a negative impact on the performance of serology in the low-risk population, the fact of all patients in our study have had a biopsy evaluation, makes our study a reflection of real clinical practice. We consider that although the diagnosis of these cases is uncertain, they should be included in the analysis, unlike those cases with mild inflammation (Marsh's type I) with a positive serology, which were excluded on the bases of our strict protocol.

To determine if a combination of assays could improve diagnostic accuracy, we explored the performance of all possible combinations of two serological tests, with the condition that a given combination was considered positive or negative if both assays were concordantly above or below the cut-off values, respectively. We observed that the performance of all combinations for the high-risk group was slightly lower than that of single assays, as evidenced by the AU ROC (> 0.960). However, the specificity and PPVs increased to 100% with acceptable sensitivity (above 90.5%) for all possible combinations excluding from this analysis AAA. Furthermore, we observed that combinations of the DGP/tTG Screen with either IgA a-tTG or IgA a-DGP add accuracy to the diagnosis or exclusion of CD.

In the low-risk group, all combinations had poorer performances than the single assays due to a lower sensitivity with minimally increased specificity. However, PPVs improved significantly (with most combinations approaching 100.0%) as expected. Once again, as it was for the high-risk population, the DGP/tTG Screen assay used in combination with the IgA a-DGP exhibited the best performance with acceptable sensitivity (82.3%), optimal specificity, and predictive values. Our observations are in agreement with a recent study from our group that clearly showed that the use of the DGP/tTG Screen assay enhances the sensitivity of detecting gluten sensitivity among a-tTG seronegative patients with CD-like enteropathy (including cases with dermatitis herpetiformis)[29]. Interestingly, it is well-established in clinical practice to use the IgA a-tTG test to select patients for biopsy, in both case-finding processes and in population screening studies. The performance of this popular assay in the low pretest population suggests that its use alone does not seem to be a wise strategy, because it would miss up to 23% of potential new cases.

Based on the present findings, we finally analyzed the number of cases missed or biopsy procedures avoided in the theoretical situation where serology could be used as a single non-invasive tool for diagnosing CD. With this aim, we assessed the effectiveness of two algorithms for the use of a single assay or two-assay combinations. The algorithm for single assays was devised such that biopsy should only be performed for patients with a positive test, as the pretest risk was below 50% in most clinical situations and the number of biopsies avoided would be greater. The second algorithm was designed for combinations of two serological assays, in which biopsy would be omitted if a patients had two positive or negative assays. Biopsy would be reserved for patients with conflicting results.

For the high-risk group, the DGP/tTG Screen assay was the only single test that did not miss any CD cases, and would avoid duodenal biopsy in 56.5% of subjects. In contrast, the algorithm exploring combinations of two assays was highly effective, and could avoid intestinal biopsy in more than 92% of subjects. The higher performance was seen in the combinations using DGP/tTG Screen with other assays. As expected, the serological algorithms

did less well in the low-risk group, as three cases were negatives in all assays. In this population, the two diagnostic algorithms did not differ significantly in terms of false negatives or biopsies avoided. The use of the DGP/tTG Screen and the IgA anti-DGP assays alone, in combination with each other, or in combination with other assays, would miss the three mentioned cases and avoid biopsy in 91.3% to 95.4% of subjects.

In conclusion, we suggest that appropriate use of CD serology might accurately identify the vast majority of CD patients in populations with different pretest probabilities. Furthermore, a negative serology might still miss underlying CD, but the clinical importance of the disease in such patients is probably minimal. The combination of two assays makes diagnostic accuracy higher. However, a proportion of patients (17%) in the low-risk group would be missed by all serology tests or their combinations. Definitive confirmation of CD in these seronegative cases is often difficult and doubtful, sometimes requiring long-term observation. We also confirm the additional value of the new DGP/tTG Screen assay, which resulted in a surplus to more conventional assays and should be considered as the best initial test in investigation for CD. Our study also suggests that this assay in combination with IgA a-tTG or IgA a-DGP could be used to obviate the need for duodenal biopsy in more than 92% of individuals in the high- and low-risk populations. Future validation of the algorithms is required to confirm our findings before new diagnostic guidelines are proposed.

COMMENTS

Background

Diagnosis of celiac disease is based on a characteristic enteropathy in an intestinal biopsy and evidence that these changes are gluten-triggered. The appropriate use of simpler and more accurate tools would add reliability to the diagnosis of celiac disease. Thus, the celiac disease-related serology might have a key role in defining new diagnostic standards for celiac disease.

Research frontiers

A new diagnostic standard based on serology alone could make intestinal biopsy no longer mandatory for diagnosis of celiac disease. With this purpose in mind, the authors aimed to establish the diagnostic performance of several serological tests, individually and in combination, for diagnosing celiac disease in patients with different pretest probabilities and to explore potential serological algorithms to reduce the necessity for biopsy.

Innovations and breakthroughs

This study demonstrates that the deamidated gliadin peptide (DGP)/tissue transglutaminase (tTG) Screen assay could be considered as the best initial test for suspected CD. The authors also show that combinations of two serology tests, including the DGP/tTG Screen and IgA a-tTG or IgA a-DGP, might be able to diagnose celiac disease accurately in different clinical scenarios, and that they could diagnose or rule out the disorder, avoiding intestinal biopsy in almost 92% of subjects under study.

Applications

This study confirms the diagnostic value of the DGP/tTG Screen assay and proposes that it should be considered as the first line test in the screening algorithm for celiac disease. The combination of two tests, which include the DGP/tTG Screen and either IgA a-tTG or IgA a-DGP, strengthen the serological diagnosis of celiac disease, rendering biopsy unnecessary if both tests are congruent.

Terminology

The DGP/tTG Screen assay is a single kit that assess simultaneously the presence of both antibody isotypes (IgA and IgG), the fully synthetic selectively deamidated gliadin peptide, and the human recombinant tTG.

Peer review

Although the study seems to be an "add-on" to their original work, the methodology is adequate and it merits publication for discussion amongst the wider scientific community and for debate into the merits of saving unnecessary biopsies or in patients where gastroscopies are contraindicated/declined.

Abstract

AIM: To understand CD133 promoter hypermethylation and expression in 32 colorectal cancer cell lines.

METHODS: Nucleic acid was isolated from 32 colorectal cancer cell lines and CD133 expression levels were measured by reverse transcription-polymerase chain reaction (RT-PCR) and real-time PCR. Promoter methylation status of the *CD133* gene was analyzed with a methylation-specific PCR after sodium-bisulfite modification and by clonal sequencing analysis. The correlation between expression and promoter methylation of *CD133* gene was confirmed with treatment of 5-aza-2′-deoxycytidine.

RESULTS: We measured CD133 expression levels in 32 colorectal cancer cell lines. RT-PCR analysis showed undetectable or low levels of CD133 expression in 34.4% of cell lines. To verify the relation between CD133 expression and methylation status of the *CD133* gene promoter in colorectal carcinogenesis, *CD133* gene promoter hypermethylation was analyzed in 32 cancer cell lines. Promoter hypermethylation was detected in 13 (40.6%) of the cell lines using methylation specific-PCR and confirmed by bisulfite sequencing analysis. Treatment of 11 of the cell lines with the demethylation agent 5-aza-2′-deoxycytidine recovered CD133 expression in most of them.

CONCLUSION: Transcriptional repression of CD133 is caused by promoter hypermethylation of the CD133 CpG islands in some of colorectal cancer cell lines. The study may contribute to the understanding of the role of CD133 inactivation in the progression of colorectal cancers.

INTRODUCTION

The cell surface antigen CD133 is a glycoprotein of 858-865 amino acids with a total molecular weight of 97-120 kDa and five transmembrane domains. Originally identified in neuroepithelial stem cells, CD133 has been

detected in hematopoietic stem cells, endothelial progenitor cells, glioblastomas, neuronal and glial stem cells, and some other cell types[1,2]. As it has also been identified in cancer-initiating cells in several solid malignancies, it is regarded as one of the cancer stem cell (CSC) markers in colorectal carcinoma[3,4]. CD133 was the first identified member of a pentaspan membrane protein family in both humans and mice[1]. The glycoprotein specifically localizes in microvilli and protruding plasma membrane[5].

The CSC theory is a newly emerged concept of cancer initiation and development. According to this theory, only a small population of cells is clonogenic and contains tumor initiating potency, whereas the majority of the tumor cells have undergone differentiation and lost this potency. In colorectal cancer, these cells have been reported to express CD133 and a CD133-positive population of colon cancer cells was recently demonstrated to be highly enriched in tumor-initiating colon CSCs that have the ability to self-renew and to recapitulate the bulk tumor population[3,6-9].

The *CD133* gene transcriptional regulation is rather complicated and poorly understood. A possible involvement of five alternative TATA-less promoters has been suggested to explain the pattern of transcripts differing in the lengths and sequences of 5' untranslated regions (UTRs). Two of these promoters, P1 and P2 (Figure 1A), are active in *in vitro* tests with a reporter gene. A common transcriptional initiation site was assigned to exons 1A and 1B (Figure 1A), and an mRNA transcribed from exon 1A or 1B was found to be the major transcript, with the choice between the transcription start sites depending on tissues. In particular, colon-expressed transcripts contain both exons 1A and 1B[10-12].

Changes in DNA methylation patterns are an important hallmark of tumor development and progression. Methylation of the C^5 position of cytosine residues in DNA is one of the most fundamental epigenetic characteristics. This methylation is performed by DNA methyl-transferases (DNMTs), which have been implicated in many processes including transcriptional regulation, genomic stability, X chromosome inactivation and silencing of parasitic DNA transposable elements[13]. The importance of DNA methylation is highlighted by the finding that many human diseases result from its abnormal control[14]. Moreover, the aberrant methylation of CpG islands is characteristic of many human cancers and is detected during early carcinogenesis[15]. Hypermethylation of promoter CpG islands is the signature of transcriptional silencing of tumor suppressor genes in various human cancers, and this is as effective as inactivation by gene mutation or deletion[16,17].

To examine whether CD133 expression is related to promoter methylation of the gene, we assessed the expression of the *CD133* gene in 32 colorectal cancer cell lines and determined the methylation status of the CD133 promoter in each cell line.

MATERIALS AND METHODS

Cell culture

A total of 32 colorectal cancer cell lines were obtained from the Korean Cell Line Bank (KCLB; Seoul, Korea). Sixteen SNU-colorectal cancer cell lines were established as previously reported by our laboratory[18]. All the cell lines were maintained in RPMI1640 medium except for two cell lines; Caco-2 and WiDr were maintained in Minimum Essential Medium and Dulbecco's modified Eagle's medium, respectively. The media were supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin, and 0.1 mg/mL streptomycin. Cultures were maintained in humidified incubators at 37℃ in a 5% CO_2 and 95% air atmosphere. All cell lines were absent of mycoplasma (e-myco mycoplasma PCR detection kit, Intron Biotechnology, Gyeonggi, Korea) and bacteria contamination and genetic heterogeneity by DNA fingerprinting analysis (AmpFlSTR Identifiler PCR amplification kit, Applied Biosystems, Foster City, CA, USA).

Nucleic acid isolation and cDNA synthesis

Genomic DNA and total RNA were isolated from washed cell pellets. Genomic DNA was extracted using a G-DEX™ kit (Intron Biotechnology) according to the manufacturer's instructions. Total RNA was isolated according to the manufacturer's instructions using easy-BLUE™ kits (Intron Biotechnology). For cDNA synthesis, 2 μg of total RNA was reversely transcribed using a random primer, dNTP, and 1 μL (200 units) of Superscript™ Ⅱ reverse transcriptase (Invitrogen, Carlsbad, CA, USA) in a final volume of 20 μL for 80 min at 42℃ after a 15-min denaturation at 80℃. Eighty microliters of distilled water was then added to the reverse-transcription reaction.

Reverse transcription-polymerase chain reaction

For CD133 expression analysis, the cDNA was amplified in 25 μL of a PCR reaction mixed with 1 μL of the reverse-transcription reaction, primers and 1 unit of Taq DNA polymerase. Reverse transcription-polymerase chain reaction (RT-PCR) was carried out using RT specific primers (located +343 to +679 from the translation start site in the mRNA sequence); CD133 RT sense (5'-CTGGGGCTGCTGT TTATTATTCTG-3'), and CD133 RT antisense (5'-ACGCCTTGTCCTTGGTAGTGTTG-3'). PCR conditions consisted of 5 min at 94℃ for initial denaturation, followed by 35 cycles of 94℃ (30 s), 55℃ (30 s), and 72℃ (60 s) and a final elongation of 7 min at 72℃. PCR amplification was performed in a programmable thermal cycler (PCR System 9700; Applied Biosystems; Foster City, CA, USA). Primers for β-actin were used to confirm RNA integrity. Both CD133 and β-actin RT-PCR reactions used the same cDNA synthesis. The amplified DNA fragments were fractionated in 2% agarose gel and stained with ethidium bromide.

Quantitative real-time PCR

Real-time PCR was performed in 386 well PCR plates containing the 2X FastStart Universal SYBR Green Master (ROX) mix (Roche, Basel, Switzerland), 10 ng of cDNA template, 300 nmol/L of CD133 RT sense primer and 600 nmol/L of CD133 RT antisense primer in a final

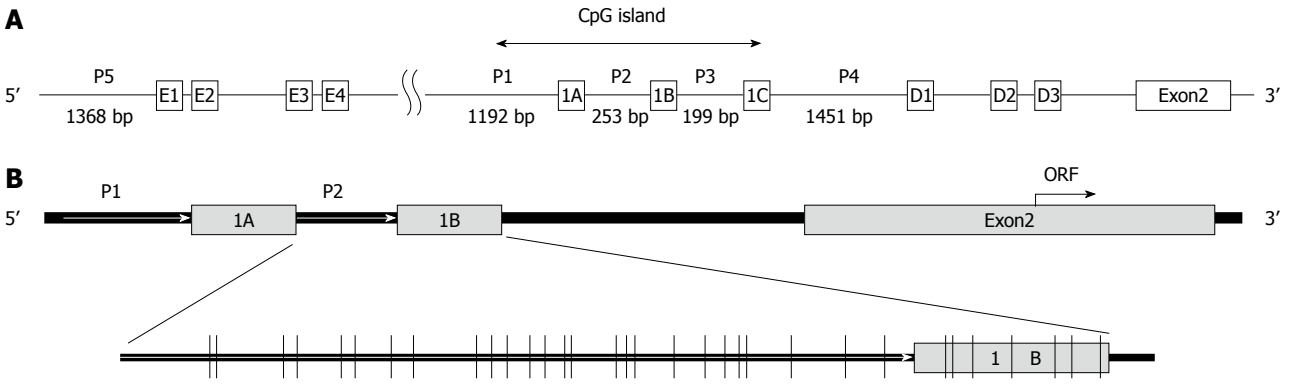

Figure 1 Schemes of the promoter region of CD133. A: Schemes of the *CD133* gene 5' terminus; B: Distribution of CpG dinucleotides in a fragment of the *CD133* gene harboring full P2 (250 bp) promoter and 5'-UTR exon 1B (The citation from Tabu *et al*[5] and Pleshkan *et al*[11]).

volume of 10 μL. Each primer/cDNA set was set up in triplicate. Real-time PCR reactions in a 7900HT Fast Real-Time PCR System (Applied Biosystems) were initiated by heating to 50℃ for 2 min and then to 95℃ for 10 min, followed by 40 cycles of 95℃ (15 s), and 60℃ (60 s). The relative quantification of gene expression was performed using the standard curve method. The standard curve for CD133 expression level was constructed using serial dilutions of SNU-407 cDNA, which in preliminary experiments displayed strong RT-PCR expression of the *CD133* gene. Samples normalized to β-actin served as an internal control.

Methylation specific-PCR

For methylation analysis, 2 μg of genomic DNA obtained from colorectal cancer cell lines was modified using EZ DNA Methylation™ Kit (Zymo Research, Orange, CA, USA). The primers specific for bisulfite modified DNA were designed using MethPrimer software (http://www.urogene.org/methprimer/index1.html). The used primers (located -8061 to -7782 from transcription start site) were as follows; CD133 M primer sense (5'-TTCGGGATAGAGGAAGTCGTAA-3'), CD133 M primer antisense (5'-CTCCCGCCCTAATCACCGCT-3'), CD133 U primer sense (5'-TTTGGGATAGAGGAAGTTGTAA-3') and CD133 U primer antisense (5'-CTCCCACCCTAATCACCACT-3'). The PCR conditions were as follows : 94℃ for 5 min, and then 43 cycles of 94℃ for 30 s, 60℃(methylation specific PCR, MSP) or 62℃ (unmethylation specific PCR, USP) for 30 s, and 72℃ for 60 s, and finally 72℃ for 7 min. The amplified DNA fragments were fractionated in a 2% agarose gel and stained with ethidium bromide.

Bisulfite sequencing analysis

Sequencing primers recognizing both methylated and unmethylated sites (MU), CD133 MU sense (5'-TATTTGGTTATGTTTTTAGTTTTTT-3') and CD133 MU antisense (5'-CCTAATCAACAAATACCTCTCTC-3') primers also were designed using the MethPrimer software. These primers were located approximately -8103 to -7708 from transcription start site. The PCR conditions used were 5 min at 94℃ for initial denaturation, 40 amplification cycles of 94℃ (30 s), 59℃ (30 s) and 72℃ (60 s) and a final elongation of 7 min at 72℃. The PCR products obtained with bisulfite sequencing primers were inserted into the pGEM-T Easy vector (Promega, Madison, WI, USA) for cloning. Sequences of five individual colonies for each analyzed cell line were determined using universal pUC/M13 primers and each sequence was analyzed using a Taq dideoxy terminator cycle sequencing kit on an ABI 3730 DNA sequencer (Applied Biosystems).

5-aza-2'-deoxycytidine treatment to cell lines

For treatment with 5-aza-2'-deoxycytidine, 2×10^5 cells were seeded in two 75 cm^2 culture flasks on day 0. The cells were untreated or treated with 5 μmol/L of 5-aza-2'-deoxycytidine (Sigma-Aldrich, St. Louis, MO, USA) for 24 h on day 2. The culture was re-dosed every 48 h (days 4 and 6) and medium was changed 24 h after adding 5-aza-2'-deoxycytidine. The cells were harvested on day 8 for RNA isolation. The RNA was used for cDNA synthesis and analysis of the CD133 expression as described above.

RESULTS

Expression of CD133 in colorectal cancer cell lines

We analyzed expression of CD133 in 32 colorectal cancer cell lines by both RT-PCR and quantitative real-time PCR. In RT-PCR analysis, CD133 expression was observed in 21 of the 32 cell lines (65.6%) (Figure 2A). On the other hand, in 11 cell lines (34.4%), CD133 expression was either undetectable (SNU-81 and SW480) or low (SNU-61, SNU-503, SNU-769A, SNU-C4, Colo320, HCT-8, LS174T, NCI-H716 and SW1116). To verity the RT-PCR results, we performed real-time PCR and quantified CD133 expression against β-actin expression. All 11 cell lines showed low relative expression (< 3.5%) (Figure 2B). Real-time PCR also demonstrated that 16 of 20 cell lines having strong expression of the *CD133* gene displayed high relative expression (> 6%); the four exceptions were SNU-1197, SNU-C1, SNU-C5 and DLD-1.

Analysis of CD133 methylation status by methylation specific-PCR

To assess if *CD133* gene expression was influenced

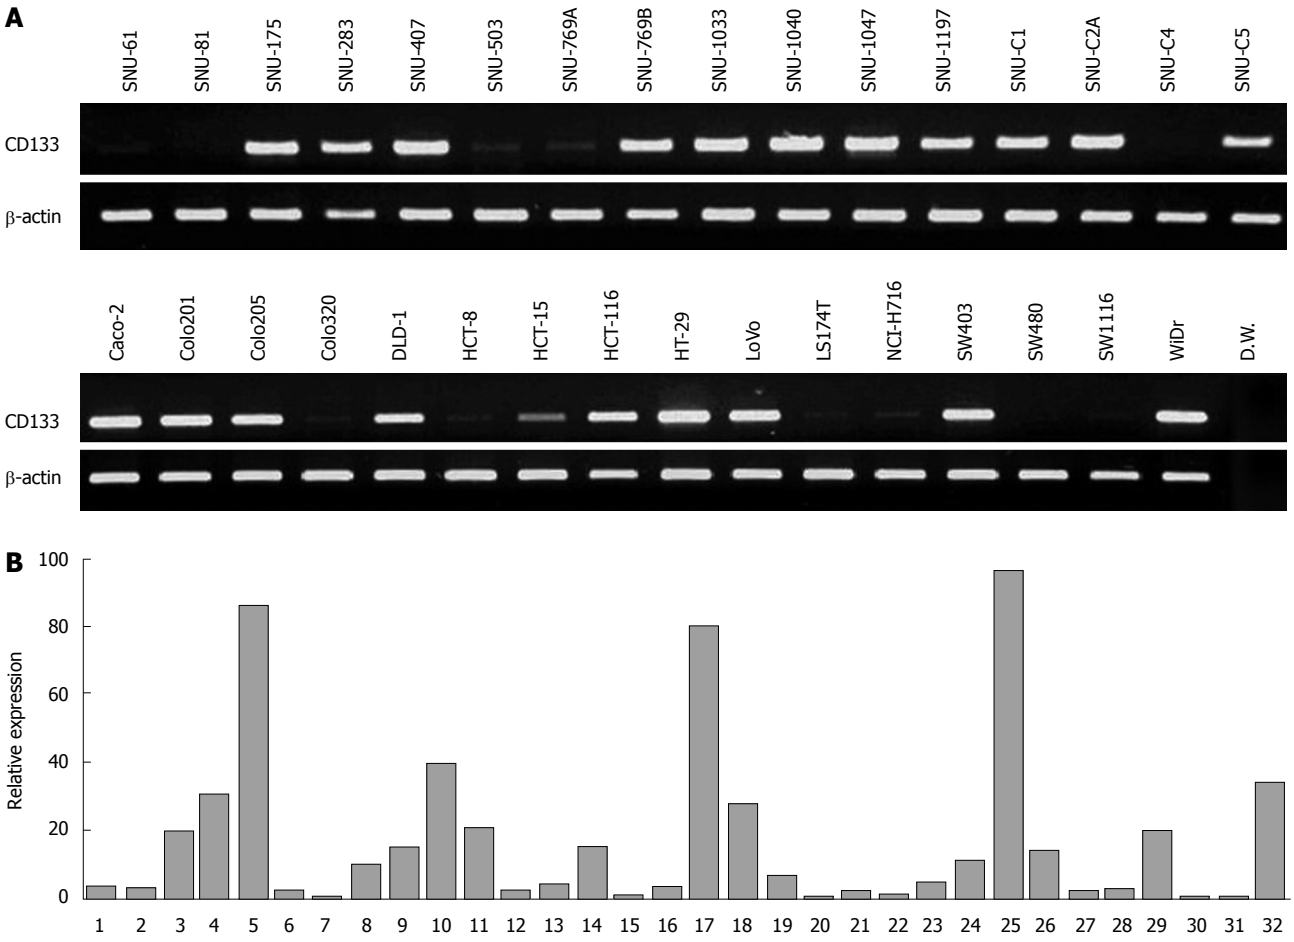

Figure 2 Expression analysis of *CD133* gene in 32 colorectal cancer cell lines. A: Reverse transcription-polymerase chain reaction (RT-PCR) analysis of the *CD133* gene in 32 colorectal cell lines; B: Quantitative differences of CD133 expression by real-time PCR analysis.

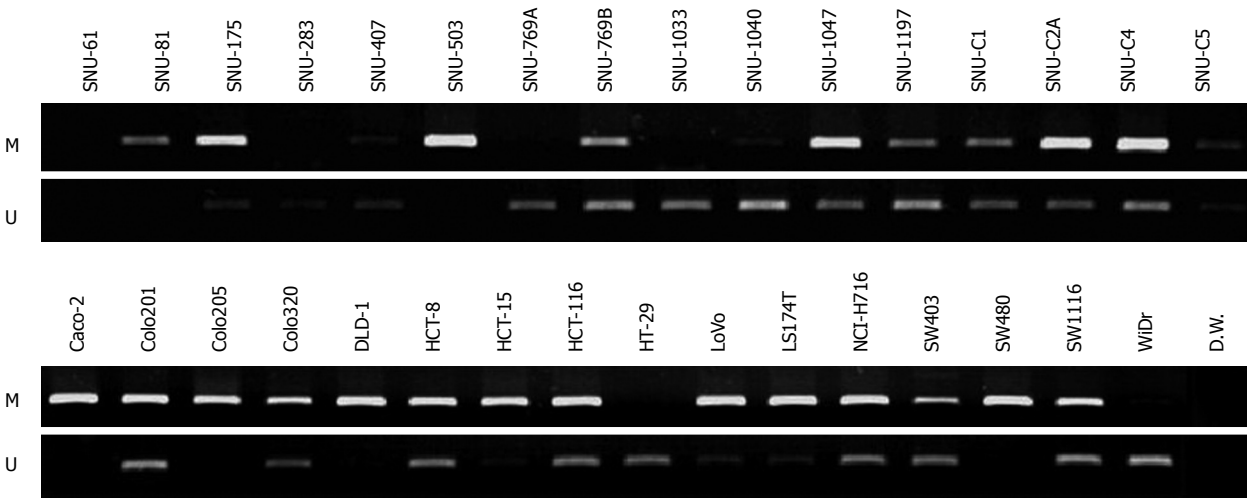

Figure 3 Methylation analysis of *CD133* gene in 32 colorectal cancer cell lines by methylation specific-PCR (MS-PCR). Lanes M and U denote that the product amplified by primer recognizing a methylated sequence and the product amplified by primer recognizing an unmethylated sequence, respectively.

by methylation of its promoter, we checked whether promoter CpG islands of the gene were methylated or unmethylated in the 32 colorectal cancer cell lines by performing methylation specific-PCR (MS-PCR) with designed methylation and unmethylation primers (Figure 3). Methylated DNAs were amplified in 26 cell lines (SNU-81, SNU-175, SNU-407, SNU-503, SNU-769B, SNU-1040, SNU-1047, SNU-1197, SNU-C1, SNU-C2A, SNU-C4, SNU-C5, Caco-2, Colo201, Colo205, Colo320, DLD-1, HCT-8, HCT-15, HCT116, LoVo, LS174T, NCI-H716, SW403, SW480 and SW1116) and unmethylated DNAs were amplified in 24 cell lines (SNU-175, SNU-283,

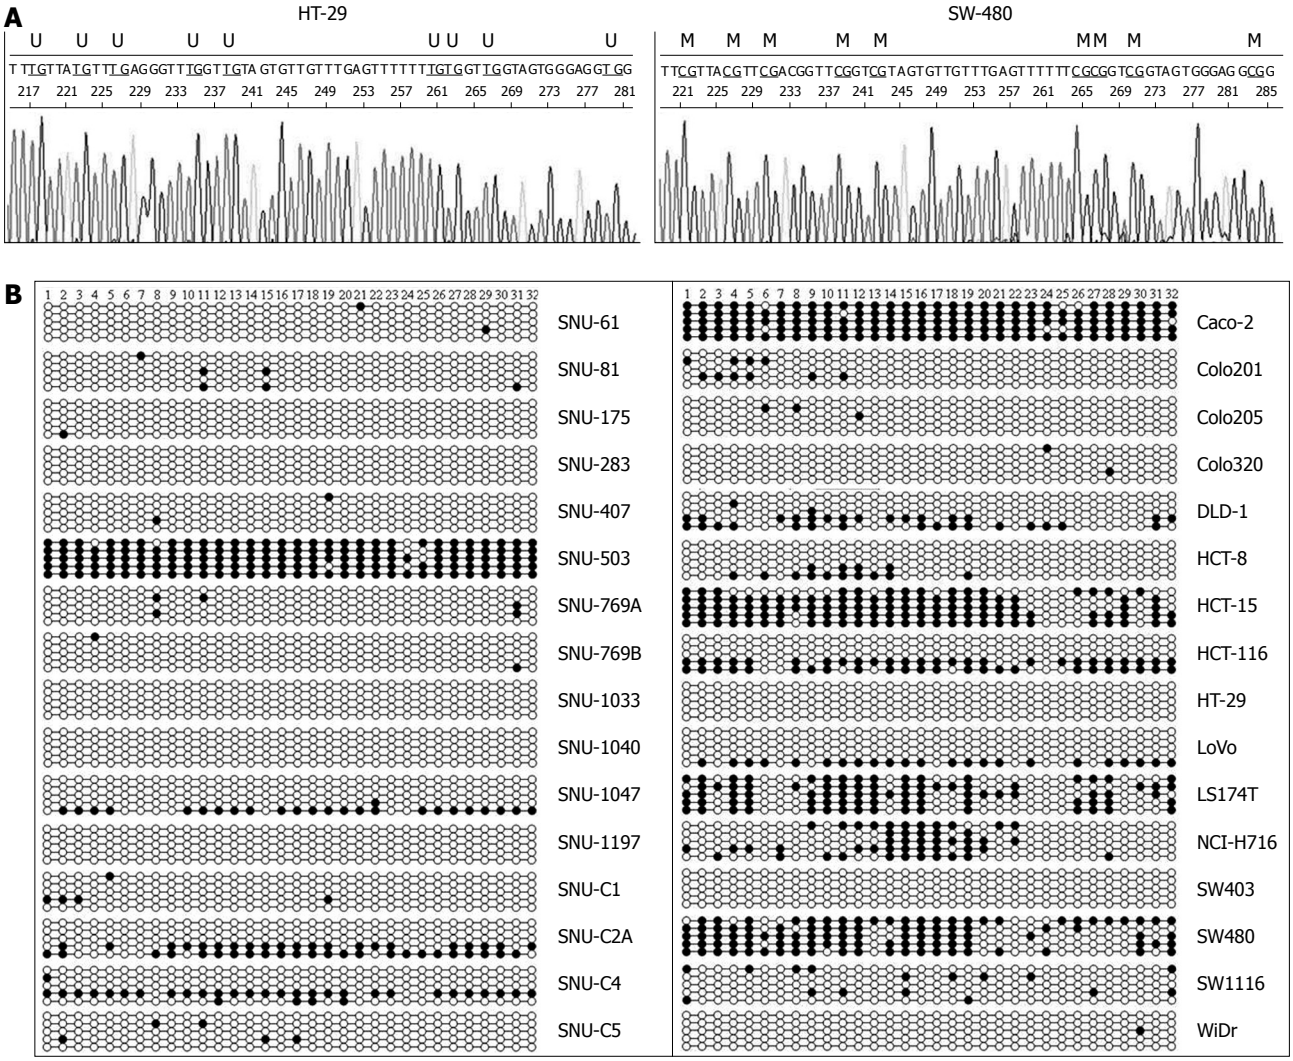

Figure 4 Analysis of methylation status of promoter CpG islands of CD133 by clonal sequencing. A: Representative sequence diagrams of DNA sequencing analysis in (a) HT-29 (unmethylated) and (b) SW480 (methylated) cell lines. M: Methylated site; U: Unmethylated site; B: DNA sequencing analysis of 32 CpG dinucleotides. The numbers at the top show the CpG sites of amplified DNA by bisulfite sequencing primers. Circle represents CpG dinucleotides; closed circle: Methylation; open circle: Unmethylation.

SNU-407, SNU-769A, SNU-769B, SNU-1033, SNU-1040, SNU-1047, SNU-1197, SNU-C1, SNU-C2A, SNU-C4, SNU-C5, Colo201, Colo320, HCT-8, HCT-15, HCT116, HT-29, LoVo, LS174T, NCI-H716, SW403, SW1116 and WiDr). Only methylated DNA bands were evident in SNU-81 and SW480, with undetectable CD133 expression, and in the SNU-503 cell line, with weak *CD133* gene expression. In contrast, only unmethylated DNA bands were evident in SNU-283, SNU-1033, HT-29, and WiDr, in which *CD133* gene expression was strong. Both methylated and unmethylated DNA bands were detected in 13 cell lines (SNU-175, SNU-407, SNU-769B, SNU-1040, SNU-1047, SNU-1197, SNU-C1, SNU-C2A, SNU-C5, Colo201, HCT116, LoVo and SW403), which also showed strong expression of the *CD133* gene. Three cell lines (Caco-2, Colo205 and DLD-1) contained only methylated DNA bands, even though these cell lines expressed CD133. Methylated or unmethylated DNA bands were not evident in SNU-61 cell line.

Analysis of promoter methylation status of CD133 gene by bisulfite sequencing analysis

A study reported that methylation of promoter P1 and exon A1 did not correlate with the *CD133* gene transcription level because promoter P1 and exon 1A were hypermethylated with a high (90%-94%) content of methylated CpG dinucleotides in all cell lines examined[11]. Appropriately, we investigated the methylation status of 32 CpG sites in promoter P2 and exon 1B (Figure 1B) relative to the transcription initiation site of *CD133* gene by clonal bisulfite sequencing analysis. Representative sequence diagrams of two cell lines are shown in Figure 4A. The methylation status of promoter CpG dinucleotides (Figure 4B) was correlated with CD133 expression (Table 1). The promoter CpG dinucleotides of CD133 of 13 cell lines (SNU-175, SNU-283, SNU-407, SNU-769B, SNU-1033, SNU-1040, SNU-1197, SNU-C1, SNU-C5, Colo201, Colo205, HT-29, SW403 and WiDr) were mostly unmethylated. Hypermethylation of CpG islands was 64% in the

M: Methylated CpG site; U: Unmethylated CpG site; -: Not detected; +: Barely detected; ++: Detected; +++: Greatly detected; % methylation: Methylation level of CpGs, (# methylated CpG/# total CpG) × 100; % expression: Relative expression level of CD133 as the ratio to the β-actin expression level, (CD133 level/β-actin level) × 100.

SW480 cell line (undetectable *CD133* gene expression), 64%-95% in SNU-503, HCT-15 and LS174T cell lines (low expression of *CD133* gene) and 9%-24% in SNU-C4, HCT-8, NCI-H716 and SW1116 cell lines (also low expression of *CD133* gene). The distribution of methylated CpG dinucleotides in different clones was not uniform. For example, in SNU-C2A cells the methylation level of CpG in promoter was markedly increased through hypermethylation in two clones, whereas the CpG dinucleotides in other clones were fully unmethylated (Figure 4B). Similar variations were observed in SNU-1047, DLD-1, HCT116, and LoVo cell lines. The variance was suggestive of the origin of different clones from different alleles of the gene. However, further studies are needed to confirm this possibility.

Re-expression of CD133 after treatment with 5-aza-2'-deoxycytidine

To confirm whether the differential CD133 expression was related to DNA methylation, 11 cell lines with undetectable or low expression of CD133 were treated with 5-aza-2'-deoxycytidine. The treatment recovered CD133 expression in four of the weakly CD133 expressing cell lines (SNU-61, SNU-769A, SNU-C4 and Colo320) and two cell lines without detectable CD133 expression (Figure 5A). However, 5-aza-2'-deoxycytidine treatment did not significantly influence *CD133* gene expression in SNU-503, HCT-8, LS174T, NCI-H716 and SW1116 cell lines. Examination of CD133 expression by real- time PCR revealed that CD133 expression was increased after 5-aza-2'-deoxycytidine treatment in SNU-503, HCT-8, LS174T and SW1116 cell lines (Figure 5B), and decreased in the NCI-H716 cell line.

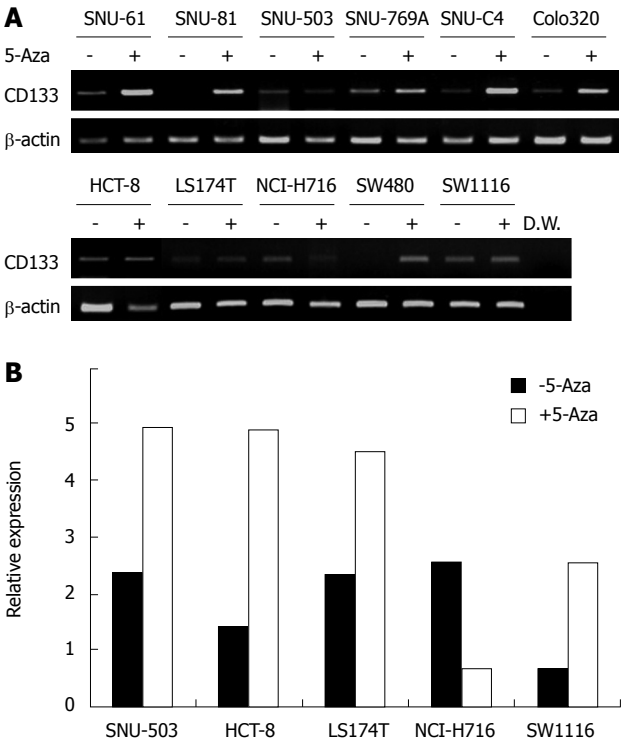

Figure 5 Expression analysis after treatment with 5-aza-2'-deoxycytidine (5-Aza). A: RT-PCR analysis of CD133 expression in 11 cell lines with or without 5-aza-2'-deoxycytidine treatment; B: Representative results of real-time PCR analysis revealing CD133 expression in 5 cell lines with or without 5-aza-2'-deoxycytidine treatment.

DISCUSSION

It has been postulated that CSCs are able to maintain tumor bulk due to the abilities of self-renewal and differentiation into cells with low potential. CD133 is one of CSC markers in colorectal carcinoma and CD133-positive cells in colon cancer exhibit a high tumorigenic ability *in vivo*. In a previous study, the CD133-positive cells separated from tumors were able to form tumor bulk in the immunocompromised mouse models with less numbers than the CD133-negative cells and these cells showed a long-term tumorigenic potential[4]. Furthermore, CD133-positive cells in colon cancer cell lines showed higher levels of proliferation, colony formation and invasive ability *in vitro* than CD133-negative cells[19].

Presently, CD133 was down-regulated in 11 of the 32 colorectal cancer cell lines. Since abnormal DNA meth-

ylation of *CD133* gene is related to CD133 expression in colorectal tumors[20], we hypothesize that CD133 expression is regulated by hypermethylation of the promoter region in this gene, and analyzed promoter methylation status of the *CD133* gene with a methylation-specific PCR after sodium-bisulfite modification and by clonal sequencing analysis. A methylation analysis of promoters P1 and P2 in cell lines demonstrated tissue specificity of the promoter P2 methylation and practically no specificity in the methylation of the P1 promoter[11]. Therefore, we designed the primers with promoter P2 sequences for MS-PCR and bisulfite sequencing analysis and sequencing primers containing 32 of CpG dinucleotides (Figure 1B).

Methylation of the *CD133* gene promoter was observed in 13 cell lines (SNU-503, SNU-1047, SNU-C2A, SNU-C4, Caco-2, DLD-1, HCT-15, HCT116, LoVo, LS174T, NCI-H716, SW403 and SW1116). These cells exhibited significant methylation bands in MS-PCR analysis, and bisulfite sequencing analysis revealed that > 10% of the total CpG islands were hypermethylated. DNA methylation in the promoter region of a gene is associated with a loss of gene expression and plays an important role in gene silencing. The inactivation of tumor-suppressor genes by aberrant methylation in the promoter region is well-recognized in carcinogenesis[20].

However, loss of CD133 expression in early colorectal cancer is different from expression loss of tumor suppressor genes. Acquisition of CD133 promoter methylation of cells without CD133 expression resulted from CD133 positive cell division. The inverse correlation between CD133 transcription and methylation provides a mechanistic explanation for the loss of cell surface CD133 expression in differentiated cells. This is consistent with the notion that cell differentiation is accompanied by epigenetic changes that are responsible for guiding the future phenotypic profile of the progeny[21]. This phenomenon is not only unique to normal stem cells but also presents aberrantly in CSCs, which may initiate carcinogenesis[22,23]. In advanced colorectal carcinoma, the *CD133* gene was more frequently demethylated[24]. The carcinomas with demethylation of *CD133* gene showed a bigger maximal tumor size and a trend toward the development of a lymph node metastasis.

In our results of bisulfite sequencing analysis, there are differences of methylation status among the colonies of the same cell line. The variance was suggestive of the origin of different clones from different alleles of the gene. Definitely, heterogeneity of DNA methylation for several genes has been observed in total cell populations from cultured and primary cancers. The present observations for CD133 promoter methylation are unique in showing striking heterogeneity between isolated cell populations in single-tumor culture lines. This seems to be a more uniform heterogeneity involving cells of the tumor and manifesting as quantitative differences between alleles of a given gene. These quantitative differences of abnormal promoter DNA methylation can be quantitatively altered by changes in environmental surrounding for cultured tumor cells[25].

CD133 has been re-expressed by demethylation with 5-aza-2'-deoxycytidine in some cell lines. This agent reactivates gene expression when gene expression is reduced by methylation of CpG islands. Our results confirm that inactivation of CD133 expression is related to epigenetic modification, which, in colorectal cancer cell lines, is promoter methylation. The function of CD133 is currently unknown, but it was reported that CD133 expression is repressed by DNA methylation in CD133-negative progeny of CD133-positive cells[26], supporting a role for CD133 in CD133-positive cells. It has been found that the expression pattern of several genes was changed in neurosphere cells by treatment of chromatin-modifying agents, 5-aza-2' -deoxycytidine and trichostatin A, and these cells induced hematopoietic activity *in vivo*[27]. Therefore, re-expression of CD133 by treatment of demethylation agent is expected to discover the functions of *CD133* gene in cancer.

The failure to detect methylated or unmethylated DNA bands in MS-PCR SNU-61 cells warrants comment. We believe that there are some problems with the quality of the modified DNA. This remains to be confirmed. The strong expression of CD133 by Caco-2 cells, in which promoter hypermethylation was detected, supports the suggestion that regulation of CD133 expression might be caused by another mechanism.

In conclusion, we observed hypermethylation in the promoter region of the *CD133* gene in 13 of 32 colorectal cancer cell lines. We confirmed the methylation status by MS-PCR, bisulfite sequencing analysis and treatment of 5-aza-2'-deoxycytidine. The expression status of the CD133, one of CSC markers, was correlated with methylation status of CpG islands in the CD133 promoter. These results may contribute to the understanding of the role of CD133 inactivation in the pathogenesis of colorectal cancers.

COMMENTS

Background

The caner stem cell theory is a newly emerged concept of cancer initiation and development. These cells have the ability to self-renew and to recapitulate the bulk tumor population. In colorectal cancer, a CD133-positive population of colon cancer cells was recently demonstrated to be highly enriched in tumor-initiating colon cancer stem cells.

Research frontiers

It is reported that tumor initiating cells in colorectal cancer cells express CD133, the cell surface glycoprotein. However, the *CD133* gene transcriptional regulation is rather complicated and poorly understood. This study demonstrates that CD133 expression could be regulated by methylation status of promoter of the gene.

Innovations and breakthroughs

Recently, a CD133 has become a matter of common interest in the research of colorectal cancer stem cells. This study suggests that transcriptional repression of CD133 is caused by promoter hypermethylation of the CD133 in some of colorectal cancer cell lines. Moreover, each colorectal cancer cell line represented different methylation status of promoter and each colony of cell lines exhibited different levels of methylation.

Applications

Cancer stem cells lost their potential during differentiation by loss of expression of stem cell-specific expressed genes. Therefore, this study may contribute to the understanding of the role of CD133 inactivation in the progression of colorectal cancers.

Terminology

Promoter methylation is one of the most essential epigenetic characteristics.

The importance of DNA methylation is highlighted by the finding that many human diseases result from its abnormal control. Moreover, the aberrant methylation of CpG islands is characteristic of many human cancers and is detected during early carcinogenesis.

Peer review

This manuscript investigates the promoter hypermethylation and expression status of CD133, which is one of several putative cancer stem cell markers in colon cancer. The overall findings indicate that there is a correlation between this epigenetic change in some cancer cell lines, and that demethylation is capable of restoring CD133 expression in some cell lines. Furthermore, there is a surprising finding that different colonies of a particular cell line exhibited different levels of methylation, indicating as the authors point out, that other influences (e.g. tumor environment) may be involved.

Abstract

AIM: To investigate whether intra-procedural diffusion-weighted magnetic resonance imaging can predict response of hepatocellular carcinoma (HCC) during transcatheter arterial chemoembolization (TACE).

METHODS: Sixteen patients (15 male), aged 59 ± 11 years (range: 42-81 years) underwent a total of 21 separate treatments for unresectable HCC in a hybrid magnetic resonance/interventional radiology suite. Anatomical imaging and diffusion-weighted imaging (b = 0, 500 s/mm^2) were performed on a 1.5-T unit. Tumor enhancement and apparent diffusion coefficient (ADC, mm^2/s) values were assessed immediately before and at 1 and 3 mo after TACE. We calculated the percent change (PC) in ADC values at all time points. We compared follow-up ADC values to baseline values using a paired t test (α = 0.05).

RESULTS: The intra-procedural sensitivity, specificity, and positive and negative predictive values (%) for detecting a complete or partial 1-mo tumor response using ADC PC thresholds of ±5%, ±10%, and ±15% were 77, 67, 91, and 40; 54, 67, 88, and 25; and 46, 100, 100, and 30, respectively. There was no clear predictive value for the 3-mo follow-up. Compared to baseline, the immediate post-procedure and 1-mo mean ADC values both increased; the latter obtaining statistical significance (1.48 ± 0.29 mm^2/s *vs* 1.65 ± 0.35 × 10^{-3} mm^2/s, P < 0.014).

CONCLUSION: Intra-procedural ADC changes of > 15% predicted 1-mo anatomical HCC response with the greatest accuracy, and can provide valuable feedback at the time of TACE.

Key words: Hepatocellular carcinoma; Transcatheter arterial chemoembolization; Diffusion-weighted imaging; Apparent diffusion coefficient; Functional imaging biomarker

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third most common cause of death from cancer worldwide[1] and the main cause of death among cirrhotic patients[2]. Transcatheter arterial chemoembolization (TACE) is commonly employed to treat HCC patients who are not candidates for curative surgical resection or transplantation. To date, two separate randomized controlled trials have demonstrated survival benefit in patients undergoing TACE compared to best supportive care[3,4], and TACE is currently recommended as first-line non-curative therapy for non-surgical patients with intermediate-stage HCC[5,6].

Monitoring tumor response is paramount to determine the time interval of repeat treatment or to identify treatment failure. An imaging modality that can serve as an early surrogate marker of tumor necrosis, and objectively predict future tumor response at the time of treatment, would be immensely beneficial, especially because treatment response has been identified as an independent predictor of survival[3].

Conventionally, response is evaluated by magnetic resonance imaging (MRI) at 1-3 mo after TACE. Assessment of anatomical response in the early post-treatment period can be misleading, however, because a reduction in tumor size often does not correlate with the degree of tumor necrosis[7,8]. Furthermore, conventional gadolinium-enhanced MRI might not discern therapy-induced inflammation and granulation tissue from viable tumor[8,9]. Given these limitations, alternative MRI techniques are desired to reflect tumor response more accurately.

Diffusion-weighted imaging (DWI), a functional MRI technique, detects MR signal changes in tissues due to water proton motion that varies based upon the degree of cell membrane integrity. The intact membranes of viable tumor cells restrict water diffusion, whereas necrotic tumor cells with disrupted cell membranes exhibit increased water diffusion. This mobility of water is quantified by a constant known as the apparent diffusion coefficient (ADC). Previous preclinical[10,11] and clinical[9,12] studies have shown that tumor necrosis is associated with an increase in ADC value, thereby allowing differentiation between viable and necrotic portions of tumor. Additionally, DWI can determine treatment response several weeks earlier than anatomical imaging[9,12]. However, it remains unclear if these changes in water mobility occur immediately during TACE. If so, it is possible that such changes could provide interventional radiologists with a functional parameter to determine the endpoint of TACE and to predict future response to therapy. Therefore, we tested the hypotheses that ADC changes are present at the time of TACE, and that they can predict conventional 1.5-T MR anatomical image changes at 1 and 3 mo post-TACE.

MATERIALS AND METHODS

Clinical setting and patients

Our local Institutional Review Board approved this Health Insurance Portability and Accountability Act compliant study, which was performed at a single urban, academic tertiary care center. All patients provided informed consent. We enrolled 16 consecutive patients with a total of 21 separate treatment sessions for 21 primary HCC lesions from March 2006 to September 2009. Candidates for TACE were evaluated and treated for unresectable HCC after discussion at a multidisciplinary tumor board conference. Inclusion and exclusion criteria were modified from the report of Brown *et al*[13]. We included patients who met the following criteria: (1) age > 18 years; (2) ability to provide informed consent; (3) Eastern Cooperative Oncology Group (ECOG) performance status no greater than 2; (4) Child-Pugh class A or B disease; (5) focal or multifocal hepatic malignancy; (6) no contraindications to MRI; and (7) TACE performed in an MR/interventional radiology (IR) suite. Patients were excluded if they met any of the following criteria: (1) life expectancy < 6 mo; (2) Eastern Cooperative Oncology Group performance status ≥ 3; (3) Child-Pugh class C disease; (4) uncorrectable abnormal laboratory values (international normalized ratio > 1.5; platelet count < $5.0 \times 10^4/\mu L$; total serum bilirubin > 4.0 mg/dL; serum creatinine > 2.0 mg/dL); or (5) contraindications to MRI.

Treatment protocol

Certificate of Added Qualification (CAQ)-certified interventional radiologists who specialize in interventional oncology performed all TACE procedures in a sterile MR/IR suite (Miyabi; Siemens, Erlangen, Germany). This suite contains a 1.5-T Espree MR imager connected to an Artis dTA digital subtraction angiography (DSA) unit *via* a sliding patient table (Figure 1).

Patients first underwent DSA for superselective hepatic arterial catheter placement. Next, patients were transferred to the adjacent MR unit for pre-TACE tumor imaging. After baseline tumor imaging, patients were transferred back to the DSA unit and underwent TACE. Subsequently, patients were transferred back to the MR suite to obtain a set of post-TACE images. Lastly, patients underwent a final transfer to the IR suite to remove the vascular sheath and to compress the arterial puncture site manually to achieve hemostasis. Patients were admitted to the hospital for monitoring and discharged 1-2 d later after verification of adequate pain control, ambulation, and oral intake.

DSA and TACE protocols

DSA was performed with a 5.5-F visceral catheter and a 2.8-F microcatheter (Renegade Hi-Flo, Boston Scientific, Natick, MA, USA) that were coaxially inserted over a 0.016-inch diameter guide wire (Headliner, Terumo, Tokyo, Japan) to superselect the hepatic lobar or segmental hepatic artery that supplied the tumor. DSA was performed with iohexol injections (Omnipaque 350; Amersham Health, Princeton, NJ, USA).

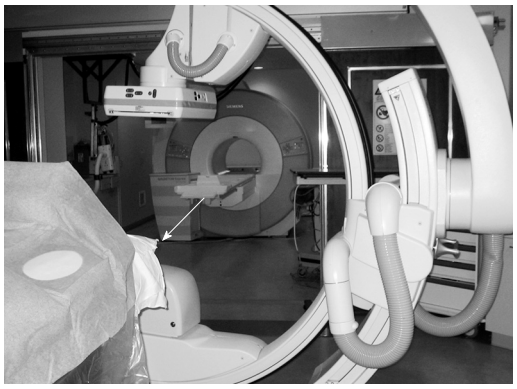

Figure 1 Hybrid MR/IR suite at investigators' institution. Moving table (arrow) allows the rapid transfer of patients between radiographic DSA and MRI during TACE. MRI: Magnetic resonance imaging; IR: Interventional radiology; DSA: Digital subtraction angiography; TACE: Transcatheter arterial chemoembolization.

We performed TACE using a 1:1 solution of emulsifying oily contrast agent and chemotherapeutic agents: 10 mL Ethiodol (Savage Laboratories, Melville, NY, USA) combined with a 10-mL mixture of 100 mg cisplatin, 30 mg doxorubicin, and 30 mg mitomycin C. Using fluoroscopic monitoring, we infused the solution until initial slowing of antegrade blood flow was noted. TACE was then completed by injecting 500-700-μm diameter Embospheres (Biosphere Medical, Rockland, MA, USA) mixed with iohexol. Angiographic endpoint was selected at the discretion of the treating interventional radiologist and ranged from subjective angiographic chemoembolization endpoint (SACE) levels Ⅱ-Ⅳ[14].

MRI protocol

All patients underwent anatomical and functional MRI prior to and immediately following TACE therapy. A subset of these patients also received imaging at the 1- and 3-mo follow-up time periods. All MRI was performed using a flexible six-channel phased-array abdominal imaging coil on a 1.5-T MRI scanner (Espree; Siemens Medical Solutions, Erlangen, Germany). Anatomical MRI included T2-weighted (T2W) half-Fourier acquisition single-shot turbo spin-echo and T1-weighted (T1W) gradient-recalled-echo imaging sequences, with and without contrast, with fat suppression in the arterial and delayed venous phases. Functional DWI was performed using single-shot spin-echo echo-planar imaging during one or more breath holds (repetition time/echo time = 2500/82 ms; slice thickness/gap = 8/4 mm; bandwidth 1.5 kHz/pixel; partial Fourier factor 6/8; non-selective fat saturation; twice refocused spin-echo diffusion weighting to reduce eddy-current induced distortion with *b* values of 0 and 500 s/mm^2). ADC parametric maps were reconstructed from each set of DW images acquired at each slice position.

Image analysis

A Siemens Argus image workstation was used to process all MR images. CAQ-certified interventional radiologists assessed anatomical tumor response on T1W contrast-material-enhanced MRI. Areas of persistent tumor enhancement after treatment were used as an indication of residual tumor, as proposed by the European Association for the Study of the Liver (EASL)[7]. Radiographic tumor enhancement was assessed at baseline and at 1 and 3 mo after therapy. Relative change in tumor enhancement was divided into four categories: (1) complete disappearance of tumor enhancement after treatment denoted a complete response (CR); (2) ⩾ 50% decrease in area of tumor enhancement corresponded to a partial response (PR); (3) progressive disease (PD) was indicated by a ⩾ 25% increase in area of tumor enhancement; and (4) tumor enhancement changes that did not fit any of the previous three categories were designated as stable disease (SD). These percentages were chosen to correspond to the World Health Organization guidelines regarding bi-dimensional tumor size measurements[15]. An objective EASL response included CR and PR alone.

DWI and ADC maps were used to determine functional tumor response. A region of interest (ROI) was drawn around each entire tumor on DWI using the T1W images as a reference. For accuracy, the ROI measurements for mean ADC values were then obtained by transferring the DWI ROI to the ADC maps at the corresponding slice positions. ADC values were measured for each tumor at baseline, immediately after treatment, and at 1 and 3 mo. Functional tumor response was reported in ADC units of mm^2/s.

To determine if the ADC values changed immediately after TACE and whether they predicted anatomical tumor response at long-term follow-up, we calculated the percent change (PC) in ADC values at all time points according to the formula PC = [(ADC_{post}-ADC_{pre})/ADC_{pre}] × 100, where ADC_{pre} was the baseline measurement and ADC_{post} was the measurement obtained at each follow-up time period. Using the anatomical response at 1 and 3 mo as the gold standard, we determined the sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of the PC in ADC immediately after TACE. These values were calculated using ADC PC absolute thresholds; an increase or decrease in ADC value of more than 5%, 10%, or 15% was considered to be a positive outcome.

Figures were prepared using Adobe Photoshop software (Adobe Systems Inc., San Jose, CA, USA).

Statistical analysis

We collected and reviewed all patient demographic data, including α-fetoprotein (AFP), total bilirubin, aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and alkaline phosphatase levels, as well as tumor characteristics, including HCC staging and radiographic evaluations before and after TACE.

The mean ± SD was calculated for patient age, time elapsed from treatment to follow-up, liver function laboratory values, and MR measurements of ADC values. A paired *t* test with α = 0.05 was used to compare differences between ADC_{pre} and ADC_{post} in all patients. In cases in which a single patient underwent multiple treatments to target separate tumors, ADC values and EASL responses

RESULTS

Patient demographics

Sixteen patients (15 male) successfully completed both baseline pre-chemoembolization and immediate post-chemoembolization anatomical MRI and DWI for a total of 21 treatment sessions. From the initial 21 treatments, 15 (71%) and eight (38%) of these cases included the 1-mo (37 ± 11 d) and 3-mo (94 ± 16 d) follow-up imaging, respectively. Mean age was 59 ± 11 years. Table 1 lists the demographic data for this 16-patient cohort. The majority of patients had multi-nodular, non-invasive HCC with moderately preserved underlying liver function (i.e. Child-Pugh class B disease). At the time of treatment, no patients exhibited advanced disease (Okuda stage Ⅲ) or a cancer of the liver

italian program (CLIP) score greater than 2 (Table 2). Liver function tests are summarized in Table 3.

Anatomical tumor response after TACE

On the anatomical contrast-material-enhanced T1W MR images, the 1-mo follow-up demonstrated CR, PR, SD, and PD rates of 6%, 75%, 13%, and 6%, respectively, whereas the 3-mo follow-up showed rates of 38%, 0%, 25%, and 38%. Thus, a favorable EASL response (CR or PR) was achieved in 81% of patients at 1 mo and 38% of patients at 3 mo.

Functional MRI changes and prediction of response after TACE

Mean baseline tumor ADC ($\times 10^{-3}$ mm^2/s) was 1.48 ± 0.30, which increased to 1.51 ± 0.36 immediately after TACE, 1.65 ± 0.35 at 1 mo, and then declined to 1.56 ± 0.48 at 3 mo. Compared to baseline, the increase in mean ADC value at 1 mo was statistically significant ($P < 0.014$); however, the immediate post-procedure ADC change was not significant.

Overall mean ADC PC was 3.00% ± 16.4% immediately after TACE, 13.4% ± 14.8% at 1 mo, and 4.25% ± 17.9% at 3 mo. Figure 2 is a scatter-plot graph of 16 different treatment sessions showing individual ADC PC during TACE and corresponding 1-mo EASL status. Shaded regions of the graph represent the ADC PC absolute threshold values of 5%, 10%, and 15%. The sensitivity, specificity, PPV, and NPV of the immediate post-TACE ADC PC in predicting an objective EASL response (CR

or PR) at 1 mo are listed in Table 4. There was no discernable predictive value related to the 3-mo anatomical tumor response. Figure 3 is composed of representative MR images from a single patient showing HCC diffusion changes during TACE and corresponding tumor anatomy 1 mo later.

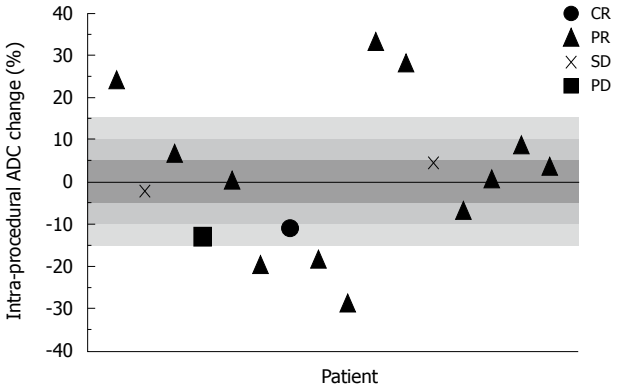

Figure 2 Scatter-plot graph of 16 separately treated HCC lesions showing intra-procedural ADC percent change and their corresponding 1-mo EASL status. DISCUSSION

In this prospective study of 16 patients undergoing 21 separate TACE sessions, we showed that intra-procedural ADC changes in tumor function could help predict future anatomical response with increasing certainty at greater absolute ADC PC cut-off values. Specifically, we showed that patients whose ADC increased or decreased from baseline by > 15% immediately after TACE had a 100% rate in predicting a positive EASL response at 1 mo. Our findings also confirm that ADC increases occur within days to weeks following TACE, but indicate that they do not change significantly at the time of therapy.

Several previous clinical studies have shown the ability of DWI to map water distribution within HCC tumors and quantify tumor necrosis after transcatheter liver-directed therapy. In patients with HCC undergoing TACE, Kamel *et al*[12,16] have confirmed the feasibility of DWI to measure tumor response, which shows an increase in ADC at 4-6 wk after TACE. In their studies, regions of increased ADC corresponded to non-enhancing regions of presumed coagulative necrosis on contrast-material-enhanced MRI. More recently, they have demonstrated ADC changes as early as 1 wk post-TACE with no significant changes occurring at 1 d of follow-up[17]. Chen *et al*[9] have further demonstrated on a 3.0-T MR scanner an increase in HCC ADC values as early as 2-3 d after therapy. Statistically significant ADC increases have also been observed following yttrium-90 radioembolization, and in a feasibility study by Rhee *et al*[18], the 1-mo ADC changes were able to predict the 3-mo anatomical tumor response. Cui *et al*[19] have also looked at the predictive potential of ADC, albeit in cases of systemic chemotherapy for hepatic metastases.

None of the aforementioned studies[9,12,16-19], however, were able to address the question of whether ADC changes at the time of chemoembolization could be used to predict future anatomical response. We were able to address this gap in knowledge through the use of an integrated MR/IR suite. Such a suite allowed us to image patients with DWI immediately before and after TACE. Using this setup, we were able to show that DWI could be used intra-procedurally to predict a future anatomical response 1 mo after TACE. A positive result (ADC PC > 15%) would likely suggest adequate HCC treatment; however, a negative result would not be useful feedback and could not be interpreted as insufficient treatment.

One explanation for the immediate post-TACE increase in ADC is the ischemic effects of embolization itself[20], as ischemia-induced cellular swelling has been shown to increase ADC values[21]. Disruption of cell membrane integrity by the cytotoxic effects of TACE would be expected to require more time to evolve, most likely within the first week after therapy[9,17,20]. Notably, large decreases in immediate ADC_{post} also predicted tumor response. Limiting perfusion could conceivably lead to a measurable ADC reduction because a significant component of ADC values can be due to micro-capillary circulation[22], as opposed to water mobility alone. The relative decrease in mean ADC value at the longer 3-mo follow-up could be due to clearance of apoptotic bodies by scavenger cells, followed by fibrosis and tissue regeneration.

This study had several important limitations. First, the cohort used in our study was limited in size, and not all patients received follow-up imaging due to morbidity, mortality, repeat TACE before 3 mo, liver transplant, or being lost to follow-up. Second, assessments of functional and anatomical tumor response depended upon the selected *b* values and the anatomical response criteria chosen. Third, while an inverse relationship was noted between an increase in ADC value and a qualitative decrease in viable tumor enhancement, a correlation of magnitude could not be determined. Finally, the results of this study need to be validated by future studies with larger cohorts to determine if intra-procedural ADC changes reliably predict patient prognosis or affect outcome.

We concluded that intra-procedural ADC change of > 15% could serve as a useful prognostic indicator of tumor response to TACE. This preliminary result is encouraging because early knowledge of HCC response after initial therapy is essential to revise prognosis and guide

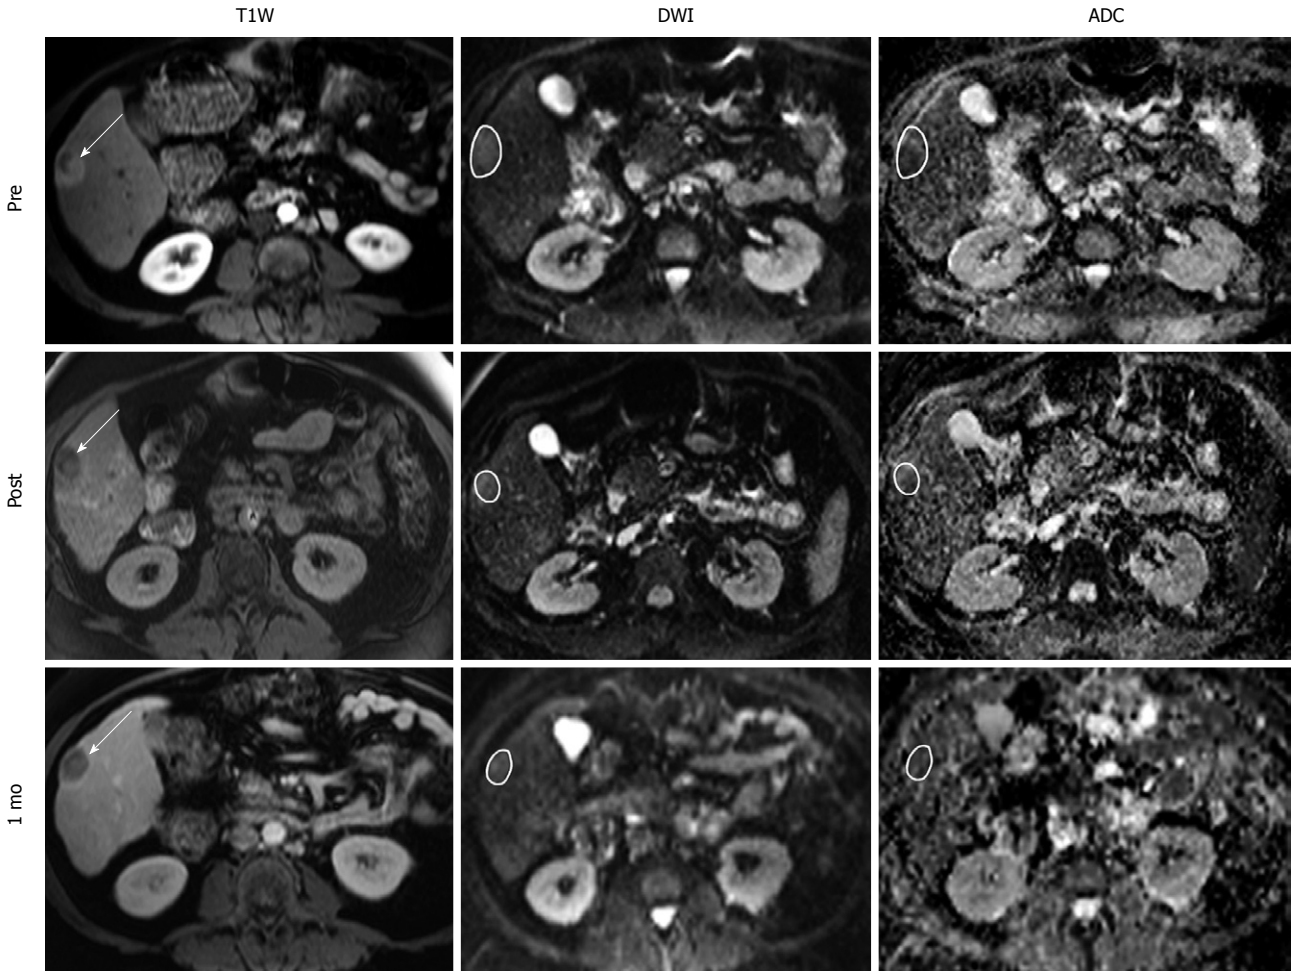

Figure 3 Representative T1W, DW, and ADC MR images from a 70 year-old man with right-lobe HCC secondary to autoimmune hepatitis. Images were acquired before, immediately after, and 1 mo after TACE. Arrows on the anatomical images indicate tumor location with sample ROIs drawn on the functional MR images. Intra-procedural ADC changed by 28.6%, which predicted a favorable EASL response at 1 mo. future therapy. Use of DWI and ADC mapping in conjunction with traditional anatomical imaging evaluation could further improve tumor response interpretation and subsequent treatment planning. At present, MR/IR suites permit the acquisition of immediate quantitative functional imaging changes, in both tumor perfusion[23,24] and now diffusion. Which of these two functional parameters is more effective as an intra-procedural biomarker to tailor HCC therapy awaits verification by future studies.

COMMENTS

Background

Early knowledge of hepatocellular carcinoma (HCC) response to transcatheter arterial chemoembolization (TACE) is crucial for determining treatment success, timing of repeat treatment, and patient prognosis. Currently, magnetic resonance imaging (MRI) is used 1-3 mo after treatment to evaluate anatomical tumor response, based upon changes in tumor size and contrast-agent enhancement. Alternatively, diffusion-weighted imaging (DWI) can be used as a functional imaging technique to depict thermally induced motion of water molecules. The extent of water mobility within biological tissues can be quantified by a parameter called the apparent diffusion coefficient (ADC). Recently, ADC values have been shown to change within days to weeks after therapy, which is earlier than changes seen by conventional HCC anatomical size assessment. However, no studies to date have reported the intra-procedural characteristics of ADC and whether these values can predict future tumor response at the time of chemoembolization.

Research frontiers

A non-invasive and non-ionizing imaging modality that could not only detect, but also predict, early HCC response to treatment would be ideal. DWI has demonstrated the capability to monitor and quantify functional tumor changes. Consequently, the ADC value obtained immediately post-treatment is of much interest because it has the potential to serve as an imaging biomarker of current and possibly future tumor response.

Innovations and breakthroughs

Previous studies have described how ADC values change over time during the follow-up period after TACE. Specifically, ADC values of HCC tend to increase after therapy. This initial increase in tumor water mobility is detected as early as 2 d post-treatment, with significant increases during several weeks thereafter. DWI has demonstrated the ability to identify and distinguish between viable and necrotic portions of tumor, and significant increases in ADC often correspond with tumor cell death. Earlier HCC evaluation, confirmation of successful treatment, or discovery of treatment failure could improve therapeutic decision making and patient prognosis. To elucidate further the role of DWI in characterizing tumor response to therapy, the authors investigated whether ADC changes could be detected immediately during intervention, and whether they could pre-

dict future HCC response at the time of treatment. They addressed this question by using a hybrid MR/interventional radiology suite, which permitted intra-procedural imaging immediately before and after chemoembolization.

Applications

This preliminary results suggest that patients whose intra-procedural ADC values increase or decrease by > 15% are more likely to have a favorable anatomical tumor response 1 mo later.

Terminology

TACE involves the minimally invasive delivery of chemotherapy directly to the site of the tumor, *via* an arterial catheter selectively placed during X-ray fluoroscopy (i.e. under real-time image guidance). This targeted method of drug administration decreases systemic drug toxicity and improves local drug efficacy. TACE is a palliative (i.e. non-curative) treatment that has been shown to improve survival for patients with intermediate-stage unresectable HCC.

Peer review

This is an excellent paper. It is a very interesting topic, especially for the radiological gastrointestinal community.

Abstract

AIM: To evaluate intensity, localization and cofactors of pain in Crohn's disease and ulcerative colitis patients in connection with health-related quality of life (HRQOL) and disease activity.

METHODS: We reviewed and analyzed the responses of 334 patients to a specifically designed questionnaire based on the short inflammatory bowel disease questionnaire (SIBDQ) and the German pain questionnaire. Pain intensity, HRQOL, Crohn's disease activity index (CDAI) and colitis activity index (CAI) were correlated and verified on a visual analog scale (VAS).

RESULTS: 87.9% of patients reported pain. Females and males reported comparable pain intensities and HRQOL. Surgery reduced pain in both genders (P = 0.023), whereas HRQOL only improved in females. Interestingly, patients on analgesics reported more pain (P = 0.003) and lower HRQOL (P = 0.039) than patients not on analgesics. A significant correlation was found in UC patients between pain intensity and HRQOL (P = 0.023) and CAI (P = 0.027), and in CD patients between HRQOL and CDAI (P = 0.0001), but not between pain intensity and CDAI (P = 0.35). No correlation was found between patients with low CDAI scores and pain intensity.

CONCLUSION: Most IBD patients suffer from pain and have decreased HRQOL. Our study reinforces the need for effective individualized pain therapy in IBD patients.

INTRODUCTION

Inflammatory bowel disease (IBD) causes inflammation of the small and large intestines. The most common symptoms are persistent bloody diarrhea, pain, weight loss and persistent fatigue. Furthermore, irritable bowel syndrome (IBS)-like symptoms and depression are common in IBD[1,2]. Most patients go through periods during which symptoms flare up followed by periods of remission when symptoms subside.

In recent years, therapy of Crohn's disease (CD) and ulcerative colitis (UC) has improved with the application of new drugs. Biologicals such as TNF-α inhibitors are among a new generation of therapeutic options that control symptoms and inflammation in IBD patients[3,4]. However, medical management of IBD remains challenging and cannot always control all aspects of the disease. Even with therapy, patients frequently suffer not only from diarrhea and rectal bleeding but also from abdominal pain, cramps and arthralgia. Although the established disease activity indices only include abdominal pain as one variable, pain occurs throughout the body with pain attacks severely diminishing the patient's health-related quality of life (HRQOL) and interfering with their social and working habits[5-7]. A strong association between pain and HRQOL is well known for other diseases including neuromuscular disorders[8], rheumatoid arthritis (reviewed in[9]) and cancer[10]. Moreover, our own experience with IBD patients suffering from pain leads us to assume that in this chronic disease HRQOL is also diminished. The degree of impairment of HRQOL due to pain in IBD remains unspecified and is currently underestimated. In addition, the correlation between pain intensity, HRQOL and disease severity is poorly defined. Clearly, in order to offer individualized therapies there is a need for new tools to identify subgroups of patients who continue to suffer from pain despite anti-inflammatory and pain treatment.

The aim of this study was to evaluate pain intensity and localization in IBD patients, to correlate pain levels with HRQOL and disease severity, and to find possible associated factors on the basis of the information provided by the respondents.

We used a questionnaire based on both the standardized short inflammatory bowel disease questionnaire (SIBDQ), one of the most commonly used tools for evaluating HRQOL in IBD patients[11-13], and the well-established and validated German pain questionnaire[13].

In the current study we present a cross sectional analysis evaluating pain intensity, localization and cofactors and examine the relationship to HRQOL in patients with IBD. Furthermore, we correlate pain intensity levels and HRQOL to the crohn's disease activity index (CDAI) and the colitis activity index (CAI), both of which are well-established scores for evaluating current disease activity[14,15].

MATERIALS AND METHODS

Patients

This cross sectional study investigated the relationship between pain experience and HRQOL as well as disease activity indices in patients with IBD. Our multicenter survey was performed during the period 2005-2007 on patients attending the outpatient clinics at three independent campuses of Charité Medical School, Campus Virchow (45%), Campus Mitte (28%) and Campus Benjamin Franklin (27%), where all patients were asked to participate. Inclusion criteria were: (1) patients (aged 18-80 years) who signed informed consent; (2) patients with an endoscopically and histologically confirmed diagnosis of CD or UC of at least 6 mo, independent of clinical activity and extent of the disease; and (3) to analyze pain and HRQOL in patients who had undergone abdominal surgery, we included patients with small or large intestinal resection due to IBD.

Exclusion criteria were: (1) patients with indeterminate colitis or microscopic colitis; and (2) patients with only surgically drained cutaneous abscesses or fistula draining were excluded from subgroup analysis for surgery.

Patient medical records were checked for disease phenotype, disease duration, medication, and concomitant diseases. The survey was approved by the local ethics committee of the Charité Berlin. Since mechanisms of pain in CD and UC may differ, we analyzed most results for each IBD type separately. As a control, a group of 100 age-matched healthy individuals without complaints or medical history were asked to complete the SIBDQ. Aiming to provide a control group with comparable data, we also used the disease-specific questionnaire for the healthy control group.

Questionnaire

To cover all aspects of pain, HRQOL, and the possible factors influencing patients' perception of pain, we developed a new questionnaire, based on the SIBDQ and the validated German pain questionnaire[13,16,17]. Out of the 25 items in the German pain questionnaire, 12 were taken for the current questionnaire (we removed items 6, 8, parts of 10 and 11; 12, 13, 16, 17, 19, 20, 23, 24, 25, module D, parts of module S, and module V). The first part of our questionnaire collected 50 single variables based on the German pain questionnaire and extended these to include demographic parameters (age, gender, working conditions), medical history (time of first diagnosis, course of disease with indication of fistula or stenosis, active disease or clinical remission), IBD-related symptoms (stool frequency, bloody stools, fever), pain characteristics (localization, duration, intensity, impairment due to pain), pain therapy and the use of other drugs (including antidepressants), lifestyle (eating habits, smoking, use of complementary medicine) and quality of life. Pain intensity was evaluated on the basis of a visual analog scale (VAS)[18]. Patients indicated their scores on a 100 mm horizontal line, where the left end point of the line was marked "no pain" (= 0 mm) and the right end point was marked "strongest imaginable pain" (= 100 mm). Patients were asked to document their symptoms over a sustained period, in this case the previous week. The patients' state-

ments were matched with information from the medical records.

The second part of the questionnaire comprised the SIBDQ, a widely accepted and standardized disease-specific health-related quality of life questionnaire for patients with CD and UC, which is composed of 10 questions each with 7 possible responses[11,12]. We used the SIBDQ because it yields results comparable to those obtained with the full 32-item IBDQ for measuring HRQOL in patients with IBD[19]. A maximum of 7 points could be scored on each question. A score of 70 indicated the highest HRQOL, whereas the lower scores indicated lower HRQOL. The questionnaire is recognized as a reliable and sensitive tool for determining health-related quality of life[7]. Both the German pain questionnaire and the SIBDQ are validated[13,16,17].

To analyze the correlation between pain intensity, HRQOL and disease activity, we collected the CDAI and CAI (according to Rachmilewitz)[20] and matched them with pain intensity and HRQOL. The CDAI consists of eight variables (stool frequency, abdominal pain, general well-being, complications, hematocrit, use of loperamide, body weight, presence of abdominal mass), each summed after adjustment with a weighting factor. CD remission is defined as a CDAI score of less than 150. Severe disease is defined as a value greater than 450[21]. Most major research studies on the use of medications in CD use the CDAI as the gold standard[22-24].

For UC the patient's overall evaluation of symptoms was assessed according to the Rachmilewitz's Clinical Activity Index (CAI)-a well established index with good validity and reliability[20,25]. The score considers the number of bloody stools, abdominal pain and cramping, frequency of incontinence and the need for anti-diarrheal drugs, and an assessment of general well-being. Clinical remission was defined as a CAI < 3. Increased mild to moderate disease activity was defined as CAI = 4-9 and relapse was defined as CAI ⩾ 10[26,27].

Statistical analysis

All statistical analyses were conducted using SPSS (version 13.0) and SAS version 9.2 (SAS Institute, Cary, NC, USA). These included means and standard deviations. The χ^2 test was used to analyze discrete variables. The Mann-Whitney *U* test and the Kruskal-Wallis test were used to compare quantitative results between groups. For correlation analysis, the bivariate Pearson correlation was used. The accepted level of statistical significance was 5% ($P < 0.05$). The effect of several factors on HRQOL was examined by analysis of covariance (ANCOVA). Results are presented as adjusted means with 95% confidence intervals for categorical variables, and regression coefficient estimates for continuous variables.

RESULTS

Patients

Four hundred patients were asked to participate in the study, 387 (96.8%) filled out the questionnaire. Of these, 53 questionnaires were incomplete and were thus excluded. 334 (86.3%) questionnaires were included in the further study. CD had been diagnosed in 179 (53.6%) and UC in 155 (46.4%) patients. Table 1 summarizes the demographic characteristics of all the study participants.

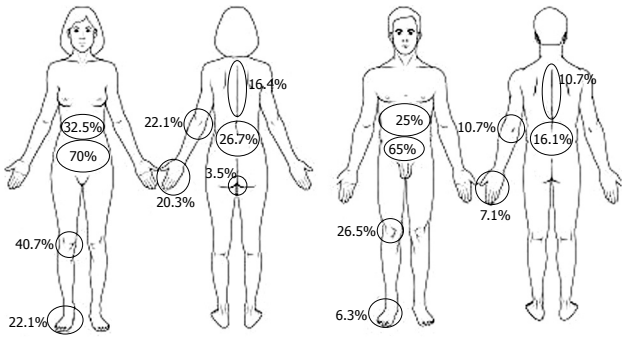

Figure 1 Distribution of pain in female and male patients. The degree of abdominal pain is quite similar in males and females, although females complain more often of arthralgia.

Description, intensity, duration, and localization of pain

In our survey 12.1% of patients reported no pain, 39.7% only had pain during flare-ups, and 48.2% mentioned persistent pain. Patients reported different durations of pain attacks ranging from seconds (17.4%), minutes (44.8%), or hours (27.4%) to days (10.4%). When asked to specify what time of day the pain occurred, 66.8% of patients reported pain unrelated to the time of day, 14.5% had pain only before noon, 14.9% during daylight hours, and 16.5% only at night. The latter group was associated with significantly lower HRQOL ($P = 0.016$).

A comparison of pain intensities and HRQOL between males and females revealed no difference ($P = 0.073$ and $P = 0.6$, respectively).

All indicated pain localizations are depicted in Figure 1 and were significantly different in males and females, with females complaining more often of arthralgia. Most patients indicated more than one pain site: 2 pain sites (18.6%), 3 pain sites (11.5%), 4 pain sites (13.6%), 5 pain sites (9.1%), and > 5 pain sites (17.7%). 39% of the patients described the pain as superficial, 61% as "deep insight". Multivariate analysis showed that pain intensity significantly reduced HRQOL ($P < 0.0001$), independently of sex, pain localization or disease activity.

Although we did not evaluate present disease location, a comparison of pain localization in CD and UC patients revealed higher pain frequency in the right upper abdomen in CD than in UC (39.2% *vs* 18.9%), although for abdominal pain in general there was no statistically significant difference between CD and UC. In contrast, in UC patients, lower left abdominal pain was statistically more frequent (76.4% *vs* 55.6%) than in CD patients. The lower left abdomen was the pain site that significantly influenced ($P = 0.0002$) HRQOL, independent of other factors (Table 2). Interestingly, although arthralgia was not different between CD and UC, CD patients complained more often about pain in hips, knees, and hands.

Table 1 Demographic data of IBD patients and healthy controls, separated into CD and UC groups

Demographics	CD	UC

CD: Crohn's disease; UC: Ulcerative colitis; IBD: Inflammatory bowel disease; CDAI: Crohn's disease activity index; CAI: Colitis activity index; SIBDQ: Short inflammatory bowel disease questionnaire.

Association between IBD type, pain levels and HRQOL

Pain levels in CD and UC patients were not significantly different ($P = 0.056$) and HRQOL scores were comparable ($P = 0.302$) (Figure 2A and B). Compared to healthy controls, HRQOL was significantly reduced in IBD patients (SIBDQ of healthy controls ($P < 0.0001$), regardless of whether they had CD or UC (Figure 2C).

A separate sub-analysis of CD and UC patients with abdominal pain or joint pain showed that HRQOL in UC patients was not significantly impaired by abdominal or joint pain ($P = 0.17$ and $P = 0.52$, respectively). In contrast, HRQOL in CD patients was significantly reduced by abdominal pain ($P = 0.01$) but not by joint pain ($P = 0.09$).

Cofactors of pain and reduced HRQOL

Having assessed pain intensity and HRQOL in IBD patients in general, we next assessed cofactors affecting pain and HRQOL. Pain was intensified in 38.3% of patients by mental stress, in 28.1% by ingestion of food, in 18.9% by physical activity, in 12.0% by the consumption of coffee, tobacco, or alcohol, in 9.9% by weather change, and in 7.2% by resting. In 22.9% of female patients, increased pain was associated with menses. Only 47.3% of patients declared their smoking status and remaining data were not statistically significantly different. Only 12 patients (3.6%, 7 UC, 5 CD, 9 female and 3 male) had depression.

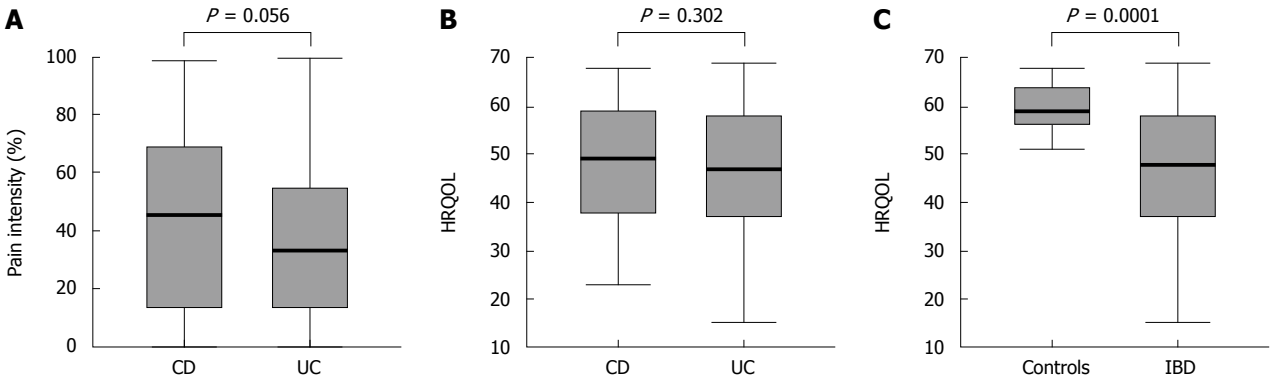

Figure 2 Differences in pain intensity (A) and health-related quality of life (HRQOL) (B) in Crohn's disease (CD) and ulcerative colitis (UC) patients. CD and UC patients have similar pain levels and HRQOL scores. Compared to healthy controls IBD patients have decreased HRQOL (C).

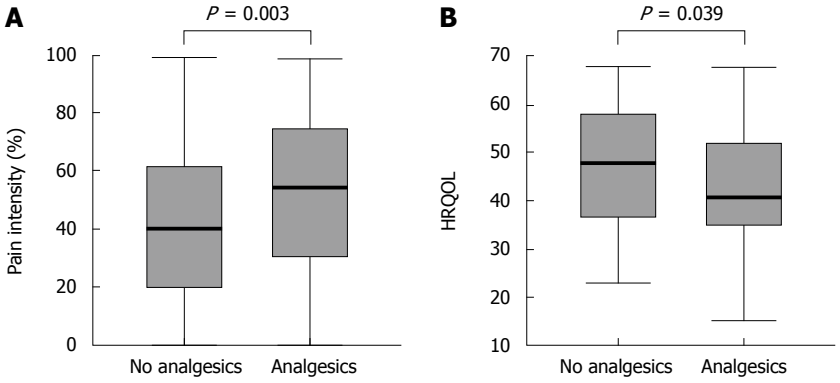

Figure 3 Comparison of (A) pain intensity and (B) HRQOL in patients with and without analgesic treatment. Pain intensity is even higher in patients receiving analgesic treatment.

Extraintestinal manifestations

In our study, 44.9% of patients had extraintestinal manifestations (EIM), including cutaneous manifestations, uveitis, primary sclerosing cholangitis, arthralgia or autoimmune hemolytic anemia (Table 1). Eighty-seven percent of patients with EIM complained of arthralgia. Patients indicated whether they had ever had or currently had EIM. Data were matched with medical records. As expected, patients with EIM had significantly more pain than patients without EIM ($P = 0.001$), irrespective of whether they had CD ($P = 0.001$) or UC ($P = 0.001$). Patients with EIM also had significantly lower HRQOL than patients without EIM ($P = 0.001$), again regardless of whether they had CD ($P = 0.005$) or UC ($P = 0.038$). Multivariate analysis revealed that EIM significantly ($P = 0.0052$) reduced HRQOL, independent of other variables (Table 2).

Association between analgesics, pain and HRQOL

In our study, 25.1% of all patients and 29.0% of patients reporting pain used analgesics. A difference between females and males was identified: 30.3% of females but only 18.0% of males took analgesics ($P = 0.033$). In CD, 29.1% of patients used analgesics, whereas in UC only 20.7% used analgesics ($P = 0.013$) (35.8% of females with CD, 18.2% of males with CD, 22.8% of females with UC, 18.3% of males with UC). Within the group of patients taking analgesics, 47.7% used morphine derivatives for no longer than 4 wk, 44.2% used metamizole (a pyrazolone derivative), and 20.9% took non-steroidal anti-inflammatory drugs (NSAID). Additionally, 5.8% of patients received antidepressants, some for pain modification and some for depression.

To evaluate the efficacy of analgesic drugs in IBD, we only included patients reporting pain for further investigation. As depicted in Figure 3A, patients taking analgesics still had higher pain intensities than patients not receiving analgesic treatment ($P = 0.003$). Accordingly, patients on analgesics reported decreased HRQOL ($P = 0.039$) (Figure 3B).

Modification of pain and HRQOL by surgery

In our analysis, 24% of patients had undergone surgery due to IBD (41.5% of CD and 8.0% of UC patients). To obtain information on whether abdominal surgery modified pain intensity or HRQOL in IBD, we included all patients who had undergone abdominal surgery in the subsequent analysis, irrespective of pain status. Patients without prior surgery were excluded from this sub-analysis.

Patients who had undergone IBD-related abdominal surgery had significantly lower pain intensity than patients who had not had surgery ($P = 0.023$), whereas HRQOL was not significantly different in patients with or without surgery ($P = 0.73$) (Table 2).

Interestingly, when analyzing IBD, regardless of whether CD or UC, we identified significant gender differences in the correlation between pain and HRQOL. Pain intensity in females was lower ($P = 0.001$) and HRQOL significantly higher ($P = 0.03$) after surgery, whereas this

Table 2 Multivariate analysis of variables affecting HRQOL

Variable	Mean (95% CI)[1]	*P* value
Sex		
Female	45.3 (43.0-47.6)	0.607

Pain RLQ		
Yes	45.5 (43.1-47.8)	0.778
No	45.9 (43.0-48.8)	
GI-related surgeries		
Yes	46.0 (42.7-49.3)	0.738
No	45.4 (43.1-47.6)	
Variable	Regression coefficient estimate[2]	*P* value
Age (yr)	0.075	0.244
IBD duration (mo)	0.004	0.635
Pain intensity (0-100 mm)[3]	-1.734	< 0.0001

Although sex does not affect HRQOL ($P = 0.6$), EIM ($P = 0.0043$) and pain in the lower left abdomen ($P = 0.0014$) do have a significant effect on HRQOL. In addition, pain intensity itself affects HRQOL, whereas sex and disease duration do not influence HRQOL. [1]Adjusted means from analysis of covariance (ANCOVA); [2]Change in HRQOL per variable unit increase; [3]Visual analog scale (VAS). LUQ: Left upper quadrant; LLQ: Left lower quadrant; RUQ: Right upper quadrant; RLQ: Right lower quadrant.

correlation was not observed for males.

Since CD and UC require different types of surgery, we next analyzed the correlation between surgery for CD and UC separately. CD patients benefited from surgery as pain intensity was significantly reduced ($P = 0.036$), however, their HRQOL remained unchanged ($P = 0.466$). In UC patients who had undergone surgery, pain levels ($P = 0.095$) and HRQOL ($P = 0.305$) did not differ from those of UC patients who had not had surgery. Considering all abdominal surgeries including non IBD-related surgeries like appendectomy (36), hysterectomy (9), ovariectomy (8), C-section (4), cholecystectomy (11), inguinal hernia revision (5), sterilization (7) and liver transplantation (1) there was no difference in pain intensity or HRQOL.

Correlation between pain intensity, HRQOL and CAI/CDAI

To assess whether disease activity indices correlate with pain intensity or HRQOL, we examined the relationship between CAI, CDAI, pain intensity and HRQOL. When separating UC patients according to their disease activity index (CAI < 4 = remission; CAI 4-9 = increased disease activity; CAI ⩾ 10 = flare-up), pain intensity increased and the HRQOL dropped with increased disease activity (Figure 4A and B).

In contrast to UC patients, in the overall CD population the disease activity did not correlate with pain intensity ($r = 0.23$). When analyzing subgroups according to the CDAI level, this lack of correlation was due to the relative high pain levels in the patient group despite remission (based on a CDAI ⩽ 150). However, in CD patients with a CDAI > 150, CDAI and pain levels correlated significantly ($r = 0.55$, $P = 0.002$). As in UC, in CD patients the CDAI correlated well with the HRQOL ($r = 0.53$, $P < 0.0001$), and increased pain intensities correlated with decreased HRQOL ($r = 0.58$, $P < 0.0001$) (Figure 4C and D). Interestingly, in both CD and UC higher disease activity levels were associated with the presence of EIM ($P = 0.04$ for both).

DISCUSSION

To optimize patient management in IBD, health care personnel not only need to know the type, localization and intensity of CD or UC to offer the best possible therapy, they also need to acknowledge that pain and impaired HRQOL is a great burden in the lives of IBD patients. Furthermore, we have to consider that anti-inflammatory therapy is not equal to pain management or improvement of HRQOL. However, to date, a systematic analysis of duration, localization and associated factors of pain and a subsequent correlation with major variables in the disease course and HRQOL is still lacking. To address this situation our study aimed to: (1) evaluate pain intensity and localization in IBD; (2) compare the results with HRQOL; and (3) explore whether pain levels and HRQOL are related to disease severity or other factors. This kind of study is timely and of special importance since treatment of patients should not only involve mucosal healing but should consider the patient as a whole.

In our study, the number of patients suffering from pain was very high (87.9%). Since we are a reference center with mostly pre-selected patients with more complex and severe disease courses, these high pain levels might be explained by referral bias. On stratifying pain levels for CD and UC separately, our data revealed that pain levels in patients with CD and UC were not significantly different, confirming the results of Heikenen and coworkers, who found similar results in children with IBD[28].

Although multivariate analysis revealed no gender differences in pain intensity or HRQOL, an analysis of a subgroup of patients who had undergone surgery showed that HRQOL was significantly lower in females, verifying that pain levels and HRQOL do not necessarily correlate[29,30]. In addition, females more often took analgesics indicating that they may be more affected by pain than males. Another explanation for the lower HRQOL in females could be a difference in pain perception with more attention to pain in females or different pain-coping mechanisms. Since IBS-like symptoms, depression and anxiety are more frequent in female than in male IBD patients[31,32], this could be an additional explanation for the gender difference in HRQOL.

Underlining the differences between male and female IBD patients, pain localization also differed between

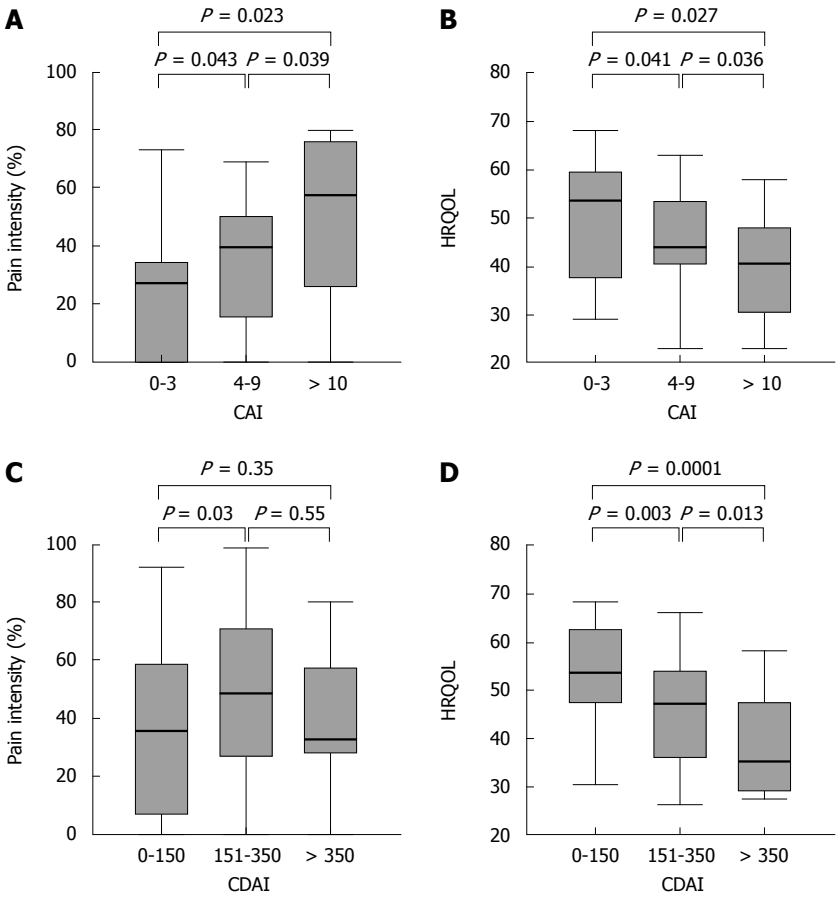

Figure 4 Distribution of disease activity index and pain intensity (A) and disease activity index and HRQOL (B) in UC patients and CD patients (C, D), respectively. UC patients with high disease activity have significantly higher pain levels and lower HRQOL. Although pain intensity does not correlate with CDAI, HRQOL correlates well with CDAI.

genders, with females complaining of significantly more arthralgia. As severe joint pain impacts the mobility of patients, the increased projection of pain in the joints in females might contribute to explaining their decreased HRQOL compared to male IBD patients. Interestingly, Palm and coworkers also found impaired HRQOL in IBD patients with non-inflammatory joint pain compared to IBD patients without joint pain, but they did not find a difference between females and males[33].

Sub-analysis of IBD type revealed differences in pain localization and corresponding HRQOL. Interestingly, in UC patients HRQOL was not significantly impaired by abdominal pain or arthralgia, whereas in CD patients, abdominal pain reduced HRQOL significantly.

Localization of pain is a matter of great interest because of the different treatment options for abdominal pain and arthralgia. While the treatment of arthralgia could be composed of physical therapy, steroids or sulfasalazine, abdominal pain requires a more effective anti-inflammatory therapy. In cases of persistent pain despite remission, IBS-like symptoms, depression or drug-related side effects must also be considered.

A multivariate analysis revealed that HRQOL is not only impaired by pain intensity but also pain localization, the presence of EIM and disease activity influences HRQOL independently of each other and other variables.

Pain can be perceived very differently and its duration varies individually. Given the chronic nature of IBD, nearly half of the patients reporting pain suffered pain irrespective of current disease activity. Accordingly, and in contrast to the pain character reported by patients with IBS, most IBD patients' pain was unrelated to the time of day. However, clearly correlating with disturbed nighttime sleep, patients suffering from pain mostly at night had significantly lower HRQOL, indicating the necessity for increased pain relief therapy in the evening in this group.

More than 40% of IBD patients have EIM of their disease[34,35]. This was confirmed by our study; 44.9% of our patients had EIM, manifesting most frequently as joint pain. Females had significantly more EIM than males ($P = 0.001$). Spondyloarthropathy is the most frequent extraintestinal complication of IBD and is associated with pain and stiffness[36]. Therefore, it was not surprising that patients with EIM had significantly more pain ($P = 0.001$) and significantly lower HRQOL than patients without EIM. EIM in IBD are frequent and play an important role in disease management[37]. The overall incidence of EIM in IBD ranges from 25% to 36%, with more than 60 different manifestations. Rheumatoid extraintestinal manifestations are frequent in patients with CD (38%) and UC (30%)[38,39].

In our study, less than one third of the patients reporting pain took analgesics. Interestingly, although their pain levels were comparable, females more frequently used analgesics than males. Whether or not this suggests a gender-specific approach to pain or pain killers, or a greater fear of side effects, this significant difference

indicates the need to individualize pain therapy. Current pain therapy seems to be ineffective and, in addition, pain perception differs in each individual, which is illustrated by the fact that patients taking pain killers still complained of more pain than patients who reported pain but were not receiving pain treatment.

The use of analgesics and their dosage is difficult to gauge and should be well evaluated. Pain killers have a variety of known effects and side effects. Given the gastrointestinal side effects and the possibility of aggravating mucosal inflammation, NSAR should be avoided in IBD. However, opioids might also worsen pain in IBD patients because long-term use of opioids may also be associated with the development of abnormal sensitivity to pain and a progressive decline in plasma cortisol levels[40]. Consequently, Smith and coworkers recently showed that treatment with naltrexone improved disease course and HRQOL of CD patients[41]. An alternative explanation for the discrepancy between use of analgesics and perception of pain might be the high prevalence of functional somatic symptoms (IBS-like symptoms) among IBD patients[2].

Surgery is an important therapeutic component in the course of IBD. During their lifetime more than 55% of IBD patients undergo abdominal surgery[42-45]. Surgery is often used as a last resort in severe cases with disease complications or in patients who do not respond adequately to therapy. In our study, particularly female CD patients who had undergone IBD-related surgery had significantly lower pain levels and higher HRQOL compared to patients who had not had surgery. Although this phenomenon might be a reflection of the selected patient population treated at university clinics, the observed improvement in HRQOL was confirmed in other studies on CD[46-48] as well as on UC[49] where the disease-related symptoms improved after surgery. In addition, performance of non IBD-related surgeries did not alter pain intensity or HRQOL.

Not surprisingly, we confirmed that compared to healthy individuals HRQOL was significantly decreased in IBD patients[13,50] and correlated with the respective disease activity scores[51]. Most previous clinical studies determined a positive effect of different substances in the treatment of IBD on disease activity and therefore HRQOL[52]. Contrastingly, in our study population disease activity correlated with pain levels in UC patients, but not in CD patients. CD patients, in particular, indicated pain despite low or moderate CDAI scores. This new perception may be due to the dominance of other factors that influence the CDAI, such as EIM or fistulizing disease course, and the underrepresentation of pain in this disease activity index, whereas in the CAI indication of pain is weightier for the complete score. In addition, as mentioned before, IBS-like symptoms, depression or drug-related side effects could cause pain without increased disease activity. Therefore, it is very important to have this new questionnaire in addition to the commonly used disease activity indices to measure pain as a strong impact factor for HRQOL in patients with IBD. The new combined questionnaire contains some questions that have not been validated before, which might affect interpretation of the results.

The strength of our study is its combined analysis of physiological complaints and parameters relevant to HRQOL, but it also has limitations. First, our study population consisted of referred patients who may have more complex and severe disease courses and higher pain levels compared to other IBD patient cohorts with more moderate disease courses.

Second, the cross sectional design of this study prohibits any determination in causality of analyzed factors or process of disease due to certain circumstances. Moreover, although we measured many potential modifiers of pain, the descriptive design allows for possible influence by unknown and unmeasured confounders.

Third, we did not evaluate anxiety or depression, conditions which can worsen the disease course and influence pain perception and HRQOL[1]. Nor did we evaluate disease phenotype according to the Montreal classification, which would have allowed a better correlation with pain localization. Nevertheless, we believe that our data will encourage physicians to devise patient-specific therapy plans for a subgroup of patients suffering from pain independent of disease activity.

In conclusion, most IBD patients suffer from pain and have decreased HRQOL. Duration and localization vary widely and differ not only between CD and UC patients, but also between genders. Most interestingly, our data point out that pain levels and HRQOL do not necessarily correlate with disease activity. By using this newly designed questionnaire we now bring to light that the CDAI does not sufficiently consider pain as a major limitation of HRQL in IBD. On the other hand, when defining the absence of diarrhea and pain as true remission, a CDAI below 150 might not indicate remission in the perception of a CD patient. Our results focus new attention on currently insufficient pain therapy in IBD patients and stress the need for sufficient and continually reviewed individualized pain therapy. Whether this insufficient pain therapy is due to the inadequate effect of pain killers, additional IBS-like symptoms, underrepresented complaints of pain, or physicians' underestimation of pain intensity remains unclear and will require further studies.

ACKNOWLEDGMENTS

We thank the patients who participated in the trial and the supporting nursing staff at the Charité.

COMMENTS

Background

Despite recent advances in the treatment of inflammatory bowel diseases (IBD), acute and chronic pain continues to have a profound negative impact on patients' health-related quality of life (HRQOL). Moreover, the methods for evaluating pain and its impact on HRQOL in IBD patients are still insufficient.

Research frontiers

The development of a new questionnaire based on both the short inflammatory bowel disease questionnaire (SIBDQ) and the German pain questionnaire enabled us to investigate localization and levels of pain and their impact on

HRQOL in IBD patients. Many clinical studies have been performed to investigate the effect of anti-inflammatory therapies on HRQOL but there are no data available on the correlation of pain and HRQOL.

Innovations and breakthroughs

This study provides the first evidence that the majority of IBD patients suffer from pain despite anti-inflammatory therapy and that HRQOL is impaired by pain. Interestingly, ulcerative colitis pain and HRQOL are well correlated with disease activity, whereas Crohn's disease patients also suffer from pain during remission.

Applications

This study focuses new attention on pain as a burden to patients and urges physicians to devise sufficient and individualized pain therapy plans to improve patients' HRQOL.

Peer review

There is increasing focus upon QOL in patients with chronic IBD, and upon factors determining and modifying this. Pain is a frequent symptom in IBD, and may contribute adversely to QOL in these patients.

Abstract

AIM: To evaluate the efficacy of the isolated Roux loop technique in decreasing the frequency of pancreaticojejunal anastomosis failure.

METHODS: We retrospectively reviewed 88 consecutive patients who underwent pancreaticoduodenectomy (standard or pylorus-preserving). Single jejunal loop was used in 42 patients (SL group) while isolated Roux loop was used in 46 patients (RL group). Demographic characteristics (age, gender) and perioperative results (major/minor complications, mortality, hospital stay) were compared between the two groups.

RESULTS: Mortality was almost equal in both groups and overall mortality was 2.27%. Leak rate from the pancreaticojejunal anastomosis and hospital stay were lower in the RL group without significant difference. Morbidity was 39.1% in the RL group, insignificantly higher than the SL group. Operative time was almost 30 min longer in the RL group.

CONCLUSION: The isolated Roux loop, although an equally safe alternative, does not present advantages over the traditional use of a single jejunal loop. Randomized controlled studies are required to further clarify its efficacy.

Key words: Pancreaticojejunal anastomosis; Isolated Roux loop; Whipple pancreaticoduodenectomy; Pancreatic leak

INTRODUCTION

Pancreaticoduodenectomy (PD) is the procedure of choice for the treatment of peri-ampullary and pancreatic head malignancies and was first described by Allen Whipple *et al*[1] back in the 1930s. Early enthusiasm concerning the procedure was followed by skepticism because of the associated high morbidity and mortality rates[2]. However,

advances in operative techniques and perioperative patient care have resulted in lower hospital mortality and longer survival, making the procedure relatively safe in expert hands[3,4].

Despite recent favorable outcomes, leakage from the pancreaticojejunal anastomosis is still considered a significant source of morbidity and associated mortality. Various methods of surgical management of the pancreatic remnant have been proposed to address this serious problem. The rationale of creating an isolated Roux loop for the drainage of the pancreatic stump was initially introduced by Machado *et al*[5] in 1976. They proposed that this isolated Roux loop can prevent the activation of pancreatic fluid by the intestinal contents and bile, and therefore protect the pancreaticojejunal anastomosis from erosion.

The aim of this study was to assess the outcome of the pancreaticojejunal anastomosis formed with an isolated Roux loop compared to the standard single loop technique.

MATERIALS AND METHODS

Study design

We retrospectively studied all patients who underwent PD for malignancy in our department from 1994 to 2006. The medical records of 88 consecutive patients were reviewed. All PDs were performed by two experienced pancreatic surgeons. There have been two distinct periods in our study during which the management of the pancreatic remnant was different. In period I (1994 to 1999) the pancreatic stump was anastomosed sequentially to the single jejunal loop (followed by hepaticojejunal and gastrojejunal anastomoses) used for the reconstruction of all anastomoses (Group SL). During period Ⅱ (2000 to 2006) an isolated Roux loop (Group RL) was used for the pancreatic reconstruction. Informed consent for the surgical procedures was obtained from each patient.

Preoperative assessment

Preoperative diagnostic workup during the early period of study included abdominal computerized tomography scan with oral/intravenous contrast, endoscopic retrograde cholangiopancreatography, percutaneous transhepatic cholangiography and mesenteric angiography in selected patients. The advent of magnetic resonance imaging and magnetic resonance cholangio-pancreatography in the late 1990s provided an excellent adjunct to diagnosis and a safe alternative for biliary-pancreatic evaluation.

Surgical approach

Standard Whipple type operation was performed in 63 patients while the remaining 25 patients underwent a pylorus-preserving PD (PPPD) according to Traverso *et al*[6]. In the majority of cases an end-to-side, duct-to-mucosa pancreaticojejunal anastomosis with transanastomotic stent was preferred. Only in cases where the pancreatic remnant was considered to be very friable was invagination of pancreatic stump into the jejunal loop preferred.

Table 1 Demographic characteristics of the patients and type of operation for the two different groups

	Single loop group (SL)	Isolated Roux loop group (RL)	Total
Patients (*n*)	42	46	88
Age	60.9 ± 11.5	64.4 ± 9.5	62.7 ± 10.5
Gender			
Men/women	23/19	29/17	52/36
Type of operation			
Standard Whipple	25	38	63
Traverso-Longmire	17	8	25

Data collection

Patient data concerning postoperative complications, mortality and hospital stay were evaluated and compared between the two groups. Pancreatic anastomotic failure was initially as described according to the Heidelberg and Johns Hopkins groups as the drainage of more than 50 mL of fluid in 24 h, with an amylase content of more than 3 times the serum amylase activity for more than 10 d after operation[7,8]. In order to adopt a more universally uniform definition we used the ISGPF (International Study Group on Pancreatic Fistula) proposal which is based on the high amylase content of the drain fluid on or after the third postoperative day[9].

Statistical analysis

Statistical analysis was performed by using the Statistical Package for Social Sciences 13.0 for Windows (SPSS Inc., Chicago, IL). Demographic, operative data and postoperative outcome were collected retrospectively. Continuous variables were compared by using Mann-Whitney *U* test and categorical variables were compared by using the χ^2 or Fisher's exact test, depending on the frequency distribution. $P < 0.05$ was considered statistically significant.

RESULTS

Between 1994 and 2004, 88 patients underwent PD for malignancy. The underlying disease was pancreatic head carcinoma ($n = 59$), ampullary carcinoma ($n = 13$), cholangiocarcinoma ($n = 8$), duodenal carcinoma ($n = 6$) and two rare cases of ampullary carcinoid. The male to female ratio was 52:36. The patients' mean age was 62.7 ± 10.5 years (range 33-78). Period I (1994 to 1999-single loop group) included 42 patients, while period Ⅱ (2000 to 2004-isolated Roux loop group) included 46 patients. The demographic data of these patients are shown in Table 1.

Perioperative outcomes

Postoperative complications are demonstrated in Table 2. Mean operative time for the RL group was 366.1 min (range 270-520), which was significantly longer ($P = 0.046$) than the operative time of 338.8 min (range 240-470) recorded in the SL group. No major intraoperative compli-

Table 2 Major and minor complications in both groups *n* (%)

	Single loop group (SL) *n* = 42	Isolated Roux loop group (RL) *n* = 46	*P*
Major complications			
PJ anastomosis failure	3 (7.1)	2 (4.3)	NS
Hemorrhage	1 (2.3)	1 (2.2)	NS
Minor complications			
Wound infection	2 (4.8)	3 (6.5)	
Pulmonary infection	2 (4.8)	4 (8.7)	
Delayed gastric emptying	4 (9.5)	7 (15.2)	
Subhepatic fluid collection	-	1 (2.2)	
Cardiac failure	1 (2.3)	-	
Morbidity	13 (30.9)	18 (39.1)	NS
Mortality	1 (2.3)	1 (2.2)	NS
Operative time (min)	338.8 ± 52.7	366.1 ± 60.1	< 0.05
Hospital stay (d)	19.5 ± 10.1	14.6 ± 5.5	NS

PJ: Pancreaticojejunal; NS: Non-significant.

cation occurred in patients of either group. Two patients died in the early postoperative period (overall mortality; 2.27%). Mortality did not differ significantly between the two groups (P = 1.0). One fatality occurred in a patient of the SL group (mortality; 2.3%) who presented with postoperative pancreatic leak and subsequent massive gastrointestinal bleeding. Death in a patient of the RL group (mortality; 2.17%) resulted after the patient who had pancreaticojejunal anastomotic failure also developed postoperative intrabdominal bleeding accompanied by profound hypoglycemia. Although the patient was reoperated and hemostasis was achieved, he died a few days later as he developed sepsis and multiple organ failure.

Leak from the pancreaticojejunal anastomosis, as defined above, occurred in 3 patients of the SL group (7.1%) and in 2 patients of the RL group (4.3%). The overall leak rate was 5.7%. Comparison of the leak rate between the two groups showed no significant difference (P = 0.66). The incidence of the other grave complication of the procedure, hemorrhage, was not found significantly different between the two groups (P = 1.0) as it occurred in one patient each. Minor complications reported in both groups were wound infection, pulmonary infection and delayed gastric emptying, contributing to morbidity rates of 30.9% for the SL group and 39.1% for the RL group, without significant difference between the two groups (P = 0.422). One patient of the SL group developed cardiac failure, and in one patient of the RL group a subhepatic biloma was detected which was treated nonoperatively with CT-guided drainage.

Patients of the SL group remained in hospital postoperatively for a mean of 19.5 ± 10.1 d (range 9-49). The mean hospital stay of the patients of the RL group was shorter (14.6 ± 5.5 d, range 9-31), but without statistically significant difference between the two groups.

DISCUSSION

The present study failed to demonstrate any significant reduction of pancreatic anastomosis failure when the isolated Roux loop technique was performed for the construction of pancreaticojejunal anastomosis instead of the single loop technique.

The operative mortality rate of pancreaticoduodenectomy, which had remained at unacceptably high levels since the 1970s[6,10,11], dropped dramatically in the last two decades to less than 5% in many reports[3,12,13]. The improved mortality rates can be attributed to a variety of reasons including better perioperative care, accumulated experience on the part of the pancreatic surgeons, refinement of surgical instruments and materials and better anesthesiologic management[14].

Despite reductions in mortality after pancreaticoduodenectomy, the incidence of postoperative morbidity remains high, ranging between 30%-50%[12,13,15,16]. Common postoperative complications include pancreatic fistula, delayed gastric emptying and wound infection. Pancreatic anastomosis failure, which is a major source of morbidity, is considered as the "Achilles' heel" of the procedure. Pancreatic fistula rate can reach 20% even in specialized centers and does not seem to have declined in the same way as mortality rate has done over the last few decades[13,14,17]. Hemorrhage and sepsis are the most frequent sequels of pancreatic fistula, both of which contribute largely to the mortality (20%-40%) as well as to prolonged hospitalization and increased hospital cost[15,18,19].

We analyzed a series of 88 consecutive patients who underwent PD in our department. During the first period (1994-1999), the pancreatic stump was anastomosed sequentially to the single jejunal loop used for the reconstruction of all anastomoses. Mortality (2.3%), morbidity (30.9%) and failure rate of the pancreaticojejunal anastomosis (7.1%) did not differ significantly from those reported in the literature. Although initial reports concerning the use of an isolated jejunal loop for the construction of the pancreaticojejunal anastomosis were far from encouraging with high fistula rates[5,20], various studies published during this first period supported this alternative technique, presenting considerably improved results[21-24]. These studies demonstrated extremely low anastomotic leak rates ranging from 0% to 5.7% and zero fistula-related mortality. Table 3 demonstrates results of the isolated Roux loop technique from various studies[20-28].

The concept of isolation of the pancreatic anastomosis was based mainly on the rationale of diverting biliary from pancreatic secretions. On one hand, this results in avoidance of activation of pancreatic enzymes which could, in theory, erode the anastomotic line and weaken the anastomosis. On the other hand, the jejuno-jejunal anastomosis carries the risk of occlusion due to edema which could increase intraluminal pressure with probably detrimental consequences for the pancreatic anastomosis.

Influenced by these data and aiming to reduce the anastomotic leak rate, in the second period of the study (2000-2006) we adopted the isolated Roux loop technique. However, in our study no significant advantage of this method was found. Although many previous studies utilizing an isolated Roux loop reported zero anastomotic leaks[21-23,25,26], in our study the leak rate was higher (4.3%).

Table 3 Roux-en-Y pancreaticojejunostomy results from various studies

Series	Study type	Patients (total)	Fistulae (%)	Mortality related to fistula (%)	Overall mortality (%)	Hospital stay (d)

NA: Not available; CS: Case series; RC: Retrospective comparative.

This rate was lower than the leak rate of the group in which a single loop of jejunum was used, but without statistical significance. In contrast to previous series of isolated Roux-en-Y pancreaticojejunal anastomosis, which presented no pancreatic fistula-associated mortality[5,20-26], both our fatalities (one from each group) died due to sequels of pancreatic anastomosis failure.

Overall postoperative morbidity in our study is in accordance with major series[29,30]. The lower anastomotic failure rate reported in the RL group possibly contributes to the shorter hospital stay, but also increases the duration of the operation (adding 30 min) and subsequently exposes patients with concomitant diseases to increased risk of complications not related to the operation. Delayed gastric emptying occurred at an increased frequency in patients of the isolated Roux loop group due to the small percentage of pylorus-preserving procedures taken place in this group.

Our study does not confirm that construction of the pancreaticojejunal anastomosis with an isolated Roux loop proves beneficial. Success may well depend on already known parameters, such as consistency of the pancreatic parenchyma and diameter of the pancreatic duct. Hard pancreatic tissue accompanied by wide, dilated duct, as seen in chronic pancreatitis, can result in a safer anastomosis than one constructed over soft tissue and thin duct[31,32].

In conclusion, creation of an isolated Roux-en-Y loop in 46 out of 88 patients in our study did not provide sufficient evidence of superiority over the single loop technique regarding the leak rate, morbidity, mortality and hospital stay.

COMMENTS

Background

Pancreaticojejunal anastomosis failure remains the leading cause of postoperative morbidity and mortality after pancreaticoduodenectomy. Various methods of surgical management of the pancreatic remnant have been proposed, addressing this serious problem. One of these methods utilizes an isolated Roux loop for the construction of the pancreaticojejunal anastomosis.

Research frontiers

This study investigated the outcome of the isolated Roux loop pancreaticojejunal anastomosis and compared it to the single loop technique.

Innovations and breakthroughs

Although the isolated Roux loop technique has been previously described and evaluated, its comparison with the standard single loop technique was not fully studied.

Applications

The isolated Roux loop technique has not been proven to reduce the incidence of pancreatic fistula formation and additionally prolonged the operation time. Single loop technique with sequentially constructed anastomoses remains the operation of choice for reconstruction after pancreaticoduodenectomy. Further randomized controlled studies could strengthen this conclusion.

Peer review

This is a nice series of pancreaticoduodenectomies. The mortality is acceptable and the authors note the limitations of their study.

Abstract

AIM: To evaluate the technical failures of the Bravo pH test in a population with nonerosive gastroesophageal reflux disease.

METHODS: Over the course of a year, we prospectively studied a population of 66 nonerosive reflux disease patients who received a Bravo pH test. The number and frequency of all technical failures were documented, quantified and analyzed.

RESULTS: A total of 66 patients, with a mean age of 41.7 years, were studied. Technical failures occurred in 15.15% of the sample. The most frequent failures were due to poor data reception (4.5%), early dislodgement (4.5%) and capsule removal (6.1%).

CONCLUSION: The Bravo capsule pH test involves a low but non-negligible rate of technical problems, a fact that must always be considered by physicians.

Key words: Bravo test; Capsule dislodgement; Nonerosive reflux disease; Poor data reception; Technical problems

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a condition characterized by heartburn and regurgitation with or without esophageal lesions[1]. It is a common condition, with a prevalence of up to 52.8%, and occurs more frequently in women than in men[2]. Erosive esophagitis and nonerosive reflux disease (NERD) are the primary presentations, with NERD being the most common phenotype[3,4]. This group of patients must undergo pH measurements to confirm the diagnosis of acid reflux, as they lack visible esophageal reflux lesions[5].

To date, the two best methods employed for objectively demonstrating the presence of acid reflux are conventional ambulatory catheter pH-metry monitoring and the Bravo capsule (Medtronic, Minneapolis, MN, USA) catheter-free pH test[6-8]. Both methods are valid and reliable for the measurement of esophageal acid exposure[9,10].

The traditional catheter pH-metry remains the more commonly used of the two methods. However, it can cause undue burden on the patient due to the discomfort and embarrassment of the transnasal pH probe placement, which is known to be uncomfortable and is poorly tolerated[11]. Although the Bravo capsule is a device that is designed to overcome the disadvantages of traditional pH

monitoring, to improve acceptance of testing and to extend the period of monitoring, it is not exempt from technical problems and side effects[12,13]. The primary technical problems of this test are related to failures in transmission or early detachment of the Bravo capsule. Nevertheless, there are many case reports that describe a list of unusual and diverse problems. Both novice and expert gastroenterologists must be familiar with the various possible technical problems that can occur with this device so that they can solve them promptly and efficiently, avoiding additional complications.

In this paper, we quantify and describe our experience of the technical problems that can occur with the use and physical presence of the Bravo capsule in a sample of patients with NERD.

MATERIALS AND METHODS

Patients

We enrolled a total of 66 consecutive patients in a prospective study of 48-h ambulatory pH monitoring using the Bravo capsule, in order to record all technical failures. Before enrollment, each patient had undergone an upper endoscopy which showed an absence of lesions on the esophageal mucosa and were thus diagnosed as having NERD. Patients were asked to discontinue the use of proton pump inhibitors and histamine-2 receptor antagonists for one week prior to the study and to avoid the use of anti-acids 24 h prior to the examination.

None of the patients had significant comorbidities, such as coronary artery disease. The study was conducted in accordance with the Declaration of Helsinki, and written informed consent was obtained from all participants.

Bravo procedure and pH recording

The Bravo capsule was placed 6 cm from the squamocolumnar junction, using standard techniques. All the capsules were placed orally. A second-look esophagoscopy documented suitable capsule attachment. Once the pH recording was initiated, patients were encouraged to engage in their usual daily activities and to consume their usual diet without restrictions. All subjects were instructed to document their food intake, sleep periods and the occurrence of GERD symptoms in a diary to complete the pH-metry evaluation. From the pH records of the first and second day, the average pH value was obtained.

To confirm any capsule dislodgment, a chest X-ray was obtained seven days after the the beginning of the study. Those patients who still showed the device in the esophagus were asked to undergo another plain radiography seven days later to record the detachment.

Assessment of technical problems and statistical analysis

Technical failures of the device were recorded in a "database" and analyzed with a statistical package. Quantitative data, including age and the fraction of time with pH < 4 on the first and second monitoring days were also added. The percentages, means and standard deviations were calculated for each variable. The analysis was performed with the statistical software package SPSS, version 9.0 (SPSS Inc., Chicago, IL, USA).

Table 1 Technical failures, removals and feasibility of the Bravo capsule procedure *n* (%)

Technical problems	Patients (*n* = 66)
Technical failure	10 (15.15)
Transmission failure	3 (4.5)
Early dislodgement	3 (4.5)
Capsule removal	4 (6.1)
Absolute	
Intolerable chest pain	1 (1.5)
Relative	
Detachment failure	1 (1.5)
Transmission failure	1 (1.5)
Error in placement	1 (1.5)
Capsule replacements	2 (3.0)
Feasibility	
Fully finished tests (48 h)	59 (89.39)
Half-finished tests (24 h)	4 (6.0)
Tests without record (0 h)	3 (4.5)

RESULTS

Patient population

Between July 2007 and June 2008, a total of 66 patients were enrolled in the trial. These patients included 27 men (40.9%) and 39 (59.1%) women, aged 11-73 years (mean age = 41.7 years; standard deviation = 13.3 years).

Of the total population, 31 patients reported typical gastroesophageal reflux symptoms, 15 had atypical manifestations and 20 had a mixed symptomatology.

Technical failures and recording efficacy

All of the technical failures observed in our trial are described in Table 1. In the 66 patients, 10 technical failures (15.15%) were observed. Three probes had poor data reception (4.5%), and three more presented with early dislodgement (4.5%). In four cases (6.1%), the capsule had to be removed. We considered intolerable chest pain in one case as an absolute indication for removal. On the contrary, we considered cases of detachment failure (12 d after implantation, because a Heller myotomy was to be performed), transmission failure and placement error to be relative indications for removal. In the last two cases, new capsules (3%) were reinstalled so that those patients could complete the study.

Of the total sample, 89.39% completed the 48-h examination period, and 6% were able to complete only 24 h. However, 24 h was enough time to gather sufficient information to obtain a diagnosis; indeed, using 24 h of data, the Bravo test was accurate in 95% of patients. Only three (4.5%) patients lacked records.

DISCUSSION

This study describes our experience with the Bravo pH test in patients with NERD, a patient population with special features in terms of sensibility and treatment issues.

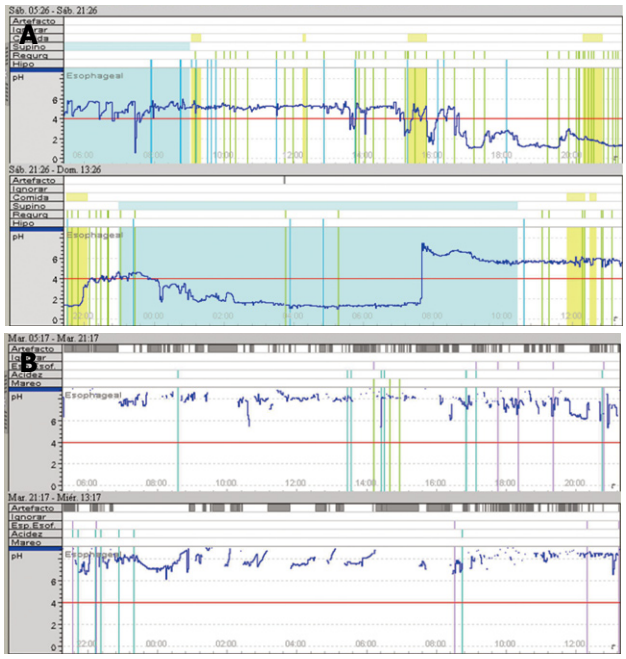

Figure 1 Tracings of problems. A: pH tracing with the typical prolonged drop in the pH line when the capsule drops into the stomach; B: pH tracing (in blue) showing gaps as a result of poor data reception.

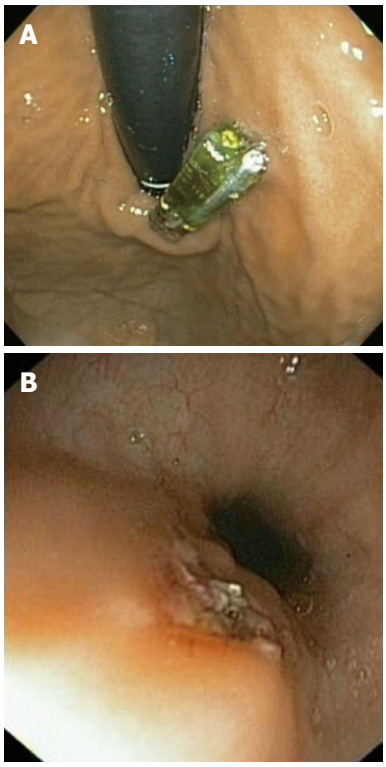

Figure 2 Improper delivery and removal. A: Capsule placement at an erroneous site; B: Mucosal appearance after a hot snare removal.

Technical problems occurred in a low but non-negligible proportion (15.15%) of the sample. Our most remarkable problems were early dislodgement, poor data reception and capsule removals, which occurred at similar rates.

In early capsule dislodgement, the Bravo probe detaches from its location and falls prematurely, i.e., before the 48 h monitoring period is complete. This finding can be observed in the pH tracing as a sudden prolonged drop in the pH value line when the capsule drops into the stomach, followed by a subsequent sharp rise in the pH line as the capsule enters the small intestine (Figure 1A). This early capsule dislodgement rate of 4.5% is similar to those in other reports, which registered rates between 0% and 3.22%[6,14]. Although early dislodgement is considered a failure, it is sometimes possible to complete at least 24 h of monitoring, a time period that still allows a diagnosis of NERD (Table 1).

In the same way, the poor data reception rate of 4.5% (3 of our 66 patients) presented a similar problem to that of early capsule dislodgment. Some authors have reported transmission failure rates of 8.2%[6]. This electromechanical flaw may be seen in the pH tracing as time periods during which data capture was interrupted and are shown as gaps on pH tracings (Figure 1B); these gaps may be interpreted as artifacts during the computerized data analysis. They are potentially attributable to malfunctions in the electronics or possibly the receiver being beyond the range of the signal emanating from the pH capsule.

The need for capsule removal is another frequently observed problem. The capsule removal frequency reached 6.1% (4 of our 66 patients), higher than previously documented frequencies, which ranged from 0% to 3.5%[6,15]. However, the higher incidence observed in our study may have been due to the fact that we considered absolute and relative indications, even though our only absolute indication was a patient with intolerable chest pain (1.5%). This symptom was the primary indication in most previous studies[12,16]. The other three patients had a relative indication. One of these patients presented with transmission failure, and another with a placement error (gastroesophageal junction) (Figure 2A). We decided to remove and replace the capsule with a new one in order to finish the test and to avoid the side effects produced by the presence of two probes in the esophagus, as the presence of the capsule produces esophageal contractions associated with pain[17,18]. Finally, a fourth capsule was retrieved twelve days after implantation, as a Heller myotomy was to be performed. Three of these capsules were retrieved by a cold snare technique, and the other by a hot snare technique (Figure 2B), as previously described[19].

Other studies have reported different and unusual technical problems. Ward *et al*[15] observed that the capsules did not attach properly on the first attempt in at least 7 of 60 (12%) patients. Although there are some reports of major complications, we did not observe any. The main complications previously described were trauma, severe bleeding, esophageal perforations and aspiration into the bronchus[20,21]. In addition, minor incidents have been reported, such as localized inflammation, capsules not deploying from the delivery system, the plunger being broken off during delivery, mucosal tearing and probes not being correctly calibrated[22].

In conclusion, the Bravo capsule results in a low but non-negligible rate of heterogeneous technical difficulties, and although most of them are not life-threatening,

gastroenterologists must be aware of these difficulties in order to interpret and address them appropriately.

COMMENTS

Background

The Bravo capsule pH test is a relatively new method for the assessment of reflux disease, and as a new method, the authors have tried to evaluate the possible technical problems that may occur during its application, course and interpretation.

Research frontiers

This article describes the most common technical failures. Gastroenterologists will find the causes of these technical failures useful in order to avoid them in the future.

Innovations and breakthrough

This trial focuses on patients with nonerosive reflux disease. Up to now, this population has not received much attention.

Applications

The present study will find application in making people aware of the possible problems and failures associated with the Bravo capsule pH test, giving people the opportunity to solve them.

Peer review

The paper is straightforward and clear.

Abstract

AIM: To evaluate the relationship between thiopurine S-methyltransferase (TPMT) polymorphisms and thiopurine-induced adverse drug reactions (ADRs) in inflammatory bowel disease (IBD).

METHODS: Eligible articles that compared the frequency of TPMT polymorphisms among thiopurine-tolerant and -intolerant adult IBD patients were included. Statistical analysis was performed with Review Manager 5.0. Sub-analysis/sensitivity analysis was also performed.

RESULTS: Nine studies that investigated a total of 1309 participants met our inclusion criteria. The incidence of TPMT gene mutation was increased 2.93-fold (95% CI: 1.68-5.09, P = 0.0001) and 5.93-fold (95% CI: 2.96-11.88, P < 0.00001), respectively, in IBD patients with thiopurine-induced overall ADRs and bone marrow toxicity (BMT), compared with controls. The OR for TPMT gene mutation in IBD patients with thiopurine-induced hepatotoxicity and pancreatitis was 1.51 (95% CI: 0.54-4.19, P = 0.43) and 1.02 (95% CI: 0.26-3.99, P = 0.98) *vs* controls, respectively.

CONCLUSION: This meta-analysis suggests that the TPMT polymorphisms are associated with thiopurine-induced overall ADRs and BMT, but not with hepatotoxicity and pancreatitis.

Key words: Methyltransferases; Inflammatory bowel diseases; Meta-analysis; Adverse drug reactions; Bone marrow toxicity

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic, relapsing and remitting disease of the gastrointestinal tract. The major types of IBD are Crohn's disease (CD) and ulcerative colitis (UC). The thiopurine drugs azathioprine (AZA) and 6-mercaptopurine (6-MP) are widely used to treat patients with active, steroid-refractory, and steroid-dependent IBD, and have been proven to be effective for inducing and maintaining remission of CD[1,2]. Unfortu-

nately, the dose of thiopurine often has to be reduced or the therapy has to be discontinued in 9%-28% of patients because of adverse drug reactions (ADRs)[3]. Gastrointestinal disturbances, bone marrow toxicity (BMT), hepatotoxicity and pancreatitis are among the most frequent reasons to prevent their use in some patients.

Blood tests have been performed regularly to monitor the blood count and liver function to detect BMT and hepatotoxicity at an early enough stage to discontinue therapy and avoid life-threatening toxicity. However, the ADRs might develop suddenly and unpredictably during the interval between two tests. Thus, screening the patients before thiopurine treatment for genetic susceptibilities to predict the risk of toxicity has aroused considerable interest in several clinical centers.

Thiopurine S-methyltransferase (TPMT) is a very important enzyme for the metabolism of thiopurine compounds. Lack of its activity has been associated with the incidence of BMT induced by thiopurine therapy. Genetic polymorphisms that account for reduced (heterozygote) or absent (homozygote) TPMT activity have been confirmed. About 10% of the patients have intermediate activity due to heterozygosity of the TPMT, and 1 in 300 patients inherit TPMT deficiency as an homozygote[4]. TPMT*1 is the wild type, TPMT*3A is the most prevalent mutant allele (85%) in Caucasians[4] and TPMT*3C is the most common reported mutant alleles in African and South-East Asian populations[5]. Although several studies have shown that low TPMT activity is associated with BMT, the efficacy of the strategy of screening the TPMT gene mutation in all patients prior to initiating treatment with thiopurine drugs has not yet been definitively confirmed.

The aim of this meta-analysis was to evaluate whether there is a relationship between TPMT polymorphisms and incidence of ADRs in IBD patients.

MATERIALS AND METHODS

Search strategy

The databases PubMed (1966 to July 2009), Embase (1980 to July 2009), Cochrane Controlled Trials Register (Issue 1, 2009), Science Citation Index (1945 to July 2009) and Chinese Biomedical Database (1981 to July 2009) were used for systematic literature searches. We employed both MeSH and free-language terms for "TPMT", "thiopurine S-methyltransferase" AND "inflammatory bowel disease", "ulcerative colitis", OR "Crohn's disease" combined with each of the following: "thiopurine", "azathioprine", "imuran", "6-mercaptopurine" as search terms. A comprehensive search of reference lists of all review articles and original studies retrieved by this method was performed to identify additional studies. Furthermore, we also searched abstracts of major gastroenterological meetings, such as the Digestive Disease Week of the American Gastroenterological Association, the World Congress of Gastroenterology and British Society of Gastroenterology. Authors of some identified trials were asked whether they knew of additional studies, including unpublished ones.

Inclusion and exclusion criteria

The selection criteria were as follows: cross-sectional cohort, prospective cohort and case-control studies were included in the meta-analysis. Studies in abstract form or meeting reports, without publication of the full paper, were also included in the meta-analysis. Only IBD patients aged over 18 years were included.

Studies were included that compared TPMT polymorphism frequencies among thiopurine-tolerant and -intolerant adult IBD patients. Two of the most prevalent mutant types of the TPMT gene were studied, namely, TPMT*3A and TPMT*3C polymorphisms. Studies were included if they provided information on at least one outcome parameter as follows: proper OR of overall ADRs, BMT, hepatotoxicity or pancreatitis.

Furthermore, articles published in English and Chinese were included. Studies in other languages were excluded unless a translation was available.

Data extraction

Standardized data abstraction sheets were prepared. Data were extracted for author and year, location of trials, trial design, diseases, number of enrolled subjects, and dose of thiopurine, meanwhile, key outcome data, such as TPMT polymorphisms and thiopurine induced overall ADRs, BMT, hepatotoxicity and pancreatitis were abstracted from the selected studies. All papers were examined independently for eligibility by two reviewers (Dong XW and Zheng Q). Disagreements were resolved by consulting a third reviewer (Ran ZH). When the results of a particular study were reported in more than one publication, only the most recent and complete data were included in the meta-analysis. Finally, the manuscripts were studied for their comparability by Zhu MM and Tong JL.

Statistical analysis

Data were entered into the Cochrane Collaboration RevMan 5.0 (Copenhagen, 2008). OR with 95% CI was calculated for the TPMT*3A and TPMT*3C polymorphisms *vs* overall ADRs, BMT, hepatotoxicity and pancreatitis. Because of too small a number of patients, heterozygous and homozygous patients were combined as "polymorphism-positive". An OR of < 1 favored the control group, $P < 0.05$ and 95% CI that did not include the value 1 were considered to be statistically significant. The included studies displayed heterogeneity regarding study design, definition of ADRs, and follow-up periods. Therefore, it would be inappropriate to combine the data for further analysis with the fixed-effects model, whereas the random effects model was used for calculations. Finally, we used funnel plot asymmetry to detect any publication bias in the meta-analysis, and Egger's regression test to measure funnel plot asymmetry.

RESULTS

Description of the studies

We reviewed 181 citations and abstracts obtained from our computerized literature searches. Fifty-nine papers

Table 1 Characteristics of excluded studies

Author	Location	Study design	Participants	TPMT genotypes was determined	Dose of thiopurine	Reason for exclusion
Cao *et al*[6], 2009	China	Cross-sectional	43 treated IBD patients	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	AZA 1.35 mg/kg per day	Incomplete data
Takatsu *et al*[7], 2009	Japan	Cross-sectional	147 treated IBD patients	TPMT*2, TPMT*3B TPMT*3C, TPMT*8	AZA 25 mg/d or 75 mg/d or 100 mg/d	Incomplete data
Uchiyama *et al*[8], 2009	Japan	Cross-sectional	16 treated IBD patients with ADRs	TPMT*2, *3A, *3B TPMT*3C, *3D, *4 TPMT*5, *6, *7, *8	AZA < 50 mg/d or 6-MP < 30 mg/d	Incomparable control group No definition of ADRs Pediatric patients included
Ban *et al*[9], 2008	Japan	Case-control	70 treated IBD patients 41 healthy controls	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	Not mentioned	Dose of thiopurine not mentioned
Gearry *et al*[10], 2003	New Zealand	Case-control	56 treated IBD patients with ADRs 50 treated IBD patients without ADRs	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	Not mentioned	Dose of thiopurine not mentioned
Regueiro *et al*[11], 2002	USA	Cross-sectional	71 treated CD patients	TPMT*3A, TPMT*3B TPMT*3C	AZA 2.35 mg/kg per day or 1.28 mg/kg per day	38 patients had determination of TPMT by phenotype
Evans *et al*[12], 2001	USA	Cross-sectional	23 treated patients with ADRs	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	AZA 32 mg/m^2 per week or 175 mg/m^2 per week or 280 mg/m^2 per week	Non-IBD patients
Naughton *et al*[13], 1999	UK	Cross-sectional	15 treated IBD patients	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	Not mentioned	Dose of thiopurine not mentioned

Dose of thiopurine: mean or median dose of thiopurine. TPMT: Thiopurine S-methyltransferase; IBD: Inflammatory bowel disease; AZA: Azathioprine; ADRs: Adverse drug reactions; 6-MP: 6-mercaptopurine; CD: Crohn's disease.

were excluded on the basis of publication type and another 105 were excluded after examining the title and abstract. Among these 17 potentially appropriate studies, we found that all of them had studied the association between TPMT polymorphisms and thiopurine-induced ADRs. Abstracts and full texts of the remaining 17 papers were retrieved for further assessment. Of these potential eligible articles, we excluded another eight[6-13], which are listed in Table 1. Two studies were not able to extract the data from the published results, and we also failed to contact the authors of this manuscript, therefore, these two studies were excluded. Three studies were excluded for not mentioning the prescription dose of thiopurine. One study was excluded as it did not set a control group, such that a proper OR could not be calculated. One study was excluded since it included non-IBD patients. In one study, not all of the patients had determination of TPMT genotype. Finally, nine studies[3,5,14-20] met the inclusion criteria; all of which were published in the last 7 years. Three were prospective cohort studies, with the remaining six being cross-sectional. The flowchart of reviews showed the detailed process of selection (Figure 1). The characteristics of the nine trials included in the meta-analysis are summarized in Table 2. The outcomes of the meta-analysis are shown in Figure 2.

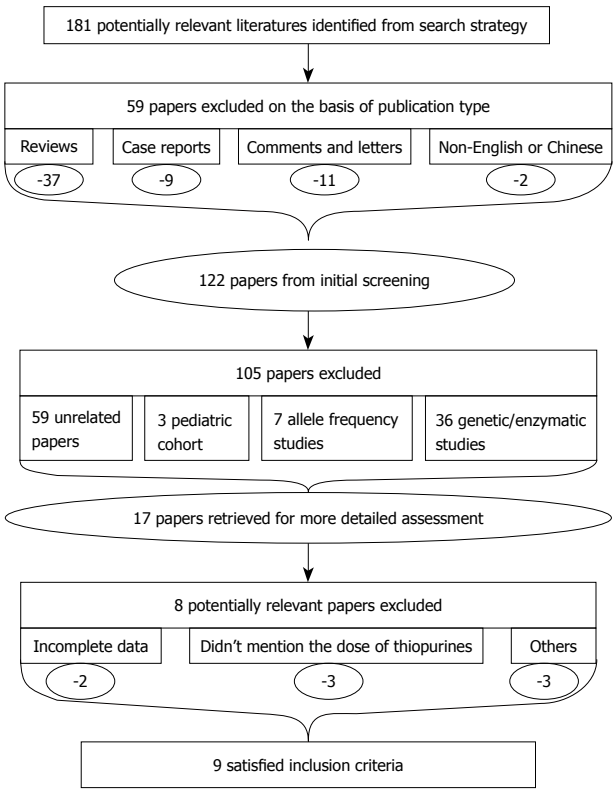

Figure 1 The flowchart of study selection for the meta-analysis.

OVERAll ADRs

Six[3,5,14,17,18,20] of the nine studies reported on the incidence of overall ADRs in 273 IBD patients exposed to thiopurine drugs *vs* 708 IBD patients without ADRs. ADRs included BMT, hepatotoxicity, pancreatitis, gastrointestinal disturbances and adverse reactions during treatment that required reduction of thiopurine dose or discontinuation of therapy. Three[3,5,20] of the studies demonstrated that the AZA/6-MP-induced ADRs were independent of the TPMT polymorphisms; the remaining three showed that TPMT polymorphisms strongly predicted ADRs. The TPMT polymorphisms were significantly associated with ADRs in the overall calculated OR (OR: 2.93, 95% CI: 1.68-5.09, P = 0.0001). When excluding hepatotoxicity and

Table 2 Characteristics of included studies

Author	Location	Study design	Participants	TPMT genotypes was determined	Dose of thiopurine	ADRs and definitions
Ansari *et al*[14], 2008	UK	Prospective cohort	215 treated IBD patients	TPMT*3A, TPMT*3B TPMT*3C	AZA 2 mg/kg per day	All ADRs BMT: WBC < 3.5×10^9 or Ne < 1.5×10^9 H: ALT > 2 × ULN P: AP and amylase > 4 × ULN and supportive radiological findings
Hawwa *et al*[15], 2008	UK	Cross-sectional	36 treated IBD patients	TPMT*3A, TPMT*3B TPMT*3C	AZA 1.49 mg/kg per day	BMT: WBC < 3.0×10^9 or Ne < 1.5×10^9 or PLT < 150×10^9
Winter *et al*[5], 2007	UK	Cross-sectional	130 treated IBD patients	TPMT*2, TPMT*3A TPMT*3C	AZA 1.6 mg/kg per day	All ADRs BMT: WBC < 3×10^9 H: No definition P: No definition
Stocco *et al*[16], 2007	Italy	Cross-sectional	70 treated IBD patients	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	AZA: 2 mg/kg per day	All ADRs BMT: WBC < 3×10^9 or PLT < 100×10^9 H: ALT, AST or ALP > 2 × ULN P: AP and amylase > 2 × ULN
Palmieri *et al*[17], 2007	Italy	Cross-sectional	422 treated IBD patients	TPMT*3A, TPMT*3B TPMT*3C	AZA 2-2.5 mg/kg per day or 6-MP 1-1.25 mg/kg per day	All ADRs BMT: WBC < 3×10^9 or PLT < 100×10^9 H: ALT > 2 × ULN P: Amylase, lipase > 2 × ULN and AP
Zelinkova *et al*[18], 2006	Netherlands	Cross-sectional	262 treated IBD patients	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	AZA 2-2.5 mg/kg per day[1]	BMT: WBC < 3×10^9 or PLT < 100×10^9 H: ALT > 2 × ULN
Hindorf *et al*[3], 2006	Sweden	Prospective cohort	60 treated IBD patients	TPMT*2, *3A, *3B TPMT*3C, *3D, *4 TPMT*5, *6, *7, *8 TPMT*10, *14, *15	AZA 2.5 mg/kg per day or 6-MP 1.25 mg/kg per day	All ADRs BMT: WBC < 3×10^9 or PLT < 100×10^9 or Ne < 1.5×10^9 P: No definition
Derijks *et al*[19], 2004	Netherlands	Prospective cohort	30 treated IBD patients	TPMT*2, TPMT*3A TPMT*3B, TPMT*3C	6-MP 0.71 mg/kg per day	BMT: WBC < 4×10^9 or PLT < 100×10^9
Schwab *et al*[20], 2002	Germany	Cross-sectional	93 treated IBD patients	TPMT*2, TPMT*3A TPMT*3B, *3C, *3D	AZA 1.5 mg/kg per day or 1.9 mg/kg per day	All ADRs BMT: WBC < 3×10^9 or PLT < 100×10^9 H: ALT or AST > 2 × ULN P: Amylase, lipase > 2 × ULN and AP

[1]The initial dose. White blood cells (WBC), neutrophils (Ne), and platelets (PLT) are expressed per liter; H: Hepatotoxicity; P: Pancreatitis; AP: Abdominal pain; BMT: Bone marrow toxicity; ALT: Alanine transaminase; ULN: Upper limit of normal; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase.

pancreatitis from the overall ADRs group, it still indicated that IBD patients exposed to thiopurine drugs, with ADRs, were more likely to have TPMT polymorphisms than the controls (OR: 4.37, 95% CI: 1.69-11.29, $P = 0.002$).

BMT

All of the nine studies[3,5,14-20] reported on the incidence of BMT in 1309 IBD patients treated with thiopurine. Twenty-three of 77 IBD patients with BMT and 87 of 1232 IBD patients without BMT had the TPMT gene mutation. Researchers from the United Kingdom[14] defined BMT as a white blood cells count of < 3.5×10^9/L or a neutrophil count of < 1.5×10^9/L. In the study of Winter *et al*[5], BMT was defined as a white blood cells count of < 3.0×10^9/L. Researchers from Sweden[3] have defined BMT as a white blood cells count of < 3.0×10^9/L, a neutrophil count of < 1.5×10^9/L, or a platelet count of < 100×10^9/L. Hawwa *et al*[15] have defined BMT as a white blood cells count of < 3.0×10^9/L, a neutrophil count of < 1.5×10^9/L, or a platelet count of < 150×10^9/L. Dutch researchers[19] have defined BMT as a white blood cells count of < 4.0×10^9/L or a platelet count of < 100×10^9/L. BMT was defined in the remaining four studies[16-18,20] as a white blood cells count of < 3.0×10^9/L or a platelet count of < 100×10^9/L. Of these selected studies, five reported that heterozygous TPMT genotype strongly predicted BMT, and the remaining four failed to demonstrate an association between TPMT gene mutation and risk of BMT. The pooled OR demonstrated that TPMT polymorphisms were significantly associated with BMT (OR: 5.93, 95% CI: 2.96-11.88, $P < 0.00001$).

Hepatotoxicity

Six studies[5,14,16-18,20] have reported on the incidence of hepatotoxicity in IBD patients treated with thiopurines. Three[14,17-18] of these have defined hepatotoxicity as alanine transaminase (ALT) levels of at least twice the upper limit of normal (ULN). A German research group[20] has defined hepatotoxicity as either ALT levels or aspartate aminotransferase (AST) levels of at least twice the ULN. Stocco *et al*[16] have defined hepatotoxicity as ALT, AST or alkaline phosphatase (ALP) levels of at least twice the ULN. No definition of hepatotoxicity was provided in the study of Winter *et al*[5], therefore, this study was excluded in this sub-analysis. Only three of the 37 IBD patients with hepatotoxicity were TPMT heterozygotes/homozygotes, while 82 of 1017 IBD patients without hepatotoxicity were TPMT heterozygotes/homozygotes. All of the remaining five have shown that there was no association between AZA-related hepatotoxicity and TPMT poly-

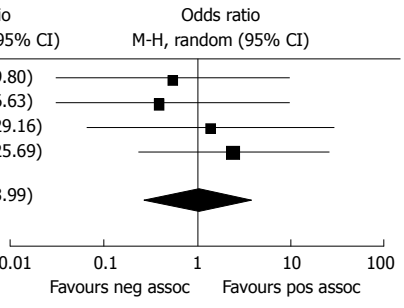

Figure 2 Association between thiopurine S-methyltransferase (TPMT) polymorphisms and all adverse drug reactions (ADRs) (A), bone marrow toxicity (B), hepatotoxicity (C) and pancreatitis (D). Total: Total number of patients within the ADRs or no ADRs group; Events: Number of patients with one or more TPMT alleles within the ADRs or no ADRs group. neg assoc: Favoured the no ADRs group; pos assoc: Favoured the ADRs group.

morphisms. The pooled OR indicated that no significant difference in TPMT polymorphisms was seen between IBD patients with thiopurine-induced hepatotoxicity and controls (OR: 1.51, 95% CI: 0.54-4.19, *P* = 0.43).

Pancreatitis

Six studies[3,5,14,17,18,20] have reported on the incidence of pancreatitis in IBD patients treated with thiopurine and detected TPMT polymorphisms. In the study of Ansari

et al[14], pancreatitis was defined as serum amylase of more than four times the ULN, associated with severe abdominal pain, and supportive radiological findings. Winter *et al*[5] and Hindorf *et al*[3] have not defined the criteria of pancreatitis, thus, we also excluded these two studies from the sub-analysis. The remaining studies[17,18,20] have defined pancreatitis as either serum amylase or serum lipase of more than two times the ULN, associated with severe abdominal pain. Only one of 34 IBD patients with pancreatitis and 60 of 758 without pancreatitis had the TPMT gene mutation. All of the four studies have demonstrated that there was no association between pancreatitis and TPMT polymorphisms. Pooled data have demonstrated that there was no significant difference in TPMT polymorphisms between IBD patients with thiopurine-induced pancreatitis and controls (OR: 1.02, 95% CI: 0.26-3.99, $P = 0.98$).

Subgroup analysis

We performed subgroup analysis in which we excluded the studies with different definitions of BMT to determine the effect on the test of heterogeneity and the overall pooled estimates. Because the results were nearly identical, only results based on the four studies[16-18,20] that have defined BMT as a white blood cells count of $< 3.0 \times 10^9$/L or a platelet count of $< 100 \times 10^9$/L were reported. The pooled OR of the four studies[16-18,20] was 5.05 (95% CI: 2.58-9.88, $P < 0.01$). This result still showed a significant difference in TPMT polymorphisms between IBD patients with and without BMT. Similarly, we also performed subgroup analysis in which we individually excluded the studies with different definitions of hepatotoxicity and pancreatitis, to determine the effect on the test of heterogeneity and the overall pooled estimates. Because the results were nearly identical, they were not reported.

Sensitivity analysis

Studies that prescribed AZA $\leqslant$ 2 mg/kg per day or 6-MP $\leqslant$ 1 mg/kg per day.

When the studies[5,14,16,19,20] that prescribed AZA > 2 mg/kg per day or 6-MP > 1 mg/kg per day were excluded, results remained consistent with original results. A significant difference in the incidence of TPMT polymorphisms was observed in the overall ADRs group (OR: 7.82, 95% CI: 2.18-28.12, $P < 0.01$) and BMT group (OR: 6.73, 95% CI: 3.52-12.85, $P < 0.01$) compared with the controls. However, no significant difference was found in the hepatotoxicity group (OR: 1.04, 95% CI: 0.18-5.90, $P = 0.96$) and pancreatitis group (OR: 1.36, 95% CI: 0.28-6.49, $P = 0.70$) compared with the controls.

Including the excluded studies

When the excluded studies[9,10,13] that provided information on at least one outcome parameter such as proper OR of overall ADRs, BMT, hepatotoxicity or pancreatitis were taken into account, there was still a significant difference in TPMT polymorphisms between IBD patients with or without ADRs. It also showed an increase in the risk of the incidence of TPMT polymorphisms in the overall ADRs group (OR: 2.76, 95% CI: 1.69-4.50, $P < 0.0001$) and BMT group (OR: 6.73, 95% CI: 3.52-12.58, $P < 0.00001$) compared with the controls. No significant difference in the incidence of TPMT polymorphisms was found in the hepatotoxicity group (OR: 1.27, 95% CI: 0.53-3.07, $P = 0.59$) and pancreatitis group (OR: 1.32, 95% CI: 0.46-3.76, $P = 0.60$) compared with the controls.

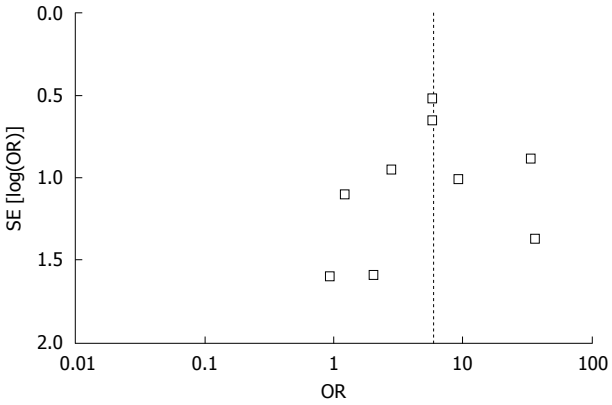

Figure 3 Funnel plot of included studies for this meta-analysis.

Studies reporting on $\geqslant$ 100 patients

Analysis of the studies[5,14,17,18] that reported on $\geqslant$ 100 IBD patients treated with thiopurine, and detected TPMT polymorphisms showed that the results were consistent with the overall results and the analysis of the original studies. A significant difference in the incidence of TPMT polymorphisms was observed in the overall ADRs group (OR: 2.64, 95% CI: 1.06-6.53, $P = 0.04$) and BMT group (OR: 6.53, 95% CI: 2.35-18.19, $P = 0.0003$) compared with the controls. No significant difference in the incidence of TPMT polymorphisms was found in the hepatotoxicity group (OR: 1.51, 95% CI: 0.47-4.82, $P = 0.49$) and pancreatitis group (OR: 0.46, 95% CI: 0.06-3.47, $P = 0.45$) compared with the controls.

Publication bias

Figure 3 shows a funnel plot of the studies used in this meta-analysis that have reported on the incidence of TPMT polymorphisms in BMT. We found that the funnel plot was slightly asymmetrical in distribution, but Egger's regression test suggested no significant asymmetry of the funnel plot ($P = 0.623$), which indicated no evidence of substantial publication bias.

DISCUSSION

This review evaluated 17 published studies that have studied the association between TMPT gene polymorphisms and the development of ADRs in thiopurine-treated IBD patients. Nine studies among adult IBD patients were included, while the random effects model was used for the meta-analysis. The results of the present meta-analysis suggested that IBD patients with TPMT polymorphisms are more likely to experience ADRs, in particular BMT, but not hepatotoxicity and pancreatitis. Notably, the result

remained significant after the sensitivity analysis.

The association of TPMT polymorphisms with thiopurine toxicity suggested by previous studies[14] is confirmed in this meta-analysis. The study of Ansari *et al*[14] was the largest prospective study to use full-dose AZA (2 mg/kg) without dose adjustment in IBD patients. They have found that heterozygous TPMT genotype strongly predicted ADRs (79% heterozygous *vs* 35% wild-type TPMT, $P < 0.001$), especially for gastric intolerance and BMT. Another study[21] has shown that heterozygous TPMT genotypes were significantly associated with IBD patients experiencing nausea and vomiting. Although several studies[3,5,20] have demonstrated that there was no association between thiopurine-related ADRs and TPMT polymorphisms, the retrospective nature of most of these studies may not have provided a true measure of ADRs. The OR for mutations of the TPMT gene in thiopurine-treated IBD patients suffering from overall ADRs was 2.93.

A higher frequency of TPMT mutation was seen in thiopurine-treated IBD patients with BMT than in those without BMT. This was corroborated in the sensitivity analysis. TPMT polymorphisms results in greater conversion of 6-MP to 6-thioguanine nucleotides (6-TGNs) and methylthioinosine monophosphate (meTIMP) *via* the hypoxanthine guanine phosphoribosyltransferase pathway. 6-TGNs and meTIMP are thought to be associated with BMT[3,22]. The study by Hindorf *et al*[3] has suggested that BMT might be dose-related; 67% of the 27 patients with ADRs tolerated long-term treatment with a lower dose (median 1.32 mg/kg per day AZA), and low-dose AZA/6-MP was as effective as the standard dose for remission induction and maintenance of remission in patients with UC and CD[23], but this was not confirmed in the sensitivity analysis of studies that prescribed AZA $\leqslant$ 2 mg/kg per day or 6-MP $\leqslant$ 1 mg/kg per day. That could be explained by the small sample sizes. Hawwa *et al*[15] have found that patients with a heterozygous TPMT genotype usually experienced early and severe myelosuppression when they were treated with AZA/6-MP at standard dosage, but all of the included studies showed that BMT occurred after an average exposure time of 1 mo, except the studies by Hawwa *et al*[15] and Derijks *et al*[19].

Previous studies[24] have found an association between heterozygotes for the TPMT*3A allele and hepatotoxicity in acute lymphocytic leukemia patients who received a standard dose of 6-MP/6-TG. However, it was not shown in this meta-analysis. The results of the present study showed no increase in the incidence of TPMT polymorphisms in thiopurine-treated IBD patients with hepatotoxicity compared with those without hepatotoxicity. This was confirmed in the sensitivity analysis. TPMT polymorphisms are seldom found in patients exhibiting thiopurine-related hepatotoxicity, and thiopurine-induced hepatotoxicity cannot be generally attributed to it[20]. It has been suggested that elevated concentrations of 6-methylmercaptopurine (6-MMP) are associated with thiopurine-induced hepatotoxicity, and elevated concentrations of 6-MMP could be due to high TPMT activity but not TPMT polymorphisms[25].

No significant difference was found in the incidence of TPMT polymorphisms between the thiopurine-treated IBD patients with and without pancreatitis. The results of the sensitivity analysis also showed no significant difference. Thiopurine-induced pancreatitis is dose-independent and seems to be independent of TPMT polymorphisms. AZA is a drug that can induce pancreatitis, especially when it is used in the treatment of CD, which might be due to an immune-mediated idiosyncratic drug reaction because of a genetic predisposition[26].

Recently, Higgs *et al*[27] have published a meta-analysis of myelosuppression in patients with intermediate TPMT activity compared with wild-type. They have found that individuals with intermediate TPMT activity or one TPMT variant allele had an increased risk of developing thiopurine-induced BMT, compared with individuals with normal activity. The search was not limited to a specific disease or condition. They included a total of 67 studies, but most of them were retrospective cohorts. The genotype and/or phenotype tests were described in 57 studies. As we know, the overall concordance rate between the genetic and phenotypic tests for TPMT was 71.6%[28]. In addition, the cutoff points of TPMT activity have varied in different groups. The phenotype test might also be influenced by blood transfusion during the previous 3 mo. The most important thing is that prospective studies that have evaluated the cost-effectiveness of the phenotype test used in IBD treatment have been rather scarce.

This meta-analysis has several weaknesses, most of which relate to heterogeneous definitions of BMT, hepatotoxicity and pancreatitis. Therefore, we had to base our analysis on studies that were vulnerable to bias. Second, all of the included studies were performed in populations of European descent. Further studies are needed in other countries because of ethnic differences in TPMT polymorphisms. Third, the low number of ADRs made statistical precision difficult. Finally, it should be noted that not all of the ADRs could be explained only by TPMT genotyping, but also by other reasons, such as concurrent viral infections[29] or co-medication (e.g. mesalamine or sulfasalazine)[30], which can interfere with thiopurine metabolism.

In conclusion, this meta-analysis provides strong evidence that TPMT polymorphisms are associated with overall ADRs and BMT in patients taking 6-MP or AZA, and thus may be useful in the management of these patients. The present study also clearly demonstrates that thiopurine-related hepatotoxicity and pancreatitis cannot be explained by TPMT polymorphisms. Although there is no consensus that TPMT genotype should be measured before embarking on therapy with thiopurine in IBD patients[31], based on our meta-analysis, we believe that TPMT genotyping is warranted before embarking on therapy with thiopurine in IBD patients. This is also suggested by the US Food and Drug Administration recommendations[32] and by one socioeconomic study of IBD patients[33].

COMMENTS

Background

The efficacy of the thiopurines has been well established for the treatment of

inflammatory bowel disease (IBD). However, they have severe adverse drug reactions (ADRs) such as gastrointestinal disturbances, bone marrow toxicity (BMT), hepatotoxicity and pancreatitis that prevent their use in some patients. The impact of genetic variation of the thiopurine S-methyltransferase (TPMT) gene on its toxicity has been evaluated in several studies, with varying outcomes.

Research frontiers

Recent pharmacogenetic advances have led to the development of novel strategies to optimize and individualize therapy with azathioprine (AZA) and 6-mercaptopurine (6-MP). The strategy of screening the TPMT gene mutation might maximize efficacy while minimizing toxicity.

Innovations and breakthroughs

The results of the previous studies on TPMT polymorphisms and thiopurine toxicity have been inconsistent. Recently, one meta-analysis has found that individuals with both intermediate and absent TPMT activity had an increased risk of developing thiopurine-induced BMT. However, there is still no prospective study that has evaluated the cost-effectiveness and utility of the TPMT phenotyping test before taking thiopurine medication, while TPMT genotyping is recommended by one socioeconomic study in IBD patients. This meta-analysis has shown that IBD patients with TPMT polymorphisms are at risk of increased thiopurine toxicity when taking thiopurine medications.

Applications

The meta-analysis provides strong evidence that the TPMT polymorphisms are associated with overall ADRs and BMT in patients taking 6-MP or AZA. Based on the meta-analysis, it is believed that TPMT genotyping is warranted before embarking upon therapy with thiopurine in IBD patients.

Terminology

TPMT is a cytosolic enzyme that methylates thiopurine compounds. This gene encodes the enzyme that metabolizes thiopurine drugs *via* S-adenosyl-L-methionine as the S-methyl donor and S-adenosyl-L-homocysteine as a byproduct. Genetic polymorphisms that affect this enzymatic activity are correlated with variations in sensitivity and toxicity to such drugs within individuals.

Peer review

The authors describe a meta-analysis of associations between TPMT genetic polymorphisms and ADRs, including BMT, hepatotoxicity, and pancreatitis. The authors' attempt at meta-analysis is interesting, considering current contradictory data about the efficacy of TPMT genotyping in predicting AZA/6-MP toxicity. Moreover, their claims are reasonable.

Abstract

AIM: To determine the clinical value of diffusion-weighted imaging (DWI) for the diagnosis of extrahepatic cholangiocarcinoma (EHCC) by comparing the diagnostic sensitivity of DWI and magnetic resonance cholangiopancreatography (MRCP).

METHODS: Magnetic resonance imaging examination was performed in 56 patients with suspected EHCC. T1-weighted imaging, T2-weighted imaging, MRCP and DWI sequence, DWI using single-shot spin-echo echo-planar imaging sequence with different b values (100, 300, 500, 800 and 1000 s/mm^2), were performed. All cases were further confirmed by surgery or histopathological diagnosis. Two radiologists jointly performed the analysis of the DWI and MRCP images. Apparent diffusion coefficient (ADC) value and signal-noise ratio were calculated for EHCC. Sensitivity, specificity, accuracy, positive predictive value and negative predictive value were tested using DWI with a b value of 500 s/mm^2 and MRCP images, respectively.

RESULTS: Histopathological diagnosis confirmed that among the 56 cases, 35 were EHCC (20 hilar and 15 distal extrahepatic), 16 were cholangitis, and 5 were calculus of bile duct. Thirty-three out of the 35 EHCC cases were detected by DWI. EHCC exhibited differential levels of high signal intensity in DWI and low signal intensity in the ADC map. The mean value for ADC was (1.31 ± 0.29) × 10^{-3} mm^2/s. The detection rate of EHCC was significantly higher by DWI (94.3%) than by MRCP (74.3%) (P < 0.05). There was a significant difference in sensitivity (94.3% *vs* 74.3%), specificity (100% *vs* 71.4%), accuracy (96.4% *vs* 73.2%), positive predictive value (100% *vs* 81.3%), and negative predictive value (91.3% *vs* 62.5%) between DWI and MRCP in diagnosing EHCC.

CONCLUSION: DWI has a high sensitivity for the detection of EHCC as it shows the EHCC lesion more unambiguously than MRCP does. DWI can also provide additional clinically important information in EHCC patients when added to routine bile duct MR imaging protocols.

INTRODUCTION

Extrahepatic cholangiocarcinoma (EHCC) refers to cancers occurring at the left or right hepatic duct to the

ampulla. In clinical practice, the lack of typical early symptoms often results in a delayed or incorrect diagnosis. In recent years, advances in imaging technology have significantly improved the detection rate and accuracy of definitive diagnosis for EHCC.

With the continuous development and improvement of magnetic resonance imaging (MRI) hardware and software, the use of parallel acquisition techniques to reduce scan time and improve spatial resolution, and the wide application of the shortened echo chain technique in spin-echo echo-planar imaging (SE-EPI), diffusion-weighted imaging (DWI) has been increasingly used in a wide range of clinical applications[1,2]. Although the application of DWI to the diagnosis of numerous conditions has attracted increased attention and is the focus of many researches, to our knowledge, there exists no literature on the clinical application of DWI to the diagnosis of EHCC.

MATERIALS AND METHODS

Patients

A total of 56 patients (34 male and 22 female) were examined between March 2008 and December 2009. The patients had a suspected diagnosis of EHCC, and the main clinical symptom was jaundice. Patient ages ranged from 38 to 75, with an average age of 61.0. Thirty-three patients had an elevated level of carbohydrate antigen 19-9 (CA19-9).

MRI scan sequence and parameters

All imaging was performed on a 1.5T MRI scanner (Signa Excite HD, General Electric Healthcare) and a body phased array coil. Patients were asked to fast 4-6 h before imaging, were coached in breathing and breath-hold and were imaged in the supine position. All patients underwent MR axial fast spoiled gradient echo (FSPGR) T1-weighted (T1W), fast recovery fast spin echo (FRFSE) fat-suppressed T2-weighted (T2W), coronal fast imaging employing steady-state acquisition (FIESTA), 3D MRCP and DWI axial scans. 3D MRCP using fast recovery fast spin echo sequence (FRFSE-XL), heavily T2W with respiratory gating, triggered at exhale, and thin multi-plane collection. The scan parameters were: TR and TE time adjusted according to the respiratory rate, and set at approximately 2000-4500 ms and 550-750 ms, respectively; bandwidth 62.5 kHz, echo chain length (ETL) 8; field of view (FOV) 360-400 mm, matrix 320 × 256; slice thickness 3 mm, without interval (-1.5 mm), 80 slices, NEX 1, acquisition time was 2 min and 20 s to 3 min. The original 2D multi-plane formation image was reconstructed into 3D MRCP images using the maximum intensity projection (MIP) and volume-rendering (VR) functions in the workstation, thereby allowing the reconstructed 3D MRCP images to be rotated in any direction. Axial DWI used a single-shot SE-EPI sequence, space parallel acquisition and array spatial sensitivity encoding technique (ASSET), and the scan was performed under breath-hold. Diffusion gradients were applied along three orthogonal directions: frequency encoding (X), phase encoding (Y) and slice-select (Z). The diffusion sensitivity coefficients were b = 100, 300, 500, 800, and 1000 s/mm^2. The DWI scan parameters were: TR 1300 ms, effective TE 41.0-69.2 ms; bandwidth 166.67 kHz, flip angle 90°, slice thickness 5 mm, slice gap 1 mm, single acquisition, FOV 340-400 mm, matrix 128 × 128, NEX 4, acceleration factor 2.

Image analysis

All MR images were jointly viewed and analyzed by two senior radiologists with more than 5 years of combined experience in abdominal MRI diagnosis. All image post-processing was performed using the Advantage Workstation 4.3 (AW4.3, General Electric Healthcare) and the FuncTool software package.

The apparent diffusion coefficient (ADC) values and signal-noise ratio (SNR) of the lesions imaged in the DWI sequence were calculated for different b values. The formula[3] for calculating the value of ADC is given by: $ADC = [\ln (S_{low}/S_{high})]/(b_{high}-b_{low})$. Where S_{low} and S_{high} represent low signal intensity and high signal intensity, respectively, and b_{high}, and b_{low} represent the high b value and low b value, respectively.

After calculating the ADC map using AW4.3, the ADC values can be automatically measured by mapping regions of interest (ROI). The ROI is mapped by selecting lesion areas with high signal intensity in DWI and low signal intensity in ADC. Preferably, the size of ROI is between 8-20 mm^2. Two radiologists performed these tests three times each to derive the mean value. The SNR represents the ratio of lesion signal intensity to the standard deviation of background noise along the phase-encoding direction.

For DWI-based detection and confirmation of diagnosis of EHCC, the b value used was 500 s/mm^2. The evaluation criteria for EHCC were the status of the malignant lesions, the intensity of the malignant lesion signal, the degree of reduction in the malignant lesion signal with the increase of b value, and the ADC value of the malignant lesion. In detail, the following descriptions were assigned[4]: malignant lesions demonstrate mild to moderate high signal intensity in DWI with a b value of 0 s/mm^2; compared with the surrounding tissue, malignant lesions continue to demonstrate high signal intensity in DWI with a b value of 500 s/mm^2; ADC map demonstrates low signal intensity and has a relatively low ADC value. Otherwise, the lesion was considered benign.

In MRCP, the malignant stricture is characterized by an irregular narrow edge, non-symmetry of the narrow and an abrupt cut-off[5,6].

Statistical analysis

All data were processed using the SPSS 13.0 statistical package. Measurement data are represented by mean ± SD. To compare the ADC value and SNR under different b values, the Friedman test was performed over

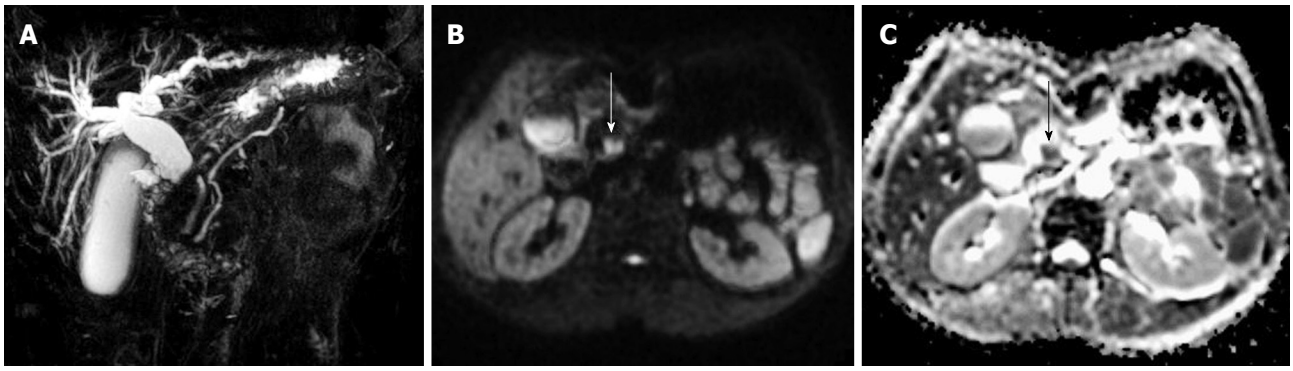

Figure 1 A 55-year-old man with extrahepatic cholangiocarcinoma. A: Magnetic resonance cholangiopancreatography (MRCP) demonstrates the dilatation of intrahepatic ductal and gallbladder with abrupt cutoff of the common bile duct; B: The diffusion-weighted image (b = 500 s/mm^2) shows the cholangiocarcinoma lesion to be a high-signal intensity lesion (arrow); C: Apparent diffusion coefficient (ADC) map (b = 500 s/mm^2) image shows a low-signal intensity area (arrow) and the ADC value of this cholangiocarcinoma was 1.30 × 10^{-3} mm^2/s.

Table 1 ADC value and SNR for EHCC with different b value

B value (s/mm^2)	ADC (× 10^{-3} mm^2/s)	SNR
100	2.73 ± 0.55	135.81 ± 33.27
300	1.84 ± 0.42	99.17 ± 22.63
500	1.31 ± 0.29	69.31 ± 16.36
800	1.22 ± 0.29	47.90 ± 12.35
1000	0.89 ± 0.23	29.48 ± 9.72
M	136.23	142.79
P	< 0.01	< 0.01

All *P* values are less than 0.05 for each two b values exhibited above. ADC: Apparent diffusion coefficient; SNR: Signal-noise ratio; EHCC: Extrahepatic cholangiocarcinoma.

multiple relevant samples, and the detection sensitivity of DWI and MRCP for EHCC was determined using the χ^2 test. A *P* value of < 0.05 was used as the statistical significance level of the observed differences.

RESULTS

Clinical and pathological results

All 56 cases collected in the study were confirmed by histopathological diagnosis. Of the 56 cases, 35 were EHCC (20 located near the hepatic hilum, 15 located at the far end of the extrahepatic bile duct), 16 were cholangitis, and 5 were bile duct stones.

EHCC presentation in DWI imaging and ADC map

Out of the 35 histopathologically-confirmed EHCC cases, 33 cases were detected by DWI. Compared with the surrounding tissues, these cases of EHCC exhibited differential levels of high signal intensity in the DWI image and exhibited low signal intensity in the ADC map (Figure 1). The average size of the EHCC was 28.5 mm (range, 5.0-67.2 mm). For EHCC, the mean ADC value (n = 33) was (1.31 ± 0.29) × 10^{-3} mm^2/s (95% CI, 1.20-1.47). For bile duct stones, the mean ADC value was (0.48 ± 0.22) × 10^{-3} mm^2/s (95% CI, 0.21-0.75). The two cases of EHCC undetected by DWI were due to the interference of artifacts around the bile duct and the small size of the malignant transformation of the bile duct adenoma (5 mm), respectively.

Table 2 Evaluation of diagnostic accuracy of DWI and MRCP for EHCC

	Confirmed pathological diagnosis		Total

Non-EHCC	9	15	24
Total	35	21	56

DWI: Diffusion-weighted imaging; MRCP: Magnetic resonance cholangio pancreatography.

ADC value and SNR for EHCC lesion under different b values

For the DWI sequence, the SNR gradually decreased in the lesion of EHCC as the b value was increased (Table 1). The difference was statistically significant (P < 0.01). With the increase in b value, the ADC value for the lesion gradually decreased (Table 1), and a *P* value of less than 0.05 was considered statistically significant.

Detection and definitive diagnostic accuracy of DWI and MRCP for EHCC

MRCP correctly diagnosed 4 out of 5 cases of bile duct stones, 11 out of 16 cases of cholangitis (5 cases were incorrectly diagnosed as EHCC), and 26 out of 35 cases of EHCC (2 cases were not detected and 7 were incorrectly diagnosed). The overall rate of correct diagnosis was 73.2% (41/56) (Table 2). DWI correctly diagnosed all 5 cases of calculi, all 16 cases of inflammation and 33 out of 35 cases of EHCC (1 case was not detected and 1 was incorrectly diagnosed). The overall rate of correct diagnosis was 96.4% (54/56) (Table 2). The detection sensitivity and specificity of MRCP was 74.3% and 71.4%, respectively.

For DWI, the sensitivity and specificity was 94.3% and 100%, respectively. The differences in detection sensitivity, specificity, and accuracy between the two examination methods for EHCC were of statistical significance ($P < 0.05$). The positive predictive value and negative predictive value of DWI (100%, 91.3%) were higher than those of MRCP (81.3%, 62.5%). The differences between the two sets of values were of statistical significance ($P < 0.05$).

DISCUSSION

DWI reflects the micro-movements of water molecules. It produces images by comparing the inter-tissue diffusion coefficient. It can be used to investigate tissue organization, structure and functional status of a biological object at the cellular and molecular level. Unlike conventional MRI examination, DWI enables imaging of the human body to be performed at a microscopic level, thereby allowing for accurate, rapid and reliable characterization of the spatial organization and composition of tissues, and the functional status of water exchange between tissue components affected by pathological or physiological status.

The extent of water molecule diffusion ability in a tissue is negatively correlated to that tissue's cell density and integrity of the cell membranes. The degree of water molecule movement was found to positively correlate with signal reductions in DWI. The movement of water molecules is more restricted as the cell membrane becomes more intact or if the cell density is higher (i.e. tumor tissue). Therefore, the observation of a relative reduction of signal in tissue imaged with DWI can assist in the detection and confirmation of tumor. The solid portion of the tumor has a higher cell density than normal tissues, and thus should continuously exhibit relatively higher signal intensity on DWI. However, given the fact that DWI is inherently T2-weighted, an extra-long T2 relaxation time can also show as continuously higher signal intensity in DWI, which may then be misdiagnosed as restricted diffusion. This is known as the T2 shine-through effect[7,8]. To avoid this effect, ADC values can be calculated using two images obtained under different b values. The ADC map can then be used to overcome the T2 shine-through effect by observing the relative reduction in signal in images obtained under different b values. Confirmation of tumor through differences in tissue water molecule diffusion is thus made possible. Higher cell densities restrict diffusion and exhibit low ADC values, otherwise, high ADC values are present. The b value is the sensitivity coefficient for diffusion; it can be used to determine the sensitivity for detection of diffusion of water molecules in the tissue under examination. The larger the b value used in DWI, the greater the dispersion of water molecules, and the more obvious the signal intensity reduction. This work focused on observing different ADC values for EHCC under different b values, followed by a comparison of the impact of b value on the ADC value measurement. The ADC value for EHCC was $(1.84 \pm 0.42) \times 10^{-3}$ mm^2/s under a b value of 300 smm^2; the ADC value was $(0.89 \pm 0.23) \times 10^{-3}$mm^2/s under a b value of 1000 s/mm^2. Using a smaller b value can produce a relatively higher ADC value, and with the increase in b value, the ADC value for lesions decreased. This correlation was of statistical significance. In biological tissues, the signal reduction in DWI is determined not only by the diffusion effect of water molecules, but also by reperfusion from the capillary microcirculation. In the work by Yamada *et al*[9], when a low b value was used, the derived ADC value mainly reflected the blood perfusion status of the tissue. Hence, large b values should be used to reflect the true diffusion ability of water molecules in the lesion. The larger the b value used, the better the image will reflect the true diffusion ability of water molecules in the lesion. In theory, when deriving the ADC value, a larger b value should cause the lesion to exhibit relatively higher signal intensity in DWI, producing greater lesion contrast in the ADC map, and increasing the accuracy of the derived ADC value. However, it is worth noting that increasing the b value will likely result in an increase in the diffusion gradient pulse time. The increased TE value can reduce the SNR of DWI and impact on the image quality. Our results show that the SNR of the lesion in DWI decreases following an increase in b value. Hence, the b value should be set between 500 and 800 s/mm^2 to ensure good image quality and an accurate ADC value, which is relatively close to the true diffusion value.

Previously, image quality for abdominal imaging has been relatively poor due to the impact of such factors as abdominal breathing, cardiac motion and chemical shifts. With the development of fast imaging techniques, i.e. single-shot echo planar imaging[10-14], the technology for performing abdominal DWI has improved rapidly[15,16]. DWI has been widely applied to the detection and confirmation of cancer in liver, pancreas, kidney, colon and prostate[17-21]. It has been reported that the characterization sensitivity of MRCP combined with an enhanced 3D MRI scan for EHCC is 87%, and the characterization specificity is 51%[22]. Our results demonstrate that DWI has a greater detection sensitivity and specificity than MRCP in terms of detection of EHCC. DWI reflects microstructural changes in tumor cells, where increases in the DWI signal are mainly caused by diffusion contrast, while T2W and T1W imaging cause signal increases by relaxation time differences. EHCC leads to increased cell density, diminished extracellular space, and restricted movement of water molecules due to an increase of macromolecular materials, all of which increase the EHCC signal. DWI possesses good background suppression effects; blood vessels, the bile duct and intra-abdominal fat all exhibit obvious low signal intensities. This increases tumor contrast to surrounding tissues, which improves lesion detection and facilitates observation of the size and scope of EHCC. DWI also provides a good image-based reference for clinical treatment. By contrast, MRCP only performs analysis over the site and shape of the bile duct stricture, and does not provide intuitive data by which to judge the characteristics and scope of the disease. When

the cholangiocarcinoma is of an infiltrating growth along the bile wall, MRCP shows the lesion as funnel-shaped or a gradually narrowing cone shape, which is difficult to differentiate from chronic inflammatory bile duct stricture. It is also hard to distinguish non-typical cholangiolithiasis and cholangiocarcinoma growing in the bile cavity, as both exhibit low signal intensity filling defects in the high signal intensity bile of MRCP. In theory, different compositions and spatial distributions of lesion tissue and cells lead to different diffusion coefficients, which can contribute to the identification of bile duct lesions. This work shows that with a b value of 500 s/mm^2, the ADC value for EHCC was (1.31 ± 0.29) × 10^{-3}mm^2/s, while the ADC value for cholangiolithiasis was (0.48 ± 0.22) × 10^{-3}mm^2/s. Hence, the measurement of lesion ADC values is useful for distinguishing non-typical cholangiolithiasis and cholangiocarcinoma growing in the bile cavity. However, due to the fact that the size of the ROI often exceeds the size of the thickened bile wall, it is difficult to derive an accurate ADC value for cholangitis. Distinguishing between cholangitis and EHCC only depends on changes in DWI signal but lacks quantitative indicators.

There remain challenges in the use of DWI for examination of the bile duct. The EPI-DWI technique currently in use employs small matrix scanning methods, which produce a low spatial resolution and SNR. The high frequency switching of the high-intensity gradient field can easily produce eddy currents and is highly sensitive to magnetic field inhomogeneities, which will result in unavoidable reverse geometry of space artifacts and partial image signal loss. These artifacts and signal loss become more obvious at air-tissue interfaces. As the b value increases, these artifacts worsen. In this study, one instance of undetected EHCC was attributed to the interference of artifacts around the common bile duct. In addition, the use of fat-suppression techniques to avoid artifacts due to chemical shifts can further degrade image quality. The other exception in the study was due to the partial malignant transformation of bile duct adenoma, where the lesion was too small for the DWI signal change to be obvious. Improvements to MR technology may further enhance image quality in DWI. Comparing with MRCP, DWI is a more intuitive approach to detect and confirm the diagnosis for EHCC. The cholangiocarcinoma DWI results are still preliminary and more research should be conducted to determine its value in clinical applications.

COMMENTS

Background

Extrahepatic cholangiocarcinomas account for 65% of primary neoplasms of the biliary tract. In recent years, improvement in imaging technology has significantly improved the detection rate and accuracy of definitive diagnosis for extrahepatic cholangiocarcinoma (EHCC). Diffusion-weighted imaging (DWI) has recently emerged as a method for detecting cancers in the abdomen. This study aimed to evaluate the usefulness of DWI in the differential diagnosis of extrahepatic cholangiocarcinomas.

Innovations and breakthroughs

DWI has been increasingly used in a wide range of clinical applications. Although the application of DWI in the diagnosis of various conditions has attracted increased attention and has become the focus of many researches, literature on clinical application of DWI for the diagnosis of EHCC has not been observed.

Applications

The authors suggest that all patients presenting with an EHCC or who are suspected to have EHCC, should have an abdominal DWI scan as a regular diagnostic test. DWI can also provide additional clinically important information in EHCC patients when added to routine bile duct MR imaging protocols.

Terminology

DWI is used to observe the random motion of water molecules in the body. The degree of restriction to water diffusion in biologic tissue is inversely correlated to the tissue cellularity and integrity of cell membranes. The motion of water molecules is more restricted in tissues with a high cellular density, associated with numerous intact cell membranes (e.g. tumor tissues). The degree of water motion has been found to be proportional to the degree of signal attenuation in DWI. Visual assessment of the relative tissue signal attenuation in DWI has been applied to tumor detection and tumor characterization. By observing the relative attenuation of signal intensity on images obtained at different b values, tissue characterization based on differences in water diffusion becomes possible. More cellular solid tumor areas will continue to show relatively high signal intensity in DWI. Therefore, the observation of the relative reduction of tissue signal in DWI can help with the detection and confirmation of tumors.

Peer review

The authors compare DWI with magnetic resonance cholangiopancreatography in 56 patients with suspected extrahepatic cholangiocarcinoma. Basically this is an extremely interesting study for assessing the new DWI in more tumor entities. It is nicely performed and provides a histopathological correlation.

Abstract

AIM: To investigate the microcirculation changes in liver of patients with tumor during chemotherapy by perfusion computed tomography (CT).

METHODS: Sixty patients with tumor and 20 controls were enrolled in this study. Perfusion CT parameters of patients and controls were compared, including hepatic perfusion index (HPI), mean transit time (MTT), and permeability-surface area product (PS). Correlation between perfusion CT parameters, treatment cycle and alanine aminotransferase (ALT) level was studied.

RESULTS: No difference was found in HPI (25.68% ± 7.38% *vs* 26.82% ± 5.13%), MTT (19.67 ± 5.68 s *vs* 21.70 ± 5.43 s) and PS (17.00 ± 4.56 mL/100 mL per min *vs* 19.92 ± 6.35 mL/100 mL per min) between patients and controls. The HPI and MTT were significantly higher in patients undergoing 2 cycles of chemotherapy than in controls and those undergoing 1 cycle of chemotherapy (29.76% ± 5.87% *vs* 25.68% ± 7.38% and 25.35% ± 4.05%, and 25.61 ± 5.01 s *vs* 19.67 ± 5.68 s and 19.74 ± 4.54 s, respectively, $P < 0.05$). The HPI was higher in patients with hepatic steatosis than in controls and those without hepatic steatosis (30.85% ± 6.17% *vs* 25.68% ± 7.38% and 25.70% ± 4.24%, $P < 0.05$). Treatment cycle was well correlated with HPI and MTT ($r = 0.40$, $r = 0.50$, $P < 0.01$). ALT level was not correlated with perfusion CT parameters.

CONCLUSION: HPI and MTT are significantly increased in patients with tumor during chemotherapy and well correlated with treatment cycle. Chemotherapy affects hepatic microcirculation in patients with tumor. Changes in hepatic microcirculation can be quantitatively assessed by perfusion CT.

INTRODUCTION

Liver damage secondary to chemotherapy in patients with

tumor is common, and hepatic toxicity differs from mild inflammatory changes of nonspecific hepatitis to fibrosis and marked cirrhosis[1,2]. Although early liver damage causes no symptoms and is reversible in most patients, it occasionally progresses to more severe liver impairment, which may be irreversible. It is, therefore, necessary to demonstrate the presence and severity of drug-related parenchymal changes with effective imaging.

Early liver damage cannot be demonstrated by traditional computed tomography (CT). Perfusion CT is a noninvasive method showing hemodynamic changes in living tissue and has been used in evaluation of liver diseases. However, microcirculation changes in liver on perfusion CT image during chemotherapy have not been described. In this study, we investigated the hemodynamic changes in liver during chemotherapy, and estimated the correlation between the perfusion CT parameters and alanine aminotransferase (ALT) level.

MATERIALS AND METHODS

Patients and study design

Eighty consecutive individuals including 60 patients with tumor and 20 controls were enrolled in this study. Although history, physical examination, laboratory test, and Doppler sonography of liver showed that the 20 controls including 8 women at a mean age of 47.3 ± 8.6 years (range 35-64 years) had no evidence of liver disease, they underwent abdominal perfusion CT for unrelated causes. Inclusion criteria included patients with tumor confirmed by appropriate clinical and laboratory examinations, those still on chemotherapy when perfusion CT was performed, those with hepatic carcinoma or metastasis who had an adequate space in liver parenchyma for later calculation, those who had no history of alcohol abuse, viral hepatitis, liver cirrhosis or other hepatic/biliary diseases, and those who had adequate heart, renal and liver function for perfusion CT. The 60 patients including 24 women at a mean age of 53.2 ± 7.1 years (range 25-71 years) met the criteria. All patients received 1-2 cycles of chemotherapy (6-8 courses in one treatment cycle). Perfusion CT parameters were compared between controls and patients. The diagnostic criteria for hepatic steatosis were the density of liver parenchyma lower than that of spleen or the CT value of liver parenchyma less than 40 Hu on CT image without contrast agent.

The study was approved by the institutional ethics committee. Written informed consent was obtained from each patient or his or her family members after the nature of procedures was fully explained.

Perfusion CT imaging and data processing

Perfusion CT was performed for patients at the end of each treatment cycle. After an overnight fast, patients and controls lying supine on a table underwent perfusion CT with a 64-row multi-detector CT scanner (Light Speed VCT, GE Healthcare, Chalfont St. Giles, UK). Before perfusion CT, patients underwent an abdominal scan without contrast medium during a breath hold at the end of expiration. We selected a slice with the right hepatic lobe, spleen and portal trunk clearly visualized. Then, multiple-slice dynamic sequences lasting 80 s were scanned 8 s after injection of a contrast material (iohexol, 350 mg I/mL, Changfujiejing Pharmaceutical Co. Ltd., Shandong, China). The CT perfusion protocol comprised 80 scans, for 320 images. Because blood vessels of patients with tumor during chemotherapy became too fragile to endure a high injection pressure, a bolus infusion of 40 mL contrast material was given at a speed of 2.5-3.0 mL/s *via* a 20-gauge intravenous catheter in the antecubital vein with a power injector (SCT-210, Medrad Inc., Indianola, PA, USA). The patients kept normal respiration during the perfusion study. The CT parameters used in this study were 120 kV, 250 mA, 5-mm slice thickness, 1-s cycle time and standard reconstruction algorithm.

After image acquisition, the data were transferred to an image processing workstation (AW4.1, GE Healthcare, Chalfont St. Giles, UK) and analyzed with the integrated software of CT Perfusion 3. Four regions of interest (ROI) were set on the abdominal aorta, portal vein trunk, spleen and right liver lobe. The ROI of right liver lobe was drawn on the whole visible right lobe carefully, avoiding blood vessels, margin of liver parenchyma and possible lesions. Hepatic perfusion index (HPI), mean transit time (MTT), and permeability-surface area product (PS) were calculated.

Statistical analysis

All data were expressed as mean ± SD. Independent-sample *t* test was used to determine differences between patients and controls. Data about controls and patients were compared by one-way ANOVA. Spearman correlation coefficient was used to assess the correlation between perfusion parameters, treatment cycle and ALT level. All tests were two-tailed. $P < 0.05$ was considered statistically significant. Data processing and analysis involved use of SPSS v11.5 (SPSS Inc., Chicago, IL, USA).

RESULTS

Differences in perfusion parameters

No significant difference was found in HPI (25.68% ± 7.38% *vs* 26.82% ± 5.13%, $t = 0.77$, $P = 0.44$), MTT (19.67 ± 5.68 s *vs* 21.70 ± 5.43 s, $t = 1.43$, $P = 0.16$) and PS (17.00 ± 4.56 mL/100 mL per min *vs* 19.92 ± 6.35 mL/100 mL per min, $t = 1.90$, $P = 0.06$) between patients and controls.

Patients were divided into two subgroups: one receiving 1 cycle of chemotherapy ($n = 40$) and the other receiving 2 cycles of chemotherapy ($n = 20$). The HPI and MTT were higher in patients receiving 2 cycles of chemotherapy than in those receiving 1 cycle of chemotherapy and controls (29.76% ± 5.87% *vs* 25.35% ± 4.05% and 25.68% ± 7.38%, and 25.61 ± 5.01 s *vs* 19.74 ± 4.54 s and 19.67 ± 5.68 s, $P < 0.05$). No significant difference was observed in HPI and MTT between patients receiving 1 cycle of chemotherapy and controls, and in PS between patients and controls ($F = 1.78$, $P = 0.18$) (Table 1).

Table 1 Comparison of perfusion parameters between controls and patients by treatment cycle (mean ± SD)

Parameters	Controls (n = 20)	1 cycle (n = 20)	2 cycles (n = 40)	F value	P value
HPI (%)	25.68 ± 7.38	25.35 ± 4.05	29.76 ± 5.87	4.62	0.01
MTT (s)	19.67 ± 5.68	19.74 ± 4.54	25.61 ± 5.01	10.59	< 0.01
PS (mL/100 mL per min)	17.00 ± 4.56	19.95 ± 6.76	19.86 ± 5.60	1.78	0.18

Of the 60 patients, 13 (21.7%) showed hepatic steatosis. The incidence of hepatic steatosis was higher in patients receiving 2 cycles of chemotherapy than in those receiving 1 cycle of chemotherapy (P = 0.01). The HPI was higher in patients with hepatic steatosis than in those without hepatic steatosis and controls (30.85% ± 6.17% *vs* 25.70% ± 4.24% and 25.68% ± 7.38%, P < 0.05). No significant difference was found in HPI between patients without hepatic steatosis and controls, and in MTT or in PS between patients and controls (Table 2).

Correlation between CT perfusion parameters, treatment cycle and ALT level

Treatment cycle was well correlated with HPI (r = 0.40, P < 0.01) and MTT (r = 0.50, P < 0.01) but not with PS (r = 0.02, P = 0.89). ALT level was not correlated with treatment cycle (r = -0.05), HPI (r = -0.06), MTT (r = 0.19), and PS (r = 0.18).

DISCUSSION

Hepatic toxicity is often encountered in patients with tumor following chemotherapy. Chemotherapy agents can impair many vital functions of liver cells and cause their death[3]. Severe cell death is followed by nodular regeneration and obstruction of sinusoids, including transformation of fenestrated sinusoids into continuous capillaries and deposition of collagen in extravascular tissue spaces located between sinusoidal endothelium and hepatocytes[4,5]. These morphologic alterations modify blood transit time and distribution volume of small and large molecules[6,7], increase vascular resistance and reduce portal perfusion[8,9]. The reduction in portal perfusion is then buffered by liver arterialization, thereby increasing the arterial fraction of liver perfusion[8,10,11]. These alterations following chemotherapy are non-specific and can mimic any form of acute or chronic liver disease.

Perfusion CT can be used to evaluate the hemodynamic changes in liver disease. However, since the results of previous studies are varied[12-14], no established conclusion is available on the change in liver perfusion, especially in early chronic liver disease. Some studies showed that HPI and MTT values are significantly increased in patients or rats with chronic liver disease[12,13]. However, another study showed that the MTT is lower while the PS is higher in patients than in controls[14]. In the present study, the hepatic HPI and MTT values were higher in patients during chemotherapy than in controls, and well correlated with treatment cycle. No significant difference was observed in PS between patients and controls.

Table 2 Comparison of perfusion parameters between controls and patients with or without hepatic steatosis (mean ± SD)

Parameters	Controls (n = 20)	Patients without steatosis (n = 47)	Patients with steatosis (n = 13)	F value	P value
HPI (%)	25.68 ± 7.38	25.70 ± 4.24	30.85 ± 6.17	4.79	0.01

Steatosis is a common manifestation of drug hepatotoxicity and a form of liver damage most readily recognized on CT image. Several studies have shown that the incidence of hepatic steatosis is increased in patients undergoing chemotherapy[15-18]. In this study, hepatic steatosis was observed in 13 (21.7%) of the 60 patients, which was higher in patients receiving 2 cycles of chemotherapy than in those receiving 1 cycle of chemotherapy. The HPI was higher in patients with hepatic steatosis than in those without hepatic steatosis and controls. No difference was found in MTT or in PS between patients and controls.

At present, ALT level is the main index of drug-induced hepatic damage[19]. However, the ALT level was found to be a less sensitive index of hepatic damage and could not thoroughly reflect hepatic toxicity in this study. In clinical practice, many liver function tests remain normal despite obvious liver changes seen on CT images. In the present study, only 4 of 13 patients with hepatic steatosis had abnormal ALT, which was not correlated with HPI, MTT or PS. However, it has been shown that perfusion CT parameters are correlated with the severity of hepatic disease[13], indicating that further study is needed to classify the severity of liver damage with perfusion CT parameters.

Our study has some limitations. First, the injection rate of contrast agent was low. Because the detection of perfusion parameters is affected by many factors such as the type and injection rate of contrast agent, drawing of ROI and calculation method[20,21], the low injection rate may be a major obstacle to comparison with other results. Second, our sample size was small. Third, we only investigated the changes in perfusion CT in liver of patients during chemotherapy, and did not observe the entire changing characteristics of hepatic microcirculation during and after chemotherapy.

In conclusion, hepatic microcirculation is changed in patients with tumor during chemotherapy and can be quantitatively assessed by perfusion CT. Perfusion CT may be used as a noninvasive tool in detection of hepatic toxicity.

COMMENTS

Background

Liver damage is common in patients with tumor following chemotherapy. Although early liver damage causes no symptoms and is reversible in most patients, it occasionally progresses to more severe liver impairment, which may be irreversible, it is thus necessary to demonstrate the presence and severity of drug-related parenchymal changes.

Research frontiers

Hepatic microcirculation changes in patients with tumor during chemotherapy were evaluated by perfusion computed tomography (CT). The hotspot of this research is whether hepatic microvascular changes can be quantified with perfusion CT and what kind of modifications can be detected.

Innovations and breakthroughs

At present, alanine aminotransferase (ALT) level is the main index in diagnosis of drug-induced hepatic damage. In this study, however, ALT level was found to be a less sensitive index and could not thoroughly reflect hepatic toxicity. The aim of this study was to investigate the microcirculation changes in liver of patients with tumor during chemotherapy, showing that hepatic perfusion index and mean transit time are significantly increased in patients undergoing 2 cycles chemotherapy.

Applications

The findings of this study may underscore the possibility of using perfusion CT parameters as indicators of hepatic microcirculation alteration in drug-induced liver damage. Perfusion CT may be used as a noninvasive tool in detection of hepatic toxicity.

Peer review

The paper is a concise documentation of a good study.

Abstract

Annular pancreas (AP) is a rare congenital anomaly. Coexisting malignancy has been reported only in a few cases. We report what is, to the best of our knowledge, the first case in the English literature of duodenal adenocarcinoma in a patient with AP. In a 55-year old woman with duodenal outlet stenosis magnetic resonance cholangiopancreatography showed an aberrant pancreatic duct encircling the duodenum. Duodenojejunostomy was performed. Eight weeks later she presented with painless jaundice. Duodenopancreatectomy revealed a duodenal adenocarcinoma, surrounded by an incomplete AP. Thus, co-existent malignancy with AP can be present without obstructive jaundice and without being visible through preoperative diagnostics.

Key words: Duodenal carcinoma; Annular pancreas; Duodenopancreatectomy; Whipples operation

INTRODUCTION

Annular pancreas is a rare congenital anomaly, which consists of a ring of pancreatic tissue, confluent with the head of the pancreas, and partially or completely encircling the second segment of the duodenum. It was first described by Tiedemann in 1818[1] and first named "pancreas anulare " by Ecker in 1862[2].

Studies based on cases where the diagnosis was made on autopsy or during surgery estimate the incidence of annular pancreas of 3 in 20 000[3,4]. When the diagnosis is based on modern imaging methods, such as multislice computed tomography (MSCT), magnetic resonance imaging (MRI), magnetic resonance cholangiopancreatography (MRCP) or endoscopic retrograde cholangiopancreatography (ERCP), the incidence seems to be higher; up to 1 in 250[5,6]. About 700 cases of annular pancreas have been reported in the literature[7]. During normal organogenesis, the pancreas is formed by merging the ventral with the dorsal pancreatic bud during the first four to nine weeks of gestation. Two main theories, sustained by Lecco[8] and Badwin[9] respectively, describe the pathogenesis of annular pancreas. Lecco[8] explained the development of the anomaly as an adherence of the ventral pancreatic bud to the duodenum, which leads to an improper rotation of the ventral bud, resulting in the encirclement of the duodenum. Badwin[9] contends that the persistence and enlargement of the left ventral bud causes the pancreatic obstructing ring. Although the pancreatic band usually adheres to the muscularis of the du-

odenum, it may also be loosely applied to the serosa of the duodenum[10]. The annular pancreas has been associated with other congenital anomalies, such as trisomy 21, tracheoesophageal fistula, cardiac anomalies, and intestinal malrotation[7]. Association of annular pancreas with malignancy is rare. It has been described only 14 times in the English literature (five pancreatic carcinomas, six ampullary carcinomas, two cholangiocarcinomas, and one Insulinoma)[11-22]. A review of 151 cases of annular pancreas in Japan by Ogawa *et al*[11] revealed an association with malignant tumors of the duodenopancreatobiliary system in 15 patients (five cholangiocarcinomas, four gallbladder carcinomas, four duodenal, and two pancreatic carcinomas). Primary carcinoma of the duodenum is rare, representing about 0.3% of all malignant neoplasms of the gastrointestinal tract and 25%-45% of malignant neoplasms of the small intestine[23].

We report what is, to the best of our knowledge, the first case in the English literature of duodenal adenocarcinoma in a patient with annular pancreas.

CASE REPORT

A 55-year-old Caucasian woman was admitted to our hospital with a six-week history of persistent postprandial nausea and vomiting, associated with a weight loss of 7 kg compared to a total weight of 70 kg. There was no associated pain, hematemesis, fever, diarrhoea, or jaundice. Domperidone therapy was ineffectual. Four years prior to the diagnosis, the patient had intermittent occasional mild epigastric pain. She also reported occasional vomiting during the previous 15 years, which was not medically investigated.

On clinical examination, the patient appeared weak and dehydrated. Her abdomen was soft, without tenderness or palpable masses. Laboratory results revealed a hypokalemia of 1.9 mmol/L, which was substituted, and a metabolic alkalosis with an initial pH of 7.65. Serum amylase, bilirubin, and C-reactive protein (CRP) levels were not elevated.

Gastroscopy showed a reflux esophagitis, a massive distension of the stomach and the first part of the duodenum, respectively, and a stenosis of the second part of the duodenum, which could not be passed with the thin gastroscope.

Abdominal MSCT depicted a fluid filled stomach and second segment of the duodenum (Figure 1). The pancreatic head was enlarged, surrounding the second segment of the duodenum; no dilation of the main pancreatic duct and common bile duct was noticed. For further evaluation, an MRCP was done. This showed an aberrant pancreatic duct encircling the duodenum, linked to the main pancreatic duct (Figure 2). No dilation of the common hepatic bile duct or the main pancreatic duct was evident. Due to the annular pancreas, there was an obstruction at the level of the second segment of the duodenum. During surgery, we found a massively distended and elongated first segment with a conic ste-

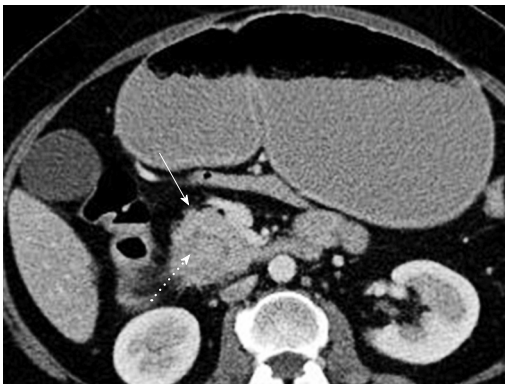

Figure 1 Multislice computed tomography. A fluid filled stomach and enlargement of the pancreatic head (arrow) are detected, which encircles the second segment of the duodenum (dotted arrow).

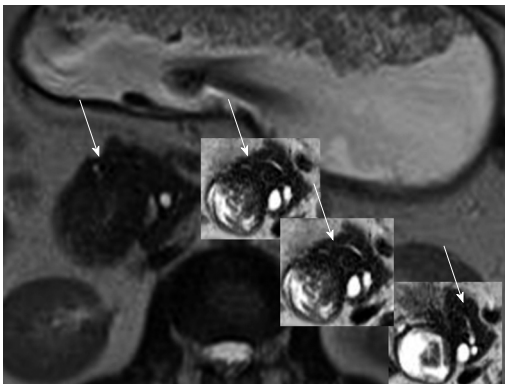

Figure 2 T2 weighted magnetic resonance cholangiopancreatography images depict the aberrant pancreatic duct, which encircles the duodenum and connects with the main pancreatic duct (arrows).

nosis of the second segment of the duodenum due to the annular pancreas (Figure 3). A duodenojejunostomy was performed. There was no visible prestenotic tumor in the duodenum and the duodenal mucosa appeared to be normal. No tumor mass was palpated. The patient had an uneventful recovery and was discharged home with no complaints nine days later. After eight weeks, the patient was readmitted presenting with painless jaundice. She had no other complaints. No further weight loss was reported. Laboratory investigations showed elevated total bilirubin (112 μmol/L; reference range: 5-18) and alkaline phosphatases (178 U/L; reference range: < 104). An MRCP demonstrated dilatation of the common bile duct (Figure 4). On explorative laparotomy, a hard mass was palpated in the pancreatic head region. The frozen section of one of several suspicious superior pancreatic lymph nodes revealed adenocarcinoma cells. A duodenopancreatectomy was performed. The tumor was clearly located in the duodenum, with infiltration of the surrounding structures (Figure 5). No tumor was observed in the head of the pancreas. Pathological examination showed a poorly differentiated, infiltrating adenocarcinoma of the duodenum, surrounded by the incomplete annular pancreas (Figure 5). The tumor stage was pT4,

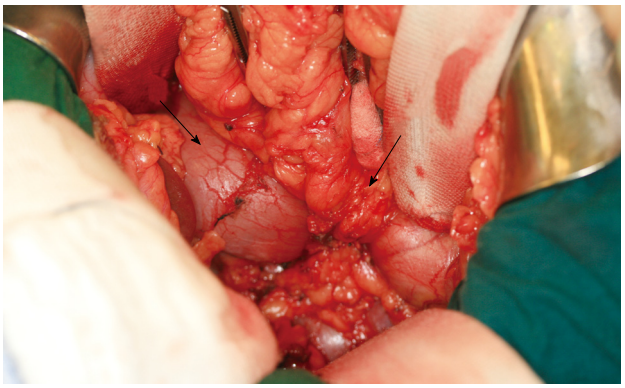

Figure 3 During surgery, a massively distended and elongated first segment (left arrow) and a conic stenosis of the second segment of the duodenum were observed due to the annular pancreas (right arrow).

pN1 (8/12), G3, L0, V0, R0. The tumor seemed to have arisen from the duodenal epithelium.

DISCUSSION

Symptoms

Clinical manifestation of annular pancreas can occur at any age, from neonatal period to adulthood. When the duodenal constriction is minimal or absent, annular pancreas can remain asymptomatic lifelong[24]. In infants, the common clinical symptoms are vomiting and feeding intolerance[7]. Clinical manifestation in adults can present with cramping epigastric pain, postprandial fullness, vomiting, and weight loss[10,25,26]. Association with pancreatitis, or a gastric/duodenal ulcer, can also occur[7,25]. The most frequent symptom in adult annular pancreas seems to be abdominal pain[7,10]. Most adults become symptomatic between the ages of 20 and 50[25]. The differential diagnosis includes other upper gastrointestinal pathologies, such as peptic ulcer disease, duodenal web, pancreatitis, or pancreatic carcinoma[19,27]. Obstructive jaundice is described as a rare direct result of annular pancreas, but appears in coexisting periampullary malignancies[19]. Of the above-mentioned 14 cases of carcinoma associated with annular pancreas, 10 presented obstructive jaundice. The most

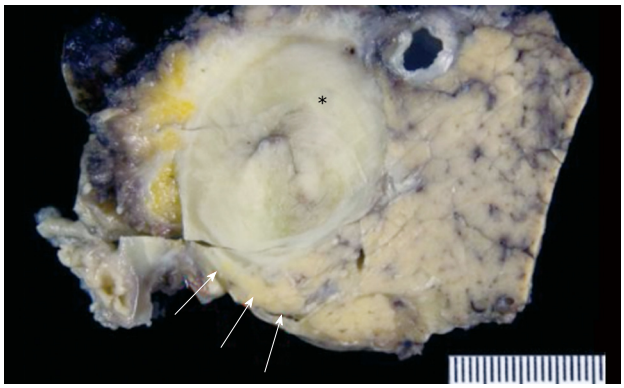

Figure 5 Cross sectional view showing the tumor within the duodenum (asterisk). The duodenum is surrounded by the incomplete annular pancreas (arrows).

common symptoms of primary carcinoma of the duodenum are abdominal pain and weight loss[28]. Upon her first hospitalisation, our patient's main symptoms were postprandial nausea and vomiting, associated with a significant weight loss. No abdominal pain was reported. Neither pancreatitis nor obstructive jaundice was apparent. Four years prior to diagnosis, the patient had been complaining intermittent occasional mild epigastric pain. In addition, over the previous 15 years, she had reported occasional vomiting. Fifteen years had passed from first symptoms until diagnosis of annular pancreas. Upon her second hospitalisation, her only symptom was jaundice.

Diagnosis/radiology

Annular pancreas is diagnosed by ERCP or by CT[29]. Since MRCP has become widely used, annular pancreas can be diagnosed non-invasively[30,31]. A recent study reviewed 55 cases with annular pancreas in adults[7]. Diagnosis was made with ERCP in 47%, MSCT in 18%, with MRCP in 16%, and in 13% of the patients, diagnosis was made at the time of surgery. We were able to make the diagnosis of annular pancreas non-invasively by abdominal MSCT (Sensation 16, Siemens Medical Solutions, Erlangen, Germany) and MRCP using a 1.5T scanner (1.5T Symphony, Siemens Medical Solutions, Erlangen, Germany). Due to the duodenal obstruction by the pancreatic ring, ERCP was not a feasible diagnostic alternative. Upon readmission, dilatation of the common bile duct was demonstrated by MRCP. Malignancy was found during explorative laparotomy. The final diagnosis was made by the pathologist. During her first hospitalisation, malignancy was not suspected either by preoperative diagnostics nor laparotomy. Upper gastrointestinal tract endoscopy is the most frequently performed test to diagnose duodenal adenocarcinoma[28]. In the present case, the tumor was hidden behind the annular pancreas and not within reach of the endoscope.

Therapy and prognosis

The treatment of annular pancreas is always surgical. The goal is to relieve the duodenal or gastric outlet obstruc-

tion. Dissection of the pancreatic ring should be avoided due to a high incidence of complications, including duodenal leak, pancreatic fistula, and postoperative pancreatitis[10]. Different surgical approaches have been described. Bypass surgery, such as duodenojejunostomy in pediatric surgery, and duodenoduodenostomy or gastrojejunostomy in adults is preferred. The safest and most successful way of bypassing the annular constriction seems to be duodenoduodenostomy or duodenojejunostomy[10]. The presence of a periampullary malignancy must be considered in adult patients with annular pancreas presenting with obstructive jaundice[19]. In cases of annular pancreas associated with proven or suspected periampullary malignancy, duodenopancreatectomy might be the treatment of choice[19]. This should also be performed when annular pancreas is associated with pancreatolithiasis and localized chronic pancreatitis[32]. Long-term survival of patients with duodenal adenocarcinoma can be achieved with a surgical procedure that produces negative resection margins, such as pancreaticoduodenectomy[28]. Adjuvant therapy seems not to improve the survival rate[33]. Initially, our patient did not show jaundice and imaging did not present a tumoral mass.

We decided to perform a duodenojejunostomy to bypass the stenosis. The postoperative course was uneventful. Five days after intervention, the patient was able to eat solid food.

After eight weeks, painless jaundice appeared and MR imaging revealed dilatation of the common bile duct but no tumoral mass. Intraoperatively, a hard mass was palpated in the pancreatic head region and adenocarcinoma cells were found in a pancreatic lymph node at frozen section. We performed a duodenopancreatectomy and the patient received no adjuvant therapy.

In conclusion, annular pancreas should be kept in mind when symptoms of upper gastrointestinal obstruction occur, but the presence of annular pancreas should not distract from a possible coexisting malignancy. As in the present case, such a malignancy can also be present without obstructive jaundice and without being visible through preoperative diagnostics. In such a case, pancreaticodudoenectomy might be the only way to exclude the coexistence of duodenal carcinoma with annular pancreas.

Surgical treatment of hepatocellular carcinoma with severe intratumoral arterioportal shunt. *World J Gastroenterol* 2010; 16(25): 3211-3214 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i25/3211.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i25.3211

Abstract

We report a case of hepatocellular carcinoma (HCC) that caused a severe arterioportal shunt (APS). A 49-year-old man was admitted to hospital due to esophagogastric variceal hemorrhage and HCC, and underwent endoscopic variceal ligation (EVL) and endoscopic injection sclerotherapy (EIS). He was then referred to our hospital. Abdominal computed tomography revealed a low-density lesion in the posterior segment of the liver and an intratumoral APS, which caused portal hypertension. Although the patient underwent EVL, EIS, Hassab's operation, and transcatheter arterial embolization for APS, he vomited blood due to rupture of esophagogastric varices. Right hepatectomy was performed for the treatment of HCC and APS, although the indocyanine green retention value at 15 min after intravenous injection was poor (30%). The patient's postoperative course was uneventful. Eventually, APS disappeared and the esophagogastric varices improved.

INTRODUCTION

Hepatocellular carcinoma (HCC) can easily invade the portal vein and form a direct communication between the hepatic artery and portal vein, which results in the formation of an arterioportal shunt (APS). Severe APS leads to life-threatening conditions, such as esophagogastric varices, refractory ascites, and hepatic encephalopathy, as a result of portal hypertension[1-3]. Furthermore, indocyanine green retention at 15 min after intravenous injection (ICG-R15) for APS is worse than the true value[4]. We report a patient who underwent successful hepatectomy for the treatment of HCC and an intratumoral APS that was not controlled with various treatments.

CASE REPORT

A 49-year-old man was admitted to hospital because of vomiting blood, which was diagnosed as esophagogastric

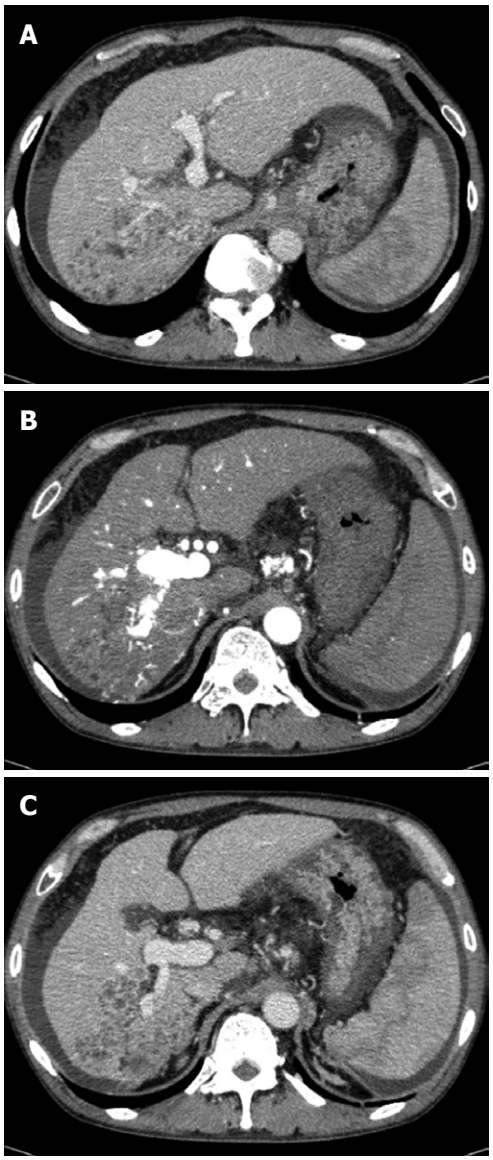

Figure 1 Computed tomography examination. A: Low-density lesion in the posterior segment of the liver, which pressed the vena cava and right hepatic vein and opposed the right anterior superior portal vein; B: Hyper-enhanced portal vein during the arterial phase; C: Tumor thrombus in the posterior branch of the portal vein. A tumor opposed the right anterior inferior portal vein.

Figure 2 Upper gastrointestinal endoscopy revealing severe esophageal varices.

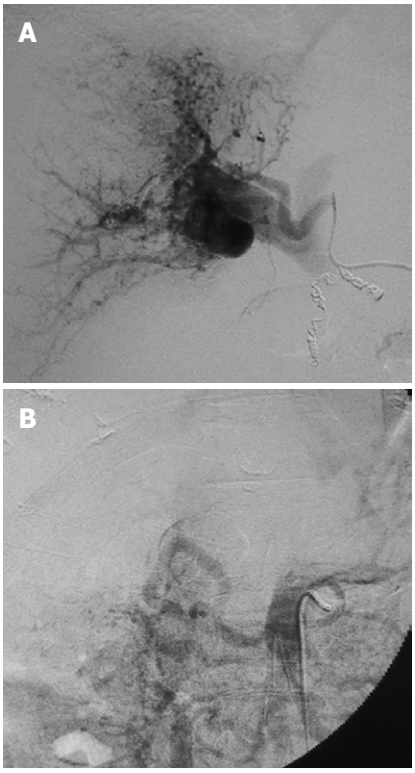

Figure 3 Arteriography. A: Right hepatic arteriography exhibiting the right portal vein, caused by severe intratumoral arterioportal shunt; B: Transarterial portography revealing non-enhancement of the portal vein because of portal hypertension.

varices and HCC. He underwent emergency endoscopic variceal ligation (EVL), followed by endoscopic injection sclerotherapy (EIS) three times at the hospital. The patient was then referred to our hospital for treatment of HCC.

The laboratory data obtained at the time of hospitalization in our hospital are shown in the Table 1. The Child-Pugh classification status was class B (8 points) and the degree of liver damage on the scoring system designed by the Liver Cancer Study Group of Japan[5] was class B. Abdominal dynamic computed tomography (CT) revealed a low-density lesion at any phases that existed in the posterior segment of the liver. The lesion was 11 cm in diameter and apposed the vena cava, the right hepatic vein, and the right anterior superior and inferior portal vein (Figure 1A and C). CT also demonstrated a hyper-enhanced portal vein during the arterial phase (CT attenuation of the portal vein was 284 HU and that of the proper hepatic artery was 294 HU) (Figure 1B); a filling defect caused by tumor thrombus in the posterior branch of the portal vein (Figure 1C); esophagogastric varices despite previous EIS; ascites and splenomegaly. Upper gastrointestinal endoscopy revealed severe esophagogastric varices (Figure 2). Right hepatic arteriography revealed severe intratumoral APS accompanied by reflux into the main portal vein (Figure 3A). Transarterial portography revealed non-enhancement of the portal vein due to portal hypertension (Figure 3B). The patient was diagnosed with HCC with severe intratumoral APS, which caused portal hypertension that lead to esophagogastric varices and hypersplenism.

Table 1 Laboratory data obtained at time of hospitalization and after TAE

	At time of hospitalization	After TAE
AST level (IU/L)	86	70
ALT level (IU/L)	66	20
Total bilirubin level (mg/dL)	0.98	0.71
Albumin level (g/dL)	3.4	3.8
White blood cell count (/μL)	1800	3900
Hemoglobin level (g/dL)	9.9	9.2
Hematocrit (%)	30.7	29.8
Platelet count (/μL)	7.5×10^4	18.2×10^4
Prothrombin activity (%)	71	80
HBsAg	Negative	-
HCV Ab	Positive	-
AFP level (ng/mL)	5570	-
PIVKA-Ⅱ level (mAU/mL)	5360	-
ICG-R15 (%)	36	30

TAE: Transcatheter arterial embolization; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; HBsAg: Hepatitis B surface antigen; HCV Ab: Hepatitis C virus antibody; AFP: α-fetoprotein; PIVKA-Ⅱ: Protein induced by vitamin K absence or antagonist Ⅱ; ICG-R15: Indocyanine green retention at 15 min after intravenous injection.

We first performed Hassab's operation (splenectomy and devascularization of the distal esophagus and proximal stomach) due to uncontrollable esophagogastric varices and hypersplenism. Despite the Hassab's operation, the esophagogastric variceal hemorrhage prevailed. Consequently, we performed transcatheter arterial embolization (TAE) with fiber platinum coils and n-butyl 2-cyanoacrylate for the APS. Although we performed TAE twice, the esophagogastric variceal hemorrhage persisted because of recanalization of the APS.

The laboratory data obtained after TAE are shown in the Table 1.

The Child-Pugh classification status was class B (7 points) and the degree of liver damage was class B. Because the liver function data other than ICG-R15 were good, we surmised that severe APS led to an ICG-R15 value that was worse than that of the actual liver function. Subsequent therapy for HCC and APS was required, and we performed right hepatectomy for resection of HCC and APS 4 mo after hospitalization. Although the tumor was located mainly in the right posterior section of the liver, the tumor apposed the right anterior superior and posterior portal vein and the right hepatic vein. Therefore, we selected right hepatectomy. The portal vein pressure improved after liver resection. The pre- and post-liver resection state was 55 and 37 cmH_2O, respectively. Pathological examination revealed a moderately differentiated HCC in the posterior section of the liver, a tumor thrombus in the right posterior branch of the portal vein, and chronic hepatitis in the non-tumorous area. The postoperative course was uncomplicated, and APS and esophagogastric varices improved. The patient is alive at 12 mo after right hepatectomy, without esophagogastric variceal hemorrhage, and has been undergoing systemic chemotherapy for multiple recurrent HCC and lymph node metastases.

DISCUSSION

HCC is frequently associated with APS. Kido *et al*[6] and Ngan *et al*[7] have determined that APS occurs in 60% of patients with HCC, and Okuda *et al*[8] have reported that marked APS of the main, right or left portal vein occurs in 30% of HCC patients. Severe APS leads to or aggravates portal hypertension, which causes life-threatening conditions, such as rupture of esophagogastric varices, refractory ascites, and hepatic encephalopathy[1-3]. Luo *et al*[9] have reported that severe APS exhibits strong enhancement of the main portal trunk and/or the first-order branches at the hepatic arterial phase of CT. HCC with tumorous APS is frequently unenhanced at the arterial phase in dynamic CT[9,10] because APS reduces arterial flow to the tumor. In our case, the patient presented with rupture of esophagogastric varices. CT revealed a low-density lesion in the posterior segment of the liver, and tumor staining at the arterial phase was not visible because of the tumorous APS.

Endoscopic treatment is the standard treatment for esophageal varices. EVL is safer and more convenient to perform compared to EIS, but does not completely disrupt the interconnecting perforating and feeder vessels[11]. For this reason, EIS is used additionally to improve the clinical results of EVL. Hassab's operation[12] is performed when esophagogastric varices are not controlled with endoscopic treatment and/or if hypersplenism is present. In the present case, we performed Hassab's operation because esophagogastric varices were not controlled with endoscopic treatment and hypersplenism was present; however, the esophagogastric variceal hemorrhage prevailed. We suspect that the esophagogastric variceal hemorrhage occurred as a result of the development of submucosal collateral vessels. APS needs to be treated to improve portal hypertension caused by severe APS. Although TAE with several embolic materials such as gelatin sponge, coil, and ethanol is an effective treatment for APS, Huang *et al*[13] have reported that the recanalization rate of APS was 18% and 86% in the ethanol and gelatin sponge groups, respectively. In our patient, unfortunately, APS was resistant to two TAE procedures, and the esophagogastric variceal hemorrhage prevailed. Only right hepatectomy is effective for the treatment of HCC and intratumoral APS. Although the ICG-R15 value was poor (30%), we performed right hepatectomy. The ICG clearance test is one of the most commonly used liver function tests[14], and Imamura *et al*[15] have reported that the cutoff value of ICG-R15 that allows safe right hepatectomy is 10%, and patients with 30%-39% ICG-R15 are treated with limited hepatic resection alone. However, this is premised on the assumption that there is no portosystemic shunt and that the intrahepatic blood flow is even, and thus, the ICG-R15 value is worse than the true value in patients with APS[4]. In such cases, technetium-99m diethylenetriaminepentaacetic acid galactosyl human serum albumin (^{99m}Tc-GSA) scintigraphy demonstrates great potential and is used more widely because the results are not affected by the presence of a shunt. Many institutions

have described methods for predicting hepatic functional reserve with ^{99m}Tc-GSA scintigraphy; however, a consensus on the best method has not yet been reached[16]. Thus, we did not perform ^{99m}Tc-GSA scintigraphy. We judged that the poor value of ICG-R15 resulted from APS because the value of ICG-R15 was improved by TAE for APS, despite an incompletely occluded APS (ICG-R15 was 36% before TAE and 30% after). Thus, we judged that the patient could tolerate right hepatectomy because the standard liver function test results were almost in the normal range. The patient had no major postoperative complications and his quality of life was improved due to correction of APS.

In conclusion, we reported a patient with HCC and intratumoral APS. We encountered difficulty in controlling esophagogastric varices and APS and evaluating hepatic functional reserve; however, he was treated successfully with hepatectomy. In patients with severe APS, we must estimate hepatic functional reserve, and hope that a consensus on the best method for evaluating hepatic functional reserve will be obtained.

Abstract

We report a case of hepatocellular carcinoma (HCC) occurring in a patient with Crohn's disease (CD) without chronic hepatitis or liver cirrhosis, and review the clinicopathological features of HCC in CD patients. A 37-year-old Japanese man with an 8-year history of CD and a medication history of azathioprine underwent resection of a liver tumor. The histopathology of the liver tumor was pseudoglandular type HCC. In the non-neoplastic liver, focal hepatocyte glycogenosis (FHG) was observed, however, there was no evidence of liver cirrhosis or primary sclerosing cholangitis. Only nine cases of HCC in CD patients have been reported previously in the English-language literature. Eight of 10 cases (including the present case) had received azathioprine treatment, and four of these cases also showed FHG, which is considered a preneoplastic liver lesion, within the non-neoplastic liver. Although the precise mechanism of the development of HCC in CD patients is controversial, these results suggest that azathioprine therapy and FHG in the non-neoplastic liver contribute to the development of HCC. These findings also indicate that it is important to survey CD patients treated with prolonged azathioprine therapy for potential liver tumors.

Key words: Crohn's disease; Hepatocellular carcinoma; Azathioprine; Focal hepatocyte glycogenosis; Hepatocarcinogenesis

INTRODUCTION

Fatty liver and primary sclerosing cholangitis are known to be associated with Crohn's disease (CD), and patients with CD also experience an increased risk of malignant lymphoma and cancers of the small intestine or colon[1,2]. Nonetheless, hepatocellular carcinoma (HCC) in CD pa-

tients is extremely rare, with only nine cases reported in the English-language literature[3-11]. Here, we report one additional case of HCC in a CD patient without established chronic liver disease, and review the clinicopathological features of HCC in CD patients. In addition, we discuss the tumorigenesis of HCC in CD patients and the relationship between HCC and azathioprine treatment.

CASE REPORT

A 37-year-old Japanese man with an 8-year history of CD was admitted to our hospital for examination of a liver tumor. He had been diagnosed with CD at age 29 years, when he required surgery for a bowel fistula. He had been treated with elemental diet, prednisolone, azathioprine, and 5-aminosalicylic acid. Two years prior to this admission, magnetic resonance imaging (MRI) showed a liver tumor in S7, which measured 4 cm × 3 cm. The liver tumor enlarged gradually in follow-up computed tomography (CT) and MRI. Preoperative abdominal contrast-enhanced CT disclosed the S7 tumor that measured 8 cm × 5 cm, which showed early arterial enhancement (Figure 1).

Upon admission, biopsy of the S7 tumor was performed, and histopathological study showed HCC. Then, the patient underwent hepatic resection of the posterior segment.

Preoperative colorectal endoscopic examination revealed mucosal redness and pseudopolyposis throughout the entire colorectum. Histopathological findings of the colorectal mucosa corresponded to CD, with the presence of discontinuous lymphoplasmacytic infiltrate in the lamina propria and a few non-caseating granulomas, unrelated to crypt rupture (Figure 2A).

Preoperative laboratory data revealed mild anemia (hemoglobin 11.1 g/dL; range 12.4-17.0). Liver enzymes were within normal limits (aspartate aminotransferase 14 IU/L; range 7-38, and alanine aminotransferase 15 IU/L; range 4-43). C-reactive protein was slightly elevated (2.57 mg/dL; range < 0.3). Although serum alpha-fetoprotein level was normal (7.7 ng/mL; range < 20), protein induced by vitamin K absence Ⅱ (PIVKA Ⅱ) level was markedly elevated (757 mAU/mL; range < 40). Serology was negative for hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibody, and hepatitis C antibody. In addition, he had no history of alcohol consumption.

Microscopically, the resected specimen of the S7 tumor was almost well-circumscribed by a fibrous capsule, but focal extracapsular invasion was observed. The tumor displayed pseudoglandular to focal trabecular growth of tumor cells with rich eosinophilic cytoplasm and enlarged, round to oval nuclei with a nucleolus (Figure 2B). These histopathological findings were typical of pseudoglandular type HCC.

Non-neoplastic resected liver tissue showed no evidence of liver cirrhosis, chronic hepatitis, or primary sclerosing cholangitis. However, some foci of benign-appearing clear hepatocytes were observed (Figure 2C).

Figure 1 Contrast-enhanced abdominal computed tomography. A well-circumscribed tumor showing early arterial enhancement is present in S7.

These clear hepatocytes were confirmed to have glycogen accumulation (focal hepatocyte glycogenosis; FHG), because they stained positive for periodic acid-Schiff and were digested by diastase. In addition, no histopathological evidence suggestive of non-alcoholic steatohepatitis, such as macrovesicular steatosis, pericellular fibrosis, and neutrophils infiltration, was observed in the non-neoplastic liver tissue.

The postoperative course was uneventful, and no tumor recurrence has been observed during 2 years follow-up.

DISCUSSION

HCC generally occurs in patients with established chronic liver disease, such as liver cirrhosis and viral hepatitis. HCC in CD patients is extremely rare; to the best of our knowledge, only nine cases have been reported previously in the English-language literature[3-11]. The Table 1 summarizes the clinicopathological features of HCC in CD patients. The mean duration from the onset of CD to the development of HCC is 15.1 years (range: 0-36). Although no patients, including the present case, demonstrated apparent risk factors for developing HCC, such as liver cirrhosis or viral hepatitis, two patients had primary sclerosing cholangitis (Table 1)[6,8]. In the five cases in which histological typing of HCC was available, there were three cases of pleomorphic type HCC and two of trabecular type HCC (Table 1). The present case is believed to be the first case of pseudoglandular type HCC occurring in CD.

Most of the CD patients showed a history of medication with one or more drugs (Table 1). Eight of 10 cases had been treated with azathioprine and six had a medication history with 5-aminosalicylic acid. Azathioprine is an inhibitor of purine synthesis, and is prescribed widely in patients with organ transplantation or inflammatory bowel disease[12]. Patients who undergo long-term azathioprine-based immunosuppressive treatment have been reported to show an increased risk of non-Hodgkin lymphoma and cutaneous squamous cell carcinoma[13,14].

The occurrence of HCC in patients who received azathioprine therapy in the absence of liver cirrhosis and viral hepatitis remains exceptional; however, one case of

5-ASA: 5-aminosalicylic acid; AZA: Azathioprine; DOD: Died of disease; FHG: Focal hepatocyte glycogenosis; HCC: Hepatocellular carcinoma; CD: Crohn's disease; IFx: Infliximab; NA: Not available; PSC: Primary sclerosing cholangitis; PSL: Prednisolone; CT: Computed tomography.

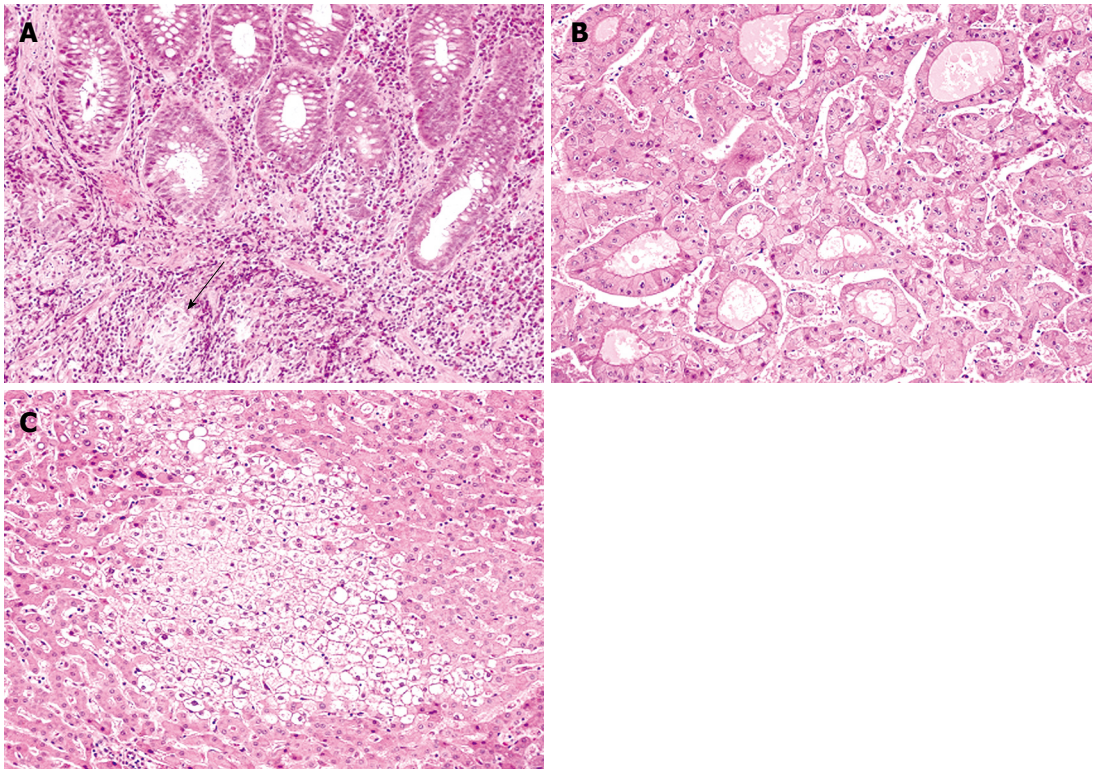

Figure 2 The histopathology of colorectal mucosa (A), the liver tumor (B) and non-neoplastic liver (C) (hematoxylin and eosion stain, × 100). A: Lymphoplasmacytic infiltrate and a tiny granuloma without association with crypt rupture (arrow) are observed; B: The neoplastic hepatocytes show pseudoglandular growth; C: Focal hepatocyte glycogenosis is observed.

HCC in a renal transplant patient without apparent risk factors other than prolonged azathioprine therapy has been reported (no hepatitis C studies were available at that time)[15], and one case of HCC after azathioprine therapy has also been reported in a patient with ulcerative colitis but no hepatitis B and C[16]. In addition, 80% of CD patients who developed HCC had a medication history of azathioprine (Table 1).

The precise mechanism involved in the development of HCC in CD patients is controversial. In one experi-

mental study, azathioprine was shown to increase hepatocyte turnover[17]. It was hypothesized that the degree of immunosuppression by prolonged azathioprine therapy was associated with the incidence of neoplasia[15]. These results suggest that azathioprine therapy is associated with the development of HCC in CD patients.

FHG was observed in the present case, as well as in three other CD patients previously reported to have developed HCC[4,7,11]. Although the cause and significance of FHG are not well established, glycogenated foci can be considered preneoplastic lesions, because FHG and lesions observed during drug-induced hepatocarcinogenesis have histological and biochemical similarities, and the presence of FHG within non-malignant hepatocellular nodules of cirrhotic liver can predict their malignant transformation[18]. Cattan *et al*[4] have reported previously on a CD patient with HCC who had both a medication history of azathioprine as well as disseminated FHG in the non-neoplastic liver. They suspected the pathogenic link between long-term azathioprine therapy and FHG. These results suggest that FHG could be related to hepatocarcinogenesis in CD patients.

In conclusion, we reported a case of pseudoglandular type HCC in a CD patient without established chronic liver disease. The patient had a medication history of azathioprine and FHG in the non-neoplastic liver. Although the precise mechanism of the development of HCC in CD patients is controversial, azathioprine therapy and FHG are likely to be involved. Therefore, accumulation of cases is necessary to clarify the precise mechanism of the development of HCC in CD patients, and we stress the importance of surveying CD patients with prolonged azathioprine therapy for liver tumors.

Acknowledgments to reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Rakesh Aggarwal, Additional Professor, Department of Gastroenterology, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow 226014, India

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Electronic journal (list all authors)

15 Morse SS. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Patent (list all authors)

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology

Contents

Weekly Volume 16 Number 26 July 14, 2010

EDITORIAL

3219 Black esophagus: Acute esophageal necrosis syndrome
Gurvits GE

3226 *Helicobacter pylori* and gastric cancer in the Middle East: A new enigma?
Hussein NR

GUIDELINES FOR BASIC SCIENCE

3235 Two-layer cold storage method for pancreas and islet cell transplantation
Fujino Y

REVIEW

3239 Interstitial cells of Cajal, the Maestro in health and disease
Mostafa RM, Moustafa YM, Hamdy H

ORIGINAL ARTICLE

3249 *Nardostachys jatamansi* extract protects against cytokine-induced β-cell damage and streptozotocin-induced diabetes
Song MY, Bae UJ, Lee BH, Kwon KB, Seo EA, Park SJ, Kim MS, Song HJ, Kwon KS, Park JW, Ryu DG, Park BH

3258 CD74 is a survival receptor on colon epithelial cells
Maharshak N, Cohen S, Lantner F, Hart G, Leng L, Bucala R, Shachar I

3267 Identification of cytokines involved in hepatic differentiation of mBM-MSCs under liver-injury conditions
Dong XJ, Zhang H, Pan RL, Xiang LX, Shao JZ

3279 Randomized controlled trial of minimally invasive surgery using acellular dermal matrix for complex anorectal fistula
A ba-bai-ke-re MMTJ, Wen H, Huang HG, Chu H, Lu M, Chang ZS, Ai EHT, Fan K

BRIEF ARTICLE

3287 Safety of same-day endoscopic ultrasound and endoscopic retrograde cholangiopancreatography under conscious sedation
Che K, Muckova N, Olafsson S, Srikureja W

3292 Functional magnetic resonance imaging in an animal model of pancreatic cancer
Lewandowski RJ, Eifler AC, Bentrem DJ, Chung JC, Wang D, Woloschak GE, Yang GY, Ryu R, Salem R, Larson AC, Omary RA

3299 Wireless capsule endoscopy and proximal small bowel lesions in Crohn's disease
Petruzziello C, Onali S, Calabrese E, Zorzi F, Ascolani M, Condino G, Lolli E, Naccarato P, Pallone F, Biancone L

3305 Experience with the surgical treatment of hepatic hydatidosis: Case series with follow-up
Losada Morales H, Burgos San Juan L, Silva Abarca J, Muñoz Castro C

3310 Comparison of different nutritional assessments in detecting malnutrition among gastric cancer patients
Ryu SW, Kim IH

3318 Oncological outcome of unresectable lung metastases without extrapulmonary metastases in colorectal cancer
Li WH, Peng JJ, Xiang JQ, Chen W, Cai SJ, Zhang W

3325 Relationship between let-7a and gastric mucosa cancerization and its significance
Zhu YM, Zhong ZX, Liu ZM

3330 Paclitaxel ameliorates fibrosis in hepatic stellate cells *via* inhibition of TGF-β/Smad activity
Zhou J, Zhong DW, Wang QW, Miao XY, Xu XD

CASE REPORT

3335 Vanishing bile duct syndrome in human immunodeficiency virus: Nevirapine hepatotoxicity revisited
Kochar R, Nevah MI, Lukens FJ, Fallon MB, Machicao VI

3339 Isolated ileal perforation due to cytomegalovirus reactivation during management of terbinafine hypersensitivity
Sano S, Ueno H, Yamagami K, Yakushiji Y, Isaka Y, Kawasaki I, Takemura M, Inoue T, Hosoi M

3343 Abdominal separation in an adult male patient with acute abdominal pain
Liu BL, Chen Y, Liu SQ, Zhang XB, Cui DX, Dai XW

ACKNOWLEDGMENTS	I	Acknowledgments to reviewers of *World Journal of Gastroenterology*
APPENDIX	I	Meetings
	I-IV	Instructions to authors
AIM AND SCOPE		*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries. The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.
FLYLEAF	I-VII	Editorial Board

NAME OF JOURNAL
World Journal of Gastroenterology

Abstract

Acute esophageal necrosis (AEN), commonly referred to as "black esophagus", is a rare clinical entity arising from a combination of ischemic insult seen in hemodynamic compromise and low-flow states, corrosive injury from gastric contents in the setting of esophago-gastroparesis and gastric outlet obstruction, and decreased function of mucosal barrier systems and reparative mechanisms present in malnourished and debilitated physical states. AEN may arise in the setting of multiorgan dysfunction, hypoperfusion, vasculopathy, sepsis, diabetic ketoacidosis, alcohol intoxication, gastric volvulus, traumatic transection of the thoracic aorta, thromboembolic phenomena, and malignancy. Clinical presentation is remarkable for upper gastrointestinal bleeding. Notable symptoms may include epigastric/abdominal pain, vomiting, dysphagia, fever, nausea, and syncope. Associated laboratory findings may reflect anemia and leukocytosis. The hallmark of this syndrome is the development of diffuse circumferential black mucosal discoloration in the distal esophagus that may extend proximally to involve variable length of the organ. Classic "black esophagus" abruptly stops at the gastroesophageal junction. Biopsy is recommended but not required for the diagnosis. Histologically, necrotic debris, absence of viable squamous epithelium, and necrosis of esophageal mucosa, with possible involvement of submucosa and muscularis propria, are present. Classification of the disease spectrum is best described by a staging system. Treatment is directed at correcting coexisting clinical conditions, restoring hemodynamic stability, nil-per-os restriction, supportive red blood cell transfusion, and intravenous acid suppression with proton pump inhibitors. Complications include perforation with mediastinal infection/abscess, esophageal stricture and stenosis, superinfection, and death. A high mortality of 32% seen in the setting of AEN syndrome is usually related to the underlying medical co-morbidities and diseases.

Key words: Acute esophageal necrosis; Black esophagus; Acute necrotizing esophagitis; Ischemia; Endoscopy; Gastrointestinal hemorrhage

INTRODUCTION

Acute esophageal necrosis (AEN), commonly referred to as "black esophagus" or "acute necrotizing esophagitis", is a rare clinical disorder classically characterized by a striking endoscopic image of diffuse, circumferential, black-appearing, distal esophageal mucosa on esophagogastroduodenoscopy (EGD) (Figure 1) that stops abruptly at the gastroesophageal junction (GEJ)[1,2]. Proximal esophageal extension is common. Biopsy is recommended although not required to make the diagnosis. First described in 1990 by Goldenberg *et al*[3], this medical phenomenon was again brought into the spotlight by our large review series

in 2007, in which we analyzed all cases reported in the English literature to date and formulated the concept of a distinct clinical syndrome[2]. Its etiology is likely multifactorial. AEN is thought to arise from a combination of an ischemic insult to the esophagus, impaired mucosal barrier systems, and a backflow injury from chemical contents of gastric secretions[2,4-6]. Male sex, older age, chronic medical conditions, including diabetes mellitus, hematologic and solid organ malignancy, malnutrition, renal insufficiency, cardiovascular compromise, trauma, and thromboembolic phenomena place a patient at a higher risk for developing AEN[4,7-13]. Clinical presentation is almost universally related to upper gastrointestinal bleeding. Complications may include stenosis or stricture formation in the distal esophagus, perforation, mediastinitis, and death. Overall mortality is largely related to the underlying medical condition and approaches 32%[2].

In this latest review, we discuss the epidemiology of AEN syndrome, its pathophysiological and clinical features, etiology, presentation, distinction from other mimickers of "black esophagus", natural course of the disease, staging, complications, suggested treatment options, and prognosis.

EPIDEMIOLOGY

Literature analysis shows that the estimated prevalence of AEN is low. Two large autopsy series from the United States and France have reported zero cases in a series of 1000 adult autopsies[14] and 0.2% in 3000 autopsies, respectively[15]. Two large retrospective series that have reviewed the findings in > 100 000 endoscopies have estimated the incidence at approximately 0.01% (12 patients)[5,12], and another retrospective analysis of 10 295 endoscopies has shown an incidence of 0.28% (29 patients)[13]. A 1-year prospective study of EGD findings in 3900 patients has identified eight cases of AEN (0.2%)[6]. However, these numbers are likely underestimated and the true prevalence of AEN remains unknown, largely due to the potential of subclinical presentation of the disease and the early healing of the mucosa that can be seen with transient ischemic or chemical injury. An intriguing paper by Japanese authors has reported AEN as the fourth leading cause of coffee ground emesis, hematemesis, or melena in a series of 239 hospital admissions for upper gastrointestinal bleeding, which accounted for approximately 6% of the cases[16].

AEN clearly shows sex and age predilection. Men are four times more commonly affected than women, and although the disease has been documented in every age group, the peak incidence occurs in the sixth decade of life with an average age of 67 years[2]. General debilitation and poor clinical condition with multiple medical co-morbidities are associated with increased likelihood of development of AEN. Personal history of diabetes mellitus (24%), malignancy (20%), hypertension (20%), alcohol abuse (10%), and coronary artery disease (9%) places a patient at risk of developing AEN[2].

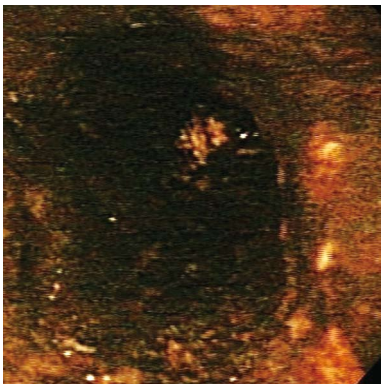

Figure 1 Black esophagus: acute esophageal necrosis.

ANATOMY AND PATHOPHYSIOLOGY

The esophagus is an expandable muscular organ lined by a stratified squamous epithelium. Characteristically, esophageal wall is composed of four distinct layers: mucosa, submucosa, muscularis propria, and adventitia. Unlike the rest of gastrointestinal tract, the esophagus lacks serosa and is separated from the adjacent organs by few millimeters of connective tissue, an important factor in potential development of extrinsic necrotic injury to the organ and spread of the infectious processes.

The esophagus receives an intricate segmental vascular supply that separates this organ into three parts: upper, middle, and distal esophagus. The arterial network of the upper esophagus is derived from the descending branches of the inferior thyroid arteries. Additional variable supply may come from branches of the subclavian, thyroidea ima, common carotid, or superior thyroid arteries. Mid-esophageal blood supply is derived from the bronchial arteries, right third or fourth intercostal arteries, and numerous small esophageal arteries off the descending aorta. Distal esophagus receives its blood flow from branches off the left gastric artery or left inferior phrenic artery, but variations are common and small branches off the celiac, splenic, short gastric, or left hepatic arteries may provide additional or alternative blood supplies[17,18]. Relative to the densely vascularized proximal and middle parts of the organ, the distal esophagus is slightly more "watershed" and therefore the first signs of the ischemic injury to the esophagus typically appear there. Overall, the complex anastomotic vascular network that is present in the esophageal submucosa generally makes esophageal infarction a rare clinical disease[18].

An important physiological property of the esophagus is the ability to use intricate protective barrier systems to shield itself from the injurious chemical reflux of the stomach contents. A delicate microarray of the epithelial tight junctions, zonula adherens, intercellular glycoconjugated material, intrinsic cellular buffering systems and anion exchangers, and extensive desmosomal network, coupled with bicarbonate, lubricant, mucus, and epidermal growth factor production by submucosal glands account for comprehensive defense mechanisms and restorative

function of the organ[18]. Compromise or inadequacy of these barriers may lead to cell damage, and ultimately, death. Local blood supply to the lamina propria and submucosa, which is essential in maintaining effective buffering systems, is influenced by a variety of factors, including autoregulation in response to the intraluminal acidic pH of gastric contents[19,20]. Initial augmentation in blood delivery needed for maintenance of protective and reparative processes may be significantly downregulated by an overwhelming back diffusion of hydrogen ions[19,21]; an important factor in pathogenesis of AEN, particularly in the setting of an already compromised blood flow. At the cellular and molecular level, the mechanism of the esophageal injury is similar to the development of ischemic changes in the small and large bowel. Reactive oxygen metabolites formed as a result of reperfusion injury and leukocytic migration may directly and indirectly damage important mechanisms of cellular viability and function, which results in cellular lysis and death[18,22].

Finally, anti-reflux barriers and luminal clearance are important factors in preventing significant esophageal injury. Integrity of the lower esophageal sphincter mechanism, gravity and esophageal peristalsis are vital. Compromise or ineffectiveness of any one of these may deeply potentiate necrotic injury[23].

ETIOLOGY

Tissue insult seen in AEN is likely multifactorial and usually results from a combination of tissue hypoperfusion, impaired local defense barriers, and massive influx of gastric contents that acutely overwhelm the already vulnerable esophageal mucosa[2]. Perfusion injury in the development of AEN is best demonstrated by an avascular distal esophagus reported by Goldenberg *et al*[24]. Significant vasculopathy that is typically associated with diabetes mellitus, atherosclerosis, cardiovascular and renal diseases is an important risk factor that may predispose some patients to rapid tissue injury, as well as general susceptibility to hemodynamic instability and compromise. Low-flow state related to sepsis, cardiac arrhythmias, congestive heart failure, severe third spacing, systemic inflammatory response syndrome due to severe pancreatitis, lactic- and ketoacidosis, acute blood loss, hypothermia, trauma and shock may lead to ischemic compromise of the esophagus[2,12,16,25-31]. Thromboembolic phenomena and underlying coagulopathy seen in patients with solid tumor or hematological malignancies, anticardiolipin antibody syndrome, and atherosclerosis have also been implicated in the development of AEN[8,9,11,16,29]. Striking predilection to the distal esophagus is likely explained by its lesser degree of vascularization relative to the proximal and middle portions of the organ[12].

Vascular compromise to the distal esophageal tissue can also explain some of the duodenal pathology commonly seen in association with AEN, namely, duodenal bulb ulcers, erosions, inflammation, and edema[3,6,24]. The common blood supply from the branches off the celiac axis makes distal esophageal and duodenal pathologies less of a coincidence, but rather possibly related entities. Characteristic relative sparing of the gastric mucosa can be explained by the acidic impact on the ischemic esophageal and duodenal surface[7], as well as typically rapid repair of the injured gastric mucosa (within hours) compared to the esophagus (may take days)[18]. The duodenal bulb ulcers and edema may result in gastric outlet obstruction that, in turn, potentiates the development of mucosal necrosis of the distal esophagus[5,32]. A transient form of non-obstructive gastropathy can be seen in acute alcohol intoxication and diabetic ketoacidosis, two medical conditions that are linked to the development of AEN[25,26,33,34]. Back flow injury from the acid, pepsin, and other gastric contents is augmented by the increased transient lower esophageal sphincter relaxation, decreased resting lower esophageal pressure, prolonged recumbence, decreased esophageal peristalsis, and increased gastroesophageal reflux that may be related to the multiple medical conditions seen in the patient with AEN (debilitated condition, significant hiatal hernia, alcohol use, diabetes mellitus, postoperative state, *etc.*).

Alteration in physiological processes is an important co-factor in the development of AEN. Critical illness, poor nutritional status, and general deconditioning may contribute to the diminished mucosal buffering, compromised local protective barriers, and impaired defensive mechanisms that may potentiate ischemic and chemical injury to the esophagus[6]. Such risk factors include malignancy, cirrhosis, chronic pulmonary disease, neutropenia, renal insufficiency or failure, diabetes mellitus, hypoalbuminemia, immunosupression after solid organ transplantation, acquired immune deficiency syndrome (AIDS), postoperative status, and sepsis[2,10,12,13,27,35-39].

Diffuse AEN may be associated with local infection and tissue biopsy is essential for proper management, which includes antiviral or antimicrobial agents. Exact distribution is variable and probably depends on mode of transmission of the infectious agent, from external spread reported from a superior mediastinitis that affects cervical and thoracic esophagus[40], to primary esophageal intraluminal infection seen in viral and fungal disease in immunocompromised patients[35,36,41]. Reported pathogens include *Klebsiella pneumoniae*[40] and cytomegalovirus[36,41], herpes simplex virus[37], *Penicillium chrysogenum*[35], *Candida*[7], and other fungal species.

Other diseases and medical conditions associated with the development of AEN include erythema multiforme or Stevens-Johnson syndrome, gastric volvulus, hematoma from traumatic transection of thoracic aorta, hypersensitivity to antibiotics, acute fatty liver of pregnancy, drug-induced hepatitis, photodynamic therapy, polyarteritis nodosa, pulmonary lobectomy with paraesophageal lymph node dissection, severe infectious mediastinitis, emphysematous gastritis, hypoxia, and pancreatitis[2,7,12,39,40,42-49]. A single case of isolated proximal black esophagus has been reported in a patient who underwent cardiac catheterization, an event that was possibly related to the procedure[50,51].

PRESENTATION

A typical patient with AEN is an elderly male with mul-

tiple medical comorbidities, who manifests with signs of upper gastrointestinal bleeding. Clinical presentation of AEN ranges from hematemesis, coffee ground emesis, and melena (overall, accounting for nearly 90% of the cases) to asymptomatic black esophagus that was noted during a percutaneous gastrostomy tube placement[2,52]. Review of systems may be remarkable for epigastric/abdominal pain, vomiting, dysphagia, nausea, low-grade fever, lightheadedness, and syncope. Other associated clinical conditions or endoscopic findings may include multiorgan failure[53], cardiac, pulmonary, and renal disease, diabetes mellitus and ketoacidosis, vasculopathy, coagulopathy, peptic ulcer disease, general debilitation and malnourishment, cirrhosis, acute alcoholic hepatitis, acute fatty liver of pregnancy, acute pancreatitis, sepsis, ischemic processes (stroke, ischemic bowel, ischemic gangrene), and trauma. Physical findings in a patient with AEN are usually confounded by the underlying medical conditions but may be notable for cachectia, fever, hypoxia, hemodynamic instability or compromise, including arrhythmia and hypotension, pallor, abdominal tenderness, and guaiac-positive stools. Laboratory analysis may show leukocytosis and anemia and computed tomography (CT) may reveal thickened distal esophagus, hiatal hernia, distended fluid-filled stomach with possible gastric outlet obstruction, and rarely, external compression of the esophagus by a large mediastinal process.

DIFFERENTIAL DIAGNOSIS

Classic AEN presents as a circumferential, black-appearing, diffusely necrotic esophageal mucosa, preferentially affecting the distal esophagus, of variable length, that stops abruptly at the GEJ. Proximal extension of the mucosal injury is common and the entire esophagus can appear black. Differential diagnosis includes malignant melanoma, acanthosis nigricans, coal dust deposition, pseudomelanosis, and melanocytosis of the esophagus[54-63]. Detailed history and physical examination provide essential clues to the diagnosis. Classic endoscopic appearance may be supported by brush cytology or biopsy specimen that will confirm the diagnosis. This is especially important in rare cases of isolated involvement of proximal and middle esophagus. Additionally, a history of corrosive ingestion[64] should be sought for and diligently excluded.

CLINICAL DIAGNOSIS

The characteristic endoscopic appearance described above makes the diagnosis of AEN. Almost universal predilection to the distal esophagus (97%) is a remarkable feature of this disorder[2]. Additional endoscopic findings may include duodenal peptic ulcer disease, erosions, edema, and sings of gastric outlet obstruction[23]. Early evaluation may also be notable for signs of bleeding, including active oozing from the distal esophagus and blood clots and "coffee grounds" material in the stomach. Esophageal biopsy or brushings of the affected esophageal tissue are supportive but not required to make the proper diagnosis. Histological findings include absence of viable epithelium, abundant necrotic debris, and necrotic changes in the mucosa, possibly extending into the submucosa and even muscularis propria. Full-thickness necrosis has been described in the surgical specimens. Associated findings may include heavy leukocytic infiltrate, visible vascular thrombi, deranged muscle fibers, and severe inflammatory changes[2]. Biopsy specimens should be sent for bacterial, fungal, and viral cultures to exclude infectious etiologies associated with AEN or a superimposed infection[7,26]. Special care should be taken to evaluate for the presence of multinucleated giant cells or viral inclusion bodies, particularly in immunocompromised patients. At this time, the role of angiography for diagnosis of AEN is not clearly defined, likely related to its potential risks, lack of effective therapeutic intervention in the absence of a recognizable lesion, and tendency for a spontaneous recovery with correction of the underlying medical illness.

Upper gastrointestinal bleeding in a patient with multiple medical conditions, vasculopathy, hemodynamic compromise, general debilitation, malignancy, ischemic disease, and hypercoagulable state should raise the possibility of AEN among other diagnoses. A strong association between diabetic ketoacidosis and AEN has been suggested by some authors, with four cases of black esophagus seen in 29 hospital admissions (14%)[16].

DISEASE COURSE AND STAGING

Generally, uncomplicated AEN follows an indolent clinical course and has a predictable endoscopic and histopathological trajectory. The recently proposed staging system attempts to classify disease progression and detail the distinct phases of AEN[2]. Stage 0 designates a prenecrotic viable esophagus. Stage 1 refers to an acutely diseased organ with an endoscopic picture dominated by a striking diffuse, circumferential, black-appearing esophageal mucosa with occasional yellow exudates and signs of friability, loss of light reflex, rigidity and under-distension of the lumen. These endoscopic findings nearly universally start at the GEJ, involve the distal esophagus, and variably extend proximally, potentially covering the entire organ. Histological appearance is notable for lack of viable squamous epithelium, presence of necrotic debris, and pronounced necrosis of the mucosa with possible extension into the submucosa and muscularis propria. Associated findings may include heavy leukocytic infiltrate with severe inflammatory changes, visible vascular thrombi, deranged muscle fibers, and mucosal infection with viral, fungal, and bacterial pathogens. Stage 2 describes the healing phase of the AEN dominated by residual black areas in the esophagus and thick white exudates composed of necrotic debris that cover friable pink mucosa. This "chess-board" appearance can sometimes be the presenting endoscopic picture of AEN on delayed endoscopy. The exact timing of this change is unknown and it likely parallels the underlying general condition of the patient. However, it has been observed as late as 1 mo after the diagnosis. Stage 2 is also notable for some improvement

in histological appearance of the esophageal tissue, with scattered areas of necrosis among underlying cellular regeneration, granulation tissue, and inflammatory changes. As early as 1-2 wk after diagnosis, the esophageal mucosa acquires its normal endoscopic appearance in stage 3 of the AEN with only microscopically present granulation tissue, a sequelae of recent injury.

COMPLICATIONS

The most serious complication of AEN is perforation, which can occur in severe cases that result in full-thickness necrosis of the esophageal tissue. Its reported incidence is just below 7%[2], and should be suspected in rapidly decompensating patients. Traumatic or spontaneous rupture of the thoracic aorta resulting in extrinsic esophageal compression by hematoma, photodynamic therapy for esophageal cancer, herniated gastric volvulus, and severe thromboembolic disease place a patient at a higher risk for this complication. Perforation can be seen in stage 1 of the disease, and it may lead to rapid clinical deterioration, mediastinitis, mediastinal abscess formation, empyema, and generalized sepsis. Prompt recognition, intravenous antibiotics, and surgical intervention are life-saving. Mortality may be especially high given a generally poor underlying medical condition and a limited reserve in many patients with AEN.

Another possible sequela of AEN is the formation of stenotic areas or strictures, which can be seen in > 10% of patients. These findings typically occur in stages 2 and 3 of the disease and likely result from protective scar formation during the acute, reparative, and healing phase of AEN. Acid suppression followed by possible endoscopic dilatation, if needed, typically produces resolution of reported symptoms.

Microbial superinfection of necrotic media is an important consideration in treating patients with AEN[26]. Patients should be diligently monitored for early signs of clinical decompensation and sepsis with prompt institution of intravenous antimicrobial therapy.

MANAGEMENT

Development of AEN carries a generally poor prognosis and the goal of therapy should be directed at treating the coexisting medical diseases. Timely systemic resuscitation and patient stabilization play pivotal roles in the management of this disease. Intravenous hydration, correcting anemia with packed red blood cell transfusion, and keeping the patient nil-per-os should be instituted. Parenteral support may be needed in malnourished patients to improve their nutritional status and expedite healing. Passage of the nasogastric tube should not be undertaken, to avoid perforation.

Medical management of AEN includes aggressive intravenous proton pump inhibitor or histamine receptor blocker therapy until improvement in clinical status, at which time, a change to an oral formulation is appropriate. Probably, oral therapy should be continued for a few months after the resolution of symptoms to aid prevention of stricture formation, in the absence of underlying reflux disease. Recent reports of esophageal manometry and pH monitoring in patients with AEN have shown a lack of significant acid reflux and normal motility at 5-7 mo after recovery[23,65]. Oral suspension of sucralfate may be used as a single therapy or as a supplement to the intravenous acid-reducing agents, excluding the cases with concomitant renal failure.

Antimicrobial therapy is important in the setting of positive esophageal cultures, stains for fungal agents, or visualization of multinucleated giant cells or inclusion bodies on histological evaluation of the biopsy specimen. Empirical antibiotics should be initiated in cases of suspected esophageal perforation, rapid clinical decompensation, unexplained fevers, and immune compromise in AIDS, cirrhosis, transplant recipient, and dialysis patients. Prophylactic use of antibiotics in sterile necrosis is probably not necessary and few reports have potentially linked the antibiotic use itself to the development of AEN[49].

Surgical intervention in patients with AEN is reserved for perforated esophagus with resultant mediastinitis and abscess formation. Esophagectomy, decortication, lavage, and delayed reconstruction may be performed in addition to standard surgical approaches in the setting of gastric volvulus or transected thoracic aorta. Primary closure of the perforated esophageal tissue should not be attempted. Subtotal esophagectomy and esophagogastrostomy have been reported in AEN-induced esophageal stricture that was refractory to repeated dilatations[3,26].

PROGNOSIS AND ROLE OF REPEAT ENDOSCOPY

Prognosis of AEN largely depends on coexisting medical conditions and ordinarily parallels the general state of health of a patient. As a rule, overall prognosis is poor with nearly one third of patients succumbing to the underlying critical illness. However, mortality specific to the AEN is much lower, at around 6%[2]. Important risk factors include esophageal perforation, diabetic ketoacidosis, and compromised immune system. Overall, reversible phenomena of the disease and its tendency for spontaneous healing are favorable factors in predicting complete recovery in otherwise healthy individuals. Relapsing AEN has been reported only once[66] but may be an important diagnosis to consider in the appropriate clinical setting. It may also explain some of the observed color changes of black esophagus reported in the literature[4]. Repeat endoscopic evaluation should be done to assess mucosal healing and document resolution of AEN, as well as to determine the duration of antacid therapy. Endoscopic sessions with balloon dilatation may be necessary in patients suffering from dysphasia in the setting of esophageal stenosis or stricture formation, which are well-known complications of AEN.

CONCLUSION

AEN is a rare syndrome that arises in the characteristic

clinical setting of combined ischemia from hemodynamic compromise, gastric outlet obstruction with backflow chemical injury, and inadequate protective barriers and physiological reserve due to critical illness and general deconditioning. It presents with signs of upper gastrointestinal bleeding and has a characteristic appearance on upper endoscopy of circumferential, diffuse, black-appearing, friable esophageal mucosa, almost universally affecting the distal part of the organ and abruptly ending at the GEJ. Histological tissue necrosis confirms the diagnosis. Treatment relies on aggressive resuscitation, correction of underlying medical conditions, institution of therapy with proton pump inhibitors and sucralfate, and monitoring for signs of infection or perforation. Mortality is high and is largely related to the principal medical conditions and the gravity of the overall state of health.

Abstract

The Middle East is the home of ethnic groups from three main backgrounds: Semitic (Arabs and Jews), Indo-European (Persians and Kurdish) and Turkic (Turkish and Turkmens). Its geographic location, which has been under continuous influences from Asia, Europe and Africa, has made it an ideal site for epidemiological studies on *Helicobacter pylori* (*H. pylori*) infection and genotyping. The gastric cancer rate differs in this region from very high in Iran ($26.1/10^5$) to low in Israel ($12.5/10^5$) and very low in Egypt ($3.4/10^5$). Epidemiological studies showed that the prevalence of *H. pylori* is almost similar in those countries with a high level of infection in childhood. Importantly, the frequency of *vacA* s1 and m1 regions and *cagA*+ genotypes were higher in non Semitic populations who inhabit the North than Semitic populations, the inhabitants of Southern parts of the Middle East. *H. pylori* infection prevalence, distribution pattern of virulence factors, diet and smoking could not have explained the difference in cancer rate. This reflects the multifactorial aetiology of gastric cancer and suggests that *H. pylori* infection does not always directly correlate with the risk for gastrointestinal disease, such as gastric cancer. Further detailed investigations and international comparative studies of each risk factor need to be performed to investigate whether this represents a true enigma.

INTRODUCTION

Helicobacter pylori (*H. pylori*) causes gastritis and peptic ulceration and it is an important risk factor for gastric adenocarcinoma, the second highest cause of cancer deaths worldwide. The disease process is thought to have a multifactorial aetiology, and bacterial strain type, pattern of gastritis, and environmental conditions, are all thought to contribute[1]. *H. pylori* strains differ, and possession of specific virulence factors greatly increases the risk of disease. The best recognised of these are the cag pathogenicity island and active forms of the vacuolating cytotoxin (VacA). Duodenal ulcer promoting gene A (*dupA*) is a recently described gene shown to be associated with duodenal ulceration and protective against gastric cancer[2]. It was observed that the early acquisition of *H. pylori* infection in childhood resulted in pangastritis in adulthood. This pattern of gastritis is usually associated with mucosal atrophy which is a precancerous condition[3]. Therefore, acquiring the infection at an early age is a recognised risk factor for the development of

gastric cancer[4]. Additionally, antral predominant gastritis is usually associated with duodenal ulcer. Furthermore, different environmental factors such as high salt intake and inadequate consumption of fruit and vegetables containing vitamin C has been regarded as risk a factor for development of gastric cancer[5].

The Middle East is home to ethnic groups from three main backgrounds: Semitic (Arabs and Jews), Indo-European (Persians and Kurdish) and Turkic (Turkish and Turkmens)[6-8]. Its geographic location, which has been under continuous influences from Asia, Europe and Africa, has made it an ideal site for epidemiological studies on *H. pylori* infection and genotyping. The prevalence of *H. pylori* infection has been reported from many Middle Eastern countries, including Iraq, Iran, Turkey, Libya, Egypt, Israel, Bahrain, Oman, Saudi Arabia, and the United Arab Emirates. It has been shown that the prevalence rates of infection in these countries are almost similar to each other and to the reported prevalence from Europe and United States. However, gastric cancer and other *H. pylori* related diseases rates vary from very high in Iran to rare in Iraq and Egypt (Table 1)[9]. It is not known whether the difference is due to host, environment, or bacterial factors or a combination of these factors. In this review I tried to find a reason for the difference in *H. pylori* related diseases amongst Middle Eastern countries by discussing the prevalence of *H. pylori* and its virulence determinants, the pattern of gastritis, and environmental factors that might influence the disease process in the Middle East.

PREVALENCE OF *H. PYLORI*

The prevalence of *H. pylori* infection varies between countries; generally, the prevalence is about 30% in developed and up to 80% in developing countries[5]. Diagnosis of *H. pylori* can be achieved by taking biopsies by endoscopy. However, this procedure is invasive and might not give accurate results if colonisation is patchy[10]. Furthermore, it does not suit population based studies. For population screening, serodiagnosis remains one of the methods of choice for detecting the prevalence of infection[11]. Systemic humoral immunoglobulin G (IgG) immune responses to the organism are developed by humans infected with *H. pylori*[12-14]. Serological tests are useful tools for the diagnosis of *H. pylon* infection because all *H. pylori*-infected patients produce an antibody response which can be detected in the serum[14]. The technique of choice is currently enzyme-linked immunosorbent assay because it is a simple, quick, and low-cost technique that permits immunoglobulin class-specific determinations[14].

In a study conducted in Iraq, the prevalence varied in various ages (age: percentage, 6 mo: 0%; 6-24 mo: 27%; 2-18 years: 58%). In the same study, it was shown that 78% of adults were infected with *H. pylori* which was significantly higher than children. The prevalence of *H. pylori* increased markedly with age with the maximum colonization (81.5%) occurring in adults (40-60 years)[15]. The same scenario was found in Saudi Arabia, Iran, Libya and Israel. In Saudi, the prevalence of *H. pylori* infection markedly increased with age. The prevalence of *H. pylori* infection rose from 32.4% in those aged 0-10 years to more than 66.4% in those aged 20-30 years and 75% in those over 50 years[16]. In Iran, the prevalence of *H. pylori* infection increased with age [age (years): percentage, 6-10: 46%; 10-20: 50%; 20-30: 67%; 30-40: 80%; 40-50: 85%; 50-60: 84%; 60-70: 81%; over 70: 83%][17]. In Libya, overall prevalence was 67% with a steady increase with age [age (years): percentage, 0-10: 50%; 10-20: 84%; 20-30: 66%; 30-40: 80%; 40-50: 88%; 50-60: 83%; 60-70: 83%; over 70: 94%][18]. In a study conducted in Israeli rural communal settlements with an age range from 6 to 90 years[19], the prevalence *H. pylori* infection was shown to be 72%. It was also found that the prevalence of *H. pylori* increased with age [age (years): percentage, 6-10: 10%; 10-20: 39%; 30-40: 60%; 40-60: 70%; over 60: 85%]. In the same study, a significant association was shown between *H. pylori* infection and the country of origin of Israeli migrants. The highest prevalence (85%) was found in migrants from the Mediterranean and Asia. While 80% of East European migrants were *H. pylori* positive, the prevalence in West Europeans was 57%. The prevalence in people born in Israel was 66%. The association between *H. pylori* infection and country of origin was not changed after age adjustment[19].

In Turkey[20], the overall prevalence of *H. pylori* infection was 81%. There is no marked difference in *H. pylori* prevalence in different ages [age (years): percentage, 0-10: 70%; 10-20: 83%; 20-30: 77%; 30-40: 87%; 40-50: 88%; 50-60: 90%].

In some countries in the Middle East, the prevalence of *H. pylori* infection has been studied using polymerase chain reaction and histopathology. The prevalence of *H. pylori* infection in Jordan and Bahrain was 77.5% and 79%, respectively[21,22]. In Kuwait and Egypt, *H. pylori*, as detected by H and E and *H. pylori* special stains, was present in 84% and 86% of the biopsy samples, respectively[23,24]. There was no significant difference in the prevalence of infection between male and female subjects in this region. In a study conducted in Western Saudi, the prevalence of VacA and CagA were significantly elevated in males *vs* females[25]. In another study in Jordan, there was a clear trend that females were infected with less virulent *H. pylori* strains, though the correlation was not significant[22].

INCIDENCE OF GASTRIC CANCER IN THE MIDDLE EAST

Despite declining incidence rates in Western countries, gastric cancer remains the second most common cancer type and second cause of cancer-related death worldwide. *H. pylori* infection is strongly associated with gastric cancer risk. Gastric cancer rate varies from country to country and from region to region. For example, it is very high in Japan ($62.7/10^5$) and estimated to be 12 times higher than India[9]. Gastric cancer occurs nearly 7 times more frequently in Iran than in Iraq (Table 1). These data might not be very accurate because of incompetent di-

Table 1 Prevalence of atrophy, gastric cancer and the distribution of *vacA* allelic types and *cagA* status among *H. pylori* strains isolated in the Middle East

agnostic methods, limitation of medical services, and the lack of unique reporting systems. However, I searched through all published literature and could not find any major discordance. Despite the geographical proximity, the gastric cancer rate varies from very low in Iraq and Egypt to intermediate in Israel and Turkey to high in Iran (Table 1)[9,26-28]. Interestingly, *H. pylori* infection prevalence in these countries is relatively high and almost the same. This discordance between gastric cancer incidence and *H. pylori* seroprevalence might imply that *H. pylori* infection is not the only factor related to gastric cancer risk[29,30]. A 6-fold variation was found in the association between gastric cancer risk and *H. pylori* infection[31]. *H. pylori* virulence factors, immune response, diet, environment, and other factors should be considered.

BACTERIAL VIRULENCE FACTORS

Cytotoxin associated gene A

The cytotoxin associated gene A (CagA) protein, which is encoded by the *cagA* gene, is a highly immunogenic protein. *H. pylori* strains possessing *cagA* are associated with a significantly increased risk for the development of atrophic gastritis, peptic ulcer diseases and gastric cancer[32-36]. The *cagA* gene is situated at one end of a 40 kb DNA insertion called the *cag* PAI and may have been acquired from a non-*Helicobacter* origin[33,37]. The *cag* PAI contains approximately 30 genes which are multicistronic. The difference in the ability of *H. pylori* strains to trigger chemokines from gastric mucosa depends upon the expression of genes within the *cag* PAI[33,37,38].

Strains from Iraq, Turkey and Iran possessing *cagA* were found in 71%, 78% and 76% of the samples analysed, respectively. *cagA* presence was significantly associated with peptic ulcer disease incidence in Iraq and Turkey but not in Iran[39,40]. In Iraq, the majority of the population are Arabs. However in a study by Hussein *et al*[39], samples were collected from Kurdish majority (Kurdistan) region.

In Jordan, the *cagA* genotype was detected in 26.4%[22]. While Kuwaitis and other Arabian Gulf Arabs had essentially the same prevalence rate of about 41%, Egyptians had a modest positivity of 35.7%[23,41]. In a study conducted in Israel, *cagA* and *cagE* genes were present in only 25.5% and 24.5%, respectively[42]. The prevalence of *cagA* positivity in Saudi was 52%[43]. *cagA* was associated with gastric cancer and/or peptic ulceration in Iran, Iraq, Saudi, Turkey and Israel[39,42-45]. However, Hussein *et al*[39] could not find significant relationships between *cagA* status and disease risk in the Iranian population.

Argent *et al*[46], suggested that the presence or absence of *cagA* is not enough to understand the relationship between *cagA* and clinical outcomes. It was found that there was a size variation of the CagA protein and this variation was shown to be related to the presence of the repeat tyrosine phosphorylation motifs (TPM) sequences containing the EPIYA within the 3' variable ends[47]. It was found that *H. pylori* strains in Western and East Asian countries carry the EPIYA-A, EPIYA-B. While Western *H. pylori* strains carry Western *cagA*-specific EPIYA-C segments which vary in number ranging from 1-3[48], East Asian strains carry the CagA-specific EPIYA-D motif. We previously studied the TPM of the *cagA* in Iraq and Iran. The presence of *cagA* alleles with more than 3 phosphorylation motifs was significantly higher amongst Iranian strains than those from Iraq (there was no Iraqi *cagA*-positive strain with more than 3 TPM, 12% in Iran). We thought that the presence of *cagA* with more phosphorylation motifs in Iran may help explain the higher cancer incidence rate in Iran[39]. However, a recent study from Turkey, where the gastric cancer rate is much lower than Iran, found that 34% of *cagA*-positive Turkish strains carried more than three motifs. For the first time, in this study, they reported a *cagA* positive strain with 5 C motifs[49]. The absence of *cagA* with more than 3 motifs in Iraq can be due to a type 2 error.

There is clear discrimination in *cagA* distribution between Semitic (Arab and Jew) and non Semitic (Kurd, Turk and Persian) populations[39,40,50]. Semitic populations tend to carry less virulent *H. pylori*[22,23,41]. The *cagA* positivity in Saudi Arabia is higher than other Semitic countries. This might be due the fact that Saudi society has been influenced by Hajj.

VacA

The VacA is another *H. pylori* virulence factor[35]. Unlike *cagA*, almost all *H. pylori* strains posses the vacuolating cytotoxin gene (*vacA*). Vacuolating cytotoxin activity is related to the mosaic structure of *vacA*. In general, type s1/m1 and s1/m2 strains produce high and moderate levels of toxin activity, respectively, whereas s2/m2 strains produce no vacuolating activity[51]. A 12-amino-acid hydrophilic amino-terminal segment, present in type s2 but absent from type s1 *VacA* proteins, slows the capacity of *VacA* to form membrane channels and abolishes vacuolation.

Some type s1/m2 *VacA* toxins show cytotoxic activity toward selected cell types, including RK-13, but relatively little activity for HeLa or AGS cells[51-53]. Heterogeneity among *vacA* alleles may be an important factor in understanding variations in clinical manifestations among *H. pylori*-infected subjects. Several studies have demonstrated that gastric infection with *H. pylori* strains containing type s1 *vacA* alleles is associated with a higher risk for development of peptic ulcer disease than infection with strains containing type s2 *vacA* alleles[51]. This relation is not seen in East Asia as the vast majority of East Asian strains are *vacA* type s1[51,54-56]. Thus in these countries, s1 cannot be used as a marker for the presence of peptic ulcer disease because the prevalence of the s1 genotype is uniformly high.

Rhead *et al*[45] have described a novel determinant of VacA toxicity, called the intermediate or i-region. They showed that two allelic variants of this region existed, i1, and i2. Furthermore, only s1/m2 strains varied in i-type; s1/m1 and s2/m2 strains were exclusively i1 and i2, respectively. This novel region determines vacuolating activity among these s1/m2 strains. More importantly, a significant correlation has been established between the i1 region and gastric cancer[45]. In contrast to Rhead *et al*[45], no disease association between *vacA* i genotypes and outcome was found in East Asian and Southeast Asian countries. More studies, from other countries, are needed to determine whether this region is a true virulence determinant[57].

The studies from Turkey, Iran and Iraq (non-Semitic countries) had a high prevalence of *vacA* s1 genotype of more than 70%, whereas strains from Semitic countries such as Egypt, Jordan, Saudi Arabia, Kuwait and Israel, had a low prevalence of less than 60%. The prevalence of *vacA* s1 genotype in the non Semitic countries was significantly higher than that in the Semitic countries[41,58].

Reports from Turkey, Iraq and Iran showed that *vacA* m2 was found in around 70% of typed strains. In Egypt, Saudi and Israel, the percentage of *vacA* m2 was between 85% and 92%. 51.1% of Jordanian strains typed *vacA* m2. *vacA* i region was studied in Iran and Iraq only. *vacA* i1 was associated with gastric cancer and gastric ulcer in Iran and Iraq, respectively.

Studies from Iraq, Kuwait, Jordan, Israel and Iran did not show any association between *vacA* s and m genotypes and gastroduodenal diseases[22,23,39,42,59]. In Iraq, an association with gastroduodenal diseases and *vacA* i-region genotype was shown. Studies from Iran and Turkey[44,60] reported a significant relationship between *vacA* s1 genotype and peptic ulcers. The *vacA* m1 genotype was linked to an increased risk for peptic ulcers in Turkey and Saudi Arabia[61,62].

Studies from Iran, Iraq, Jordan, Turkey and Israel have shown a significant association between *cagA* status and *vacA* s1, m1 and/or i1 genotypes[22,39,42,44,45]. In *cagA*-negative strains, most of the *vacA* genotypes were i2 genotypes[58].

Other virulence factors

***dupA*:** Recently, a novel virulence factor *dupA* (duodenal ulcer promoting gene A) (jhp0917-jhp0918) was shown to be associated with duodenal ulceration and increased epithelial cell interleukin-8 secretion[2]. The *dupA* gene is located in the region of the bacterial genome that encodes surface proteins. A significant relationship between *dupA* and duodenal ulcer was found, and the presence of *dupA* was associated with neutrophil infiltration. These findings, however, were not confirmed in a study of Brazilian children and adults[63], thus indicating possible geographic differences. More recently, it has been found that *dupA* was not significantly associated with duodenal ulceration in populations from Belgium, South Africa, China, and the USA, but was significantly associated with gastric cancer development[64]. In the Middle East, *dupA* was studied in Iraq and Iran. *dupA* was found to be associated with duodenal ulcers in Iraq but not Iran[39]. In addition, *dupA*-negative *H. pylori* strains were found to associate with pre-malignant lesions in Iran[65]. No other studies have been conducted in the Middle East. More studies are needed to address the prevalence of *dupA*-negative strains and the association between this gene and clinical outcome.

***iceA*:** *iceA* (induced by contact with epithelium) exists in allelic variants including *iceA*1 and *iceA*2. *iceA*1 only can be induced in the gastric epithelium. The *iceA*1-positive *H. pylori* strains were shown to be associated with peptic ulceration and increased mucosal IL-8 secretion, while a higher prevalence of *iceA*2 strains was found among patients with non-ulcer dyspepsia[66,67]. In Turkey, *iceA*1 was found to be positive in 32.2% of the strains[68]. In Jordan, analyses of virulence genes revealed that *iceA*2 (73.6%) was the predominant genotype[22]. In a study conducted in Saudi, it was shown that all ulcer cases were infected with *iceA*1, while 94.6% of gastritis and 90.9% of normal subjects were infected with *iceA*2[43]. In Israel, *iceA1* was found in 37% and *iceA*2 in 52% of cases. Both *iceA* alleles were found in 11%[42]. More research is needed to study *iceA* and its association with diseases in this region.

HISTOPATHOLOGICAL CHANGES

All strains of *H. pylori* induce a marked inflammation in the gastric mucosa which is characterised by neutrophil, lymphocyte and other inflammatory cell infiltration. While antral-predominant gastritis leads to increased acid production from the uninflamed corpus and predisposes to duodenal ulceration, corpus-predominant gastritis leads to hypochlorhydria and predisposes to gastric ulceration and adenocarcinoma[3]. In studies conducted in Iraq, Turkey and UAE, it was found there is antral-predominant mononuclear cell infiltration[59,69,70]. In a study conducted in Iran, where the gastric cancer rate is very high, it was found that mononuclear cell infiltration was similar throughout the stomach; on average, patients had pangastritis[71].

Gradual loss of gastric glandular tissue as a consequence of long term mucosal destruction is called atrophic gastritis[3]. The tissue damage may involve progressive loss of all specific mucosal cells including the acid pro-

ducing parietal cells, pepsinogen producing chief cells and mucus producing gland cells. When these cell types have shrunk, the protective mucus layer will gradually disappear and acid secretion will cease[5]. Such pathological changes increase the risk of gastric ulceration and development of gastric adenocarcinoma[72]. However, this protects against duodenal ulcers because of low acid secretion[5]. In a study conducted in Turkey, histological evidence of mucosal atrophy was found in 43% of *H. pylori*-infected subjects[72] while in another study in Turkey atrophy was found in 75% of the subjects[73]. In UAE, gastric atrophy in *Helicobacter* associated gastritis was seen in 54% of cases[70]. In a study conducted in Iran, where the gastric cancer rate is much higher than Turkey, histological evidence of mucosal atrophy was found in 39% and 22% of antral and corpus biopsies, respectively[74]. In Iraq, glandular atrophy was found in only one (3%) specimen taken from the antrum. In Kuwait, *H. pylori* were found in 81.7% patients, of which 28.3% had atrophic gastritis and 15.1% intestinal metaplasia[75]. Atrophy was found in 65% and 54% of examined subjects in Jordan and Egypt, respectively[24,76] (Table 1).

In a study conducted in Saudi where a comparison of Sydney scores from younger and older patients was made, no significant differences were seen in the scores of *H. pylori* density, neutrophilic activity, or chronic inflammatory cell infiltration between the two groups. While intestinal metaplasia was not found in any young patient, 22% of older patients had focal metaplastic changes. The atrophic changes were seen in 19% of older patients and one (3%) younger patient[77].

In Turkey, while a significant relationship was found between *cagA* positivity and neutrophil activity and glandular atrophy in antral specimens, corpus neutrophil infiltration was found to be more severe in the *vacA* m1 group than in the v*acA* m2 group[59]. No association between virulence factors and histopathology was found in Iraq[69]. In Iran, *dupA*-negative strains were associated with premalignant histological changes[65].

In most of the studies conducted in the Middle East, histological changes seen in the antral sections (such as neutrophil infiltration of the lamina propria and the glands and the increase in the number of lymphocytes and plasma cells) were on average of mild scores.

DIET IN THE MIDDLE EAST

Diet pattern correlates with gastric diseases. Most populations in the Mediterranean region (including Middle Eastern populations) adhere to the Mediterranean dietary pattern. Mediterranean food has several common features including low consumption of meat and animal products, a high consumption of fish, vegetables, fruit, and cereal, and olive oil as the main source of fat. A Mediterranean diet, particularly olive oil, vegetable and fruit consumption, has been shown to be related to a low risk of cardiovascular disease and several cancers including upper gastrointestinal tract cancer[78,79]. Whole grain is also related to low risk of gastric cancer[78]. In contrast, intake of refined grains by some Mediterranean populations was associated with increased risk of stomach cancer[78]. Overall, the Mediterranean dietary pattern is associated with better health and protects against various chronic diseases. After revision of most recently published papers about diet and food in the Middle East, I did not find any significant differences in the diet pattern amongst the countries of this region[80,81].

Table 2 Smoking prevalence in different countries (%)

	Males	Females
Saudi: Male Adult (30-70 yr and older), 1996-2001	19.1	8.3
Kuwait: Adult, 1996	29.6	1.5
Italy: Adult (15 yr and older), 2002	31.1	22.3
Iraq: Adult (16 yr and older), 1990	40	5
Jordan: Adult, 1999	48	10
Japan: Adult (15 yr and older), 2002	51	10
Iran: Adult (15 yr and older), 1999-2000	22.2	2.1
Egypt: Adult (15 yr and older), 2000	40	18
Spain: Adult (16 yr and older), 2001	39.1	24.6
Turkey: Adult (20 yr and older), 1997-1998	50.9	10.9
Israel: Adult (25-64 yr and older), 1999-2001	38.6	22.1
Costa Rica: Adult (20-49 yr and older), 2001	29	9.7

SMOKING IN THE MIDDLE EAST

The association between smoking and increased risk of gastric cancer has been observed. In an epidemiological study conducted in Portugal it was shown that smoking is associated with gastric intestinal metaplasia[82]. In other studies, it was shown that tobacco can increase the risk of gastric cancer[83], and epidemiological evidence linking smoking and gastric cancer has been found[84]. The prevalence of smoking in Iraq where the gastric cancer rate is very low is twice as the prevalence in Iran where the gastric cancer is very high. On the other hand, the highest prevalence was found in Turkey[85]. The prevalence of smoking in other Middle Eastern countries can be seen in Table 2.

GENERAL CONSIDERATIONS

H. pylori is a causative agent of peptic ulcer disease and an important risk factor of gastric cancer. Despite the high *H. pylori* infection rate in Middle Eastern countries, gastric cancer incidence is low in all countries but Iran. Previous reports have shown that the age of patients at the onset of infection may help predict the disease development process as the early acquisition of infection carries more risk of disease development. As shown above, *H. pylori* infection is acquired early in life in this region. In spite of this, the cancer rate is low.

In the Middle East, the populations can ethnically be divided into two main groups: Semitic populations (Arab and Jew who are southern region inhabitants) and non Semitic populations (Kurd, Turk, and Persian who are northern region inhabitants).

The prevalence of virulence factors in countries inhabited by non Semitic populations (Turkey, Iran and Iraq) is similar to what was found in South Asian and

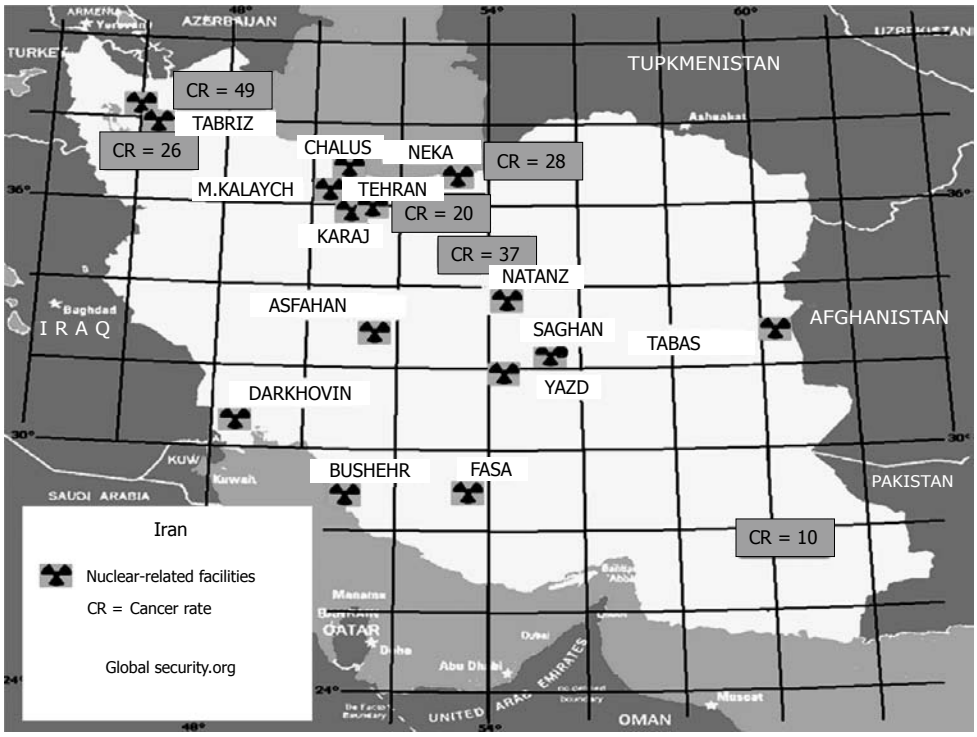

Figure 1 Map showing Iran's nuclear sites and annual incidence of gastric cancer in Iran reported from different cancer registries presented as male age standardized rate per 100 000.

Europe[41] and significantly more than what was found in countries with a Semitic background. This might be because populations which lived in the northern part of the Middle East near Europe and south Asia might correlate with European and south Asian populations. Additionally, this provides more evidence of the ethnical tropism of *H. pylori* infection. It is noticed that virulence factor rates in Saudi *H. pylori* are higher than other Arabic countries. This might be due the fact that Saudi society has been an open society due to continued population movement into this region to perform pilgrimage (Hajj).

Graham *et al*[86] suggested a better strategy for the explanation of the relationship between *H. pylori* and diseases by focusing on underlying patterns of gastritis. This, to a certain extent, is true in this region because all histopathology reports have shown that antral predominant gastritis is the main pattern of gastritis in this region apart from Iran where corpus or pan gastritis is the main pattern. However, if atrophic gastritis, which is precancerous and shown to be associated with cancer, is considered, the high cancer rate in Iran cannot be explained because atrophic gastritis is very high in Turkey, Jordan, UAE, and Egypt with much lower cancer rates. Yet another question to be answered: why this difference in gastritis pattern? Previous reports have blamed environmental factors and diet. For the sake of argument, one would accept the blame but which environmental factor can play such a role in a region which has almost the same environment and traditions. Moreover, as seen above, most Mediterranean countries (including Middle Eastern and South European countries) adhere to a Mediterranean diet pattern and neither diet pattern nor smoking rates seem to explain the difference in cancer rate. The only difference, however, that can be found between Iran and other countries (apart from Israel) is the presence of nuclear facilities in Iran. Examining the map of Iran's nuclear sites, Iranian uranium mines, nuclear reactors, and uranium processing facilities that include three known uranium enrichment plants can be found in Iran's most populous urban areas especially in the northwest and central region where there is a very high gastric cancer rate (Figure 1)[87]. On the other hand, there is no nuclear facility in the southeast where the gastric cancer rate is similar to that found in neighboring countries[87]. In Israel, these facilities are in the desert and relatively isolated areas. But if the theory of the relationship between those facilities and cancer is true, one would expect high rates of other cancers in Iran and this is not true[28].

Host genetics play an essential role in the inflammatory process and in the interactions between the host and *H. pylori* (see review by Kusters *et al*[88]). It has been shown that proinflammatory genetic polymorphisms tend to increase the risk of development of gastric cancer. Hence, would the genetic make-up explain the dilemma of cancer rate in this region? Proinflammatory host genetic facilitates gastric cancer through the development of hypochlorhydric and atrophic gastritis which has been studied and could not have explained the difference in cancer rate. Graham *et al*[86], suggested that host genetics affect individuals and generally cannot explain widespread changes. In addition, the genetic markers we have at present are not sensitive or specific enough to form the basis of a screening strategy[89]. According to Canedo *et al*[89], any genetic association studies should fulfil specific criteria among which there should be no evidence of population admixture. This criterion is almost impossible to fulfil in this region. When looking back through history, you will find that Indo-European races (Kurd and Iranian) are not indigenous. In addition, after the rise of Islam and the Arab conquest of the surrounding countries, there was much

intermixture between Indo-European and Semitic populations. Further evidence for this intermixture is that in a study of human genetics, a close relatedness of Semitic and Indo-Europeans with each other and with neighbouring geographic groups was shown. In the same study it was shown that Semitic North African groups are more distant genetically from Semitic-speaking groups from the Near East and Iran[90]. Hence, avoiding a mixed population is insuperable in this region. However, this does not negate the importance of the host genetic analyses of cytokine polymorphisms affecting mucosal inflammation and gastric acid secretion. Carefully planned projects would provide additional information to identify predictive markers for an individual's risk for gastric atrophy and malignancy.

CONCLUSION

To conclude, there is unexplained variation in the distribution of virulence factors and gastritis patterns in the Middle East. These variations fail to explain the discordance between *H. pylori* infection rates and the variations in gastric cancer prevalence. Although detailed studies are needed to investigate dietary pattern, generally diet is unlikely to contribute because all the countries are following the same Mediterranean pattern. Smoking rates could not explain the variation in cancer rates as we have seen countries with a very high smoking rate but low cancer rate. This might indicate the presence of an enigma similar to or part of that reported (controversially) in Africa and Asia[91,92]. Further detailed investigations and international comparative studies of each risk factor need to be performed to investigate whether this phenomenon represents a true enigma.

Abstract

The two-layer cold storage method (TLM) was first reported in 1988, consisting of a perfluorochemical (PFC) and initially Euro-Collins' solution, which was later replaced by University of Wisconsin solution (UW). PFC is a biologically inert liquid and acts as an oxygen-supplying agent. A pancreas preserved using the TLM is oxygenated through the PFC and substrates are supplied by the UW solution. This allows the pancreas preserved using the TLM to generate adenosine triphosphate during storage, prolonging the preservation time. In a canine model, the TLM was shown to repair and resuscitate warm ischemically damaged pancreata during preservation, improve pancreas graft survival after transplantation, and also improve the islet yield after isolation. Clinical trials using the TLM in pancreas preservation before whole-pancreas transplantation and islet isolation have shown promising outcomes. We describe the role of the TLM in pancreas and islet transplantation.

Key words: Two-layer method; Pancreas preservation; Pancreas transplantation; Islet transplantation; Perfluorochemical

INTRODUCTION

Successful transplantation depends on multiple factors including the prevention of preservation injuries incurred by cold storage and reperfusion[1,2]. A shortage of donor organs has an impact on the development of preservation methods. We developed the two-layer cold storage method (TLM) using perfluorochemicals (PFC) to reduce ischemic injury and maintain cellular integrity during preservation.

In 1966, it was reported that mice could breathe and survive in oxygen-saturated PFC[3]. PFC is a hydrocarbon, comprising a colorless and odorless solution with specific gravity approximately twice that of water. The most interesting property of PFC is a very high capacity for dissolving respiratory and other nonpolar gases[4]. A negligible O_2-binding constant of PFC allows them to release O_2 more effectively than hemoglobin into the surrounding tissue. As a result of this unique property, PFC-based solutions have been examined as oxygen carriers for blood substitutes, myocardial protection, respiratory support[4], and organ preservation before transplantation[5].

In this editorial, the role of the TLM in pancreas and islet transplantation is discussed.

DEVELOPMENT OF TWO-LAYER COLD STORAGE METHOD

The TLM was first reported in 1988 at Kobe University as a pancreas cold storage method[5]. The TLM first consisted of a PFC and initially Euro-Collins' solution (EC), which was later replaced by University of Wiscon-

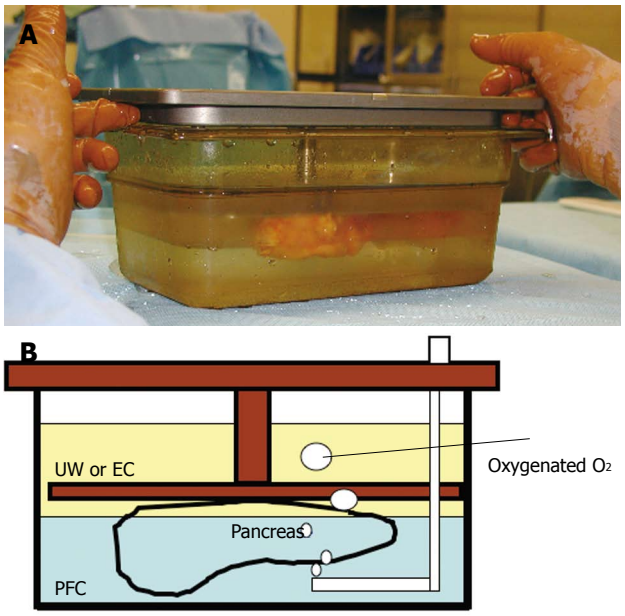

Figure 1 The two-layer method. The pancreas graft is surrounded by UW or EC and floated on the oxygenated PFC. A: The photograph; B: The schema. UW: University of Wisconsin solution; EC: Euro-Collin's solution; PFC: Perfluorochemical.

sin solution (UW)[6]. Because the PFC is lipophilic and has a high density, the PFC and EC or UW separate into layers. This allows for the pancreas graft to float on the oxygenated PFC surrounded by EC or UW (Figure 1).

Before UW was developed, EC was the standard solution for pancreas preservation before whole-pancreas transplantation. EC could preserve human pancreata for up to 10 h[7] and canine pancreata for up to 24 h[5]. The original TLM (EC/ PFC) could preserve canine pancreata for up to 72 h[5]. UW solution could preserve canine pancreata for up to 72 h[6], and the modified TLM (UW/ PFC) could preserve canine pancreata for up to 96 h[6]. Although PFC alone may provide an excellent preservation solution, this solution only preserved canine pancreata for 48 h[8]. Despite evidence for the superiority of the TLM, simple cold storage using UW has become the standard organ preservation method in clinical pancreas transplantation. This is likely to be because UW effectively preserves human pancreata for more than 24 h and the TLM is relatively more complicated compared with UW cold storage.

MECHANISM OF THE TWO-LAYER METHOD

The TLM reduced cold ischemic[6], warm ischemic[9], rewarming ischemic[10], and reperfusion[11] injuries in pancreas and islet transplantation. The mechanisms of the TLM have been vigorously examined using experimental transplantation models. During preservation by the TLM, the pancreas is directly oxygenated through PFC and maintains an oxygen tension at about 60% of the normal physiologic level[12].

During ischemia, tissue adenosine triphosphate (ATP) degrades to hypoxanthine following an increase of xanthine oxidase. Next, reactive oxygen radicals are generated and involved in a complex interaction of immediate cellular damage in ischemia-reperfusion injury[13,14]. On the other hand, tissue ATP is maintained in grafts preserved by the two-layer method and is rapidly recovered after reperfusion, which may be a better prophylaxis and treatment for the first step of ischemia-reperfusion injuries. During preservation by the TLM, pancreas grafts continuously generate ATP for up to 96 h[6]. ATP levels are also enhanced in human pancreas stored using the TLM. This proves the ability of the TLM to oxygenate human pancreas[15,16]. The ATP generated is used to drive a sodium-potassium pump to maintain cell integrity; thus, the TLM prevents pancreas swelling more effectively than UW solution[17]. Furthermore, the TLM improves the viability of the vascular endothelium and microcirculation[18]. Although the mechanisms involved in reducing ischemic reperfusion injury are unclear, one possibility is the induction of heat shock proteins during preservation[11]. ATP is essential for protein synthesis, and we demonstrated that protein synthesis was likely to be involved in the process of postischemic cellular recovery during preservation by the two-layer method[11,19]. These heat shock proteins may work to provide an anti-reperfusion or cell repair property.

The TLM also has an excellent ability to resuscitate pancreas grafts that have suffered from warm ischemic injury and to prolong the preservation time of ischemically damaged pancreata[20]. After 90 min of warm ischemic injury, the canine pancreas grafts lost ATP and were no longer viable. However, when the damaged pancreata were preserved and resuscitated by the TLM for 24 to 48 h at 4℃, the grafts regained tissue ATP and became viable[19]. The resuscitation effect is associated with active protein synthesis, suggesting active cell repair, and may involve heat shock proteins[19]. This suggested the possibility of pancreas transplantation from ischemically damaged or non-heart-beating donors.

Resuscitation by the TLM before pancreas transplantation correlates with the pancreatic tissue ATP levels after the TLM[21]. This is important because it predicts the outcomes of marginal donor grafts before transplantation. Recently, the TLM has shown promise in small intestine[22] and heart preservation[23].

PANCREAS PRESERVATION BEFORE ISLET ISOLATION

The most common exclusion criteria of pancreata for islet isolation are an unstable blood pressure, significant downtime, and high-level vasopressor usage for donor management. All of these criteria are related to warm ischemic injury and can be alleviated using the TLM; thus, the TLM could potentially make the majority of the donor pancreata usable for islet isolation.

Tanioka *et al*[24] first reported islet isolation after preservation by the TLM in a canine pancreas model. After

24 h storage of the canine pancreas in UW solution, islet yields were significantly decreased and the posttransplant outcome was further deteriorated. However, after 24 h of preservation by the TLM, the islet yield and posttransplant outcome were essentially equal to the immediate isolation.

After 60 min of warm ischemia, the islet yield after islet isolation was significantly decreased compared with the islet yield from the pancreas without warm ischemia[25]. When pancreata ischemically damaged for 60 min were preserved using the TLM for 24 h, the level of islet yield became similar to that from pancreata without warm ischemia[26]. Tanaka *et al*[27] also demonstrated that pancreata damaged on 30 min warm ischemia were restored by 3 h TLM preservation. The TLM may facilitate the selective use of non-heart-beating donors as an alternative source for islet transplantation.

In the rat model, the TLM for pancreas preservation prior to islet isolation resulted in an excellent islet function in addition to improved islet yield, which was almost comparable to freshly isolated islets[28].

At the University of Alberta (Edmonton, Canada), it was observed that seven of seven patients with type 1 diabetes receiving allogeneic islet transplants became insulin independent[29]. Two major drawbacks of the Edmonton protocol are that it requires pancreata to have short preservation periods before islet isolation, and almost always requires two or more donor pancreata to cure one diabetic patient.

On the basis of these data, Matsumoto *et al*[30] examined the effect of the TLM on the pancreas before islet isolation using preclinical, nonhuman primate pancreata and human pancreata. In the primate model, storing pancreata in UW solution for 5 h yielded a similar islet number, viability, and *in vitro* function compared with immediate isolation. However, 5 h of TLM preservation significantly increased the islet yield, viability, and *in vitro* function. They also suggested that the TLM maintains or repairs exocrine cell integrity and prevents trypsin activation, which enables effective collagenase delivery and protects islets from enzymatic digestion.

Zhang *et al*[31] also demonstrated that the islet yield from pancreata preserved using the TLM was more than that from pancreata stored in UW solution. Islet viability was significantly higher with the TLM *vs* UW solution. This experiment confirmed the superiority of the TLM-based preservation of pancreata for human islet isolation compared with UW solution. Although the beneficial effect of the TLM is controversial, the overall performance of the TLM could improve the outcome of islet isolation and transplantation[32].

CLINICAL APPLICATION OF THE TWO-LAYER METHOD

The TLM was clinically employed for pancreas transplantation at the University of Minnesota for the first time in 1999[33]. In this first clinical trial involving 10 cases, the TLM had no adverse effect on the recipients after transplantation. Furthermore, the morphologic quality of the human pancreas grafts after reperfusion was excellent compared with the pancreata stored in UW solution. There was no episode of acute rejection of pancreata preserved using the TLM. This is interesting because the immunosuppressive property of PFCs was one of the reasons not to use them as a blood substitute[34]. This immunosuppressive property could be beneficial for allogeneic organ preservation, and the role is under investigation.

Pancreas preservation using the TLM before islet isolation for clinical islet transplantation began at the University of Minnesota[35]. Hering *et al*[35] reported the cure of four patients with islets from a single donor. In this report, cadaver pancreata were subjected to the TLM immediately after retrieval at the procurement site without UW solution storage before islet isolation. Their islet yield was sufficient to cure one patient from one donor. Their experiment suggests that pancreata should be preserved by the TLM immediately at the time of procurement.

CONCLUSION

Irrespective of these promising data, the role of the TLM requires further investigation in pancreas and islet transplantation.

Abstract

Interstitial cells of Cajal (ICC) are important players in the symphony of gut motility. They have a very significant physiological role orchestrating the normal peristaltic activity of the digestive system. They are the pacemaker cells in gastrointestinal (GI) muscles. Absence, reduction in number or altered integrity of the ICC network may have a dramatic effect on GI system motility. More understanding of ICC physiology will foster advances in physiology of gut motility which will help in a future breakthrough in the pharmacological interventions to restore normal motor function of GI tract. This mini review describes what is known about the physiologic function and role of ICCs in GI system motility and in a variety of GI system motility disorders.

Key words: Interstitial cells of Cajal; Gastrointestinal motility; Peristalsis

INTRODUCTION

Physiology of gut motility has been always a fascinating chapter in gastroenterology. It poses interesting challenges to physiologists. Our understanding of basic gut motility processes is advancing; a major emphasis is placed on elucidating gut regulatory mechanisms. A better appreciation of the importance of the presence of normal function of interstitial cells of Cajal (ICC) transformed this field of research. In 1893, Spanish Nobel Laureate physician and neuropathologist Santiago Ramon y Cajal, was the first to describe cells that are located between the nerve endings and smooth muscle cells in the gastrointestinal (GI) tract. Their location prompted him to call them "interstitial". They are now known as the ICC.

ICC may be considered to be a specialized population of smooth muscle cells. Both arise from common mesenchymal cells[1-3]. However, whereas smooth muscle cells develop an extensive array of contractile elements, ICC have few contractile elements but contain large numbers of mitochondria, an abundance of endoplasmic reticulum and distinct sets of channels in their membrane. The ICC consist of a fusiform cell body with a thin cytoplasm, a large oval nucleus and dendritic-like processes[4]. Two to five primary dendritic processes divide further into secondary and tertiary processes[5]. Many ICC express Kit, a tyrosine kinase receptor (Kit-ir); this allows them to be recognized by their ability to bind antibodies to Kit[4]. Similarly ICC readily react with

antibodies to vimentin whereas nearby smooth muscle cells do not[6]. The presence of ICC is not restricted to the GI tract. They can be found in the bladder[7,8], the ureteropelvic junction[9], the vas deferens[10], the prostate[11], the penis[12,13], the mammary gland, the uterus[14], the pancreas[15], blood vessels[16] such as the portal vein[17] and the vagina[18]. More recently, they have been found in the vermiform appendix in childhood[19]. Some of these cells are thought to have a pacemaker function (such as those in the portal vein, in the lymphatics or prostate) but not those in the arteries, uterus (where the influence is, if any, an inhibitory one) or bladder[20].

The motor activity of the GI tract is critical for life[21]. It is a complex process involving multiple cell types such as enteric neurons that can sense the contents of the GI tract, integrate information and devise a suitable motor pattern, ICC that transduce inputs from enteric motor neurons and generate intrinsic electrical rhythmicity, and smooth muscle cells that can interpret and integrate large arrays of inputs and develop appropriate responses[22]. ICC are a minor component of the tunica muscularis of the GI tract (only about 5% of cells present[23]); however, these cells have very significant physiological roles in GI motility[22].

Many tissues, isolated from different regions of the GI tract, contract rhythmically in the absence of neuronal or hormonal stimulation. When contractions and membrane potential are recorded simultaneously each contraction is seen to be triggered by a long lasting wave of depolarization: because of their low frequency of occurrence and long duration, the waves of depolarization have been termed slow waves[24]. The origin and basis of the generation of slow waves have been debated for many years. It was initially thought that the generation of slow waves reflected some properties of GI smooth muscle cells[25,26], but studies on isolated smooth muscle cells have consistently failed to demonstrate a capability to generate slow wave activity[27]. It has also long been recognized that the generation of slow waves does not rely on the sequential activation of voltage-dependent ion channels as do cardiac pacemaker cells. Rather, many early studies raised the possibility that rhythmical activity relied on the cycling of one or more metabolic processes within cells of the gut wall. Thus Conner and his colleagues proposed that the generation of slow waves involved changes in the activity of the sodium pump[25].

Subsequently Nakayama *et al*[28] suggested an involvement of glycolytic pathways, again assuming that pace making activity originated in smooth muscle cells. Although ICC were first described in the intestine a century ago by Cajal, they were long viewed as an oddity. Their role in the generation of pacemaker activity in the GI tract was suggested on the basis of histological studies[29]. More recently, studies on mutants that lack subpopulations of ICC revealed their role in the generation of rhythmicity[30].

Critically, whereas isolated smooth muscle cells rarely generate spontaneous electrical activity[27], isolated ICC invariably do[31,32].

STRUCTURAL ORGANIZATION AND IDENTIFICATION OF SPECIFIC POPULATIONS OF ICC

The discovery that ICC express *c-Kit*, the proto-oncogene that encodes the receptor tyrosine kinase Kit has offered a simple and reliable immunohistochemical method for determining the structure and distribution of ICC networks[30]. ICC are found throughout the GI tract from the esophagus to the internal anal sphincter[33,34]. Hanani *et al*[35] mentioned that while it is becoming clear that more than one type of ICC exists, based on both morphological and functional data, we still subdivide ICC based on location. Furthermore, Farrugia[36] emphasized the importance of revisiting a classification based solely on location and move towards a classification that is based on function, suggesting a reasonable start, to subdivide ICC into those that have the machinery to, and generate, unitary potential and slow waves and those that do not. Morphological studies now supported by some functional evidence suggest that at least three separate functional groups of ICC exist. In most regions of the GI tract, a network of ICC are located within the intermuscular space at the level of the myenteric plexus (ICC-MY) between the circular and longitudinal muscle layers. ICC-MY are the pacemaker cells in the stomach and small intestine that trigger the generation of slow waves in the tunica muscularis[37].

A second population of ICC (referred to as intramuscular ICC or ICC-IM) are found within the muscle layers of the GI tract and are innervated preferentially by enteric motor nerves[37]. ICC-IM are closely associated with not only enteric motor nerves but also vagal afferent nerves. Vagal afferent nerve fibers, labeled by the injection of neural tracers into the nodose ganglia, can terminate as intramuscular arrays within the musculature and as intraganglionic laminar ending within the myenteric ganglion of the stomach and duodenum. These afferent fibers transmit mechanoreceptive information from the muscle wall[38,39]. Horiguchi *et al*[40] gave histological evidence that a third population of ICC, ICC-SEP, lies within the septa between the circular muscle bundles, and suggested that it may play a role in conducting electrical information from ICC-MY deep into the distant circular muscle bundles, Figure 1 showing functional organization of ICC in the canine gastric antrum[41].

Electrophysiological data are presented which indicate that when the normal pathway from ICC-MY is sectioned, electrical stimulation of the cut ends of the muscle bundles can initiate slow waves over considerable distances. In the absence of stimulation, the muscle bundles isolated from ICC-MY can generate rhythmical activity but do so at low frequencies. Thus a distinct population of ICC, ICC-SEP, exists which can transfer pacemaker depolarization from ICC-MY deep into the distant bundles of circular muscle. Although ICC-SEP have the potential to generate pacemaker activity they are not normally the dominant pacemaker centre. As an analogy with the

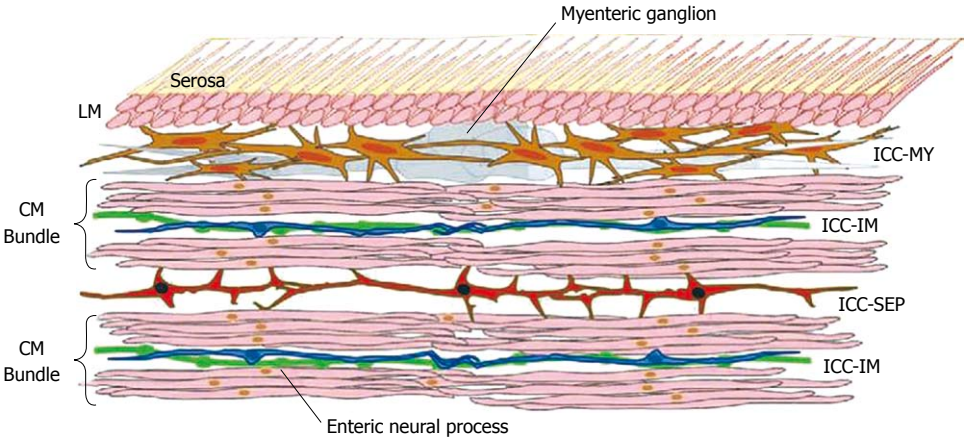

Figure 1 Diagram showing functional organization of ICC in the canine gastric antrum[41]. ICC: Interstitial cells of Cajal.

generation of pacemaker activity in the heart, the plexus of ICC-MY, like the sino-atrial node, is the dominant pacemaker centre. ICC-SEP, like Purkinje fibers, have the potential to generate pacemaker activity, but normally function to convey electrical activity from the dominant pacemaker region to more distant tissues[41].

PHYSIOLOGICAL FUNCTIONS OF ICC

Peristaltic motor activity is a motor pattern orchestrated by complex sequencing of neural excitation and inhibition in cooperation with intrinsic muscular control mechanisms, including those residing in ICC[42]. Peristalsis is defined as waves of contraction propagating along the GI tract for various distances as a means of mixing and propelling its content distally. Both the type of neural activity and the type of intrinsic myogenic control mechanism differ widely throughout the GI tract[42]. Physiological activation of peristalsis will in most cases involve the stretching of a segment of stomach, intestine, or colon and it will occur by neural pathways that contain additional mechanisms to those required for the ascending excitatory reflex[43]. When peristaltic motor activity occurs, in particular in stomach and proximal small intestine, the waves of contraction always have rhythmicity to it. This rhythmicity is determined by electrical slow wave activity in the musculature, referred to as pace maker activity[44].

New reagents, coupled with immunohistochemical techniques and new electrophysiological experimental approaches opened the door to recent progress in identification of the important roles of ICC as pacemakers, in propagation of slow waves and as mediators of inputs from enteric motor neurons[45]. Other functions, such as mechanosensors have also been proposed, but little physiological evidence supporting this function has been published[45].

Laboratory approaches used for ICC study

Isolated ICC have been examined using conventional patch clamp recording techniques. This approach, which has been applied to ICC-MY, allows a description of the specific populations of ion channels present in their membrane[31,32,46] and an analysis of the cellular mechanisms which regulate the channels[47,48]. Simple intracellular recording from smooth muscle cells in isolated segments of GI tissues and isolated segments of urethra, after blocking smooth muscle L-type Ca^{2+} channels, record primarily the activity of the ICC in the tissues. The properties of ICC-MY can be determined *in situ* using sharp electrodes, allowing one to monitor the behavior of populations of interconnected ICC-MY and to determine how pacemaker potentials generate signals in adjacent smooth muscle layers[47,49,50]. A third method used to study the properties of ICC IM involves recording from small isolated segments of circular muscles; if dissected appropriately the preparations are isopotential and contain up to 2000 smooth muscle cells linked to up to 200 ICC-IM. The membrane potential of both smooth muscle cells and ICC-IM, can be varied over a limited range and the effects of nerve stimulation can be analyzed[51-53]. Finally, the use of mutant mice in which specific sets of ICC are either absent of dramatically reduced in numbers has allowed an evaluation of the physiological properties of tissues, with and without different sets of ICC[24].

PATHOPHYSIOLOGY OF ICCs

Many GI motor disorders can be related to changes in number and/or structure and/or density of ICCs[54-57]. These changes can be primary, due to toxin substances, neurotoxins or viral diseases, or secondary as a consequence of neural damage, degraded tissue or treatment effect[54,58].

An absence or reduction in the number of ICCs causes abnormal electrical slow waves causing a decreased contractility of smooth muscle cells resulting in a diminished intestinal transit[56]. Although the density decreases, the slow wave is still present in most affected patients but the frequency and duration are prolonged[54].

COMMON GI MOTILITY PROBLEMS

ICC in the human esophagus and cardia

ICC in human esophagus has a myoid ultrastructure with abundant smooth endoplasmic reticulum, numerous mitochondria, intermediate filaments, scattered caveolae, and discontinuous basal lamina. They are most frequent in the esophageal part of the lower esophageal sphincter (LES)

but rare in the gastric part. They are in close contact with nerve terminals and make specific junctions with smooth muscle cells[59,60].

Achalasia: Achalasia is a disorder of esophageal motility that has been well documented for over 300 years[61]. Achalasia is characterized by relaxation failure of the LES and lack of peristaltic contraction of the esophageal body[62]. The mechanism of LES relaxation is complex, requiring the coordinated interaction of nerves, smooth muscle, ICC and hormones. The LES is a functional and anatomic barrier between the stomach and esophagus. It consists of a thickening of the circular smooth muscle layer of the esophagus at the gastroesophageal junction. It is anatomically asymmetric, and this is reflected in the physiology of the sphincter as demonstrated by ultrasound and pharmacologic manometric studies[63]. The LES is tonically contracted. Initiation of a peristaltic wave in the esophagus is accompanied by a decrease in LES pressure as a result of smooth muscle relaxation. This allows the swallowed bolus to enter the stomach[61].

ICC involvement in achalasia is debated. Electron microscope studies of the muscle coat of the LES in seven patients with achalasia showed that muscle wall components (nerve endings, smooth muscle cells, ICC and connective tissue) were modified. ICC ultrastructure was altered, namely clear cytoplasm, fewer mitochondria, and scarce smooth endoplasmic reticulum[64].

A reduced number of contacts between nerves and ICC were reported. Specific changes in smooth muscle cells were also documented, whereas the nerve endings had abnormal ultrastructure. Alterations in older patients were more pronounced[65]. Since the LES components specifically altered in achalasia are the nerve endings and ICC, they are regarded as principally responsible for abnormal motility[65].

Achalasia is uncommon among the pediatric population. It is usually sporadic and affects mainly teenagers[66]. A rare familial form combining early onset achalasia of cardia, alacrymia (absence of tears), and ACTH insensitivity, are known as Allgrove's syndrome[67,68] or "Triple A" syndrome[69]. These forms are inherited on the autosomal recessive mode[70]. Massive loss of neural elements and neuronal nitric oxide synthase as well as a marked fibrotic process of the muscle layers of the cardia have been observed in "Triple A" syndrome[71]. ICC in the cardia are also markedly diminished or are completely absent while ICC (and neural structures) are preserved in the pylorus[59].

Gastroesophageal reflux: Gastroesophageal reflux (GERD) is a common condition and its prevalence varies in different parts of the World[72]. Typical symptoms of heartburn and acid regurgitation are encountered in 15%-20% of the general population[62]. The major mechanism for GERD is transient relaxation of the LES[73]. The role of the ICC in inhibitory transmission in the LES is still being discussed[62].

In W/Wv mutant mice (lack of ICC) LES pressure was lower than wild-type mice but a normal swallow still induced LES relaxation, arguing against the role of ICC in inhibitory transmission[74]. Another study demonstrated that in W/Wv animals, cholinergic and nitrergic neurotransmission is greatly reduced pleading for the role of ICC in mediating neural inputs[37]. However, enteric neurons, varicose processes, and the ability to release neurotransmitters are not reduced, and smooth muscle cells demonstrate responsiveness to exogenous transmitters[37].

Loss of ICC during development or in pathologic conditions would significantly compromise the ability of GI muscles to generate typical motor reflexes[75].

Esophagitis itself may be at the origin of an alteration of normal function of the Cajal cells: in advanced stages of GERD, inflammatory changes in the esophageal wall will also involve the ICC. That way, the more severe the esophagitis, the more severe is the ICC impairment. This destruction leads to loss of effective contraction of esophagus, maintaining reflux and thus aggravating the symptoms[76].

ICC in the human stomach and pylorus

Gastroparesis: The pathogenesis of gastroparesis is complicated and poorly understood. This lack of understanding remains a major impediment to the development of effective therapies for this condition. Most of the scientific information available on the pathogenesis of gastroparesis has been derived from experimental studies of diabetes in animals. These studies suggest that the disease process can affect nerves (particularly those producing nitric oxide, but also the vagus nerve), ICC and smooth muscle[77]. It is broadly defined as disordered gastric emptying, and is a commonly encountered clinical problem[78]. Delayed gastric emptying can be secondary to muscular, neural, humoral causes or use of anticholinergic and opiate medicines. In the absence of an identified cause, gastroparesis is termed as idiopathic[79]. Gastroparesis has a broad range of clinical presentations ranging from dyspeptic symptoms to nausea, vomiting, abdominal pain, malnutrition, frequent hospitalizations and incapacitation[80], chronic abdominal pain and vomiting leading to dehydration, electrolyte imbalance, nutritional impairment and weight loss[81].

The ICC are fundamental in the generation of gastric slow waves[79]. A decrease in ICC density ranging from 60%-100% depending on the area investigated was demonstrated in histologic studies of the stomach of type 1 diabetic patients[55]. The number of immunopositive cells for c-kit was significantly decreased in the corpus and antrum of the gastroparesis patients compared with control tissues[62]. The loss of intramuscular ICC and associated nerves in the gastric fundus could explain the low basal gastric tone and increased compliance of the stomach. The hypomotility of the antrum can also be explained by the absence of slow wave generation by the ICC[23].

Infantile hypertrophic pyloric stenosis: Infantile hy-

pertrophic pyloric stenosis (IHPS) is common in infants, characterized by marked delayed gastric emptying and hypertrophy of the inner (circular) muscle layer of the pylorus[59]. IHPS has been known for more than a century[82] but it remains a puzzling disorder[83]. The genetic susceptibility to development of IHPS seems to be multifactorial[84]. Hypertrophy of the pyloric musculature develops after birth[85] and produces the characteristic palpable pyloric "olive." The pyloric lumen is however not fully occluded[86] and can be intubated relatively easily[87], suggesting that the obstruction of the gastric outlet in IHPS is not merely due to a mechanical obstruction by the hypertrophied musculature. The extent of muscle hypertrophy appeared to be unrelated to the age or duration of symptoms[88].

Various neurotransmitters[89-91] and the neuronal isoform of NO synthase[92] are reduced or lacking in the hypertrophic musculature. The increased thickness of the pyloric muscular coats appears to be due to hypertrophy, rather than to hyperplasia, of the smooth muscle cells[93]. ICC, identified either by electron microscopy[94] or by Kit-ir[95,96] were consistently lacking in the hypertrophic circular muscle layer. However, Kit-ir cells, similar to Kit-ir ICC observed in controls, were observed in the innermost part of the hypertrophic pylorus and in the antrum, indicating that the lack of Kit-ir is restricted to the hypertophic pyloric musculature[95].

The lack of ICC in IHPS may interfere with the propagation of slow waves and may be, at least partly, involved in antro-pyloric incoordination[59]. Homozygous transgenic mice carrying inactivated genes ("knock-out") coding for the neuronal NO synthase developed hypertrophy of the pylorus[97]. The link between the lack of ICC, the lack of inhibitory nitrergic neurotransmission, and the hypertrophy of the smooth musculature in IHPS remains to be elucidated[59].

Small intestine and colon

Hirschsprung's disease: Hirschsprung's disease (HD) is characterized by the lack of intrinsic enteric nervous system (ENS) in the distal part of the GI tract ("aganglionosis"). The affected segment extends cranially from the anus and encompasses a variable portion of the gut. Functionally, the lack of propulsive movements may lead either to an early obstructive syndrome in infancy or to a severe constipation[98]. Lack of slow wave activity in the aganglionic segment has been identified[99]. Kit immunohistochemistry identified ICC in HD. However, the cellular density of Kit+ ICC appeared markedly reduced in the aganglionic segment[100]. ICC-MP were rather abundant in the (aganglionic) space between the muscle layers. Kit+ ICC were specially scarce in the inner part of the circular musculature and in the submuscular plexus. However, the presence of some ICC-SMP was confirmed by electron microscopy.

In contrast, another study reported a distribution of Kit+ ICC in HD comparable to controls and claimed that Kit1 ICC-MP form "normal" networks in aganglionic segments when studied by confocal microscopy on whole mount preparations[101].

Differences in interpretation may be less significant than it appears as there is an agreement in the literature to acknowledge the presence of a number of interconnecting ICC-MP in aganglionic segments but there is no objective criterion to assess the "normality" of networks. Considering the very close relationships of ICC with intrinsic nerves and glial cells in the normal gut, a normal arrangement of ICC appears quite unlikely in the absence of both intrinsic nerves and glial cells as encountered in aganglionic segments. In the embryonic chicken[1] or mouse[102] gut experimentally deprived of neural crest derivatives, ICC develop in the absence of ENS, confirming the mesenchymal nature of ICC. But it has not been established if ICC fully develop morphologically and functionally in such conditions.

HD is a heterogenous, multigenic disease and reviewing its genetic aspects is beyond the scope of this paper. Several systems regulating neural crest migration have recently been identified[103]. Some genes are expressed by the neural crest, others by the mesenchyme of the gut. Kit has previously been considered as a possible candidate in the search for genes involved in hereditary forms of HD[104] but the absence of linkage between HD and the region of the *Kit* gene has been more recently reported[105]. The genetic defects leading to aganglionosis in the HD patients enrolled in all studies on ICC published so far have not been assessed. Subtle differences may explain the discrepancies observed between studies, and a link between some specific genetic defect leading to aganglionosis and the differentiation of ICC in HD patients cannot be ruled out.

Intestinal neural dysplasia: A clinical condition that resembles HD was first described by Meier-Ruge[106] in 1971 as a malformation of the enteric plexus. In 1983, Fadda *et al*[107] subclassified intestinal neural dysplasia (IND) into two clinically and histologically distinct subtypes. Type A occurs in less than 5% of cases, is characterized by congenital aplasia or hypoplasia of the sympathetic innervations, and presents acutely in the neonatal period with episodes of intestinal obstruction, diarrhea and bloody stools. The clinical picture of Type B resembles HD and is characterized by malformation of the parasympathetic submucous and myenteric plexuses and accounts for over 95% of cases of isolated IND. IND occurring in association with HD is of Type B[108]. IND have been reported to be associated with loss or deficiency of ICC networks[109].

Chronic intestinal pseudo-obstruction: Chronic intestinal pseudoobstruction (CIPO) is characterized by defective GI propulsion together with symptoms and signs of bowel obstruction in the absence of any lesions or mechanical obstacle[110]. It is generally a serious, even life-threatening, condition with frequent need for long-term parenteral nutrition. CIPO can either be restricted to the intestine, can involve other parts of the GI tract, or can be part of

a multisystemic disorder[59]. CIPO can be secondary to a number of identified disorders or can be "idiopathic"[111]. Very little is known about the etiology of idiopathic CIPO. Pathological features of CIPO are pleiomorphic. A number of alterations of the ENS ("neuropathic" forms)[112] and "myopathic" forms, limited to the musculature of the GI tract or involving also the musculature of the urinary system[113,114], have been described.

Slow transit constipation: Functional constipation encompasses a group of functional disorders that exhibit persistent difficult, infrequent, or seemingly incomplete defecation and infrequent, lumpy, or hard stools[115,116]. This symptom is very common and may occur in up to 20% of populations, depending on demographic factors, sampling, and the definitions employed[115,117]. The term constipation is probably better viewed as a sort of semantic umbrella, covering pathophysiologic subtypes, among which 2 major groups may now be identified: slow transit constipation (STC) and pelvic floor dysfunction[118].

STC is thought to have, as a primary defect, slower than normal movement of contents from the cecum to the rectum[119]. This is a very prevalent motility problem, but its mechanisms are unclear[62]. Although STC may not be a congenital disease, the frequent onset in adolescence and strong female predominance suggest that STC could be a result of a sex modified multifactorial disorder of the GI tract with a genetic basis[120].

ICC volume was significantly lower in the STC patien^{+} cross all colonic regions[121]. Expression of *c-kit* mRNA and c-kit protein was significantly decreased in the colon of STC, suggesting that the c-kit signal pathway may play an important role in ICC reduction in STC[122]. Shafik *et al*[123] concluded that a disorder of the ICC, which generate electric activity, may have a role in inducing diminished or absent colonic motor activity, a point that should be further investigated.

TUMORS OF GI TRACT

GI stromal tumors (GISTs) have been recognized as a biologically distinctive tumor type, different from smooth muscle and neural tumors of the GI tract. They constitute the majority of GI mesenchymal tumors[124].

GISTs exhibit considerable phenotypic heterogeneity[125]. Their origin remains unclear, although origin in smooth muscle cells has been proposed[126,127]. CD34-ir is often present in GIST[125,128-130], a property shared with various other solid tumors[131,132].

Kit-ir may be a suitable marker for GIST[133], possibly superior to CD34-ir[134]. Mutations (usually activating) of the proto-oncogene Kit have been identified in GIST[133,135-137]. GIST with Kit mutation appear to have a poorer prognosis[133,135-138]. Therefore Kit mutations may merely be part of the oncogenic process rather than an indication of the origin of these tumors.

Recent studies suggesting that ICC in the human gut were both Kit-ir and CD34-ir raised the idea that Kit+ CD34+ GIST may derive from ICC[128,133,137].

The majority of GISTs occurs in the stomach (60%-70%), small intestine (20%-30%) and only 10% or less in the esophagus, colon and rectum, and they affect mainly middle aged patients. Similar tumors, sometimes known as extra-GIST, may arise in the omentum, mesentery, or retroperitoneum and at least one case of pancreatic tumor was described[139,140]. The presence of ICC in normal pancreas was demonstrated recently[15].

The symptoms may vary from none or slight abdominal discomfort to brisk GI hemorrhage, perforation or obstruction.

Imatinib mesylate, a synthetic tyrosine kinase inhibitor developed for the use in the management of interferon resistant chronic myeloid leukemia, was shown to be effective against a number of other tyrosine kinases including c-kit and platelet derived growth factor and now it is considered to be the drug of choice for metastatic and inoperable GISTs[124,141].

CONCLUSION

Knowledge on the role of ICC in GI disorders is increasing and there is currently overwhelming evidence to support the idea that ICC play important roles in GI motility in laboratory animals. Studies of several animal models have shown that the lack of specific ICC subpopulations produces major disturbances of GI motility. ICC are unique cell types with a central role in the control of gut function. Further studies of ICC may, therefore, lead to a major breakthrough in more understanding of GI physiology which may be considered as a promising target, at least in the long run, for specific pharmacological interventions to restore the normal physiology and motor functions of the GI tract.

ACKNOWLEDGMENTS

This article is dedicated to the memory of Professor Ahmed Shafik, my teacher, guide and guardian. His productive and creative mind, his unabated interest in new fields of research, and his unflagging energy were all qualities which formed part of a great personality. He is perhaps the last encyclopedic mind to be found on the crossroads of research and gastrointestinal tract surgery. May his soul rest in peace and tranquility.

Abstract

AIM: To investigate the anti-diabetogenic mechanism of *Nardostachys jatamansi* extract (NJE).

METHODS: Mice were injected with streptozotocin *via* a tail vein to induce diabetes. Rat insulinoma RINm5F cells and isolated rat islets were treated with interleukin-1β and interferon-γ to induce cytotoxicity.

RESULTS: Treatment of mice with streptozotocin resulted in hyperglycemia and hypoinsulinemia, which was confirmed by immunohistochemical staining of the islets. The diabetogenic effects of streptozotocin were completely abolished when mice were pretreated with NJE. Inhibition of streptozotocin-induced hyperglycemia by NJE was mediated by suppression of nuclear factor (NF)-κB activation. In addition, NJE protected against cytokine-mediated cytotoxicity. Incubation of RINm5F cells and islets with NJE resulted in a significant reduction in cytokine-induced NF-κB activation and downstream events, inducible nitric oxide synthase expression and nitric oxide production. The protective effect of NJE was further demonstrated by the normal insulin secretion of cytokine-treated islets in response to glucose.

CONCLUSION: NJE provided resistance to pancreatic β-cell damage from cytokine or streptozotocin treatment. The β-cell protective effect of NJE is mediated by suppressing NF-κB activation.

INTRODUCTION

Type 1 diabetes mellitus is an autoimmune disease that causes selective destruction of insulin producing β-cells in the islets of Langerhans. In early-stage disease, infiltration of inflammatory cells into the pancreatic islets can be observed histologically[1]. The inflammatory cells produce and release cytokines, including interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ). IL-1β, alone or in combination with TNF-α or IFN-γ, upregulates inducible nitric oxide synthase (iNOS), and produces high levels of nitric oxide (NO) in pancreatic islets[2,3]. NO is produced by the oxidation of L-arginine to L-citruline by NOS, and generation of excess NO can inhibit mitochondrial metabolism, protein modification, and DNA cleavage; any one of which could lead to impaired insulin secretion and β-cell death[4,5]. Streptozotocin (STZ) is a diabetogenic agent that is toxic to pancreatic β-cells and is commonly used in diabetes research[6]. Streptozotocin contains a nitroso moiety and releases NO during its metabolism[7]. In rodents, STZ activates poly-ADP ribose polymerase, depletes cellular NAD and ATP, breaks DNA strands, and initiates β-cell necrosis[8].

NO production is regulated by transcription factors that bind to specific sites in the iNOS promoter. Nuclear factor (NF)-κB, which can be activated by cytokines and STZ, has been implicated as a key signaling mediator in iNOS induction[9,10]. When inactive, NF-κB is located in the cytosol complexed with NF-κB inhibitory factor (IκB). Various inducers cause complex dissociation, presumably *via* IκB phosphorylation. Released NF-κB translocates to the nucleus, where it interacts with recognition sites to mediate gene transcription[11]. We and others have shown that NF-κB-dependent NO production is involved in the dysfunction and destruction of β-cells, which suggests NO involvement in autoimmune diabetes pathogenesis[9,12-15].

Nardostachys jatamansi (*N. jatamansi*) is used in Ayurvedic medicine to treat mental disorders, hyperlipidemia, hypertension, and convulsions[16-18]. Various sesquiterpenes such as lignans and neolignans are present in root extracts of this plant[19]. *N. jatamansi* is suggested to protect cells and tissues through its antioxidative properties[20,21]. We found that *N. jatamansi* extract (NJE) protects against development of acute cerulean-induced pancreatitis[22]. However, as far as we are aware, no studies have reported on the antidiabetic effects of NJE. Therefore, in this study we examined the effect of NJE on cytokine- or STZ-stimulated pancreatic β-cell damage and the resultant development of type 1 diabetes.

MATERIALS AND METHODS

Cell culture and reagents

Rat pancreatic β-cell line RINm5F was from the American Type Culture Collection and were grown at 37℃ in a humidified 5% CO_2 atmosphere in RPMI 1640 medium (Gibco BRL, Grand Island, NY, USA), supplemented with 10% fetal bovine serum and 2 mmol/L glutamine, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2.5 μg/mL amphotericin B. IL-1β and IFN-γ were obtained from R&D Systems (Minneapolis, MN, USA). All reagents were from Sigma (St. Louis, MO, USA), unless otherwise noted.

Preparation of NJE

N. jatamansi was from a standard commercial source (Omni Herb, Seoul, Korea), and its identity was confirmed at the Korean Drug Test Laboratory (Seoul, Korea). Voucher specimens (NO; Oh/wh/nj-43) were deposited at the School of Oriental Medicine Herbarium, Wonkwang University. NJE was prepared by decocting 200 g of dried herbs with 1800 mL boiling distilled water for approximately 2 h. The extract was filtered, freeze-dried and stored at 4℃.

Type 1 diabetes induction

Specific pathogen-free male ICR mice, weighing 25-30 g, were purchased from Orientbio Inc. (Seoungnam, Korea) and housed at our animal facility for 1 wk. All mice were kept under specific pathogen-free conditions with free access to a standard commercial diet and were used at 5-6 wk of age. To induce diabetes, mice were injected *via* the tail vein with 80 mg/kg STZ dissolved in 0.1 mol/L sodium citrate buffer (pH 4.0), prepared within 5 min of administration. Mice were divided into the following groups: (1) non-treated controls; (2) STZ; (3) NJE; and (4) NJE + STZ (n = 5 for each group). Control animals received citrate buffer alone. Group 4 received intraperitoneal injections of 125 mg/kg NJE daily for 3 d before administration of STZ. The day on which STZ was first administered was defined as day 1. At day 5, mice were sacrificed by decapitation without anesthesia and trunk blood was collected in pre-chilled tubes that contained 1 mg/mL EDTA. Plasma glucose was assayed using the glucose oxidase-peroxidase method, and plasma insulin was measured using a radioimmunoassay kit (Linco Research, St. Charles, MO, USA). All experimental procedures were approved by the Institutional Animal Care and Use Committee at Chonbuk National University, Jeonbuk, Korea.

3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay for cell viability

The viability of cultured cells was determined by the reduction of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) to formazan. RINm5F cells were seeded overnight in clear, flat-bottomed 96-well tissue culture plates at 10^5 cells/well in 100 μL medium. Cells were pretreated with NJE as indicated for 3 h, then IL-1β (1 U/mL) and IFN-γ (100 U/mL) were added for an additional 48 h. Cells were washed twice with PBS, and MTT was added (100 μg/100 μL PBS). After incubation at 37℃ for 1 h, 100 μL DMSO was added to dissolve the formazan crystals, and absorbance was measured at

570 nm using a Spectra MAX PLUS spectrophotometer (Molecular Devices, Sunnyvale, CA, USA).

NO measurement

Biologically produced NO is rapidly oxidized to nitrite and nitrate in aqueous solutions. NO production was measured as nitrite concentration in cell-free culture supernatants using a colorimetric assay. Briefly, 5×10^5 RINm5F cells or 30 islet samples were pretreated with the indicated concentrations of NJE for 3 h prior to the addition of IL-1β (1 U/mL) and IFN-γ (100 U/mL). After 24 h, 100 μL aliquots of culture supernatant were incubated with 100 μL of a modified Griess reagent of a 1:1 mixture of 1% sulfanilamide in 30% acetic acid and 0.1% N-(1-naphthyl) ethylenediamine dihydrochloride in 60% acetic acid, at room temperature for 5 min, and the absorbance was measured at 540 nm using a spectrophotometer (Ultrospec 2100 pro; Amersham Biosciences). NO concentration was determined from a linear standard curve of serial dilutions of sodium nitrite in a working medium.

Whole cell and nuclear protein extracts

Cells, islets, or pancreatic tissues were washed with PBS and lysed in CytoBuster protein extraction buffer (Novagen, Madison, WI, USA). Lysate was centrifuged at 10 000 × *g* for 5 min at 4℃, and the supernatant was used as whole cell protein extract. Cytosolic and nuclear extracts were prepared from cells using NE-PER Nuclear and Cytoplasmic Extraction Reagent (Pierce Biotechnology, Rockford, IL, USA).

Western blotting analysis

RINm5F cells (5×10^6) or 30 islet samples were homogenized in 100 μL ice-cold lysis buffer (20 mmol/L HEPES, pH 7.2, 1% Triton X-100, 10% glycerol, 1 mmol/L PMSF, 10 μg/mL leupeptin, 10 μg/mL aprotinin) and 20 μg protein separated by SDS-PAGE and transferred to nitrocellulose membranes. Blots were probed with 1 μg/mL primary antibody against p50, p65, iNOS, actin, or PCNA (Santa Cruz Biotechnology, Santa Cruz, CA, USA) and detected with horseradish peroxidase-conjugated IgG (Zymed, South San Francisco, CA, USA).

Electrophoretic mobility shift assay

NF-κB activation was assayed using a gel mobility shift assay with nuclear extracts from control and treated cells. An oligonucleotide that contained the κ-chain binding site (κB, 5'-CCGGTTAACAGAGGGGGCTTTCCGAG-3') was used as a probe. The two complementary strands were annealed and labeled with [α-^{32}P]dCTP. Binding reactions that contained labeled oligonucleotide (10 000 cpm), 10 μg nuclear extract protein, and binding buffer (10 mmol/L Tris-HCl, pH 7.6, 500 mmol/L KCl, 10 mmol/L EDTA, 50% glycerol, 100 ng poly (dI·dC), 1 mmol/L dithiothreitol) in a final volume of 20 μL were incubated for 30 min at room temperature. Reactions were separated on 4% polyacrylamide gels in 0.5 × Tris-borate buffer, and the gels were dried and visualized by autoradiography. Specificity of the DNA/NF-κB interaction was demonstrated by competitive assays with 50-fold excess unlabeled oligonucleotide.

RNA isolation and real-time RT-PCR

RNA was isolated from RINm5F cells or islets using Trizol reagent (Invitrogen, Carlsbad, CA, USA). RNA was precipitated with isopropanol and dissolved in DEPC-treated distilled water. Total RNA (2 μg) was treated with RNase-free DNase (Invitrogen), and first-strand cDNA was generated using random hexamer primer in a first-strand cDNA synthesis kit (Applied Biosystems, Foster City, CA, USA). Specific primers for iNOS were designed using primer express software (Applied Biosystems): iNOS (accession No. NM_012611), 5'-TGTGCTAATGCGGAAGGTCAT-3' (forward), and 5'-CGACTTTCCTGTCTCAGTAGCAAA-3' (reverse). Control 18S rRNA was purchased from Applied Biosystems and was used as the invariant control. Real-time RT-PCR mixtures consisted of 10 ng reverse transcribed total RNA, 167 nmol/L forward and reverse primers, and 2 × PCR Master Mix in a final volume of 10 μL. Reactions were carried out in 384-well plates using the ABI Prism 7900HT Sequence Detection System (Applied Biosystems). All experiments were performed in triplicate.

Glucose-stimulated insulin secretion assay

Pancreatic islets were isolated from 250-300 g male Sprague-Dawley rats, using the collagenase digestion method[23]. Islets were cultured for 24 h with IL-1β and IFN-γ in the presence or absence of NJE, then washed three times in Krebs-Ringer bicarbonate buffer (25 mmol/L HEPES, 115 mmol/L NaCl, 24 mmol/L $NaHCO_3$, 5 mmol/L KCl, 1 mmol/L $MgCl_2$, 2.5 mmol/L $CaCl_2$, 0.1% bovine serum albumin, pH 7.4), which contained 3 mmol/L D-glucose. Insulin secretion assays were performed with either 5.5 or 20 mmol/L D-glucose. All experiments were performed in triplicate.

Immunohistochemistry

Immunohistochemical staining was performed with the DAKO Envision system (DAKO, Carpinteria, CA, USA), which used dextran polymers conjugated with horseradish peroxidase to avoid contamination with endogenous biotin. Pancreases were removed and immediately placed in fixative (10% formalin solution in 0.1 mol/L PBS). Histological sections of 4 μm were cut from formalin-fixed, paraffin-embedded tissue blocks. After deparaffinization, tissue sections were treated using a microwave antigen retrieval procedure in 0.01 mol/L sodium citrate buffer. After blocking endogenous peroxidase, the sections were incubated with Protein Block Serum-Free (DAKO) to block nonspecific staining, then with anti-insulin antibody (Santa Cruz Biotechnology). Peroxidase activity was detected with 3-amino-9-ethylcarbazole.

Statistical analysis

Statistical analyses were performed using ANOVA and

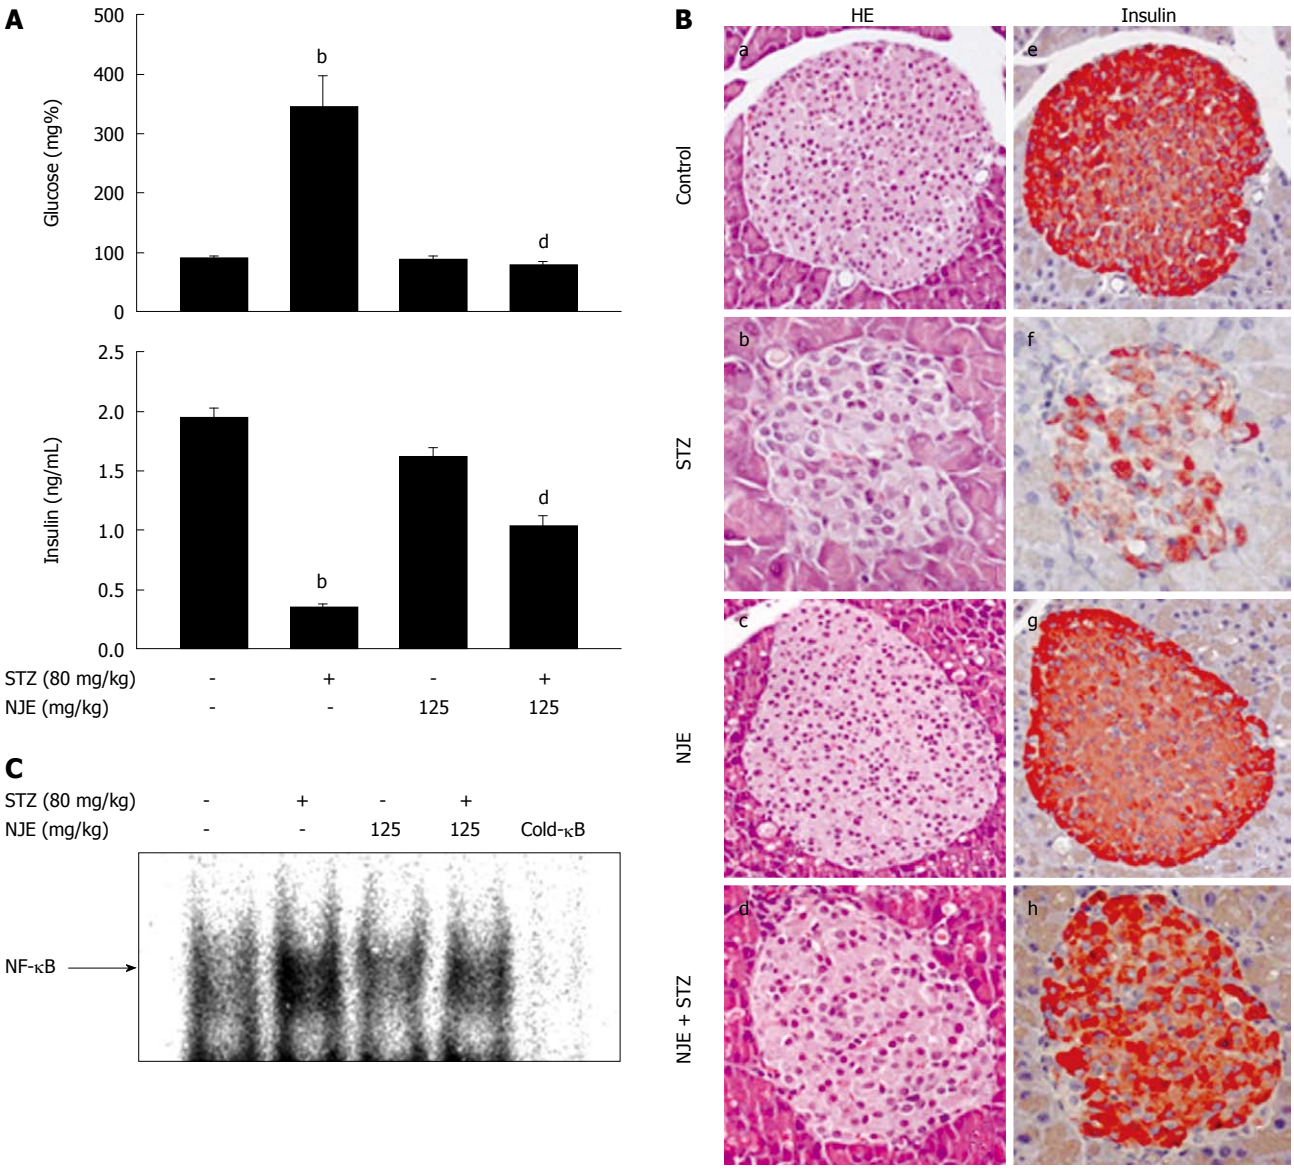

Figure 1 NJE protects islets from STZ-induced destruction. A: ICR mice were intraperitoneally injected daily with NJE at 125 mg/kg for 3 d and then injected with STZ (80 mg/kg) intravenously. Levels of fasting glucose and insulin were determined; B: Pancreases were obtained from normal controls (a, e), and STZ-injected (b, f), NJE-injected (c, g), and NJE and STZ-injected mice (d, h). Islets and adjoining exocrine regions were counterstained with HE (a-d). Islets were labeled with insulin antibody and peroxidase-labeled anti-rabbit IgG (e-h); C: Nuclear extracts from pancreatic tissues were prepared 30 min after STZ injection, and NF-κB DNA binding was analyzed using electrophoretic mobility shift assay. $^{b}P < 0.01$ *vs* untreated control; $^{d}P < 0.01$ *vs* STZ-injected group. NJE: *Nardostachys jatamansi* extract; STZ: Streptozotocin; NF-κB: Nuclear factor κB.

Duncan's tests. Differences with $P < 0.05$ were considered statistically significant.

RESULTS

Anti-diabetic effect of NJE in mice

Mice injected with STZ gradually became hyperglycemic, with an increased incidence of diabetes observed starting at day 3. At day 5, the average blood glucose level of mice injected with STZ was 344 ± 52.8 mg/dL. Mice that were pretreated with NJE were fully resistant to diabetes development (Figure 1A), and treatment with NJE alone did not affect blood glucose concentration. In addition, the mean plasma insulin level at day 5 in the STZ group decreased by 84.2% compared with the control (from 1.9 ± 0.1 to 0.3 ± 0.1 ng/mL), while the severity of hypoinsulinemia was attenuated in mice pretreated with NJE (Figure 1A). These results indicate that NJE is protective against STZ-induced diabetes.

The preventative effect of NJE on STZ-induced diabetes was histologically examined. Pancreatic tissues at 5 d after STZ administration, with or without NJE pretreatment, were subjected to hematoxylin and eosin (HE) staining and immunohistochemistry. STZ-treated mice showed degenerative and necrotic changes and islet shrinkage (Figure 1B, b), as well as weak insulin-reactivity in a few β-cells (Figure 1B, f). However, tissues from STZ-treated mice pretreated with NJE showed round, nearly normal, and clearly defined islets that were strongly positive for insulin (Figure 1B, d and h).

To elucidate the antidiabetogenic mechanism of NJE, we examined its effect on STZ-induced NF-κB activation. Figure 1C is a representative electrophoretic mobility shift assay (EMSA) that shows the ^{32}P-DNA/NF-κB complex formed with nuclear extracts from the pancreas 30 min after STZ administration. The findings were similar to those of our previous study, with STZ treatment resulting in increased NF-κB binding to DNA[10]. This complex was not detected in pancreatic nuclear extracts from NJE-pretreated mice. Taken together, these results show that NJE inhibits NF-κB activation and prevents type 1 diabetes development in mice.

NJE prevented cytokine-mediated cell death in RINm5F cells

We investigated the antidiabetogenic effect of NJE at the cellular level. Untreated RINm5F cells or cells pretreated with NJE for 3 h were exposed to cytokine for 48 h, and viability was assessed using an MTT assay. Treatment with cytokine significantly reduced cell viability to 39.8% ± 0.6% of the controls (Figure 2A). Conversely, NJE increased the viability of cytokine-treated RINm5F cells in a concentration-dependent manner. Treatment with NJE alone did not affect cell viability at the concentrations used in this study (data not shown).

NO production was also evaluated. In 24 h, control RINm5F cells generated 9.8 ± 0.5 μmol/L nitrite, while cytokine-treated cells generated 34.2 ± 2.7 μmol/L (Figure 2B). A concentration-dependent reduction in cytokine-mediated nitrite production was observed in RINm5F cells treated with cytokine plus NJE. Near complete inhibition of nitrite production was observed in cells that were pretreated with 100 μg/mL NJE.

To investigate the regulatory effects of NJE on NO production, we examined the effects of NJE on cytokine-induced iNOS mRNA and protein expression, using real-time RT-PCR and Western blotting. Cytokine increased iNOS mRNA and protein levels (Figure 2C). However, when cells were treated with NJE prior to cytokine treatment, mRNA and protein levels decreased in a concentration-dependent manner. Treatment with 100 μg/mL NJE completely blocked iNOS expression.

NF-κB was implicated in STZ toxicity (Figure 1C). Therefore, the effect of NJE on the cytokine-stimulated translocation of NF-κB from the cytosol to the nucleus in RINm5F cells was examined. Nuclear extracts from cytokine-stimulated RINm5F cells showed increased NF-κB binding activity (Figure 3A, lane 2), as well as increased nuclear levels of p65 and p50 subunits (Figure 3B), compared to those of unstimulated cells. In contrast, cytokine-induced NF-κB activation was markedly suppressed by NJE pretreatment, which suggested that NJE inhibited iNOS expression by suppressing NF-κB activation. We previously have reported that IκBα, but not IκBβ, is the major participant in cytokine-induced NF-κB activation[23]. Therefore, we investigated IκBα levels in the cytosol following cytokine treatment (Figure 3B). Cytokine-treated RINm5F cells showed a decreased level of IκBα

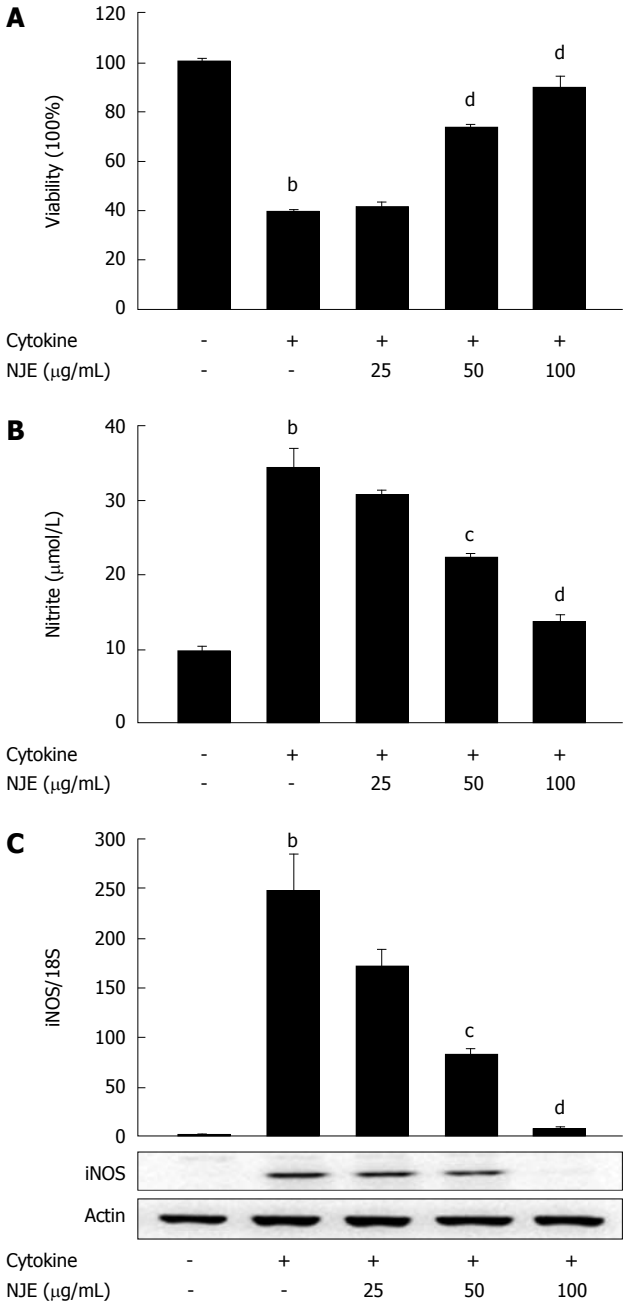

Figure 2 NJE prevents cytokine-induced cell death in RINm5F cells. A: RINm5F cells were pretreated with NJE for 3 h, and IL-1β (1 U/mL) and IFN-γ (100 U/mL) were added for 48 h. Cell viability was determined using an 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay; B and C: RINm5F cells were pretreated with NJE for 3 h, and IL-1β and IFN-γ were added. Following 24 h of incubation, the level of nitrite production and iNOS mRNA and protein expression were determined. Each value is the mean ± SE of three independent experiments. $^{b}P < 0.01$ *vs* untreated controls; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* cytokine. IL-1β: Interleukin 1β; IFN-γ: Interferon γ.

protein in the cytosol compared to a similar fraction from unstimulated cells; however, increased IκBα degradation as a result of cytokine treatment was markedly suppressed by pretreatment with NJE.

NJE suppressed the cytokine-induced NF-κB pathway and preserved glucose-stimulated insulin secretion in rat islets

We further assayed the preventive effects of NJE using rat

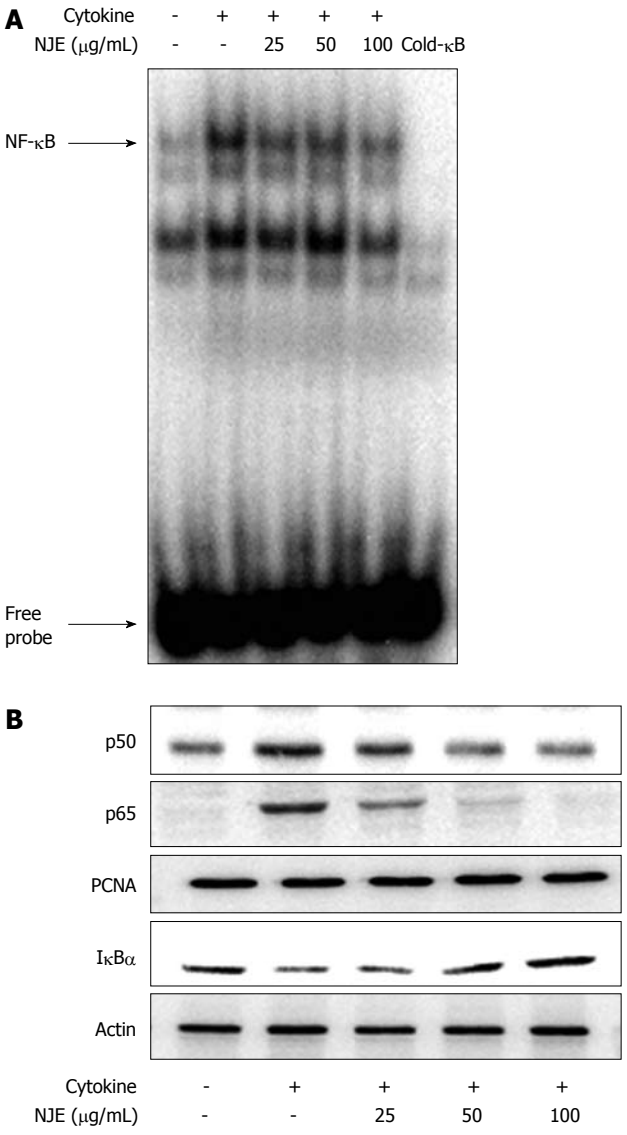

Figure 3 NJE inhibits cytokine-induced NF-κB activation in RINm5F cells. RINm5F cells were pretreated with NJE for 3 h, and IL-1β (1 U/mL) and IFN-γ (100 U/mL) were added. After 30 min, NF-κB DNA binding was analyzed by EMSA (A), and translocation of p65 and p50 to the nucleus and IκBα degradation in the cytosol (B) were determined by Western blotting. β-actin and PCNA were used as loading controls for cytosolic and nuclear proteins, respectively.

pancreatic islets isolated from male Sprague-Dawley rats. Incubation of rat islets with cytokine for 24 h resulted in a 2.8-fold increase in NO production (Figure 4A). Real time RT-PCR and Western blotting revealed that iNOS mRNA and protein levels were markedly increased by cytokines (Figure 4A). Consistent with results from RINm5F cells, pretreatment of islets with NJE abolished the cytokine effects and reduced NO production and iNOS expression to the level of those of control islets. Additionally, treatment with cytokine increased NF-κB DNA binding activity in islets (Figure 4B), and pretreatment of islets with NJE completely abolished these effects. To add functional data, NJE protection against cytokine-induced impairment of glucose-stimulated insulin secretion (GSIS) was evaluated. After 24 h of cytokine exposure, insulin secretion was assayed in response to 20 mmol/L glucose. Control islets secreted 3.4 ± 0.4 ng/mL insulin, while cytokine-treated islets secreted significantly less, at 1.2 ± 0.2 ng/mL ($P < 0.01$) (Figure 4C). However, pretreatment with NJE blocked the cytokine effect and maintained islet cell insulin secretion to levels similar to those of the controls. In addition, treatment with NJE alone did not affect insulin secretion in response to glucose (data not shown).

DISCUSSION

In this study, we present a mode of action for NJE protection against development of type 1 diabetes. Intraperitoneal administration of NJE prevented diabetes development after STZ and preserved β-cell mass. In addition, NJE protected β-cells from cytokine toxic challenge in RINm5F cells and islets.

We demonstrated that NJE prevented STZ-induced diabetes in mice. STZ destroys islet cells through several mechanisms, including the production of reactive oxygen species (ROS)[24], activation of pancreatic NF-κB[25], and induction of pronounced immune and inflammatory responses[26]. STZ-treated mice showed marked islet destruction and relatively small numbers of insulin-positive β-cells, while NJE pre-treated mice showed well-defined islets and strong insulin staining. An EMSA revealed increased NF-κB binding activity in pancreatic nuclear extracts derived from STZ-treated hyperglycemic diabetic mice. However, pretreatment with NJE prevented NF-κB activation, which resulted in the maintenance of plasma glucose and insulin levels in the normal range. NF-κB participates in the transcriptional regulation of pro-inflammatory genes, and their activation results in the production of pro-inflammatory mediators[27,28]. Therefore, NF-κB might be a key regulator in local cytokine response pathways in STZ-mediated β-cell destruction. Alternatively, the NJE anti-diabetic effect could be related to its anti-oxidative properties. Several studies have confirmed that NJE is an ROS scavenger[20,21], and that ROS induces NF-κB activation[29,30], which suggests that ROS scavenging by NJE suppresses STZ-induced NF-κB activation. Taken together, these results suggest that manipulation of NF-κB activity by NJE in pancreatic β-cells allows these cells to withstand and survive STZ-mediated immune attack.

NJE not only protected against STZ-induced diabetes, but also protected RINm5F cells and rat islets against cytokine toxicity. IL-1β has been implicated in early events in β-cell destruction. Suppression of IL-1β production or inhibition of its interaction with corresponding cellular receptors significantly inhibits IL-1β-mediated deleterious effects on β-cells[31,32]. IL-1β exerts its main effects through the NF-κB pathway[33-35]. IFN-γ alone does not stimulate iNOS expression in rodent or human islets, but it reduces the concentration of IL-1β required to induce iNOS expression in rat islets, and a combination of IL-1β and IFN-γ is required to induce iNOS expression and β-cell dysfunction in mouse and human islets[36]. In addition to cytokines, different intracellular pathways that lead to β-cell death (e.g. oxidative stress, chemical generation

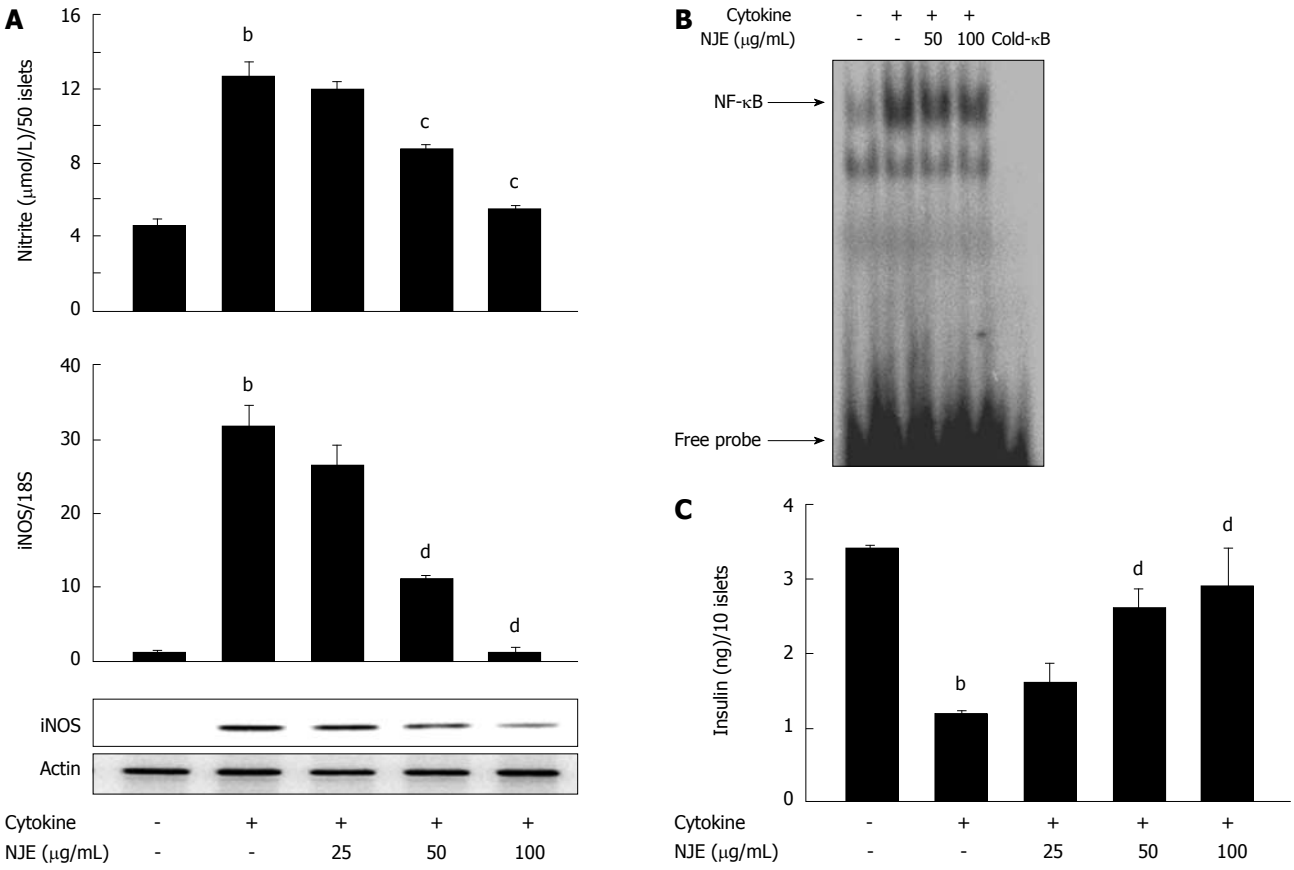

Figure 4 NJE inhibits cytokine-induced activation of NF-κB and maintains glucose-stimulated insulin secretion in rat islets. Rat islets were treated with IL-1β (1 U/mL) and IFN-γ (100 U/mL) with or without 3 h pretreatment with NJE. Nitrite production and iNOS mRNA and protein expression (A) were determined after 24 h, and NF-κB DNA binding (B) was determined 1 h later; C: Rat islets (10 islets/500 μL) were treated with IL-1β (1 U/mL) and IFN-γ (100 U/mL) with or without 3 h pretreatment with NJE. Following 24 h incubation, glucose-stimulated insulin secretion was quantified. The results of triplicate samples are expressed as the mean ± SE. $^{b}P < 0.01$ *vs* untreated controls; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* cytokine.

of NO, mitogen-activated protein kinase activation, JAK-STAT activation, and endoplasmic reticulum stress) partially converge at NF-κB[12,14,37,38]. Hypothetically, this gives us, employing only one approach, the ability to block NF-κB signaling, to save β-cell mass and thereby prevent diabetes development. In this model, NJE completely inhibits NO production in IL-1β- and IFN-γ-stimulated RINm5F cells and islets, through suppression of NF-κB-dependent iNOS expression, thereby protecting RINm5F cells and islets from IL-1β and IFN-γ cytotoxicity. In addition to increased cell viability, we observed the preservation of insulin secretion in NJE pretreated rat islets. The molecular mechanism by which NJE inhibits NF-κB activation by IL-1β and IFN-γ appears to involve both inhibition of IκBα degradation and translocation of p65 and p50 into the nucleus.

Flavonoids comprise the most common group of plant polyphenols and provide much of the flavor and color to fruits and vegetables. Several flavonoids have been shown to inhibit the expression of NF-κB-dependent cytokines, iNOS, and *cyclooxygenase-2* genes[39]. Therefore, it would be interesting to analyze flavonoid composition in NJE extracts.

In summary, this study is believed to be the first to demonstrate that NJE has a β-cell protective effect. Specifically, NJE protected β-cells from cytokine-induced injury *in vitro* and counteracted the development of type 1 diabetes in response to STZ *in vivo*. This β-cell protective effect might be mediated, at least in part, by suppressing NF-κB activation. NJE did not cause serious side effects in mice, therefore, it could be a therapeutic alternative for rescuing β-cells in cases of ongoing β-cell destruction.

COMMENTS

Background

Type 1 diabetes mellitus is an autoimmune disease that causes selective destruction of insulin-producing β-cells in the islets of Langerhans. Once those cells are destroyed, they do not ever produce insulin again. Type 1 diabetes affects younger individuals and requires lifelong insulin treatment. Without treatment, the blood glucose rises to levels which can cause hyperglycemia. Type 1 diabetes cannot be prevented. There is no practical way to predict who will develop the disease because most people who develop it are otherwise healthy. Therefore, the best way to control type 1 diabetes is understanding the disease better and finding a therapeutic regimen to preserve functional β-cell damage.

Research frontiers

Cytokines such as interleukin (IL)-1β and interferon (IFN)-γ, which are released during islet inflammation, are believed to participate in β-cell damage during the development of autoimmune type 1 diabetes. Evidence has suggested that activation of nuclear factor (NF)-κB in response to cytokines is an important component of the signal that triggers β-cell death. For this reason, NF-κB has been targeted for preventing type 1 diabetes development.

Innovations and breakthroughs

Nardostachys jatamansi is used in Ayurvedic medicine to treat mental disorders, hyperlipidemia, hypertension, and convulsions. *N. jatamansi* has been suggested to protect cells and tissues through its antioxidative properties. However, no studies to date have reported the antidiabetic effects of *N. jatamansi*. In this study, the authors observed that *N. jatamansi* extract (NJE) had antidiabetic effects in *in vitro* and *in vivo* models of diabetes.

Applications

NJE did not cause serious side effects *in vivo*, therefore, it might be a therapeutic alternative for rescuing β-cells in cases of ongoing β-cell destruction. NJE-treated islets can also be used to increase islet survival in an allograft transplantation model.

Terminology

IL-1β and IFN-γ are cytokines that are secreted from infiltrated inflammatory cells into the pancreatic islets. Streptozotocin is a diabetogenic drug and particularly toxic to pancreatic β-cells.

Peer review

The article is written well, however, there are many major queries which have to be answered by the authors. Authors have to report on the phytochemical constituents of the extract (at least qualitative analysis).

Abstract

AIM: To investigate the expression and function of CD74 in normal murine colon epithelial cells (CEC) and colon carcinoma cells.

METHODS: Expression of CD74 mRNA and protein were measured by reverse transcriptase-polymerase chain reaction (RT-PCR), Western blotting and fluorescence-activated cell sorter (FACS). The effect of migration inhibitory factor (MIF) on the survival of normal CEC from C57BL/6, NOD/SCID, and CD74 deficient mice both *in vitro* and *in vivo*, and on the CT26 carcinoma cell line was analyzed by (quantitative) qRT-PCR, RT-PCR, Western blotting and FACS.

RESULTS: CD74 was found to be expressed on normal CEC. Stimulation of CD74 by MIF induced a signaling cascade leading to up-regulation of Bcl-2 expression, resulting in a significant increased survival of CEC. CD74 was also expressed on the CT26 colon carcinoma cell line and its stimulation by MIF resulted in enhanced cell survival, up-regulation of Akt phosphorylation and Bcl-2 expression.

CONCLUSION: CD74 is expressed on CEC and colon carcinoma cells and serves as a survival receptor in these cells. These results may have implications on colorectal cancer research.

Key words: CD74; Migration inhibitory factor; Colon epithelial cells

INTRODUCTION

CD74 (Invariant chain; Ii) is a type Ⅱ integral membrane protein, which acts as a chaperone for major histocompatibility complex (MHC) class Ⅱ protein expression[1]. It is a non-polymorphic type Ⅱ integral membrane protein; the mouse protein is comprised of a 30 amino acid (aa) N-terminal cytoplasmic tail, followed by a single 24 aa transmembrane region and an approximately 150 aa long lumenal domain. The CD74 chain was initially thought to function mainly as an MHC class Ⅱ chaperone, which promotes endoplasmic reticulum (ER) exit of MHC class Ⅱ molecules, directs them to endocytic compartments,

prevents peptide binding in the ER, and contributes to peptide editing in the MHC class Ⅱ compartment[1]. A small proportion of CD74 is modified by the addition of chondroitin sulfate (CD74-CS), and this form of CD74 is expressed on the surface of antigen presenting cells (APCs), including monocytes and B cells. In addition to APCs, other cells of the gastrointestinal tract, such as epithelial cells, express class Ⅱ MHC proteins and CD74 and act as APCs[2]. The role of CD74 in the epithelium is not fully defined. It was formerly accepted that the functions of CD74 in these cells have been correlated with its role in antigen processing and presentation in conventional APCs. However, CD74 may play additional roles in epithelial cells. CD74 expression on normal human colon epithelial cells (CEC) is still controversial, as the presence of this molecule was demonstrated using immunohistochemistry by some groups[3], but not by others[4,5]. On human colonic epithelial cell lines it was found to be expressed only after interferon-γ treatment[6]. In mice, CD74 expression on CEC is also not clear, although CD74 was not demonstrated on normal murine CEC[7]. In one study, CLIP (class Ⅱ invariant chain peptide) was shown to be expressed in a complex with MHC class Ⅱ, suggesting that CD74 is expressed on these cells as well[8]. Recently, it was demonstrated that CD74 is expressed on CEC of *APC*$^{Min/+}$ mice. However, these mice bear a point mutation in the murine homolog of the *APC* gene and develop multiple intestinal adenomas[9]. In humans, on the contrary, there was no CD74 expression on normal CEC, but it was expressed on CEC of sporadic colorectal adenomas[10].

It was shown previously that macrophage migration inhibitory factor (MIF) binds to the CD74 extracellular domain, a process that results in the initiation of a signaling pathway in a CD44 dependent manner[11-13].

In our previous studies, we showed that CD74 expressed on B cells is directly involved in shaping the B cell repertoire[14-16] through a pathway leading to the activation of transcription mediated by the nuclear factor-κB (NF-κB) p65/RelA homodimer and its co-activator, TAFII105[17]. We demonstrated that CD74 stimulation with anti-CD74 antibody or MIF leads to NF-κB activation, enabling entry of the stimulated B cells into the S phase, an increase in DNA synthesis, cell division, and augmented expression of anti-apoptotic proteins. These findings indicated that surface CD74 functions as a survival receptor[13,18,19].

In addition, CD74 is expressed at high levels from an early stage of the B cell leukemia, B-CLL. The activation of CD74 on human B-CLL cells by MIF, initiates a signaling cascade that contributes to tumor progression. This pathway induces NF-κB activation, resulting in the secretion of interleukin 8, which in turn promotes cell survival. Blocking of this pathway leads to decreased cell survival. Thus, CD74 expressed on the surface of B-CLL cells plays a critical role in regulating the survival of these malignant cells[20].

MHC class Ⅱ expression was initially thought to be limited to a restricted set of cells collectively known as APCs. However, in addition to conventional APCs, other cell types, including mucosal epithelial cells, were subsequently reported to express class Ⅱ MHC molecules and to present antigens[21].

Surface expression of newly synthesized CD74 is followed by rapid internalization to the endosomal pathway. Experiments that investigate cell surface CD74 are complicated by the fact that CD74 remains on the cell surface for a very short time. The surface half-life of CD74 was calculated to be less than 10 min[22,23].

In this article, we followed CD74 expression in colonic intestinal epithelial cells in the mouse. We show that CD74 is expressed on CEC derived from C57BL/6 and on the CT26 colon carcinoma cell line and serves as a survival receptor on these cells. This finding may suggest a role for CD74 in colon cancer development.

MATERIALS AND METHODS

Mice

C57BL/6, C57BL/6 CD74 deficient[24], C57BL/6 MIF deficient[25], CD44 deficient NOD/SCID mice (Jackson Lab), were used. All animals were used at 6-10 wk of age.

All animal procedures were approved by the Animal Research Committee at the Weizmann Institute of Science.

Intraperitoneal MIF administration

Recombinant murine MIF was purified from an expression system as previously described and contaminating endotoxin removed by C8 chromatography[26]. Mice were injected daily ip with MIF (400 ng) or with PBS, as indicated. Mice were sacrificed after 3.5 or 24 h and CEC were isolated.

Isolation of CECs

CEC were isolated using a modification of the method described previously[27]. Briefly, mice were sacrificed, colons were immediately removed and washed with phosphate buffered saline (PBS) until all content was removed. Colons were inverted and washed gently with Roswell Park Memorial Institute solution. Mucus was removed by incubation for 10 min in 1 mmol/L DTT. Specimens were treated with Dispase Ⅱ (Roche Diagnostics; 3 mg/mL) in DMEM for 30 min (vortexing every 5 min) at 37℃. CEC were isolated from the remaining tissue by passage through a metal filter. In order to purify CEC, cells were centrifuged on a discontinuous Percoll gradient for 30 min, 2000 r/min. Cells found on the top 0%-30% gradient are CEC[28]. Isolated cells were washed in PBS. CEC isolated in this fashion contained over 90% viable cells as determined by Trypan blue exclusion. A total of 92%-95% of the cells stained with the anti-epithelial cell marker anti-pan cytokeratin-26 (FITC conjugated) (Sigma-Aldrich). The remaining contaminating cells represented $CD3^+$ and B_220^+ cells.

CT26 cell line

CT26 murine colon carcinoma cells were grown as monolayer cultures in DMEM-10%, fetal bovine serum (FBS) (Invitrogen) supplemented with 100 IU/mL penicillin and

100 μg/mL streptomycin. Cells were maintained in a 37℃ incubator with 5% CO_2-humidified air.

Stimulation of cells by MIF

CECs (3-6 × 10^6 cells/well) isolated from CD57BL/6 mice, were cultured in 12-well plates at 37℃ in DMEM medium supplemented with 10% FCS, 2 mmol/L glutamate, 300 U/mL penicillin, 300 μg/mL streptomycin, with or without 400 ng/mL of MIF for 17 h.

1.5 × 10^6 cells (CT26 cell line) were plated in complete medium into dishes of 6-well cell culture plates, and were allowed to adhere for 24 h. After washing the cells twice with PBS, they were incubated with MIF (400 ng/mL) for 3 or 6 h (as indicated in the text) in serum-free medium.

RNA isolation and reverse transcription

Total RNA was isolated from cells using the Tri Reagent Kit (MRC), according to the manufacturer's instructions. Reverse transcription was carried out using Superscript Ⅱ RT (Gibco-BRL).

Primers that were used in polymerase chain reaction (PCR) reactions: Bcl-2: 5'-CACCGAACACTTGATTCTG, 3'-AGATCTCTGGTTGGGATTC; Cyclin E: 5'-GAAAATCAGACCACCCAGAGCC, 3'-GAAATGATACAAAGCAGAAGCAGCG; CD74: 5'-GGAGTACCCGCAGCTGAAGGGG, 3'-GAAGATAGGTCTTCCATGTCCAGTG; HPRT: 5'-GAGGGTAGGCTGGCCTATGCCT, 3'-GTTGGATACAGGCCAGACTTTGTTG.

Real time PCR

Levels of mRNA of Actin, Bcl-2 and Cyclin E, were analyzed by quantitative real-time reverse transcriptase (RT)-PCR using a Light-Cycler instrument (Roche Diagnostics, Mannheim, Germany). Total RNA was isolated from cells using the Tri Reagent Kit (MRC). Reverse transcription was carried out using Superscript Ⅱ RT (Gibco-BRL). The reaction volume (10 mL) contained 3 mmol/L $MgCl_2$, LightCycler HotStart DNA SYBR Green I mix (Roche Diagnostics), specific primer pairs, and 2.5 mL of cDNA. Conditions for PCR were as follows: 10 min at 95℃ followed by 60 cycles of 15 s at 95℃, 15 s at 60℃, and 15 s at 72℃. PCR was performed in triplicates. Primer sequences were as follows: Bcl-2: 5'-GCTACCGTCGTGACTT-3', 5'-GCCGGTTCAGGTACTC-3'; Cyclin E: 5'-GTAACATAAGCAAACTG-3', 5'-TTCTTCTGGATTGGCTAA-3'; Actin: 5'-CAGTAACAGTCCGCCT-3', 5'-GTGACGTTGACATCCG-3'; β-actin levels were used to normalize samples for calculation of the relative expression levels of the genes.

Western blotting analysis

To detect whether CD74 protein is expressed by CEC and to examine levels of Bcl-2 protein, cells were lysed in RIPA lysis buffer (10 mmol/L Tris, pH 7.2, 150 mmol/L NaCl, 1% deoxycholate, 1% Triton X-100, 0.1% SDS, 5 mmol/L EDTA) containing complete protease inhibitor cocktail [10 μg/mL leupeptin, 10 μg/mL aprotinin, 10 μg/mL pepstatin, 10 μg/mL chymostatin (Roche), 1 mmol/L PMSF (Sigma), and 20 mmol/L N-etheyl-melamide (Sigma)], for 30 min on ice and then centrifuged at 14000 *g* at 4℃ to remove cell debris. Lysates were separated by 12% (w/v) SDS-PAGE. The proteins were then transferred onto a nitrocellulose membrane and probed with anti-CD74 (FL-293; Santa Cruz) or anti-Bcl-2 (C-2; Santa Cruz), followed by horseradish peroxidase-conjugated anti-mouse (Jackson Laboratories).

To detect changes in Akt phosphorylation, stimulated cells were lysed in buffer containing: 25 mmol/L Tris, pH 7.4; 2 mmol/L vanadate; 75 mmol/L glycophosphate, pH 7.2; 2 mmol/L EDTA; 2 mmol/L EGTA; 10 mmol/L NaPPi; and 0.5% NP-40 in the presence of protease inhibitors. Lysates were separated by 10% (w/v) SDS-PAGE. The proteins were transferred onto a nitrocellulose membrane and probed with anti-p-Akt antibody (Cell Signaling Technology) followed by peroxidase-conjugated anti-mouse (Jackson Labs). The membrane was then stripped and reprobed with anti-tubulin antibody (Sigma), followed by peroxidase-conjugated anti-mouse (Jackson Laboratories).

Immunofluorescence and flow cytometry

Staining of IECs was performed using anti-CD74 (Santa Cruz), anti pan-cytokeratin (Sigma-Aldrich).

Cell survival assays

Annexin and PI staining: Cells were centrifuged, washed, and stained with annexin (BD Biosciences) and propidium iodide (PI) for 15 min at room temperature. The extent of annexin and PI staining was analyzed by FACS. Unstained cells were classified as living cells; annexin stained cells are apoptotic, and PI stained cells were considered necrotic.

FLICA staining: Analysis of apoptosis. To detect earlier stages of apoptosis, intracellular caspase 3 and 7 activity was analyzed using the FLICA (Fluorochrome Inhibitors of Caspases) Apoptosis Detection kit from Immunochemistry Technologies (Bloomington, MN). The kit contains carboxyfluorescein-labeled valylalanylaspartic acid fluoromethyl ketone, which tightly binds activated caspases. Cells were harvested and incubated with a FLICA solution in the complete medium at 37℃ for 1 h. After washing twice cells were analyzed by FACS.

Statistical analysis

Results are represented as averages of several experiments (as indicated) ± SE. Comparison between groups was done by Student's *t*-test.

RESULTS

CD74 is expressed on mouse colonic epithelial cells

To determine whether CD74 is expressed in normal CEC, we first analyzed its mRNA and protein levels in control and CD74 deficient (CD74-/-) CEC. As shown in Figure 1, CD74 mRNA (Figure 1A) and protein (Figure 1B) were detected in CEC, while they were not observed in the CD74 deficient cells. Isolation of CEC from C57BL/6

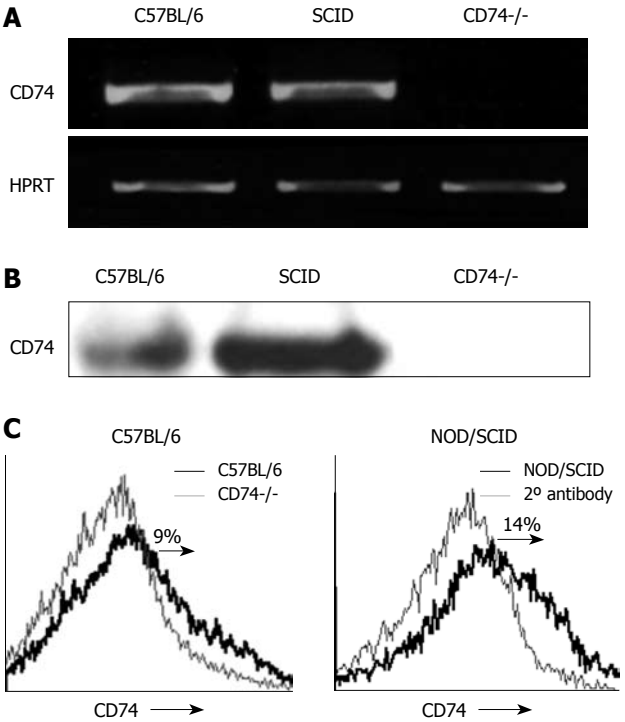

Figure 1 CD74 is expressed on naive CEC isolated from C57BL/6 mice. CEC were isolated from C57BL/6, NOD/SCID and CD74-/- mice. A: RNA was purified and CD74 or HPRT mRNA were analyzed by RT-PCR. The results presented are representative of four separate experiments; B: Cells were lysed and proteins were analyzed by Western blotting; C: Cells were stained with anti cytokeratin and anti CD74 antibodies, and analyzed by FACS. Histograms show CD74 expression on cytokeratin positive cells. CEC: Colon epithelial cells; RT-PCR: Reverse transcriptase-polymerase chain reaction; FACS: Fluorescence-activated cell sorter.

resulted in a population that was more than 90% pure, containing less than 5% B cells (data not shown), which expressed relatively high levels CD74. To eliminate contamination by B cell CD74, we analyzed CD74 mRNA and protein levels in CEC isolated from NOD/SCID mice, which lack B and T cells. As demonstrated in Figure 1, CD74 mRNA (Figure 1A) and protein (Figure 1B) were detected in CEC derived from NOD/SCID mice as well, showing that normal CEC express CD74. We next analyzed, by FACS analysis, CD74 cell surface expression on normal CEC. As shown in Figure 1C, CD74 is specifically expressed on normal CEC derived from C57BL/6 or NOD/SCID mice. Thus, CD74 is expressed on normal CEC.

CD74 serves as a survival receptor on CEC

We have previously shown that CD74 stimulation results in augmented expression of anti-apoptotic proteins, resulting in induction of cell survival[13,18]. In order to examine whether CD74 serves as a survival receptor on CEC, we followed the downstream cascade initiated by MIF in CEC. CEC from C57BL/6 mice were incubated *in vitro* for 17 h with MIF or with PBS, and the percentage of live and apoptotic cells in each group was analyzed using annexin-PI staining. As shown in Figure 2, MIF stimulation resulted in elevation of the proportion of live CEC (42%, $n = 4$, $P = 0.003$) and reduction in the apoptotic population.

To further show the *in vivo* role of MIF and CD74 in CEC survival, MIF was injected ip to control C57BL/6 and NOD/SCID mice and Bcl-2 mRNA and protein levels were determined. As can be seen in Figure 3A and B, a significant elevation in Bcl-2 mRNA and protein levels were detected following MIF stimulation compared to PBS-treated cells. The MIF-induced cascade was CD74 dependent, since in its absence, MIF was not able to increase Bcl-2 levels.

Since CEC survive poorly *in vitro*, and following 17 h incubation a large proportion of the cells are dead, we followed CEC survival immediately after their isolation. Thus, 24 h after MIF injection to C57BL/6, NOD/SCID and CD74-/- mice, cells were isolated and their cell death was analyzed using FLICA, which detects early stages of apoptosis by analyzing intracellular caspase 3 and 7 activity. The percentage of apoptotic cells was significantly higher in the PBS treated cells compared with the MIF treated cells derived from C57BL/6 and NOD/SCID mice (Figure 3C), while the CD74-/- cells were insensitive to MIF treatment. Results of four experiments are summarized in Figure 3D.

It has been recently shown that CD44 forms a complex with CD74 which regulates MIF-induced B cell survival[11,13]. CD44 expressed on CEC was previously characterized as a negative regulator of apoptosis as well[29]. Accordingly, CD44 deficient cells (CD44-/-) demonstrated an elevated basal apoptotic rate compared to control mice. In addition, there was no increase in CEC survival upon MIF stimulation (Figure 3C and D), suggesting that CD44 is a crucial component in the CD74-induced survival cascade.

Cell cycle progression is regulated by cyclin dependent kinases (Cdks). Cdks are constitutively expressed during the cell cycle and are activated upon specific cyclin binding. Different cyclins are differentially expressed during various stages of the cell cycle. This transient expression activates Cdks and regulates cell cycle progression. To further determine whether CD74 regulates cell entry to the S-phase, we followed cyclin E, which is expressed upon S-phase initiation. MIF (400 ng) was injected to C57BL/6 and NOD/SCID mice. 3.5 h later, CEC were isolated and their cyclin E mRNA levels were analyzed. As demonstrated in Figure 4A and B, cyclin E mRNA levels were upregulated in both C57BL/6 and NOD/SCID derived cells. These results demonstrate that following CD74 stimulation, CEC cells synthesize DNA, enter S phase, and probably divide.

Taken together, our results demonstrate that CD74 serves as a survival receptor on CEC. MIF binding to CD74 induces a signaling cascade resulting in Bcl-2 and cyclin E expression and survival in normal CEC.

In order to evaluate whether our finding may have implications on malignant cells, we further assessed the expression and function of CD74 in the colon carcinoma cell line CT26. We found that CD74 is expressed on the CT26 cell line (Figure 5A) and MIF stimulation reduces their apoptosis (Figure 5B and C), by upregulating Bcl-2 mRNA (Figure 5D and E), protein (Figure 5F) and cyclin E (Figure 5G) mRNA levels.

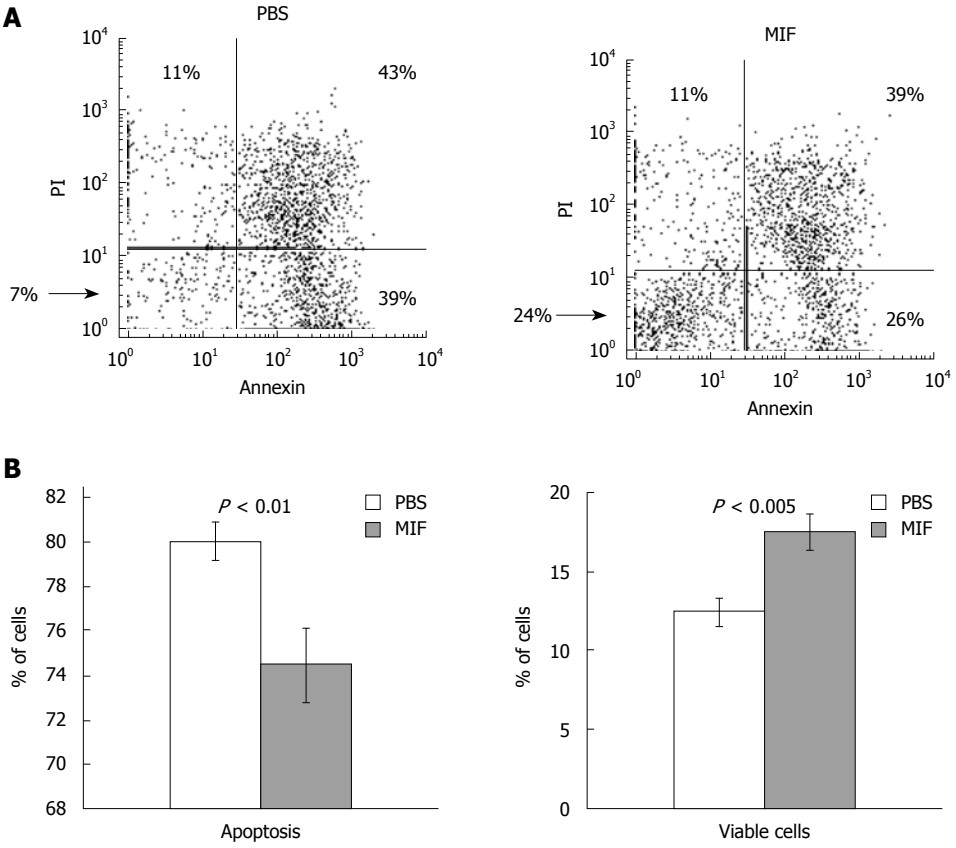

Figure 2 ***In vitro*** **stimulation with MIF induces CEC survival.** CEC from C57BL/6 mice were incubated in the presence or absence of MIF (400 ng/mL). A: After 17 h, cells were collected and analyzed for survival by annexin and propidium iodide staining; B: Graphs summarizing the results of four independent experiments. MIF: Migration inhibitory factor; PBS: Phosphate buffered saline.

We have previously shown that in B cells the CD74 induced survival cascade involves Akt phosphorylation[18]. In intestinal epithelial cells, it has been shown that phosphorylation of Akt enhances cell survival as well[30] and is closely associated with CRC[31,32]. We therefore analyzed Akt phosphorylation in CT26 cells. As shown in Figure 5H, MIF elevated Akt phosphorylation 1 min following stimulation.

Together, our results suggest that MIF and CD74 regulate colon tumor cell proliferation and survival.

DISCUSSION

The importance of CD74 as a survival receptor on B cells, and its role in the pathogenesis of certain malignancies is a subject of intense study. In the colon, CD74 is expressed on malignant cells, and its expression correlates with tumor grade[5]. Recent evidence suggests that up-regulation of CD74 and MIF on human colon adenomas is in correlation with dysplasia of the epithelial cells[10]. However, contradictory results regarding the presence of CD74 on normal human CEC were published through the years. In one report, the authors were able to detect the presence of CD74 by using immunohistochemistry, whereas, in a more recent study, using similar methodology, CD74 was not detected. In this article, we show CD74 expression in mouse normal CEC at the levels of mRNA, protein, and cell surface expression. Furthermore, we found that stimulation of CD74 by its natural ligand, MIF, results in increased survival of CEC. This can be at least partially attributed to enhanced expression of the survival gene, Bcl-2, which was found to be up-regulated in MIF-stimulated CEC. These findings suggest a role for CD74 on normal CEC.

Demonstration of CD74 on CEC is complicated by two main phenomena. First, CD74 has a very short half-life on these cells, and secondly, CEC are difficult to handle. These cells typically undergo apoptosis and/or necrosis, shortly after isolation[33]. Therefore, experiments involving incubation of these cells for more than a few hours usually result in death of most of the cells. In addition, isolates of CEC are never free of contaminating cells, specifically B cells from the lamina propria that also express CD74. In order to overcome these limitations, we performed our experiments shortly after CEC isolation. In experiments where we tested stimulation by MIF, we used mainly *in vivo* stimulation by ip injections of MIF for various amounts of time. To avoid contamination with B cells, we also repeated most of the experiments in NOD/SCID mice, which lack B cells. Our results show that CD74 is expressed on normal CEC cells.

Due to the difficulties discussed above, we used multiple models in order to demonstrate the positive effect CD74 has on CEC survival. In these experiments, we analyzed by FACS the percentage of living and apoptotic CEC. We demonstrated that stimulation by MIF either

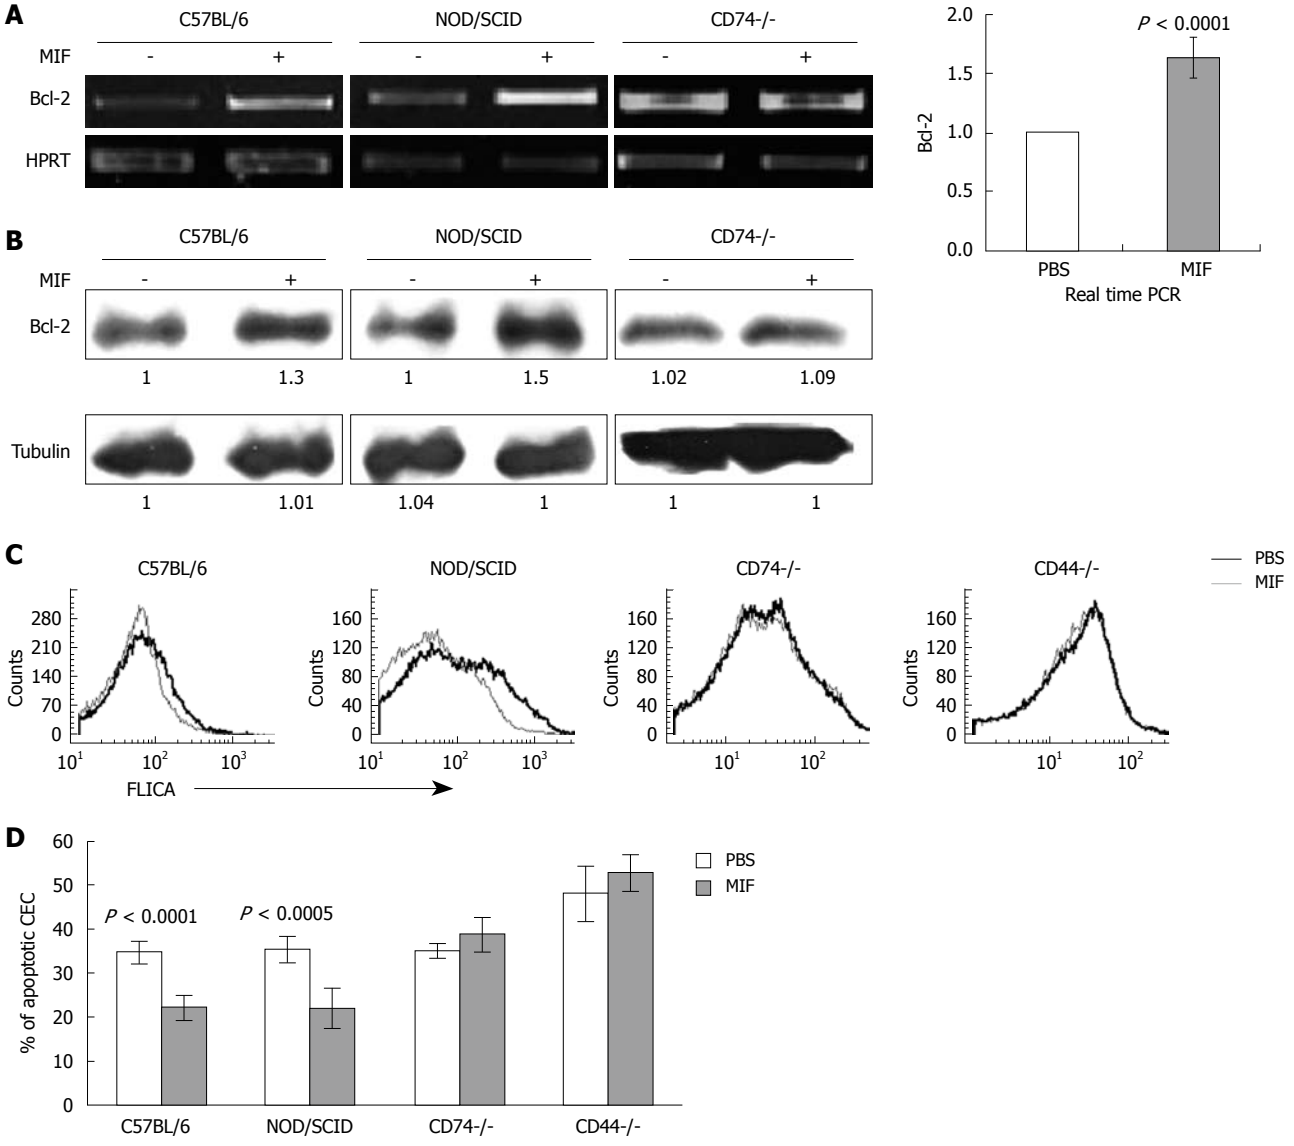

Figure 3 MIF stimulation elevates Bcl-2 and survival in CEC and their *in vivo*. CEC were isolated from CD74-/-, C57BL/6 and from NOD/SCID mice that were i.p injected with MIF (400 ng) or PBS 3.5 h before sacrifice. A: CEC were isolated, and RNA was purified; Bcl-2 or HPRT mRNA were analyzed by RT-PCR. The results presented are representative of four different experiments. The graph is a summary of four separate experiments of quantitative real time PCR using primers for Bcl-2 in CEC isolated from C57BL/6; B: Cells were lysed and Bcl-2 protein expression was analyzed by Western blotting analysis; C, D: C57BL/6, NOD/SCID, CD44-/- and CD74-/- mice were injected with MIF (400 ng) or PBS. After 24 h, mice were sacrificed and their CEC were isolated and stained with FLICA. C: Histograms show FLICA staining in MIF injected (grey line) compared to PBS injected (black line) CEC; D: Graph representing the average of five different experiments, demonstrating decreased apoptosis CEC in MIF treated C57BL/6 and NOD/SCID mice, compared to PBS treated animals.

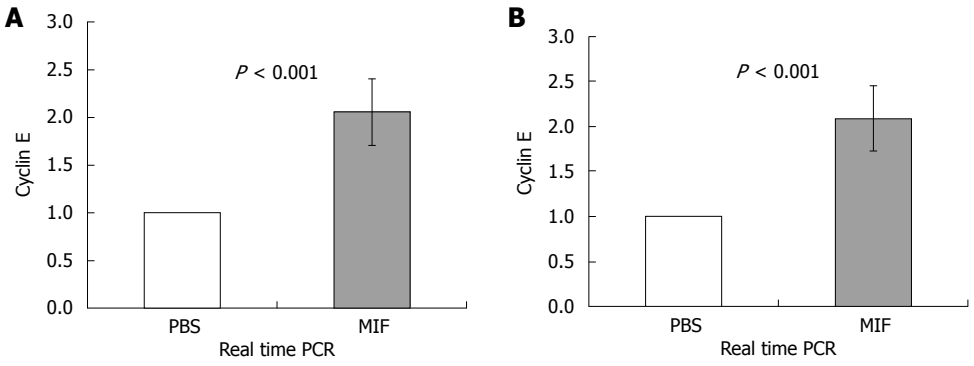

Figure 4 MIF induces cyclin E expression. CEC were isolated from C57BL/6 (A) and NOD/SCID (B) mice that were i.p injected with MIF (400 ng) or PBS 3.5 h prior to isolation of CEC. A, B: Quantitative real time PCR was performed using primers for cyclin E and β-actin. β-actin levels were used to normalize samples for calculation of the relative expression levels of cyclin E. Results are expressed as a fold of change in cyclin E expression at stimulated cells compared to non stimulated cells, which was defined as 1. Results shown are summary of four separate experiments.

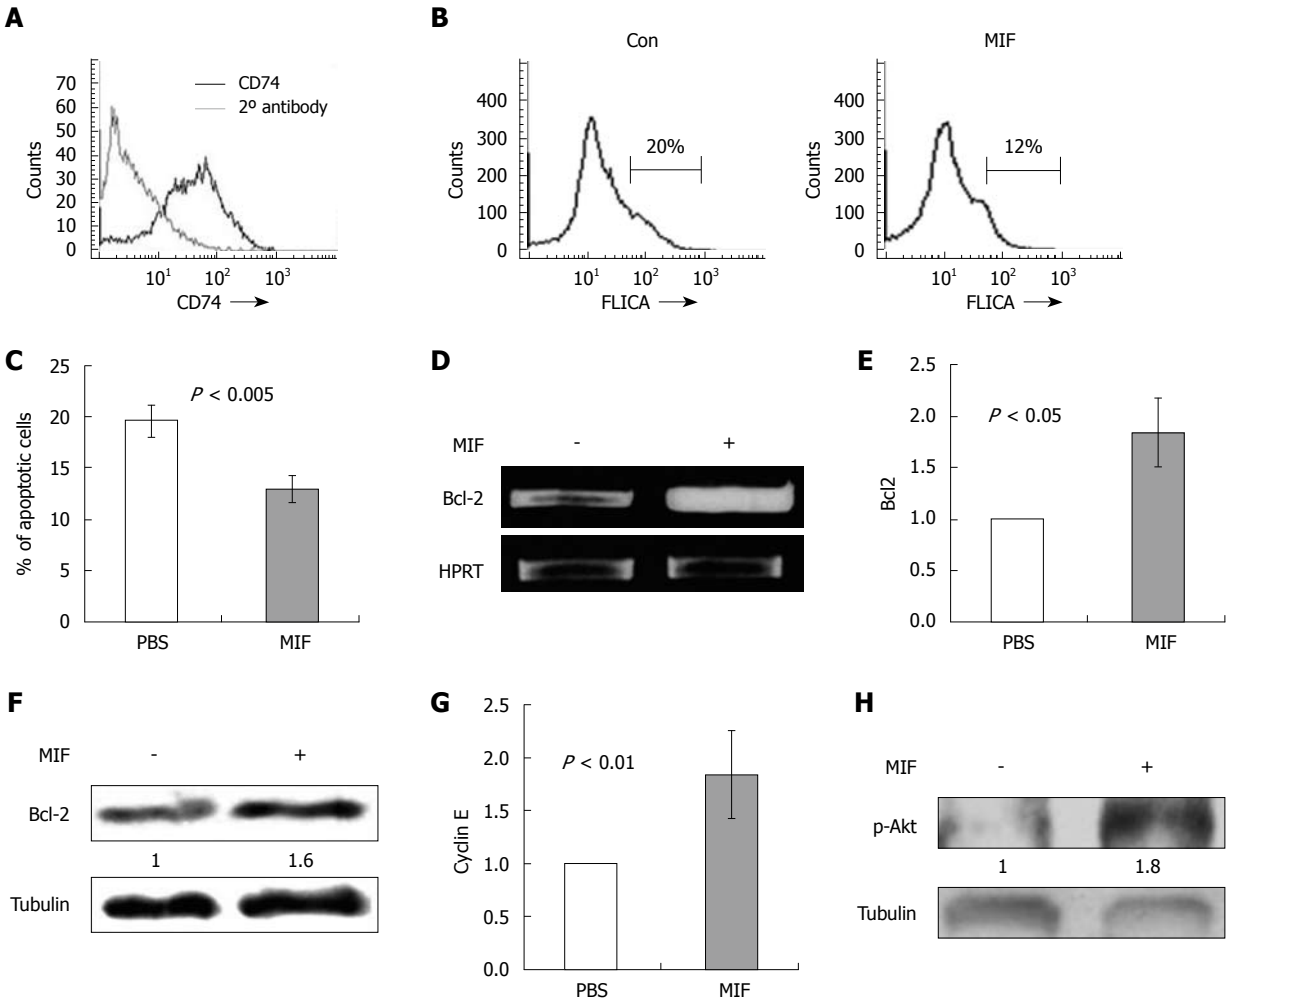

Figure 5 CD74 is expressed on CT26 cells and regulates their survival. A: CT26 cells were stained with anti CD74 antibodies, and analyzed by FACS. Histogram shows CD74 expression on these cells; B: Serum-starved CT26 cells were incubated in the presence or absence of MIF (400 ng/mL) for 6 h. Histograms show FLICA staining for apoptotic cells in both groups; C: Graph representing the average of five different experiments, demonstrating decreased apoptosis in MIF treated compared to untreated CT26 cell line; D: Serum-starved CT26 cells were either kept untreated or treated with MIF (400 ng/mL) for 3 h and levels of Bcl-2 mRNA were analyzed by RT-PCR. The results presented are representative of five different experiments; E: Quantitative real time PCR was performed using primers for Bcl-2. β-actin levels were used to normalize samples for calculation of the relative expression of Bcl2 level. Results are expressed as a fold of change in Bcl-2 expression at stimulated cells compared to non stimulated cells, which was defined as 1. Results shown are a summary of four separate experiments; F: Following 6 h of starvation the CT26 cells were lysed and Bcl-2 protein expression was analyzed by Western blotting analysis; G: Quantitative real time PCR was performed using primers for cyclin E and β-actin. β-actin levels were used to normalize samples for calculation of the relative expression levels of cyclin E. Results are expressed as a fold of change in cyclin E expression at stimulated cells compared to non stimulated cells, which was defined as 1. Results shown are a summary of four separate experiments; H: CT26 cells were incubated in the presence or absence of MIF (400 ng/mL) for 1 min. Cells were fast-frozen and lysed as described in Methods. Lysates were separated on 10% (wt/vol) SDS/PAGE and blotted with anti-p-Akt antibody (results presented are representative of three separate experiments) followed by HRP-conjugated anti-mouse antibodies. The membranes were then stripped and blotted with anti-tubulin.

by ip injection *in vivo* or by incubation of isolated CEC with MIF *in vitro*, resulted in elevated CEC survival and decreased apoptosis. These results strengthen our hypothesis that CD74 is a survival receptor on CEC and suggests that MIF is the natural ligand of CD74 on CEC, as described for B lymphocytes[13,18,19].

MIF is expressed throughout the human gastrointestinal tract, and has previously been implicated in control of apoptosis of non-epithelial and epithelial cells[34,35]. MIF induces Bcl-2 expression and cell survival. It was previously shown that CD74 forms a complex with CD44 in normal[11,12] and tumor cells[36]. We show here that CD44 is crucial for the MIF/CD74 induced survival cascade, since stimulation of CD44 deficient cells by MIF did not affect cell death.

Evidence for a role of CD74 in colorectal cancer was suggested by its expression on carcinoma cell lines of the colon[37], and by the observation that in human colorectal carcinomas, the grade of the tumor correlated with the level of CD74 expression on the transformed CEC[5]. Interestingly, both MIF and CD74 have been associated with tumor progression and metastasis. It was reported that MIF mRNA is over-expressed in various tumors[38,39] and MIF has also been associated with the growth of malignant cells[40]. Numerous studies have demonstrated the overexpression of CD74 in various cancers[20,41-46]. CD74 expression may also serve as a prognostic factor in many of these cancers, with higher relative expression of CD74 behaving as a marker of tumor progression[47]. Our findings further support a possible role for CD74 in

CRC. Additionally, CD44, which we showed essential in the MIF-CD74 survival cascade, is overexpressed in CRC, and has an anti-apoptotic effect on these cells, and probably involved in disease progression and metastases[29,48]. Moreover, we show that CD74 is expressed on the CT26 cell line and its stimulation by MIF enhances Akt phosphorylation, cyclin E and Bcl-2 expression resulting in their survival.

Our work clearly shows that CD74 is expressed on mouse intestinal epithelial cells, and serves as a survival receptor on these cells. Our results further show that CD74 may regulate survival of colorectal carcinoma tumor cells. Since we found that CD74 is a survival receptor on CEC, any change in gene expression that causes enhanced expression of CD74 or MIF may result in increased risk of colorectal cancer. Thus, CD74 may be found in the future to serve not only as a marker of colorectal cancer, but also as a therapeutic target.

COMMENTS

Background

CD74 is a protein that is expressed in and on some of the cells of the immune system, such as B lymphocytes and antigen presenting cells. This protein is known for its function in helping the immune cells to process and present foreign bodies. During recent years it was found that CD74 serves additionally as a survival receptor on cells of the immune system, and that its stimulation by its natural ligand - migration inhibitory factor (MIF) - prevents apoptosis (self destruction) of the cells.

Research frontiers

CD74 was found to be markedly expressed on numerous tumors - hematologic as well as epithelial; in some of these tumors it can serve as a tumor marker and its level of expression may be related to the prognosis. Moreover, activation of CD74 on B lymphocytes in B cell leukaemia, results in tumor progression, and blocking this pathway leads to decreased cell survival, and thus may be applicable as a therapeutic intervention. Whether CD74 is expressed on colon intestinal epithelial cells is controversial, although it was shown to be expressed on epithelial cells of colorectal adenomas.

Innovations and breakthroughs

The authors' work clearly shows that CD74 is expressed on mouse intestinal epithelial cells and serves as a novel survival receptor on these cells. They show that CD74 may regulate survival of colorectal carcinoma as well. Since they found that CD74 is a survival receptor on colonic epithelial cells, any change in gene expression that causes enhanced expression of CD74 or MIF may result in increased risk of colorectal cancer.

Applications

As CD74 is a survival receptor on colon epithelial cells and on malignant cell lines from mice, CD74 may be found in the future to serve not only as a marker of colorectal cancer, but also as a therapeutic target. Future research should focus on the role of CD74 in colorectal cancer models in animals and on human tissues.

Peer review

This paper is well written and documents expression on CD74 receptor mRNA and protein in colon epithelial cells. The study is very well done and straightforward. The experiments are of good quality.

Abstract

AIM: To identify the key cytokines involved in hepatic differentiation of mouse bone marrow mesenchymal stem cells (mBM-MSCs) under liver-injury conditions.

METHODS: Abdominal injection of CCl_4 was adopted to duplicate a mouse acute liver injury model. Global gene expression analysis was performed to evaluate the potential genes involved in hepatic commitment under liver-injury conditions. The cytokines involved in hepatic differentiation of mBM-MSCs was functionally examined by depletion experiment using specific antibodies, followed by rescue experiment and direct inducing assay. The hepatic differentiation was characterized by the expression of hepatic lineage genes and proteins, as well as functional features.

RESULTS: Cytokines potentially participating in hepatic fate commitment under liver-injury conditions were initially measured by microarray. Among the up-regulated genes determined, 18 cytokines known to closely relate to liver growth, repair and development, were selected for further identification. The fibroblast growth factor-4 (FGF-4), hepatocyte growth factor (HGF) and oncostatin M (OSM) were finally found to be involved in hepatic differentiation of mBM-MSCs under liver-injury conditions. Hepatic differentiation could be dramatically decreased after removing FGF-4, HGF and OSM from the liver-injury conditioned medium, and could be rescued by supplementing these cytokines. The FGF-4, HGF and OSM play different roles in the hepatic differentiation of mBM-MSCs, in which FGF-4 and HGF are essential for the initiation of hepatic differentiation, while OSM is critical for the maturation of hepatocytes.

CONCLUSION: FGF-4, HGF and OSM are the key cytokines involved in the liver-injury conditioned medium for the hepatic differentiation of mBM-MSCs.

Key words: Hepatic differentiation; Mouse bone marrow mesenchymal stem cells; Inducing cytokines; Fibroblast growth factor-4; Hepatocyte growth factor; Oncostatin M

Identification of cytokines involved in hepatic differentiation of mBM-MSCs under liver-injury conditions. *World J Gastroenterol* 2010; 16(26): 3267-3278 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i26/3267.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i26.3267

INTRODUCTION

It is generally believed that the bone marrow mesenchymal stem cells (BM-MSCs) provide an appropriate hematopoietic microenvironment that exerts regulatory effects on the self-renewal and differentiation of hematopoietic stem/progenitor cells. They are capable of differentiating into mesoderm cell lineages, including osteoblasts, chondrocytes and adipocytes[1-3]. However, emerging new findings suggest that BM-MSCs are able to give rise to a more broad range of cells, including hepatocytes, neurons, epithelial cells and keratinocytes[4-8]. This plasticity of BM-MSCs has attracted much attention to their *in vivo* new functions under either metabolic or pathologic conditions, and their clinical therapy for tissue repair. In fact, several studies in animal models have suggested that endogenous MSCs may "naturally" be involved in wound healing and tissue regeneration, and the engrafted exogenous MSCs have beneficial effects in tissue repair, including that of bone, myocardial tissue, skin, kidney and liver[9-19]. These may encourage further studies on the new insight into MSCs biology and the mechanisms underlying MSCs differentiation, which are still poorly understood at present.

Recently, by an *in vivo* tracing technology, we have demonstrated that BM-MSCs could be recruited from the bone marrow into peripheral blood, and toward into the wounded sites in response to the injured-liver signals, which indicated a close relationship between BM-MSCs and liver repair[20]. Moreover, we have also found that the engrafted exogenous BM-MSCs could be recruited to the injured liver, and were able to differentiate into multiple hepatic-lineage cells, which greatly improved the wound healing, providing further insight into the relationship between BM-MSCs and injured liver[20]. Our previous reports also support the idea that the liver-injury conditioned culture medium can induce the differentiation of BM-MSCs into functional hepatic cells in an *in vitro* experiment[4]. These observations indicated that the hepatic differentiation of BM-MSCs may be induced by the cytokines secreted from the injured liver cells, since no cellular interactions existed in such cell-free cultural medium. However, which cytokines direct hepatic fate specification of BM-MSCs still remains unclear. In the present study, we identified the key cytokines that play a crucial role in the differentiation of mBM-MSCs in the liver-injury conditioned medium. We hope our finding will benefit the better understanding of the novel mechanisms underlying BM-MSCs involved liver repair and regeneration, and help improve the cytokine-based hepatic inducing strategy and provide a rich cellular resource from BM-MSCs for cytotherapy of acute liver diseases.

MATERIALS AND METHODS

Experimental animals

Eight to ten-week-old male ICR mice obtained from the Laboratory Animal Unit of Zhejiang Academy of Medical Sciences (Hangzhou, China) were used in the experiments. Animals were housed under specified pathogen-free conditions. All animal experiments were done in accordance with a legal regulation, which includes approval by a local ethical committee.

Isolation and culture of bone marrow MSCs

The mouse bone marrow MSCs (mBM-MSCs) were prepared as described previously[4]. Briefly, the bone marrow was extruded by clipping of the epiphysial ends of the bones and flushing with IMDM (Sigma, St. Louis, MO), supplemented with 10% fetal bovine serum (Hyclone, Rockville, MD), 1% penicillin/streptomycin (Medium A). After 3 d, non-adherent cells and debris were removed, and the adherent cells were cultured continuously. At near confluence, the cells were replated at 5×10^4 cells/cm^2. Osteogenic, chondrogenic and adipogenic differentiations were examined for functional identification[5].

Preparation of acute liver-injury mouse model

The acute liver-injury mouse model was prepared according to the method described previously[21]. Briefly, the mice were treated with CCl_4 (1.0 mL/kg body weight of a 10% solution in mineral oil injected intraperitoneally) twice a day and then sacrificed by cervical vertebrae luxation on the 24th h after the last injection.

Hepatocyte isolation and preparation of conditioned medium

The hepatocytes were isolated by the two-step collagenase perfusion from healthy mice (as control) or liver-injury mouse model prepared by the method described above. Briefly, donor animals received 25 U heparin (Sigma) prior to cell isolation. After cannulation of the portal vein, the liver was perfused with a calcium-free buffer solution, 3 mL/min at 37℃ for 10 min. Then, the liver was perfused with 0.025% collagenase Ⅳ (Invitrogen, Carlsbad, CA), 2 mL/min at 37℃ for 15 min. The perfused liver was resected, and the cells were released by gentle shaking and collected in 20 mL IMDM. The supernatant cell suspension was filtered using a 200 mm nylon mesh and the filtrate was washed twice with PBS by centrifugation at 50 × *g* for 45 s to remove cell debris, damaged cells, and non-parenchymal cells. After washing, the hepatocytes were cultured in medium A at 5×10^4 cells/cm^2. Forty-eight hours later, the supernatant was collected and passed through a 0.25 mm filter. The filtrate was finally defined as hepatocyte-injury conditioned medium and stored in aliquots at -20℃ for future use.

Induction of hepatogenic differentiation of mBM-MSCs in conditioned medium

The mBM-MSCs of passage 3 were inoculated in differentiation medium at 5×10^4 cells/cm^2 on culture flasks. The differentiation medium consisted of 50% fresh IMDM medium (Medium A) and 50% conditioned medium. As a negative control, mBM-MSCs were cultured in medium A only. Cells were cultured in a humidified atmosphere of 5% CO_2 and 95% air at 37℃. Cultures were maintained by medium exchange every 3 d. The cell morphology was observed under a confocal laser-scanning microscope (LSM 510; Carl Zeiss Inc., Jena, Germany).

Gene expression analysis by real-time polymerase chain reaction

The expressions of hepatic linage genes [α-fetoprotein (AFP), albumin (ALB), hepatocyte nuclear factor 3β (HNF3β), tyrosine aminotransferase (TAT)] and cytokine genes [fibroblast growth factor-4 (FGF-4), hepatocyte growth factor (HGF) and oncostatin M (OSM)] involved in hepatic differentiation and commitment were analyzed by real-time polymerase chain reaction (PCR). For this, total RNA was extracted from undifferentiated control or differentiated cells, normal or injured liver cells, respectively, using NucleoSpin® RNAIIKits, and then 5 μg of which was reversely transcribed into cDNA with SuperScript Ⅲ first-strand synthesis system (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. The transcripts normalized to β-actin were measured by real-time PCR using Mastercyclerep realplex system and Real-Time Detection software (Eppendorf, Germany), in which the standard double-stranded DNA dye (SYBR Grean Ⅰ) was used. Gene-specific primers were designed using the Primer Premier software (Table 1).

Protein expression analysis by ELISA

The expressions of hepatic linage proteins (AFP and ALB) in differentiated hepatocytes and cytokine proteins (FGF-4, HGF and OSM) in injured liver cells were further analyzed by ELISA. The total proteins from differentiated cells or undifferentiated control cells, normal or injured liver cells were extracted using T-PER (a protein extraction reagent) (Qiagen, Germany) according to the manufacturer's manual, and were coated on a 96-well polystyrene plate at 4℃ overnight. The wells were washed with PBST (500 μL Tween 20/L PBS) and then blocked with 0.5% BSA for 1 h at 37℃. The hepatic linage proteins (AFP and ALB) or cytokines (FGF-4, HGF and OSM) were detected using the polyclonal antibodies, including rabbit anti-mouse HGF and FGF4, goat anti-mouse OSM (abcam, UK) rabbit anti-AFP and goat anti-ALB (Biodesign, Saco, Maine, USA) after washing with PBST for 3 times. The secondary antibodies, including goat anti-rabbit and rabbit anti-goat (Santa Cruz Biotechnology, Santa Cruz, CA, USA), labeled with horseradish peroxidase (HRP) were added at a proper dilution. Finally, the TMB was added, and the observation density was detected by a microplate reader at 450 nm after 2 mol/L sulphuric acid was added to stop the reaction.

Periodic acid-Schiff stain for glycogen

The hepatic differentiation was functionally determined by glycogen storage. For this, the culture dishes containing differentiated cells were fixed in 95% alcohol for 10 min. Samples were then oxidized in 1% periodic acid for 5 min, rinsed three times in deionized (d) H_2O, treated with Schiff's reagent for 15 min, and rinsed in dH_2O for 5 min. Finally, the preparations were assessed under light microscope, and the positive rate of differentiated cells was counted as previously described[4].

Evaluation of urea synthesis

The hepatic differentiation was functionally determined by urea synthesis. The mBM-MSCs were plated at 5×10^4 cells/cm^2 on collagen coated six-well plates in differentiation medium or control medium. After washing extensively with PBS, cells differentiated at days 0, 4, 8, 16, 20 and 21 were incubated in 2 mL of serum-free Hanks' buffered salt solution containing 5 mmol/L NH_4Cl for 2 h at 37℃. After incubation, the urea concentrations in the supernatant were measured according to the method described previously[22].

Global evaluation of cytokines potentially involved in injured liver commitment

A global gene expression analysis was performed by microarray to identify the potential cytokines responsible for hepatic commitment. Total RNA and complementary DNA were prepared from CCl_4-treated and untreated mouse livers. An Illumina Mouse WG-6 v2.0 BeadChip

(Illumina, San Diego, CA, USA) was used to generate expression profiles of more than 48 000 transcripts with 500 ng of labelled cDNA for each sample, following manufacturer's recommended protocols. A randomized design was used to minimize chip effects. Four individuals were replicated in the two batches. Expression intensity was measured with an average of 30 beads for each transcript. The BeadChips were imaged with an Illumina BeadArray Reader. The raw intensities were extracted with the Gene Expression Module in Illumina's BeadStudio software. Expression intensities were log2 transformed and median-centered by subtracting the mean value of each array from each intensity value.

Cytokine identification in depletion experiment

The cytokines involved in hepatic specification in liver-injury conditioned medium were initially identified in a depletion experiment. The liver-injury conditioned medium was incubated with a number of different cytokine antibodies (anti-HGF, -FGF-4, -OSM, -FGF-3, -FGF-10, -FGF-12, -FGF-13, -FGF-14, -FGF-15, -FGF-17, -FGF-18, -FGF-20, -FGF-21, -bNGF, -IGF-1, -TGF-β1, -TGF-β2, and -TGF-β3, abcam and Biodesign) at different concentrations (1:100, 1:200 and 1:500) overnight at 4℃ under agitation. Then, the cytokines were removed by affinity co-immunoprecipitation. The protein A-coupled sepharose beads were prepared according to the manufacturer's instructions (Abcam), and were added into the antibody pretreated liver-injury conditioned medium. After being incubated at 4℃ for 4 h, the samples were centrifuged at 10 000 × *g* for 5 min. Supernatants were collected for hepatic differentiation induction assay. The hepatic differentiation was examined based on the hepatic lineage gene and protein expressions and functional characterizations as described above. In parallel, a non-specific rabbit antibody (IgG isotype) was used in control groups.

Cytokine identification in rescue experiment

To confirm the observation from depletion experiment that HGF, FGF-4 and OSM may be involved in hepatic differentiation in liver-injury conditioned medium, a rescue experiment was performed by adding back these three cytokines into the co-immunoprecipitated liver-injury conditioned medium. The liver-injury conditioned medium was pretreated with anti-HGF, anti-FGF-4 and anti-OSM, followed by protein A-coupled Sepharose beads as described above, and mouse FGF-4 (0, 1.25, 2.5, and 5 μg/mL), HGF (0, 2.5, 5 and 10 μg/mL) and OSM (0, 1.25, 2.5 and 5 μg/mL) (R&D Systems, Abingdon, UK) were added back to this medium to rescue its liver-inducing activity. The hepatic differentiation was examined based on the hepatic lineage gene and protein expressions and functional characterizations as described above.

Induction of hepatic differentiation by FGF-4, HGF and OSM

To further investigate the role of FGF-4, HGF and OSM in hepatic differentiation, an *in vitro* hepatic induction assay was conducted using different combinations of FGF-4, HGF and OSM. The mBM-MSCs were inoculated in medium A with different combinations of 10 ng/mL FGF-4, 20 ng/mL HGF and 10 ng/mL OSM[21] at 5×10^4 cells/cm^2 on culture flasks. As a negative control, the mBM-MSCs were cultured in medium A without FGF-4, HGF and OSM. Cells were cultured in a humidified atmosphere of 5% CO_2 and 95% air at 37℃. After 72 h, non-adherent cells and debris were removed and the adherent cells were cultured continuously. Cultures were maintained by medium exchange every 3 d. The hepatic differentiation was examined based on the hepatic lineage gene and protein expressions and functional characterizations as described above.

Statistical analysis

Statistical analysis was performed using the SPSS version 16.0, and data were expressed as mean ± SD. Differences between the values were determined by paired-samples *t* test. A value of $P < 0.05$ was considered statistically significant.

RESULTS

Evaluation of cytokines in response to liver injury

To evaluate the possible cytokines that participate in the hepatic differentiation of BM-MSCs under liver-injury conditions, the gene expression levels of cytokines/proteins in injured liver were initially examined at different injury time-points (12, 24 and 48 h) by microarray analysis. The results showed that more than 1200 genes were significantly up- or down-regulated during these time periods, and most of them were closely related to hepatocyte detoxification and metabolisms (data not shown). Totally, 40 cytokines/chemokines or their corresponding receptors closely associated with cellular growth, differentiation and migration were found to be significantly up-regulated (2-62 folds), among which 18 cytokines, including FGF-3, FGF-4, FGF-10, FGF-12, FGF-13, FGF-14, FGF-15, FGF-17, FGF-18, FGF-20, FGF-21, HGF, OSM, b-NGF, IGF-2, TGFβ-1, TGFβ-2 and TGFβ-3, were largely contributed to the hepatic growth and development. Therefore, these cytokines were considered to be potentially involved in the hepatic differentiation of mBM-MSCs under liver-injury conditions, and to be the candidates for further identification.

Cytokine identification in depletion experiment

Based on the microarray analysis as described above, the cytokine candidates were removed from the conditioned medium by a co-immunoprecipitation strategy using different combinations of specific antibodies which fall into several groups, designated as E1 (anti-FGF-3 and -FGF-4), E2 (anti-FGF-10, -FGF-12 and -FGF-13), E3 (anti-FGF-14, -FGF-15 and -FGF-17), E4 (anti-FGF-18, -FGF-20 and -FGF-21), E5 (anti-HGF, -OSM and -bNGF) and E6 (anti-IGF-1, -TGF-β1, -TGF-β2 and -TGF-β3). The conditioned medium from each group

MSC group: Control MSCs cultured in medium A with PBS; C group: MSCs induced with liver-injury conditioned medium with nonspecific IgG; (A) E1-E6 groups: MSCs induced with liver-injury conditioned medium and different combinations of specific antibodies (E1: Anti-FGF-3 + anti-FGF-4; E2: Anti-FGF-10 + anti-FGF-12 + anti-FGF13; E3: Anti-FGF-14 + anti-FGF-15 + anti-FGF-17; E4: Anti-FGF-18 + anti-FGF-20 + anti-FGF-21; E5: Anti-HGF + anti-OSM + anti-bNGF; E6: Anti-IGF-1 + anti-TGF-β1 + anti-TGF-β2 + anti-TGF-β3); (B) E1-E5 groups: MSCs induced with liver-injury conditioned medium and different specific antibody lonely (E1: Anti-FGF-4; E2: Anti-FGF-3; E3: Anti-bNGF; E4: Anti-HGF; E5: Anti-OSM). $^{b}P < 0.01$ *vs* C group. ELISA: Enzyme-linked immunosorbent assay; MSC: Mesenchymal stem cells; PBS: Phosphate buffered saline; FGF: Fibroblast growth factor; HGF: Hepatocyte growth factor; OSM: Oncostatin M.

was used for further hepatic differentiation. The results showed that, after being induced for 20 d, the ALB in differentiated cells in E1 and E5 groups was more significantly down-regulated ($P < 0.01$) than that in the control group. However, no significant down-regulations of ALB could be observed in other experimental groups (E2, E3, E4 and E6), suggesting that FGF-3, FGF-4, HGF, OSM and bNGF in the conditioned medium examined in E1 and E5 groups may play essential roles in the hepatic differentiation of mBM-MSCs (Figure 1A). In an attempt to verify this observation, the FGF-3, FGF-4, HGF, OSM and bNGF were removed selectively: E1, anti-FGF-4; E2, anti-FGF-3; E3, anti-bNGF; E4, anti-HGF; and E5, anti-OSM. The hepatic differentiation of mBM-MSCs in each group was detected and the results showed that the ALB in differentiated cells in E1, E4 and E5 groups was significantly down-regulated ($P < 0.01$) compared with that in the control group. However, no significant down-regulations of ALB could be observed in E2 and E3 groups (Figure 1B). These results indicated that FGF-4, HGF and OSM are key factors involved in the hepatic differentiation of mBM-MSCs. This observation seems in accordance with some previous reports showing that FGF-4, HGF and OSM played important roles in liver healing, regeneration and initiation of development[23-26].

Expression analysis of FGF-4, HGF and OSM during liver injury

To obtain a deep insight into the role of FGF-4, HGF and OSM in liver injury, a kinetic expression analysis of these cytokines during liver injury was performed. The results showed that the expression of HGF mRNA was significantly up-regulated at 6 h after injury ($P < 0.05$), peaked at 12 h ($P < 0.01$) and kept in high level up to 72 h (Figure 2A). Similarly, the expressions of FGF-4 and OSM mRNAs were importantly up-regulated at 12 h ($P < 0.01$) after injury, peaked in 24-48 h ($P < 0.01$) and also kept in high levels up to 72 h (Figure 2B and C). Accordingly, the expression changes of HGF, FGF-4 and OSM proteins were generally identical with their mRNA expressions (Figure 2D-F).

Detection of FGF-4, HGF and OSM in culture medium

To further investigate the existence and occurrence of FGF-4, HGF and OSM in liver-injury conditioned medium, the kinetic secretion of FGF-4, HGF and OSM into the cultured medium was determined. The results showed that the concentrations of HGF and OSM proteins were dramatically up-regulated at 12 h after culture, peaked at 24 or 48 h and kept in high levels up to 72 h (Figure 3A and C); while the FGF-4 was significantly up-regulated at 24 h and peaked at 48 h (Figure 3B). Notably, it showed that FGF-4, HGF and OSM protein expressions could also be detected in the cell culture without undergoing liver injury (Figure 3), possibly due to the fact that isolation of cells from liver itself is a tissue "anatomy" which may result in the "injured signal" to stimulate the cells to secrete cytokines.

Effects of FGF-4, HGF and OSM in hepatic differentiation

To investigate the effects of each cytokine in the hepatic differentiation, a number of depletion experiments were conducted using different combinations of antibodies. The results showed that after treatment with anti-FGF-4 and anti-HGF independently, the hepatic differentiation induced by the conditioned medium was significantly ($P < 0.01$) down-regulated with the increased use of antibody (E1: 1:500, E2: 1:200, E3: 1:100) as determined by the expression of both the early liver-specific marker (HNF3β and AFP) and the late liver-specific marker (ALB and TAT) at mRNA or protein levels, and by the functional [Periodic acid-Schiff (PAS) and urea production] analyses (Figure 4A-H). However, after treatment with anti-OSM alone, the expressions of HNF3β and AFP in cells were not significantly decreased (Figure 4A and B), while the expressions of ALB and TAT were dramatically ($P < 0.01$)

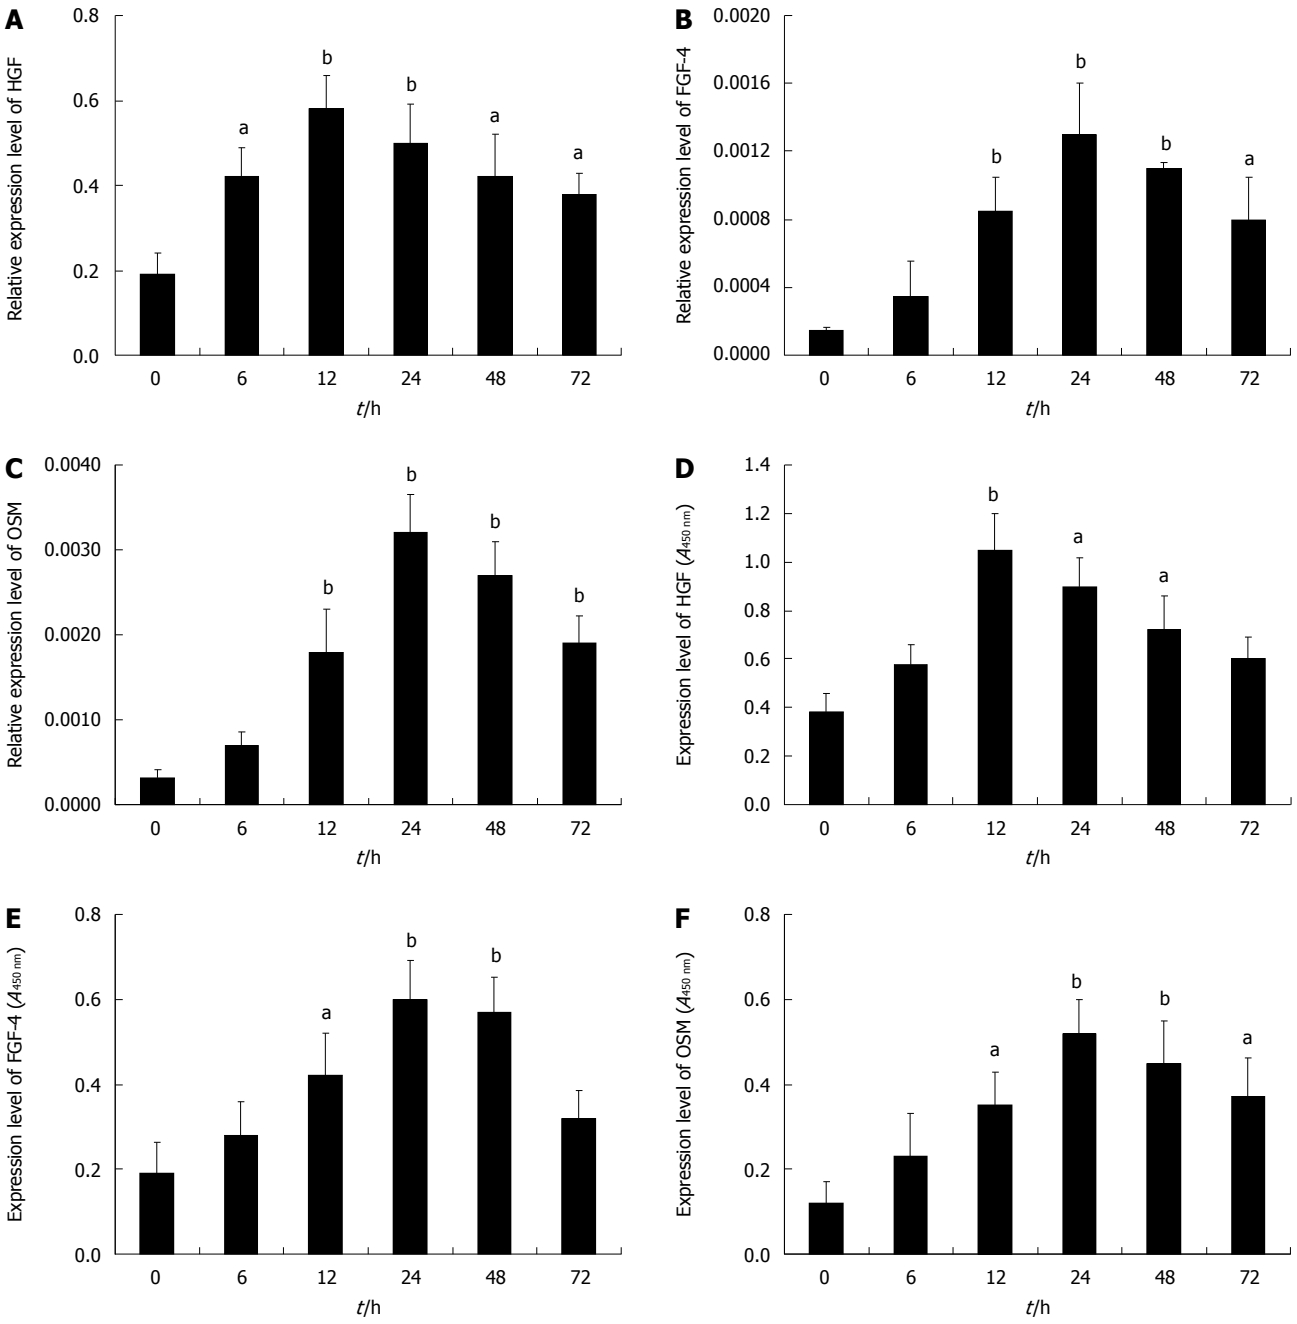

Figure 2 Expression analyses of FGF-4, HGF and OSM during liver injury. A-C: The kinetic expression of FGF-4, HGF and OSM mRNAs detected by real-time PCR during liver injury; D-F: The kinetic expression of FGF-4, HGF and OSM proteins detected by ELISA during liver injury. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* 0 h.

restrained at both mRNA and protein levels (Figure 4C, D and F). Accordingly, the PAS and urea production were also dramatically ($P < 0.01$) decreased in anti-OSM treatment groups (Figure 4G and H). These results suggested that FGF-4, HGF and OSM may play different roles in the hepatic differentiation of mBM-MSCs. Among these factors, FGF-4 and HGF may be essential for the initiation of early hepatic differentiation, while OSM may be critical for the maturation of hepatocytes.

Functional evaluation of FGF-4, HGF and OSM in rescue experiment

In order to find further evidence on the role of FGF-4, HGF and OSM in the conditioned medium in hepatic differentiation, we performed a rescue experiment in which three recombinant cytokines were added back to the cytokine-removed medium treated with anti-FGF-4 (1:100), anti-HGF (1:100) and anti-OSM (1:100). The results showed that administration of FGF-4, HGF and OSM into this cytokine-removed medium could significantly rescue the hepatic differentiation with the increased concentrations of the cytokines as determined by the expression of ALB protein and urea synthesis (E1: 0 ng/mL FGF-4 + 0 ng/mL HGF + 0 ng/mL OSM; E2: 1.25 ng/mL FGF-4 + 2.5 ng/mL HGF + 1.25 ng/mL OSM; E3: 2.5 ng/mL FGF-4 + 5 ng/mL HGF + 2.5 ng/mL OSM;

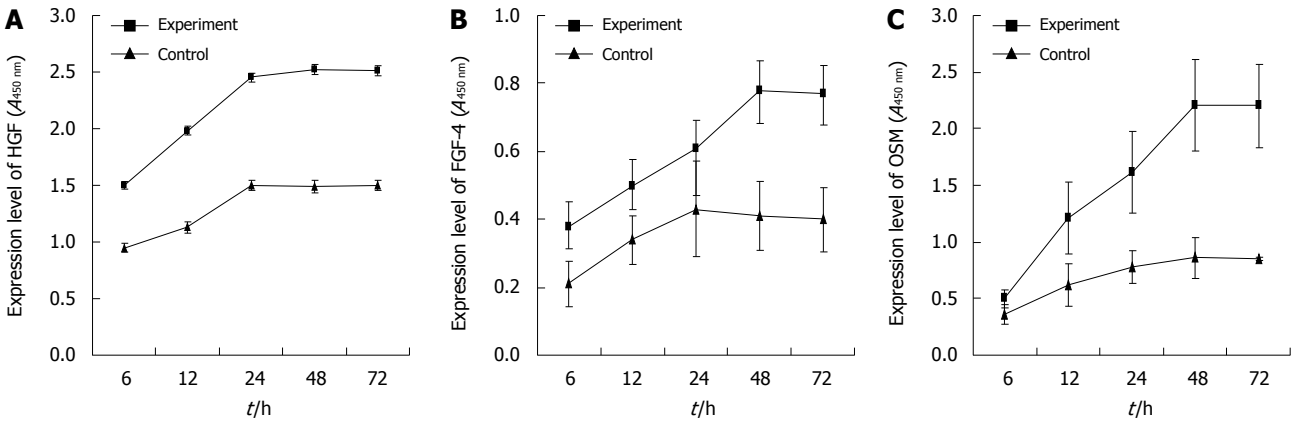

Figure 3 Detection of kinetic secretions of HGF (A), FGF-4 (B) and OSM (C) proteins in liver-injury conditioned medium. Experiment: Hepatocyte-injury conditioned medium; Control: Normal-hepatocyte conditioned medium.

E4: 5 ng/mL FGF-4 + 10 ng/mL HGF + 5 ng/mL OSM) (Figure 5A and B). These results provided solid support that FGF-4, HGF and OSM are the key cytokines that contribute to the induction of hepatic differentiation in the liver-injury conditioned medium.

Hepatic differentiation induced directly by FGF-4, HGF and OSM

Based on the observations from the above experiments that FGF-4, HGF and OSM are crucial for hepatic differentiation in the conditioned medium, we performed a further hepatic differentiation experiment induced directly by FGF-4, HGF and OSM in different combinations. The results showed that FGF-4, HGF and OSM may have synergistic effects on the hepatic differentiation of mBM-MSCs, indicating that the three cytokines may play different roles in the induction of hepatic differentiation. As shown in Figure 6, after induced with a factor alone or combination of the two, the hepatic differentiation of mBM-MSCs was lowly detectable as determined by the synthesis of both AFP (early hepatic differentiation marker) and ALB (late hepatic differentiation marker) in differentiated cells. In the group induced with FGF-4 (10 ng/mL) and HGF (20 ng/mL, E4), the concentration of AFP was highly detectable, while ALB was lowly detectable, suggesting that FGF-4 and HGF have a synergistic effect on the initiation of early hepatic differentiation. In contrast, both of the AFP and ALB proteins could be highly detected in group E5 in which the mBM-MSCs were induced by the combination of these three factors. This indicated that FGF-4, HGF and OSM had a synergistic effect in the differentiation of functional hapatocytes from mBM-MSCs. Furthermore, FGF-4 and HGF exhibited a cooperative effect on the early hepatic differentiation of mBM-MSCs, while OSM is essential to the maturation of hepatocytes in the late hepatic differentiation.

DISCUSSION

Mesenchymal stem cells (MSCs) have emerged as a promising resource of functional hepatocytes for treatment of liver diseases because of its plasticity of multiple cell lineages. To date, many inducing systems for hepatic differentiation from MSCs have been developed[22,27,28]. However, the rate of hepatocyte-like cells differentiated from MSCs is still very low and the mechanisms are also not well known. It is undoubted that exposition of MSCs to the inducing systems, resembling the conditions in liver development, injury and regeneration, could acquire a more efficient differentiation[29]. Our previous studies have shown that mBM-MSCs could be induced to differentiate into hepatic cells by conditioned culture medium of hepatocytes[4]. Thus identification of the exact cytokines involved in liver-injury conditions for the mBM-MSCs differentiation needed further studies. This study provides such investigation. Eighteen cytokines closely related to liver growth, repair and development were chosen as candidates from numerous up-regulated cytokine genes by microarray. It was found that three cytokines (FGF-4, HGF and OSM) may play a crucial role in the conditioned medium-induced hepatic differentiation, since hepatic differentiation was dramatically decreased after removing FGF-4, HGF and OSM from the conditioned medium. Therefore, the present study provided a direct basis on the selection of cytokines for hepatic differentiation. However, besides these three key cytokines, some other factors involved in the liver injury need to be identified for improving the cytokine-based inducing system.

FGF-4, HGF and OSM play important roles in liver regeneration, healing, initiation and development. FGF-4 was considered to be one of the most important fibroblast growth factor family members that can irritate the proliferation of mesodermal and endodermal cells and improve development of fetal liver[30]. HGF was found to be essential for the development of several epithelial organs and was one of the most well characterized cytokine for the stimulation of DNA synthesis in primary hepatocyte cultures, and for liver development[31]. The OSM, however, is a member of the interleukin-6 family produced by hematopoietic cells and induces differentiation of fetal hepatic cells, conferring various metabolic activities of

adult liver[32]. These three factors participate in different liver developmental stages. Thus, we further examined the exact roles of FGF-4, HGF and OSM in the hepatic differentiation from mBM-MSCs. It clearly showed that after removing FGF-4 and HGF from the conditioned medium by their antibodies, either the early or the late hepatic differentiation induced by the conditioned medium could be significantly down-regulated, while after removing OSM from the conditioned medium, only the late hepatic differentiation was down-regulated. It suggested that FGF-4, HGF and OSM also play different roles in the hepatic differentiation of mBM-MSCs, and FGF-4 and HGF are essential for the initiation of hepatic differentiation, while OSM is critical for the maturation of hepatocytes.

In conclusion, the present study analyzed the potential factors in injured liver for hepatic differentiation from mBM-MSCs. It was found that FGF-4, HGF and OSM might be the key cytokines. They played different roles during hepatic differentiation, which is similar to their functions in liver development. Hopefully, our study would not only provide evidence of cytokine selection for hepatic differentiation, but also benefit the exploration of the molecular mechanisms underlying the differentiation of BM-MSCs into hepatocytes.

COMMENTS

Background

Acute liver failure is a severe liver disease with a mortality of 60%-90%. The only therapeutic option, orthotopic liver transplantation, is limited because of the shortage of suitable donor organs. Mesenchymal stem cells (MSCs), known for their capacity to proliferate indefinitely and differentiate into almost all types of cells, including hepatocytes, have provided the hope of cellular replacement therapy for liver failure.

Research frontiers

Mouse liver-injury conditioned culture medium dramatically facilitated the differentiation of mouse bone marrow MSCs (mBM-MSCs) into functional hepatic cells. However, which cytokines direct hepatic fate specification of mBM-MSCs still remains unclear. In this study, the authors demonstrate that fibroblast growth factor-4 (FGF-4), hepatocyte growth factor (HGF) and oncostatin M (OSM) may play crucial roles in the differentiation of mBM-MSCs in the liver-injury conditioned medium.

Innovations and breakthroughs

In the present study, the authors reported the identification of cytokines involved in hepatic fate specification of mBM-MSCs in the liver-injury conditioned medium. By removing cytokines from conditioned medium and adding back cytokines into the "cytokine-removed" conditioned medium, it was demonstrated that FGF-4, HGF and OSM may play crucial roles in the conditioned medium-induced hepatic differentiation. Furthermore, different combinations of FGF-4, HGF and OSM were used to induce hepatic differentiation, and the result showed that FGF-4 and HGF had a cooperative effect on the early hepatic differentiation of mBM-MSCs, while OSM was essential to the maturation of hepatocytes in the late hepatic differentiation. This is the first study to report that FGF-4, HGF and OSM FGF-4, HGF and OSM not only play crucial roles in the hepatic differentiation of mBM-MSCs, but also have profound synergistic effect on the hepatic differentiation of mBM-MSCs pro and con. This *in vitro* study would contribute to the improvement of hepatic cell resource for cell-based therapies for acute and chronic end-stage liver diseases and provide a model for more detailed characterization on the molecular mechanisms underlying the differentiation of BM-MSCs into hepatocytes.

Applications

This study may benefit not only the better understanding of novel mechanisms underlying BM-MSCs involved in liver repair and regeneration, but also the improvement of cytokine-based hepatic inducing strategy, in which a rich cellular resource for cytotherapy of acute liver diseases with BM-MSCs would be provided.

Terminology

FGF-4 is one of the most important fibroblast growth factor family members that can irritate the proliferation of mesodermal and endodermal cells and improve development of fetal liver; HGF is one of the most well characterized cytokines for the stimulation of DNA synthesis in primary hepatocyte cultures and liver development; OSM is a member of the interleukin-6 family which is produced by hematopoietic cells and induces differentiation of fetal hepatic cells, conferring various metabolic activities of adult liver.

Peer review

The authors corroborate that 3 cytokines (HGF, FGF4 and OSM) are fundamental for directing the differentiation of BM-MSCs towards hepatocytes. The work is interesting and could be helpful for developing effective inducing systems of hepatic differentiation from BM-MSCs.

Abstract

AIM: To compare the efficacy and safety of acellular dermal matrix (ADM) bioprosthetic material and endorectal advancement flap (ERAF) in treatment of complex anorectal fistula.

METHODS: Ninety consecutive patients with complex anorectal fistulae admitted to Anorectal Surgical Department of First Affiliated Hospital, Xinjiang Medical University from March 2008 to July 2009, were enrolled in this study. Complex anorectal fistula was diagnosed following its clinical, radiographic, or endoscopic diagnostic criteria. Under spinal anesthesia, patients underwent identification and irrigation of the fistula tracts using hydrogen peroxide. ADM was securely sutured at the secondary opening to the primary opening using absorbable suture. Outcomes of ADM and ERAF closure were compared in terms of success rate, fecal incontinence rate, anorectal deformity rate, postoperative pain time, closure time and life quality score. Success was defined as closure of all external openings, absence of drainage without further intervention, and absence of abscess formation. Follow-up examination was performed 2 d, 2, 4, 6, 12 wk, and 5 mo after surgery, respectively.

RESULTS: No patient was lost to follow-up. The overall success rate was 82.22% (37/45) 5.7 mo after surgery. ADM dislodgement occured in 5 patients (11.11%), abscess formation was found in 1 patient, and fistula recurred in 2 patients. Of the 13 patients with recurrent fistula using ERAF, 5 (11.11%) received surgical drainage because of abscess formation. The success rate, postoperative pain time and closure time of ADM were significantly higher than those of ERAF ($P < 0.05$). However, no difference was observed in fecal incontinence rate and anorectal deformity rate after treatment with ADM and ERAF.

CONCLUSION: Closure of fistula tract opening with ADM is an effective procedure for complex anorectal fistula. ADM should be considered a first line treatment for patients with complex anorectal fistula.

Key words: Acellular dermal matrix; Surgery; Transsphincteric complex fistula

INTRODUCTION

Anal fistula, an abnormal communication between the anal or rectal lumen and perianal skin, is a common condition in general population, and occurs in 5.6 per 100 000 women and in 12.3 per 100 000 men[1], predominantly in the third and fourth decades of life[2]. It is believed that infection of the intersphincteric glands is the initiating event in anorectal fistula, in a process known as the cryptoglandular hyposis[3]. It is also commonly believed that surgery is the only way to cure it. Up to now, its treatment is diverse due to lack of standard treatment. Incorrect diagnosis and treatment are the important reason of anorectal surgery failure[4]. Traditional surgical procedures include fistulotomy, endorectal advancement flap (ERAF), loose-seton placement, and fibrin glue installation. Anal fistula is described according to the level at which it transgresses the anal sphincter. If the internal opening begins above the anal sphincter, the fistula is described as "high" or transphincteric. Traditional surgery for transsphincteric anal fistula often requires staged operations with fistulotomy and seton insertion. The surgery usually results in large and deep wounds which can take months to heal. Moreover, risk of fecal incontinence is inevitable because part of the anal sphincter is divided during surgery. The success rate of these techniques is disappointed. Fistulotomy invariably requires at least some division of the sphincter muscle with risk of incontinence[4], thus leading to a high recurrence and fecal incontinence. It has been reported that the recurrence rate of ERAF for transsphincteric anal fistula is 0%-63%[5]. Although fibrin glue is an alternative to fistulotomy, its long-term closure rate is low[6-11]. The liquid consistency of fibrin glue is not ideal for closing anorectal fistula, because it is easily extruded from the fistula tract due to the increased pressure[12]. Meta analysis indicates that the healing rate of fibrin glue is not significantly different from that of other sphincter saving procedures for fistula[13]. Complete closure of primary opening and sphincter preserving are the key to successful anorectal fistula surgery. An alternative strategy is to obliterate the fistula tract.

Using a biological substance to close complex anorectal fistula has attracted attention in recent years. A biological anal fistula plug can securely close the primary opening, thus enabling the surgeon to eradicate the fistula tract with a minimal damage to the sphincter. We report our experience with the management of complex anorectal fistulae using acellular dermal matrix (ADM) which is similar to acellular extracellular matrix (AEM). It is a newly developed biomaterial from pigs that have a collagen structure almost identical to that of humans. During manufacturing of the ADM, living cells are removed by special processes to ensure that no transmittable diseases are present in the tissue.

MATERIALS AND METHODS

Study design

Protocol synopsis for this trial and supporting CONSORT checklist were used as supporting information (Figure 1). ADM trial was a single-center, randomized, prospective, single blinded, controlled trial.

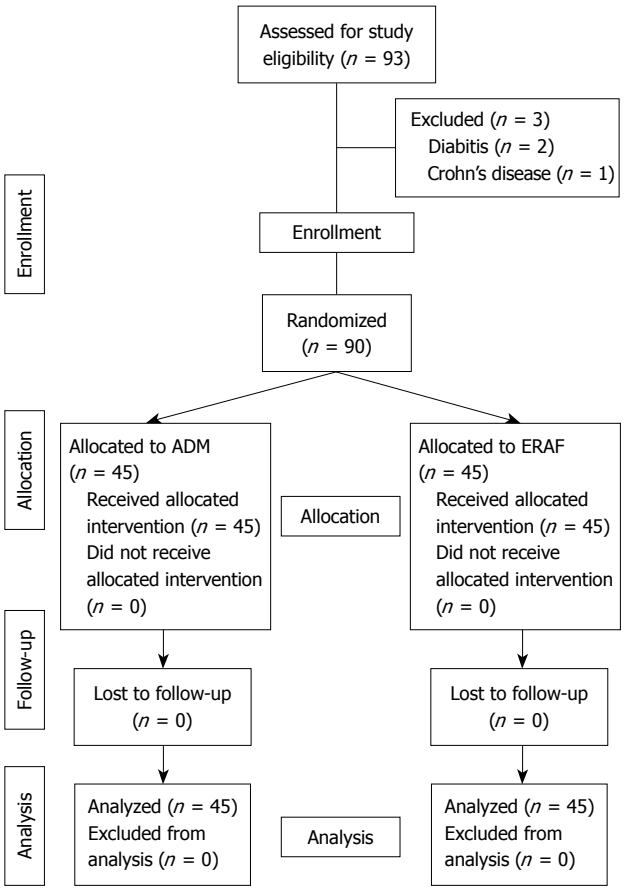

Figure 1 CONSORT diagram. ADM: Acellular dermal matrix; ERAF: Endorectal advancement flap.

Inclusion/exclusion criteria

Patients at the age of 12-60 years with 2-6 cm long intrasphincteric and transsphincteric anorectal complex fistulae identified with a fistula probe during surgery, who gave their informed consent, were included in this trial. Patients with no internal opening found during surgery, and those with positive human immunodeficiency virus, Crohn's disease, malignant cause, tuberculosis, hydradenitis suppurativa, severe cardiovascular state, diabetes, pregnancy, and sepsis were excluded.

Patients

Ninety consecutive patients with complex anorectal fistula, admitted to First Affiliated Hospital of Xinjiang Medical University from March 2008 and July 2009, were randomized into ADM group or ERAF group. Patients were blinded for ADM or ERAF. Demographic data (age and gender of the patients), smoking history, course of disease, fistula types and follow-up time of each patient were recorded (Table 1).

Randomization

Randomization was performed during surgery after the internal opening of fistula was identified. Computer-

Table 1 Demographic data about the patients included in this study

Characteristic	ADM (n = 45)	ERAF (n = 45)	P value
Gender (male/female)	24/21	25/20	NS
Age (SD, range)	18-59 (44.8)	17-61 (45.1)	NS
Smoking history, n (%)	14 (31)	11 (24)	NS
Course of disease (SD, range, mo)	3.0-7.1 (4.6)	2.8-6.9 (5.1)	NS
Type of fistula (intrasphincteric/transsphincteric)	19/26	17/28	NS
Median follow-up time	5.7 (5.1-6.4)	6.1 (5.9-6.5)	NS

ADM: Acellular dermal matrix; ERAF: Endorectal advancement flap; NS: Not significant.

generated random codes were used to produce envelopes containing the information about "ADM" or "ERAF". These envelopes were prepared by a statistician who was not involved in treatment of patients or in other work specific to the study. Computer randomization was completed at Medical Statistical Center, First Affiliated Hospital of Xinjiang Medical University.

Ethics

The trial, conducted in accordance with the Declaration of Helsinki and "good clinical practice" guidelines, local regulations, and China government laws, was approved by the Medical Ethics Committee of First Affiliated Hospital of Xinjiang Medical University. Prior to the randomization, all patients who gave their informed consent were required to comment on the informed consent before the trial.

Sample size and power

Before the trial, sample size was calculated using SPSS software 13.0 version. Armstrong reported that the success rate of anal fistula plug is 87% for the closure of fistula opening[14] and van der Hagen *et al*[5] showed that the success rate of ERAF is 37% for the closure of fistula opening, indicating that to increase the success rate from 40% to 80%, at least 44 patients in each group had to be randomized to achieve a power of 90%.

Surgical technique

All patients underwent a proctology at surgery for configuration of the fistula passage. All patients who were given prophylactic broad-spectrum antibiotics underwent preoperative regular test, endoscopy, anorectal ultrasound and mechanical bowel preparation before surgery. Anesthesia was induced with broad-spectrum parenteral antibiotics and 500 mg of intravenous metronidazole. Patients were placed in the prone jackknife position under spinal or general anesthesia. Primary opening was located using a fistula probe or by injecting hydrogen peroxide into the fistula tract. All fistula tracts were irrigated with a hydrogen peroxide solution. A fistula probe was passed through the fistula tract from the secondary opening and pulled out through the primary opening. After the fistula tract was identified and cleaned with curettage and hydrogen peroxide, ADM materials were prepared according to the length and lumen of the fistula tract, inserted into the clean fistula tracts, and pulled into a position using a silk suture passed through the fistula tract and secured to the tip of ADM, then *via* the secondary opening until it fitted snugly into the primary opening. Excess ADM material was trimmed with the secondary and primary openings flushed and secured to the mucosa and internal sphincter with a 3-0 vicryl suture. All data were recorded and analyzed by the same statistic member who did not attend the intervention.

Rectal advancement flap was done for the control group according to the following techniques. In brief, the primary opening was excised followed by mobilization of the mucosa, submucosa, and a small amount of muscular fibers from the internal sphincter complex. A rectal flap with a 2-3 cm broad base was mobilized. The rectal flap was mobilized sufficiently to cover the internal opening with overlap. Hemostasis was performed to prevent a hematoma under the flap. The fistula tract was curetted. The internal opening was not closed before the flap was advanced over the primary opening. Finally, the flap was sutured to the distal anal canal. All patients were not given analgesics after surgery. Patients were followed up at the discretion of the operating surgeon. Per-operative management (including daily activities, diet) of the two groups was identical.

ADM used in this study was an absorbable J-I type (J. Y. Life Tissue Engineering Co., Ltd., China). It is a complex collagen structure manufactured from the submucosa of porcine small intestine. According to the information about the J-I ADM product, its manufacturing is completely similar to Surgisis AFP™ (Cook Surgical Inc., Bloomington, Indiana, USA). These biologically absorbable xenografts including ADM, AEM, Surgisis or other kinds of anal fistula plug consist of an acellular scaffold similar to the human extracellular matrix[14]. In general, integration into the implant begins within a few days after such materials are placed into the fistula tract through penetrating capillaries.

Postoperative care and follow-up

All patients were hospitalized with a clear liquid diet and bed rest for 48 h. Activity was restricted to minimal. Patients were required to have a warm Sitz bath, 3 times a day. All patients were given intravenous broad-spectrum antibiotics and metronidazole for 3 d after surgery. Stool softeners were used for 10 d. No activity restriction was requested after discharge. Follow-up examination was performed in the outpatient department 2 d, 2, 4, 6, 12 wk, and 5 mo after surgery, respectively. The primary endpoints of this trial were fistula closure rate. Success was defined as closure of all external openings, absence of drainage without further intervention, and no abscess formation. The presence of one persistent fistula tract was considered surgical failure. Outcomes of ADM and ERAF closure were compared in terms of success rate, fecal incontinence rate, anorectal deformity rate, postoperative pain time, closure time and life quality score.

Continence was evaluated before and after opera-

Table 2 Vaizey score system

	Never	Rare	Some-times	Each week	Everyday
Frequency of incontinence	0	1	2	3	4
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Alteration in lifestyle				No	Yes
Need to wear a pad or plug				0	2
Use of constipating medication				0	2
Lack of ability to defer defecation for 15 min				0	4

Table 3 Life quality scale system[16]

Physical
P1 It is difficult for me to get out and do things like going to a movie or to church
P2 I avoid travelling
P3 Whenever I am away from home, I try and stay near a toilet as much as possible
P4 I can't hold on to my bowel motion long enough to get to the bathroom
P5 I try to prevent bowel accidents by staying very near a bathroom
P6 I cut down on how much I eat before I go out
P7 Whenever I go somewhere new, I make sure I know where the toilets are
Social
S1 I avoid visiting my friends
S2 I avoid staying the night away from home
S3 It is important to plan my daily activities around my bowel habit
S4 I leak stool without even noticing it
S5 I can't do many things I want to do
S6 I have sex less often than I would like
S7 I feel different from other people
S8 I avoid travelling by plane or public transport
S9 I avoid going out to eat
S10 I am afraid to have sex
Emotional
E1 I am afraid to go out
E2 I worry about not being able to get to the toilet in time
E3 I feel unhealthy
E4 I feel ashamed
E5 I worry about bowel accidents
E6 I feel depressed
E7 I worry about the smell
E8 I enjoy life less
E9 The possibility of bowel accidents is always on my mind
E10 During the past month have you felt so sad, discouraged, hopeless, or had so many
Problems that you wondered whether anything was worthwhile?
Overall sense of well-being
In general, would you say your health is excellent/very good/good/fair/poor?

tion using the Wexner score and Vaizey scale. The Vaizey scale consists of 3 items about the type (gas, fluid, solid) and frequency of incontinence (Table 2)[15]. The secondary endpoints were healing time, postoperative pain time, postoperative deformity rate, incontinence rate and quality of life. Patients after operation were asked to grade their pain on a visual analogue scale (VAS: 0 = no pain; 10 = worst imaginable pain) at different time points during the follow-up. Fecal incontinence was evaluated according to the Williams grade. Quality of life was evaluated using the life quality scale system (Table 3)[16].

Statistical analysis

Statistical analysis was performed using SPSS software 13.0 version. Recurrence rate, fecal incontinence rate and anal deformity rate associated with each intervention option were assessed by χ^2 test or Fisher's exact test. Healing time and postoperative pain time were calculated by Wilcoxon's test or log rank test. $P < 0.05$ was considered statistically significant.

RESULTS

Three patients were excluded from this trial because of diabetes and Crohn's disease. All patients completed the follow-up during which their data were collected. No patient was lost to follow-up. No significant difference was found in the characteristics of patients including age, sex, classification of fistula and median follow-up time between the two groups. The median follow-up time of ADM and ERAF groups was 5.7 mo (range 5.1-6.4 mo) and 6.1 mo (range 5.9-6.5 mo), respectively ($P = 0.12$). No severe adverse effect occurred in the patients.

The fistula recurred in 2 (4.45%) and 13 (28.89%) of the 45 patients in the ADM and ERAF groups, respectively ($P = 0.0047$), and was healed in 37 (82.22%) and 29 (64.44%) of the 45 patients in ADM and ERAF groups, respectively. Early extrusion of ADM occured in 4 patients, and late extrusion in 1 patient. The overall fistula healing rate was 82.22% (37/45) in ADM group. Five and 1 patients received drainage surgery in ERAF and ADM groups, respectively. The life quality score was higher, the fistula healing time and postoperative pain time were shorter in the ADM group than in the ERAF group ($P < 0.05$, Tables 4-7). The recurrence rate of fistula was significantly lower in the ADM group than in the ERAF group. However, no significant difference was observed in incontinence and anal deformity rate between the two groups. In order to clarify the effect of classification on the results, the efficacy and complication rate of intrasphincteric and transsphincteric fistulae were compared (Tables 5 and 6). The recurrence rate of transsphincteric fistula was significantly lower in the ADM group than in the ERAF group. However, no significant difference was observed in the incontinence and anal deformity rate between the two groups.

DISCUSSION

Surgery is considered the predominant and only procedure for anorectal fistula. Although fistulotomy is a simple procedure for fistula, it is not indicated for transsphincteric fistulae because of prohibitive risk of incontinence. Seton cutting, which can slowly divide the sphincter and prevent recurrent abscess formation, is considered a more efficient procedure for trassphincteric fistula, but can cause incontinence of solid stool in up to 25% of patients[17]. ERAF has become a treatment of choice for most fistulae. However, recent reports sug-

[1]Represents comparison between intrasphincteric fistulae using ADM and ERAF; [2]Represents comparison between transsphincteric fistulae using ADM and ERAF.

gest that the recurrence rate of fistula is 36%-45% after ERAF[5,18,19]. ERAF is also technically difficult, and carries a risk of rectal bleeding and incontinence. In our study, hemorrhage occurred in 2 (4.44%) and incontinence occurred in 4 (14.29%) patients in the ERAF group, which are lower than the reported findings[20]. Over the last few years, fibrin glue has been widely described as a better treatment of choice with no side effects, such as pain and incontinence[6,7,9,12,21,22]. However, it was reported that the healing rate of fistula is 78% and 40%-54%, respectively, after the use of fibrin glue[7,23,24], which is not improved even after antibiotics are added or mucosal advancement flap is supplemented[25].

Continence and healing are the two treatment goals to be achieved, but they often conflict with each other. Another sphincter-preserving surgical method is to use bioabsorbable material for anal fistula, which was first reported by Johnson *et al*[14] in 2006 with a success rate of 87%, and O'Connor *et al*[26] reported that the short-term success rate of bioabsorbable material is 80% for anal fistula, indicating that bioabsorbable material can be used in treatment of fistula due to its inherent resistance to infection. Placement of ADM, a minimally invasive procedure for fistula, is an attractive treatment of choice for fistula. Pocrine ADM is a regenerative tissue matrix isolated from decellularized intestines. Similar to Surgisis or other prosthetic meshes, ADM has also been shown to resist infection[27,28]. In our study, the short-term success rate of ADM was 82.22% (37/45) for complex anorectal fistula, which is consistent with the reported findings[26]. In order to compare and evaluate its efficacy, we searched most of the original effects of bioabsorbable material on anorectal fistula across the world (Table 8). Christoforidis *et al*[36] and Ky *et al*[40] showed that the success rate of biologically absorbable substance for complex anorectal fistulas is lower than that reported by Song *et al*[39].

The possible reason why our success rate was much lower than the reported findings[39] is that all the procedures were performed by 4 surgeons. Another possible explanation for this difference may be the selection bias of patients. Contrary to our results, however, Zubaidi *et al*[32] found that trassphincteric fistula is more likely to heal after plug placement. Ky *et al*[40] and Ellis[42] have reported a high success rate of plug placement for trassphincteric fistula. We focused on fistula channel debridement and complete drainage during surgery in order to prevent abscess formation as previously described[31]. Because more granulation tissues in the fistula tract can function as a barrier to cellular infiltration into ADM, it is difficult to imagine that simple irrigation with hydrogen peroxide without thorough curettage of the tract can clean the tract and allow incorporation of ADM material into its surroundings. We believe that the low success rate in the study by Safar *et al*[37] is due to inadequate debridement and curettage of granulation tissue. Complete debridement, curettage of the tract, and hydrogen peroxide irrigation may be important for the surgery to achieve a greater success rate. This point differs from that of Schwandner *et al*[31]. In our study, 5 patients (11.11%) experienced ADM dislodgement, which may be due to the poor ADM fixation to the sphincter in the primary opening. Technical failure associated with plug-falling out is an important reason for surgery failure[31].

In our study, the success rate of ADM for complex fistula was 82.22% (37/45), indicating that placement of ADM is a safe, beneficial, minimally invasive procedure for fistula, and can protect the anal function.

Lawes *et al*[41] proposed to combine anal fistula plug and advancement flap for fistula. However, we hold that selection of patients, complete debridement, tract prepa-

ration and plug fixation are closely associated with the final success rate.

It is essential to use antibiotics before surgery. It was reported that anorectal abscess is not formed in patients after treatment with AEM[39] or Surgisis[50]. However, early infection occurred in our study. Although use of Surgisis is not associated with perianal sepsis[14], it has been shown that the incidence of severe perianal sepsis is 23%[41]. Although the sepsis rate of ADM (1/45) was significantly lower than that of ERAF (5/45) in our study, more evidence is needed for the evaluation of ADM. Safar *et al*[37] suggested that the success rate of plug for fistula is not associated with the preoperative bowel preparation, but we performed mechanical bowel preparation before surgery to avoid possible constipation or infection after surgery.

In our study, ADM could obviously shorten the postoperative pain time and the fistula healing time, but not the deformity and incontinence rate of transsphincteric fistula. Transsphincteric fistula recurred in 2 patients, suggesting that it is necessary to perform multicenter randomized controlled trial to evaluate the efficiency of ADM on transsphincteric complex fistula.

A significant number of patients in ERAF group in this study had long-term continence disturbances in forms of gas and liquid stool incontinence, which may be associated with ERAF or fistulotomy, abscess drainage, and other anorectal treatment modalities.

An adequate follow-up time is essential in a comparative study of ADM and ERAF for complex fistula. Only one study is available with a long follow-up time[33]. The follow-up time in our study is similar to that in previous studies[42,43,46]. The success rate of ADM for fistula (82.22%) was associated with the ADM itself and the adequate follow-up time in our study. Zubaidi *et al*[32] showed that a longer follow-up time and over an 80% success rate of biologically absorbable substance for fistula provide better evidence for the use of ADM. Song *et al*[39] reported convincing results based on 6.3 mo follow-up time. However, Wang *et al*[35] showed that the success rate of biologically absorbable substance for fistula is only 34% after a follow-up time of 18 mo.

In conclusion, closure of the fistula tract primary opening using ADM is an effective and acceptable procedure for complex anorectal fistula. ADM is a a safe, beneficial, minimally invasive procedure for fistula, and can protect anal function. ADM dislodgement is associated with the closure techniques. Further longer-term multicenter randomized controlled clinical trials are needed to evaluate its efficacy on complex anorectal fistula.

ACKNOWLEDGMENTS

The authors thank Professor Wei-Li Yan, Department of Epidemiology and Biostatistics, School of Public Health, Xinjiang Medical University, for her help and excellent technical and methodological support to this randomized trial.

COMMENTS

Background

Anal fistula is an abnormal chronic communication between the anal or rectal lumen and perianal skin. Surgery usually results in large and deep wounds which can take months to heal. Moreover, risk of fecal incontinence is inevitable because part of the anal sphincter is divided during surgery. The success rate of different techniques is disappointed. Using a biological substance to close complex anorectal fistula is attractive.

Research frontiers

Acellular dermal matrix (ADM) is a bioabsorbable xenograft for tissue defect. Application of different kinds of ADM in treatment of anorectal fistula is a hotspot in the World.

Innovations and breakthroughs

Closure of the fistula tract primary opening using ADM is an effective and acceptable alternative to complex anorectal fistula. ADM is a safe, beneficial,

minimally invasive procedure for fistula, and can protect anal function. It should be considered a first line treatment for patients with complex anorectal fistula.

Applications

This method can reduce postoperative pain, shorten fistula healing time, and improve the postoperative life quality of patients.

Peer review

This is an interesting and generally well written paper with the effects of endorectal mucosal advancement flap and acellular dermis plug on complex fistula compared. The results are striking.

Abstract

AIM: To assess the tolerability and safety of same-day tandem procedures, endoscopic ultrasound (EUS) followed by endoscopic retrograde cholangiopancreatography (ERCP) under conscious sedation.

METHODS: A retrospective review was conducted at Loma Linda University Medical Center, a tertiary-care center. All 54 patients who underwent EUS followed by ERCP (group A) from 2004 to 2006 were included in the study. A second group of 56 patients who underwent EUS only (group B), and a third group of 53 patients who underwent ERCP only (group C) during the same time period were selected consecutively as control groups for comparison.

RESULTS: Conscious sedation was used in 96% of patients in group A. Mean dosages of meperidine and midazolam used in group A were significantly higher than in group B or C. Mean recovery time in group A was not statistically longer than in group B or C. There was no significant difference in the incidence of sedation-related and procedural-related complications.

CONCLUSION: Tandem EUS/ERCP procedure can be safely performed under conscious sedation with minimal adverse events. Combined procedures, however, are associated with higher dosages of sedatives, and slightly longer recovery time.

Key words: Conscious sedation; Safety; Same-day; Endoscopic ultrasound; Endoscopic retrograde cholangiopancreatography

Safety of same-day endoscopic ultrasound and endoscopic retrograde cholangiopancreatography under conscious sedation. *World J Gastroenterol* 2010; 16(26): 3287-3291 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i26/3287.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i26.3287

INTRODUCTION

Endoscopic ultrasound (EUS) and/or EUS-guided fine needle aspiration (EUS-guided FNA) is increasingly utilized for the diagnosis of pancreatico-biliary diseases including malignancies and choledocholithiasis. The diagnostic accuracy in reported studies of EUS or EUS-guided FNA in the diagnosis of obstructive jaundice is from 80% to 98%[1,2]. In addition, EUS is associated with lower morbidity compared to endoscopic retrograde cholangiopancreatography (ERCP), with an overall EUS-FNA complication rate of 1%-2%[2-4]. EUS is now being performed

first for evaluation in patients with suspected pancreaticobiliary diseases, especially those with obstructive jaundice[5]. Based on EUS findings, therapeutic ERCP interventions, such as stent placement for biliary drainage or stone extraction can then be performed in a tandem fashion.

The literature is scarce on the safety of same-day tandem EUS and ERCP procedures done under conscious sedation. The tandem procedure approach is believed to reduce procedure time and be cost-effective[6]. Potential risks associated with such a strategy are unknown. There are only 2 reported cases in the medical literature of bile leakage into the peritoneum as a result of performing ERCP immediately after EUS-guided FNA[7]. In 2007, Tarantino *et al*[8] evaluated the safety of performing ERCP immediately after EUS in 25 patients done under general anesthesia using propofol. In 1999, Duchmann *et al*[9] also examined the feasibility of performing EUS and ERCP in 57 patients during the same general anesthesia session. Although widely practiced, the safety of performing tandem procedures under conscious sedation is unclear. At our institution, a tandem approach with EUS and/or EUS-guided FNA is sometimes performed for patients with suspected obstructive jaundice, followed by therapeutic ERCP if indicated.

MATERIALS AND METHODS

From October 2004 to November 2005, 54 patients underwent same-day tandem EUS followed by ERCP procedures for the indication of obstructive, or post-hepatic jaundice. This cohort was designated as group A.

From the above time period, 60 consecutive patients who underwent EUS-only and 60 consecutive patients who underwent ERCP-only for the indication of jaundice were chosen as the EUS and ERCP control groups. Of the 60 EUS-only procedures reviewed, only 56 procedures had complete data for analysis (group B). Of the 60 ERCP-only procedures reviewed, only 53 procedures had complete data for analysis (group C).

This retrospective review included: demographics, indications, completion rate of procedures, sedation medication dosages, procedure and recovery times, and adverse events. Vital signs recorded during each procedure and during post-procedure recovery were reviewed. Adverse events included hypotension (defined as systolic blood pressure < 90 mmHg requiring intravenous fluids), bradycardia (heart rate < 60 bpm, or in patients with a baseline heart rate under 60 bpm, heart rate < 45 bpm), and oxygen desaturation (pulse oximetry reading < 90%). The use of reversal agents such as flumazenil and/or naloxone due to oversedation was examined. Post-ERCP pancreatitis was defined as amylase and lipase over five times normal values with abdominal pain and/or leukocytosis persisting 24 h after ERCP. Some of the patients in this study were inpatients, whereas the majority were outpatients. For those who underwent outpatient procedures, it was not standard practice to bring them back for scheduled follow-up laboratory tests.

Statistical analysis

Statistical analysis was performed using StatView version 5.0 for Windows. Numeric variables were expressed as mean ± SD. Differences between groups were analyzed using student's *t*-test for continuous variables. Fisher's exact test was performed for categorical variables but was not done if there was zero in a cell. All differences were considered statistically significant at the *P*-value of < 0.05.

Informed consent was waived for this retrospective study and the research committee at Loma Linda University Medical Center approved the study.

RESULTS

A total of 163 patients were included in this study: tandem EUS/ERCP (group A: $n = 54$), EUS-only (group B: $n = 56$), and ERCP-only (group C: $n = 53$). Mean age, gender, indication, and procedure completion rate are shown in Table 1. There were significantly less males in group A compared to group B, but not significantly different compared to group C. All procedures were performed for the indication of obstructive jaundice. When cholangitis was presumed to be the cause of jaundice, ERCP only, as it should be, was performed. Patients with jaundice and abnormal pancreatico-biliary imaging underwent EUS as part of the work-up.

All patients who underwent EUS in group A and in group B completed the procedures. There was no significant difference in the number of patients who had EUS-FNA in groups A *vs* B (57% *vs* 68%, $P = 0.32$). In group A, ERCP was not completed in five patients compared to seven patients in control group C. Two patients (one each from group A and C) had difficult anatomy and the ampulla was not reached. Eight patients (four from both group A and C) had failed deep cannulation of the desired duct. Two patients from group C had cardiac dysrhythmias (atrial fibrillation and ventricular tachycardia) necessitating early abortion of the procedures.

The amount and type of sedation used is displayed in Table 2. Conscious sedation was used in 96% of group A patients, 100% of group B and 98% of group C patients. General anesthesia and/or propofol were used in three patients, two patients in group A and one patient in group C. The mean total dose of meperidine used in group A was significantly higher than in group B (151.1 ± 64.0 mg *vs* 104.0 ± 43.6 mg, $P < 0.0001$) or in group C (151.1 ± 64.0 mg *vs* 104.5 ± 32.5 mg, $P < 0.0001$). The mean total dose of midazolam used in group A was significantly higher than in group B (8.5 ± 3.2 mg *vs* 6.3 ± 2.4 mg, $P = 0.0001$), or in group C (8.5 ± 3.2 mg *vs* 6.9 ± 3.4 mg, $P = 0.01$).

Procedure and recovery time data are shown in Table 3. The total procedure time for group A was 93.5 ± 36.1 min (range: 30-185 min), 59.0 ± 35.0 min (range: 10-129 min) for group B, and 40.1 ± 20.4 min (range: 20-170 min) for group C. The mean procedure time for EUS in group A, when compared as a separate procedure to the EUS procedure time in group B was not statistically significant (48.0 ± 28.0 min *vs* 59.0 ± 35.0 min, $P = 0.07$). Similarly, the mean procedure time for ERCP in group A, when compared as a

separate procedure to the ERCP procedure time in group C was not significantly different (45.1 ± 20.7 min *vs* 40.1 ± 20.4 min, $P = 0.20$). The mean recovery time in group A was slightly longer than in group B (105.1 ± 74.8 min *vs* 84.0 ± 51.7 min, $P = 0.06$) or in group C (105.1 ± 74.8 min *vs* 84.5 ± 42.6 min, $P = 0.07$).

The complications among the three study groups are reported in Table 4. There was no significant difference in the number of patients who had hypotension, bradycardia, or desaturation among the groups. Reversal agents (flumazenil and/or naloxone) were used in 2% of patients in group A *vs* 0% in group B ($P = 1.00$) *vs* 6% in group C ($P = 0.36$). The number of patients with post-ERCP pancreatitis when comparing group A and group C was similar. One patient in group A was hospitalized due to rectal bleeding that was unrelated to the procedures; a colonoscopy during hospital stay revealed colon cancer. Two patients were hospitalized in group C, one due to oversedation and another due to ventricular tachycardia. The patient admitted for oversedation returned home the following day with no complications. Hypokalemia was the cause of ventricular tachycardia in one patient with metastatic colon cancer who died a month later due to septic pneumonia unrelated to the ERCP procedure.

DISCUSSION

More patients with suspected pancreatico-biliary diseases are now first undergoing EUS with possible EUS-guided FNA. Some of these patients will also undergo ERCP and interventions based on EUS findings. Performing tandem procedures starting with EUS followed by ERCP is logical and is being done at many centers. However, there is little data on its safety when done under conscious sedation. There have been 2 reported cases of bile leak with ERCP following immediately after EUS-guided FNA[7]. Mergener *et al*[10] described a case of massive pneumoperitoneum in a patient who underwent ERCP immediately after EUS-

FNA. Despite this, two other studies have reported the safety of tandem procedures when done under general anesthesia[8,9]. The objective of our study was to assess safety in a retrospective review of tandem cases done under conscious sedation at our center.

Our study reviewed 54 patients with tandem procedures EUS/ERCP along with 56 control patients with EUS only and 53 control patients with ERCP only. Appropriately, patients with presumed cholangitis underwent ERCP only and more patients with obstructive jaundice and abnormal pancreatico-biliary imaging underwent EUS, EUS-FNA as part of the evaluation.

Almost all (96%) of the procedures in the tandem group were done under conscious sedation with meperidine and midazolam. The procedure time for the tandem group was longer than either the EUS or ERCP alone control groups. This is intuitive because two procedures were done at the same setting in the tandem group. Given longer procedures, the amount of meperidine and midazolam was higher in the tandem group as compared to the controls. However, a similar amount of time was needed for EUS and ERCP when the procedures were compared separately to each control group.

In our setting, EUS is performed in the GI Lab at the medical center and ERCP is done at a different location in the radiology suite under fluoroscopy. The total time reported for the tandem group would be even shorter if EUS and ERCP were performed in one place, eliminating patient transfer and transport times.

Given the higher amount of sedation used, the recovery time was slightly longer (although not statistically significant) in the tandem group compared to the two control groups. Despite the longer procedure and recovery time, no significant difference in sedation-related and procedure-related complications were noted in the tandem group compared with the controls. There was no difference in hemodynamic adverse events, use of reversal agents, or rate of hospitalization post procedures. None of the patients with bradycardia required atropine, and none of the patients were intubated due to oxygen desaturation. The post-ERCP pancreatitis rate was 4% in the tandem group, which was statistically similar to the ERCP control group and is within the accepted level. In a large prospective study by Freeman *et al*[11], post-ERCP pancreatitis occurred after 6.7% procedures. No bile leaks were noted with the tandem group.

Nonetheless, there are limitations to our study. Given that the study was a retrospective review, we were unable to assess patient tolerability through direct patient questionnaire. It was not known whether patients were comfortable during the procedures, if they had any recollection of the procedures, or if they would undergo the tandem procedure again. Another limitation was the lack of uniform follow-up of patients to evaluate long-term adverse events due to the tandem procedure. In this study, the few patients who were admitted for observation and those who were already inpatients were all discharged home without complications. It appears that tandem procedures may be safely done under conscious sedation. With the size of groups studied here, no significant complications were noted in the tandem group compared to either study alone. However, it would seem reasonable that a prospective study should be carried out, where a larger number of patients were included and patient tolerance was assessed. Overall, our study is the first of its kind to try to assess issues concerning the safety and feasibility of performing tandem EUS/ERCP procedures under conscious sedation.

In conclusion, a tandem EUS/ERCP procedure can be safely performed under conscious sedation with minimal adverse events. The combined procedure, however, is associated with higher dosages of sedatives and with slightly longer recovery time.

COMMENTS

Background

Same-day endoscopic ultrasound (EUS) followed by endoscopic retrograde cholangiopancreatography (ERCP) is performed at many medical centers for pancreatico-biliary diseases. Little data exists regarding the safety of performing tandem procedures under conscious sedation.

Research frontiers

Efficiency and cost savings are important issues in our current healthcare system, however, this should not be done at the expense of patient safety.

Innovations and breakthroughs

Several studies have examined the safety of combined procedures under propofol or general anesthesia but none, to date, have evaluated the safety of combined procedures under conscious sedation.

Applications

In medical centers where propofol or general anesthesia is not readily available, same-day combined EUS and ERCP under conscious sedation can be performed safely.

Peer review

It is a good manuscript comparing the retrospective data of the procedures (EUS, ERCP and EUS + ERCP) including a good number of patients. This manuscript will be of use for the medical fraternity.

Abstract

AIM: To test the hypotheses that diffusion weighed (DW)- and transcatheter intraarterial perfusion (TRIP)-magnetic resonance imaging (MRI) can each be used to assess regional differences in tumor function in an animal pancreatic cancer model.

METHODS: VX2 tumors were implanted in pancreata of 6 rabbits. MRI and digital subtraction angiography (DSA) were performed 3 wk following implantation. With a 2-French catheter secured in the rabbit's gastroduodenal artery, each rabbit was transferred to an adjacent 1.5T MRI scanner. DW- and TRIP-MRI were performed to determine if necrotic tumor core could be differentiated from viable tumor periphery. For each, we compared mean differences between tumor core/periphery using a 2-tailed paired *t*-test ($\alpha = 0.05$). Imaging was correlated with histopathology.

RESULTS: Tumors were successfully grown in all rabbits, confirmed by necropsy. On DW-MRI, mean apparent diffusion coefficient (ADC) value was higher in necrotic tumor core (2.1 ± 0.3 mm^2/s) than in viable tumor periphery (1.4 ± 0.5 mm^2/s) ($P < 0.05$). On TRIP-MRI, mean perfusion values was higher in tumor periphery (110 ± 47 relative units) than in tumor core (66 ± 31 relative units) ($P < 0.001$).

CONCLUSION: Functional MRI can be used to differentiate necrotic from viable tumor cells in an animal pancreatic cancer model using ADC (DW-MRI) and perfusion (TRIP-MRI) values.

INTRODUCTION

Pancreatic cancer, the fourth leading cause of cancer-related mortality in the United States[1], portends a median survival of 6 mo and a 5-year survival of less than 5%[1-4]. Operative resection is indicated in less than 20% of patients and only increases median 5-year survival to 12%[5,6]. Given these grim statistics and paucity of therapeutic options, this disease represents an arena in which the development of novel therapies is greatly needed.

Since the 1980s, innovative, minimally invasive transcatheter intraarterial techniques to treat malignancies, particularly in the liver, have been developed. These techniques, including bland-, chemo-, and radio-embolization, have been shown to improve survival and/or induce imaging responses while being well tolerated by patients[7,8]. Despite some reports demonstrating preliminary success in the treatment of advanced pancreatic cancer with the transcatheter intraarterial infusion of chemotherapy directly to the pancreas[9-12], few studies have assessed local pancreas-directed therapies.

Before catheter-directed clinical therapies can be developed, it would be useful to develop functional imaging targets in a pre-clinical animal model of pancreatic cancer. Functional imaging is important because conventional anatomic magnetic resonance imaging (MRI) has a low sensitivity to detect pancreatic cancer and separate tumor from adjacent uninvolved pancreatic tissue[13,14]. In addition, even in instances where the tumor can be readily visualized with conventional MRI, therapies might have an effect on tumor function but no effect on overall tumor size. Functional targets could include the assessment of changes in water mobility (diffusion) and tumor perfusion using MRI.

The mouse is the most commonly used animal model of pancreatic cancer[15]. However, catheter-based therapies require an animal model large enough to permit catheterization of mesenteric vessels and tumor sizes large enough that can be visible using clinical MRI scanners. The VX2 model of cancer in rabbits is established in translational studies of uterine[16], liver[17,18], lung[19,20], brain[21,22], and renal neoplasms[23,24]. We have recently established this cancer model in the pancreas[25]. The purpose of this study is to test the hypotheses that (1) diffusion weighted (DW); and (2) perfusion MRI can be used to assess regional differences in tumor function in this rabbit model of pancreatic cancer. If feasible, these functional MRI parameters could potentially be used as surrogate functional endpoints when testing future novel transcatheter pancreatic therapies.

VX2 animal model

Our Animal Care and Use Committee approved this study. Three VX2 tumors were implanted by an attending surgical oncologist and grown in the pancreata of 6 New Zealand White rabbits using the chunk implantation method[26]. At 2 wk following pancreatic VX2 implantation, MRI scans were obtained using a 1.5-T scanner (Espree; Siemens Medical Solutions, Erlangen, Germany). Rabbits were imaged in the supine position with a single-channel head coil. We obtained T2-weighted turbo spin echo images with the following parameters: 4210/86 (repetition time ms/echo time ms), 3 mm thick sections, 180 mm × 121 mm field of view, 256 × 172 matrix, 150° flip angle, 205 Hz per pixel bandwidth, and two signals acquired. Tumor growth was considered positive when tumor was identified in axial and coronal imaging planes by two independent attending interventional radiologists.

Digital subtraction angiography and catheter placement

We performed X-ray digital subtraction angiography (DSA) using a C-arm unit (Powermobil; Siemens Medical Solutions, Erlangen, Germany) 3 wk after VX2 tumor implantation. The femoral artery was accessed through a surgical cut-down and catheterized with a 22-gauge angiocatheter (Terumo Medical, Somerset, NJ, USA). A 2-F catheter (Cook, Bloomington, IN, USA) was advanced over a 0.014-inch diameter guide wire (Terumo Medical, Tokyo, Japan). We then selectively catheterized the gastroduodenal artery. We performed X-ray DSA of the celiac artery and gastroduodenal artery by using hand injections of iohexol (Omnipaque 350; Amersham Health, Princeton, NJ, USA). Once catheter placement was complete, a 2-0 silk suture in the rabbit's groin was used to hold the catheter in place while the rabbit was transferred to the adjacent MRI suite.

MRI following catheterization

MRI after catheter placement was performed using a Siemens 1.5-T Espree clinical MR scanner. To depict tumor anatomy, we first acquired two-dimensional turbo spin-echo T2-weighted images with the above described scan parameters. DW-MRI was performed with single-shot spin-echo echo planar imaging with the following scan parameters: repetition time/echo time, 4000/93 ms; slice thickness 3 mm; bandwidth, 1185 Hz/pixel; partial Fourier factor, 6/8; nonselective fat saturation; twice refocused spin-echo diffusion weighting to reduce eddy current-induced distortion with b values of 0, 50 and 500 s/mm^2. DW-MRI measures changes in the mobility of water as a means of differentiating viable and highly cellular regions from acellular or necrotic regions of tumors. The mobility of water is measured using the apparent diffusion coefficient (ADC). ADC maps, which showed water mobility measurements corresponding to separate spatial locations, were reconstructed from each series of DW images. In these ADC maps, signal intensity directly correlates with water mobility. Using T1-weighted contrast agent-enhanced images as a reference, we drew regions of interest to calculate mean tumor ADC values. Regions of interest were also drawn to compare the ADC values for the necrotic core and the viable outer ring typically present in VX2 tumors.

For tumor perfusion imaging, we used transcatheter intraarterial perfusion (TRIP)-MRI[27], an innovative first-pass perfusion technique employing direct catheter-based intraarterial injections of contrast medium. This technique can be used to detect intra-procedural changes in perfusion to targeted tumor cells and surrounding parenchyma[28]. For TRIP-MRI, we used a three-dimensional spoiled gradient echo sequence with the following parameters: repetition time/echo time, 5/1.6 ms; 15° flip angle; contiguous axial slices of 3 mm thickness; eight partitions; 200 mm × 100 mm field of view; 128 × 64 matrix; and 660 Hz/pixel bandwidth. This TRIP-MRI sequence is a real-time three-dimensional MR fluoroscopy technique[29] that rapidly and continuously images the entire tumor during transcatheter contrast medium injection. TRIP-MRI scans were obtained during hand injections of 2 mL 20% gadopentetate dimeglumine solution (Magnevist; Berlex, Wayne, NJ, USA) over 5 s *via* a catheter previously placed during DSA. Each contrast medium injection was immediately followed by a 4-mL saline solution flush injected over 5 s. For each TRIP-MRI scan, the entire pancreas area including tumor(s) was continuously sampled at 1.6-s intervals for 100 s.

Before and after TRIP-MRI, we obtained anatomic images with two-dimensional T1-weighted gradient-echo MRI. The T1-weighted scan parameters were as follows: repetition time/echo time, 193/6 ms; average of 2; flip angle of 80°; bandwidth of 475 Hz/pixel; slice thickness of 3; 256 × 160 matrix; and field of view of 180 mm × 113 mm.

With the baseline R_{10} map, a longitudinal relaxation rate R_1 map time series was derived from the signal intensity ratio between the baseline image and each TRIP-MRI series with nonlinear curve fitting. Increases in R_1 after injection are proportional to increases in contrast agent concentration. For each R_1 map time series, we calculated the first-pass area under the curve for each voxel, thereby producing spatially resolved perfusion maps for each TRIP-MRI scan. Regions of interest were drawn to measure mean tumor area under the curve. Each TRIP-MRI area under the curve (AUC) measurement served as a semi-quantitative index of tumor perfusion. Tumor regions of interest were placed in peripheral hypervascular regions to avoid the necrotic core.

Necropsy and histopathology

Once the MRI was completed, each rabbit was sacrificed with intravenous administration of 150-200 mg/kg sodium pentobarbital (Euthasol; Delmarva Laboratories, Midlothian, VA, USA). Each rabbit tumor was harvested for pathologic confirmation of VX2 tumor growth and location in pancreatic tissue. Pancreatic tumors were inspected grossly for anatomic consistency with MR images. Tumor samples, including surrounding tissue, were then removed, embedded in paraffin, and mounted on glass slides. These 4-μm-thick slices were stained with hematoxylin and eosin. An attending surgical pathologist performed histopathologic analysis using a Zeiss Axioskop Confocal (Germany) microscope and Zeiss Plan (NEOFLUAR 2.5 ×) objective lens. Imaging was performed with a Cambridge Research and Instrumentation model N-MSI-420-FL camera and Cri Nuance Multispectral Imaging System version 1.6 software.

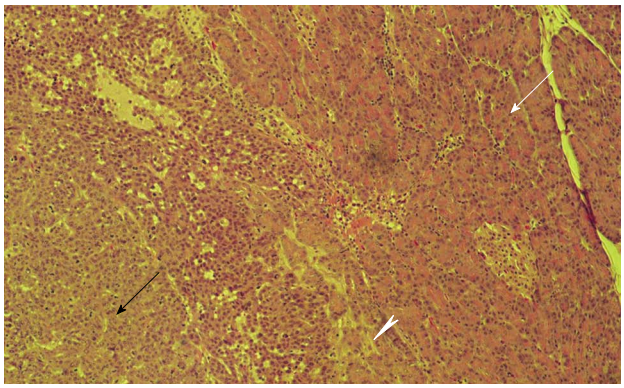

Figure 1 Histopathologic image obtained at necropsy. Border between viable VX2 tumor cells (black arrow) and healthy pancreatic tissue (white arrow) with irritated pancreatitis-like tissue at the tumor-pancreas interface (arrowhead). Note islet of Langerhans within healthy pancreatic tissue. Hematoxylin-eosin stain; original magnification × 25.

Statistical analysis

MR and X-ray DSA images were viewed in conjunction with one another. All MR images were analyzed on a computer workstation (Argus; Siemens Medical Solutions). We compared mean differences between necrotic tumor core and viable tumor periphery for DW-MRI (ADC value) and TRIP-MRI (AUC) using a 2-tailed paired *t*-test, with $\alpha = 0.05$. Mean values were reported ± 1SD. All statistical tests were performed using InStat version 3.06 for Windows (GraphPad Software, San Diego, CA, USA).

RESULTS

Eleven tumors were successfully grown in 6 rabbits, as confirmed by necropsy (Figure 1). Tumors in all 6 rabbits were successfully depicted using anatomic and DW-MRI. Anatomic T2-weighted images showed increased signal intensity within the tumors compared to surrounding tissues (Figure 2).

With DW-MRI, tumors showed regions of low water mobility within the viable periphery, as signified by increased signal intensity (SI) at higher *b* values (Figure 3). This finding suggests increased cellularity compared to the tumor core and surrounding tissues. The mean ADC value was higher in the necrotic tumor core (2.1 ± 0.3 mm^2/s) than in the viable tumor periphery (1.4 ± 0.5 mm^2/s) ($P < 0.05$).

TRIP-MRI was successful in 5 of 6 rabbits. One rabbit could not be catheterized for DSA due to severe vasospasm. TRIP-MRI scans showed tumor perfusion to the peripheral viable portions of the tumor, with lack of perfusion to the central necrotic portions of the tumor (Figure 4). Mean AUC was significantly higher in the periphery (110 ± 47 relative units) than in the central core (66 ± 31 relative units) ($P < 0.00002$) (Figure 5).

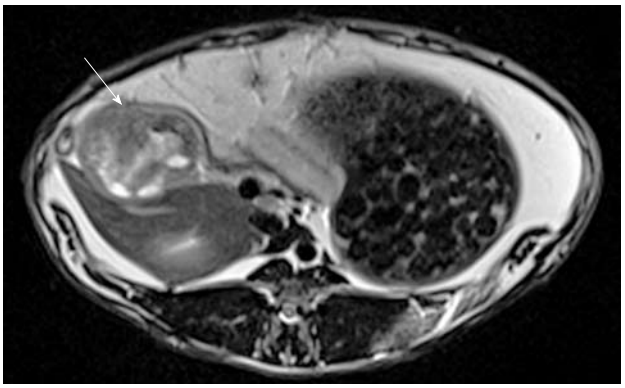

Figure 2 T2-weighted turbo spin echo magnetic resonance imaging showing pancreatic tumor (arrow) in axial view.

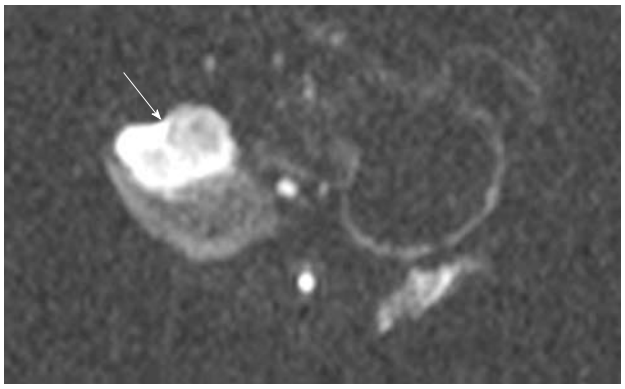

Figure 3 Single shot spin-echo planar diffusion weighted MRI (b = 500 s/mm^2) showing pancreatic tumor (arrow) in axial view.

When comparing DW- and TRIP-MRI, regions of relatively low water mobility correlated with relatively greater tissue perfusion.

DISCUSSION

The results of this study confirm the hypothesis that functional MRI can be used to differentiate necrotic from viable tumor cells in an animal model of pancreatic cancer. Regions of necrosis were delineated from viable tumor cells by larger ADC values on DW-MRI and reduced perfusion values with TRIP-MRI. These results are relevant because the differentiation between malignant and uninvolved or adequately treated pancreatic tissue is difficult with conventional anatomic MRI.

In several preliminary clinical studies enrolling 8-26 patients, DW-MRI has been shown to be able to detect pancreatic carcinoma and differentiate neoplasm from confluent pancreatitis[30-32]. Viable tumor cells are highly cellular and have intact cell membranes. This restricts the motion of water molecules and results in a decrease in the ADC value. Conversely, cellular necrosis causes increased membrane permeability, allowing free diffusion of water molecules and a marked increase in the ADC value. DW-MRI has also been shown to be able to accurately predict the degree of tumor necrosis in hepatocellular carcinoma following transcatheter liver-directed therapy[33-36]. Our current study demonstrates that DW-MRI can be used to differentiate necrotic from viable cells in this animal model of pancreatic cancer.

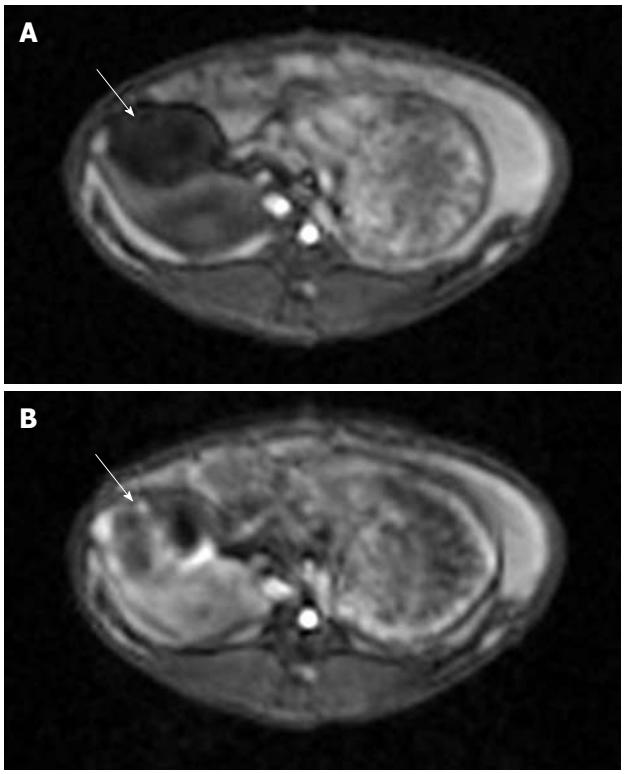

Figure 4 T1-weighted gradient-echo magnetic resonance [taken before (A) and after (B) TRIP imaging occurred]. Each image shows a VX2 tumor (solid arrows) located in the pancreas. Note the areas of increased perfusion to the viable tumor periphery in image B.

TRIP-MRI uses catheter-directed intraarterial injections of gadolinium. This technique is distinct from dynamic contrast-enhanced (DCE)-MRI, which uses intravenous injections of gadolinium. TRIP-MRI has several advantages over DCE-MRI including the capacity for dramatically lower volumes of contrast agents and the ability to perform serial injections without needing to wait > 1 h for injected contrast agent to wash-out. A pre-clinical study in the VX2 rabbit liver tumor model has validated the utility of TRIP-MRI to monitor iterative changes in liver tumor perfusion during embolization[27]. This technique has been translated clinically to measure intra-procedural changes in perfusion to targeted tumors during the treatment of patients with hepatocellular carcinoma with chemoembolization[28]. Because of its ability to enhance tissue distal to the catheter tip, TRIP-MRI can also verify that tumors will be adequately targeted by localized catheter-based techniques prior to their injection. This study demonstrates that TRIP-MRI can be used to detect differences in perfusion to necrotic and viable pancreatic tumor cells.

The development of localized therapies for unresectable pancreatic cancer represents a new avenue for research. As recently demonstrated by Olive *et al*[37], a stromal

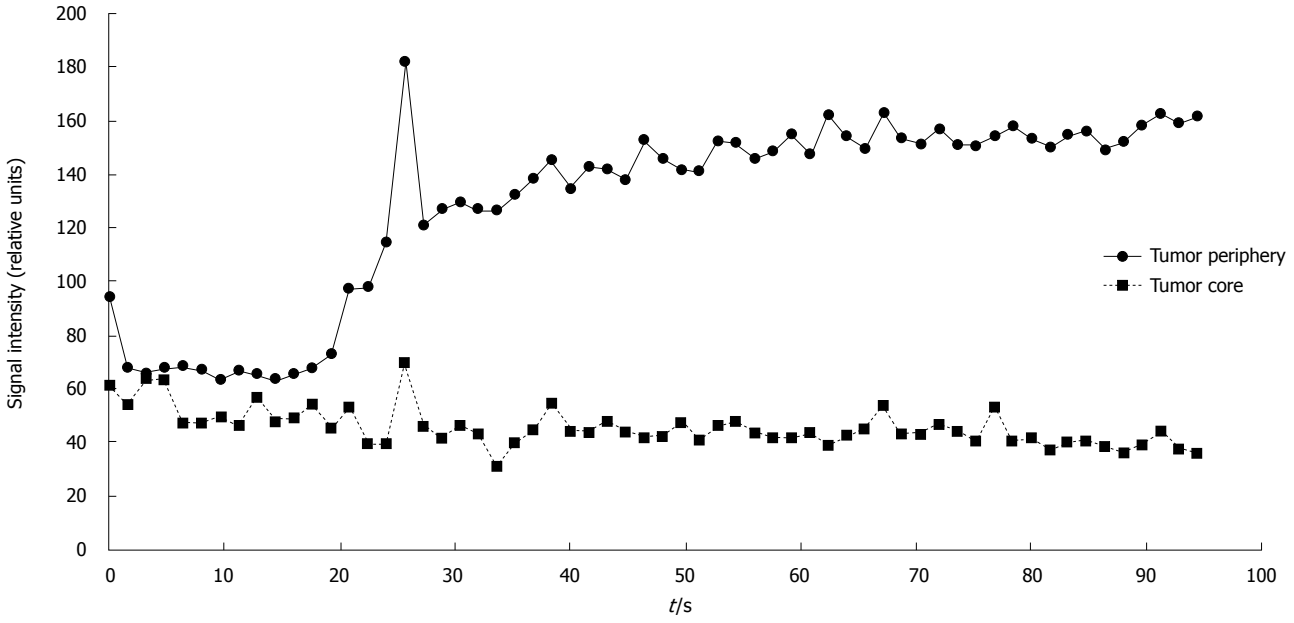

Figure 5 Signal intensity *vs* time curve for one pancreatic tumor, depicting higher signal intensity in the viable tumor periphery than in the necrotic tumor core.

desmoplastic reaction encapsulating pancreatic tumors greatly impedes systemic therapies and thus localized therapies that are able to greatly increase the local concentration of therapeutics may offer benefit in overcoming this fibrotic capsule. Preliminary studies have reported on transcatheter intraarterial infusion of chemotherapy for advanced pancreatic cancer[9-11], which may provide improved response to therapy[12]. The functional MRI parameters described in this animal model of pancreatic cancer could potentially be used as surrogate functional endpoints to test such transcatheter pancreatic therapies. The animal model and functional MRI techniques described in this paper could also be used to assess novel localized therapies intended to target some of the molecular mechanisms underlying pancreatic cancer, including a mutant *p53* tumor suppressor gene[38] or other inhibitors of apoptosis, such as survivin[39,40].

Our study had several important limitations. First, the molecular mechanisms that govern pancreatic ductal adenocarcinoma and VX2-based tumors differ. VX2 is a squamous cell carcinoma that does not have the alterations in the multiple molecular pathways seen with true pancreatic cancer[41]. Our model, however, does mimic well the position and blood supply of a human pancreatic tumor which makes it well suited to the translational development of localized therapies. Second, the smaller diameter of rabbit pancreatic arteries precluded direct catheterization of the pancreaticoduodenal, dorsal pancreatic, great pancreatic, and caudal pancreatic arteries. These arteries are also extremely difficult to selectively catheterize in patients. Additionally, TRIP-MRI verified that perfusion to viable pancreatic tumor cells could be achieved *via* catheterization of the rabbit gastroduodenal artery. Third, although functional imaging in animals is not entirely novel, previous studies have focused on rodents instead of rabbits[42], and have primarily employed high field strength magnets[43]. Using a 1.5-T scanner, we believe, allows our findings to be more readily translated into future clinical studies. Finally, we did not assess the effect of therapy in this animal model. Such assessment will be the subject of future studies.

In conclusion, functional MRI parameters can be used to differentiate necrotic from viable tumor cells in an animal model of pancreatic cancer. Regions of necrosis are delineated by larger ADC values on DW-MRI and reduced perfusion values with TRIP-MRI. In a disease that so desperately needs a more effective treatment, these functional MRI parameters could potentially be used as surrogate functional endpoints when testing future novel local transcatheter pancreatic therapies.

COMMENTS

Background

Pancreatic ductal adenocarcinoma (commonly referred to as pancreatic cancer) carries the worst prognosis of any cancer, thus novel therapies must be developed to treat this disease. Because evaluation of these new therapies may be difficult, imaging modalities to assess therapeutic efficacy based on tumor necrosis are desirable.

Research frontiers

Functional magnetic resonance imaging (MRI) modalities are quickly emerging as new imaging methods with the potential to provide more information about structures in the body than traditional anatomic MRI. In this study, the authors demonstrate that the use of two specific types of functional MRI: diffusion-weighted MRI (DW-MRI) to measure tissue diffusion; and transcatheter intraarterial perfusion MRI (TRIP-MRI) to measure perfusion, could be used to differentiate tumor cells that are dead from those that are still alive.

Innovations and breakthroughs

This study is the first to combine cutting edge imaging modalities (DW-MRI and TRIP-MRI) performed using a clinical 1.5T MRI scanner with a recently created rabbit model of pancreatic cancer which allows for intraarterial catheterization.

Applications

By characterizing this model of pancreatic cancer using functional MRI, this

study may allow for more effective development of much-needed novel therapeutics for the treatment of this disease.

Terminology

DW-MRI and TRIP-MRI are types of MRI called "functional" MRI because they provide information about tissue function in addition to anatomical information provided by traditional MRI. DW-MRI is used to acquire a value called the apparent diffusion coefficient which is a relative measure of water diffusion within a tissue. TRIP-MRI is used to acquire a measure of relative perfusion which represents the amount of blood flow to a tissue.

Peer review

The manuscript is well written and methodology is accurately described. The manuscript applied function MRI in pancreas tumor model and results showed that MR-DWI and TRIP-MRI can distinguish the necrotic tissue form living tissue of pancreas tumor model. This gives us more confidence on the potential of function MRI in the therapy response evaluation. Limitations of the study are considered by the authors themselves and substantiated in the discussion.

Abstract

AIM: To investigate the prevalence of proximal small bowel (SB) lesions detected by wireless capsule endoscopy (WCE) in Crohn's disease (CD).

METHODS: WCE was performed in 64 patients: 32 with CD of the distal ileum, and 32 controls with iron-deficiency anemia (IDA) or diarrhea. WCE was performed using the Given SB-WCE, followed by small intestine contrast ultrasonography (SICUS). Findings compatible with CD by using WCE included erosions, aphthoid or deep ulcers, and strictures/stenosis.

RESULTS: WCE detected proximal SB lesions in 16/32 (50%) patients (14 aphthoid ulcers, 2 deep ulcers, one stricture), which appeared not to be related to clinical parameters [epigastric pain, age, smoking, non-steroidal anti-inflammatory drugs (NSAIDs), IDA]. Among patients with proximal SB lesions, 6 (37%) were smokers, 3 (19%) NSAID users, 3 (19%) had epigastric pain and 4 (25%) had IDA. SICUS detected proximal SB lesions in 3/32 patients (19%) also showing lesions with WCE. No correlations were observed between proximal SB lesions assessed by WCE or by SICUS ($\chi^2 = 1.5$, $P = 0.2$).

CONCLUSION: The use of WCE allows the detection of previously unknown upper SB lesions in a high proportion of patients with a previous diagnosis of CD involving the distal ileum.

Wireless capsule endoscopy and proximal small bowel lesions in Crohn's disease. *World J Gastroenterol* 2010; 16(26): 3299-3304 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i26/3299.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i26.3299

INTRODUCTION

Wireless capsule endoscopy (WCE) is a non-invasive technique for visualizing the mucosal surface of the small bowel (SB)[1-7]. However, a variable impact risk (from 0%-6.7%) has been reported[8]. WCE showed a high sensitivity and specificity for detecting lesions related to SB Crohn's disease (CD)[1-7]. A meta-analysis showed an incremental diagnostic yield of WCE *vs* small bowel follow through (SBFT) ($P < 0.001$), ileocolonoscopy ($P =$

0.02), computed tomography enteroclysis ($P = 0.001$) and push enteroscopy ($P < 0.001$)[9]. WCE has in particular been shown to be able to detect minor lesions (erosions, aphthoid ulcer), not visualized by conventional radiologic techniques, which result in high radiation exposure. WCE has therefore been proposed as an alternative non-invasive technique for assessing CD lesions.

Ultrasonography also is a non-invasive technique proposed for detecting SB lesions in CD[10]. The use of an oral contrast [small intestine contrast ultrasonography (SICUS)] significantly increases, in experienced hands, the sensitivity of ultrasonography for assessing SB lesions in CD (> 95%)[11,12].

Although several studies concordantly showed that WCE is able to visualize superficial lesions in the SB, its role in defining the extent of the lesions in CD is undefined. In particular, the frequency and clinical relevance of superficial lesions in the upper SB as detected by WCE, but not by conventional techniques, in patients with an established diagnosis of CD involving the distal ileum, is currently unknown. Disease-specificity of the small lesions as detected by WCE is also under investigation.

On the basis of these observations we therefore aimed to assess, in a prospective longitudinal study in patients with a known diagnosis of CD of the distal ileum, the prevalence of lesions in the proximal SB (jejunum, proximal ileum) compatible with CD, as assessed by WCE. The secondary end point was to evaluate the possible concordance between WCE and SICUS, in detecting SB lesions compatible with CD. Additional end points included investigation of possible correlations between proximal SB lesions in WCE and specific signs and symptoms, including anemia and/or epigastric pain in patients with CD. A comparison between characteristics of SB lesions detected by WCE in patients with CD *vs* patients undergoing WCE for other indications was also performed. The safety of WCE in CD patients with no radiological or clinical evidence of sub/obstructive symptoms was further addressed.

MATERIALS AND METHODS

Study population

In a prospective longitudinal study, WCE was performed in all consecutive CD patients referred to our Unit from May 2004 to May 2008, fulfilling the following inclusion criteria: (1) age 18-75 years; (2) regular follow-up; and (3) established diagnosis of CD involving the distal ileum, according to standard procedures.

As a control group (C), WCE was performed in all consecutive patients referred to our Unit from May 2004 to May 2008, with the following inclusion criteria: (1) age 18-75 years; and (2) clinical indication for WCE such as iron-deficiency anemia (IDA) or chronic diarrhea of unknown origin with no diagnosis by conventional procedures. No patients showed evidence of stenoses/strictures. Written informed content was provided by all patients.

Study design

CD group: Before WCE, recorded parameters included: findings at physical examination, activity (CD activity index, CDAI)[13], epigastric pain (yes/no), IDA, laboratory tests (complete blood count, hemoglobin, serum iron, ferritin, creatine phosphate, erythrocyte sedimentation rate), non-steroidal antiinflammatory drug (NSAID) use, and smoking habit. Before WCE, all 32 patients were studied by both SICUS and ileocolonoscopy (median time interval 1 mo, range 0-7 mo, and 1 mo, range 0-14 mo, respectively). After WCE, patients were clinically followed up at least 12 mo (median 24 mo, range 12-36 mo).

C group: Before WCE, recorded parameters included: findings at physical examination, gastrointestinal symptoms, laboratory tests (as above), NSAID use, and smoking habit.

SICUS

SICUS was performed after 375 mL polyethylene glycol (PEG) ingestion[11] using 3.5 and 5 MHz convex and linear-array transducers, by the same expert gastroenterologist (> 2000 examinations). Findings compatible with CD included: increased bowel wall thickness (BWT) (≥ 3 mm), SB dilation (diameter > 2.5 cm), bowel stricture (diameter < 1 cm, at the level of the maximally distended loop)[11,12]. Fistulas or abscesses were considered.

Ileocolonoscopy

All endoscopies were performed by the same gastroenterologist, according to standard procedures.

WCE

WCE was performed with the Given Pillcam SB capsule system (Given Imaging Limited, Yoqneam, Israel)[1] after 3 d of a fiber-free diet and bowel preparation [2 L PEG, (Promefarm, Milano, Italy)]. Images were reviewed by a single gastroenterologist unaware of the SICUS findings.

CD group: The following WCE findings were considered compatible with CD: aphthoid ulcers (> 3), deep ulcers, strictures or stenoses. Erosions, villous dropouts and mucosal breaks were reported, although considered not related to CD. As no standard criteria for defining upper SB lesions using WCE were available, distal SB lesions were considered lesions proximal to the ileo-cecal valve or to the ileo-colonic anastomosis. Upper SB lesions were considered the SB lesions proximal to these areas (jejunum, proximal ileum).

In a subgroup of 10 CD patients with ileo-colonic resection, WCE findings were blindly scored by 2 independent gastroenterologists. For this purpose, lesions in the peri-anastomotic area and in the upper SB were graded as follows[5]: absent (G0), erythema/loss of villi (G1), erosions/aphthoid ulcers (G2), deep ulcers (G3).

C group: Any lesion detected by WCE was reported. A comparison with the CD group considered only those lesions in the upper or distal SB compatible with CD, including: aphthoid or deep ulcers, strictures, stenoses. Planar X-ray of the abdomen was performed in all patients

Table 1 Clinical characteristics of the 32 CD patients studied with WCE

with no WCE excretion after 48-72 h. Retention was defined as WCE persistence after 14 d. Incomplete studies were defined when WCE did not reach the cecum.

Comparison between WCE and SICUS findings

Comparison between WCE and SICUS in terms of findings compatible with SB lesions related to CD was made using the following parameters: presence (yes/no), site (upper *vs* distal SB) and severity of the lesions (deep *vs* aphthoid ulcers) by using WCE and presence (yes/no) and site (upper *vs* distal SB) of increased BWT ($\geqslant$ 3 mm) using SICUS. Correlations between WCE findings compatible with upper SB lesions and clinical parameters (age, smoking habits, epigastric pain, IDA) were determined.

Statistical analysis

Results were expressed as median and range both in the text and in the tables. Differences between groups were assessed by the Student's *t*-test. The interobserver variation in terms of presence and severity of upper SB lesions detected by WCE was assessed.

RESULTS

Study population

CD group: Thirty two consecutive patients (16 male, median age 32 years, range 19-65 years) with an established diagnosis of CD of the distal ileum fulfilled the inclusion criteria. Clinical characteristics of the enrolled patients are summarized in Table 1.

Treatment included budesonide (9 mg/d) in 6 (19%) and mesalazine 2.4 g/d in 26 (81%) patients. Among the 32 patients, 4 (12%) had IDA and 7 (22%) epigastric pain.

C group: Thirty two consecutive C patients (16 male, median age 42 years, range 18-72 years) undergoing WCE fulfilled the inclusion criteria. Clinical indications for WCE included IDA in 17 (53%) and chronic diarrhea in 15 (47%) patients.

Figure 1 Plain film of the abdomen from one Crohn's disease patient showing capsule retention for 12 wk, with no associated symptoms. The patient had 2 anastomoses (ileo-ileal and ileo-colonic). Surgical removal was required, showing wireless capsule endoscopy within the "*cul de sac*" of the side-to-side ileo-ileal anastomosis not reachable by the endoscope.

Adverse events

CD group: Retention was observed in one patient (3%) with 2 anastomoses (ileo-ileal and ileo-colonic), showing no symptoms despite capsule retention for > 12 wk (Figure 1). Surgical removal of WCE was required after 2 unsuccessful therapeutic endoscopies. During surgery, WCE was detected within the "*cul de sac*" of the side-to-side ileo-ileal anastomosis not reachable by the endoscope.

C group: No adverse events were reported.

Proximal SB lesions detected by WCE

CD group: WCE detected previously unknown proximal SB lesions compatible with CD in 16/32 (50%) patients. Among these 16 patients, lesions included > 3 aphthoid ulcers in 14 (87.5%), deep ulcers in 2 (12.5%) and one ulcerated stricture identified by WCE in one patient (Figure 2A-C). All lesions compatible with CD appeared discontinuous and surrounded by macroscopically uninvolved mucosa. In all 16 patients showing lesions in the upper SB, WCE also detected lesions in the distal ileum compatible with CD.

The median age was comparable in patients showing or not (n = 16 for both) proximal SB lesions at WCE (44 years, range 20-65 years *vs* 32 years, range 19-48 years, P = NS).

Table 2 summarizes the clinical characteristics of the 32 patients grouped according to the presence or not of upper SB lesions in WCE. No statistically significant concordance was observed between upper SB lesions in WCE for both clinical parameters and risk factors considered (CD site χ^2 = 3.3, P = 0.18, epigastric pain χ^2 = 0.0, P = 1.0, smoking habits χ^2 = 1.3, P = 0.5, NSAIDs use χ^2 = 1.5, P = 0.2, IDA χ^2 = 0.0, P = 1.0).

The interobserver agreement for SB lesions visualized by WCE (score 0-4)[5] was very high when considering proximal SB lesions (κ = 0.86) and high when considering distal SB lesions (κ = 0.61). At 12 mo, none of the 32 patients showing lesions in the upper SB developed related symptoms (anemia, epigastric pain) or symptomatic SB stenosis.

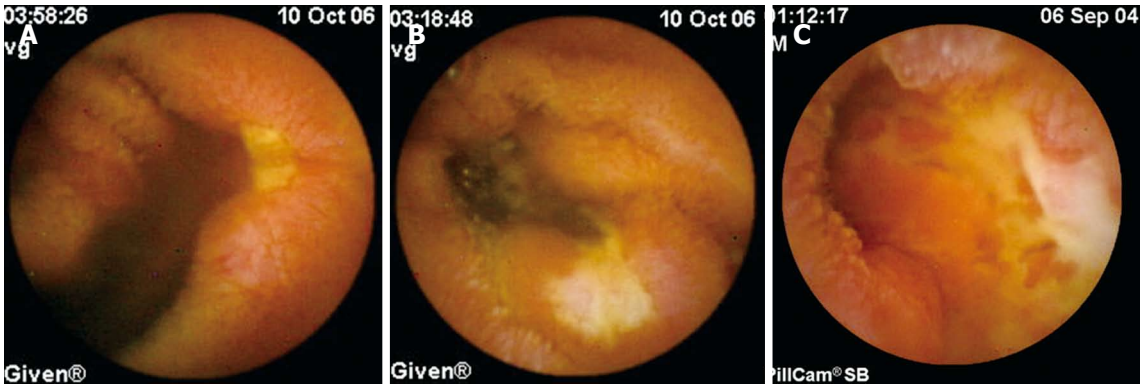

Figure 2 Upper small bowel lesions detected at wireless capsule endoscopy in 3 patients with an established diagnosis of Crohn's disease involving the distal ileum. Aphthoid ulcer (A), deep ulcer (B) and one ulcerated stricture easily identified by wireless capsule endoscopy (C). All lesions compatible with Crohn's disease detected by wireless capsule endoscopy appeared discontinuous and surrounded by macroscopically uninvolved mucosa.

Table 2 Clinical characteristics of the 32 CD patients grouped according to the presence of upper small bowel lesions at WCE

	Small bowel lesions at WCE (%)	
	Yes (n = 16)	No (n = 16)
Known CD extent before WCE

Non-smokers	7 (44)	7 (44)
NSAID use		
Yes	3 (19)	0
No	13 (81)	16 (100)
IDA		
Yes	4 (25)	5 (31)
No	12 (75)	11 (69)

IDA: Iron-deficiency anemia.

C group: WCE detected proximal SB lesions not compatible with CD in 5/32 (16%) patients, represented by erosions in 3 (9%) and angiodysplasia in 2 (6%). In contrast to CD patients, none of the 32 C patients showed aphthoid or deep ulcers in the SB with WCE.

Proximal SB lesions detected by SICUS

SICUS detected proximal SB lesions in 3/32 (9%) CD patients, represented by increased jejunal BWT with bowel dilation, associated with stenosis in one patient.

Comparison between WCE and SICUS in detecting upper SB lesions

When considering the 16 CD patients showing upper SB lesions with WCE, only 3 (19%) also showed SICUS findings compatible with CD lesions in the same area (BWT > 3 mm). Therefore, all 3 (9%) patients showing SICUS results compatible with CD lesions in the proximal SB had the findings confirmed by WCE. Upper SB lesions in WCE in these patients included deep ulcers in 2 and aphthoid ulcers in one patient. The only stricture identified by WCE was also visualized by SICUS. However, these 2 techniques showed no significant concordance in detecting proximal SB lesions ($\chi^2 = 1.5$, $P = 0.2$).

Distal SB lesions detected by WCE

CD group: Findings compatible with CD lesions in the distal SB were detected by WCE in 30/32 (93%) patients. In the remaining 2 patients, WCE did not visualize the colon, thus not allowing the evaluation of the distal SB. Of the 30 patients with available distal SB images with WCE, lesions included erosions in 2 (7%), aphthoid ulcers in 13 (43%), deep ulcers in 11 (37%), both aphthoid and deep ulcers in 3 (10%) and one single ulcerated substenosis in one (3%) patient. In all patients showing lesions in the upper SB, WCE also showed lesions in the distal SB.

One patient (PL) showed WCE impaction at the level of the anastomosis as detected by a plain film of the abdomen showing capsule retention for 12 wk, with no associated symptoms (Figure 1). The patient had 2 anastomoses (ileo-ileal and ileo-colonic) for CD-related surgery. Surgical removal of the WCE was required, showing the capsule retained within the "*cul de sac*" of the side-to-side ileo-ileal anastomosis not reachable by the endoscope. In a second patient (CE) with IDA, WCE images stopped at the level of a bleeding ulcerated substenosis in the proximal SB, with no retention (Figure 2C). In this patient indication for surgery was also determined after WCE examination, followed by resection of the ulcerated substenosis not detected by conventional techniques, with histological findings compatible with CD.

C group: WCE detected distal SB lesions not compatible with CD in 2/32 (6%) patients, including erosions in one patient and one single angiodysplasia in the other patient. No patients showed aphthoid or deep ulcers compatible with CD.

Distal SB lesions detected by SICUS

CD group: SICUS detected distal SB lesions in 30/32

(93%) patients, including all 3 patients showing upper SB lesions by SICUS. In both patients with normal SICUS, conventional techniques detected lesions in the distal ileum.

Comparison between WCE and SICUS in detecting distal SB lesions

Findings compatible with CD in the distal SB were detected by both WCE and SICUS in 30/32 (93%) patients, as SICUS detected no lesions in 2 patients. These 2 techniques showed no significant concordance in detecting proximal SB lesions ($\chi^2 = 0.5$, $P = 0.4$).

Additional findings at WCE

CD group: WCE detected gastric and/or duodenal lesions in 7/32 (22%) patients. Gastric lesions were detected in 5/32 (15%) patients, including aphthoid ulcers in one and erosions in 4 patients. Duodenal lesions (erosions) were detected by WCE in 5/32 (15%) patients, and were also visualized in the stomach in 4 patients. Of the 7 patients showing gastric/duodenal lesions at WCE, 5 (71%) also showed upper SB lesions with WCE.

C group: Additional findings were detected in 6/32 (19%) C patients, including gastric/duodenal erosions in 5 and colonic angiodysplasia in 2 (with gastric erosions in one).

DISCUSSION

Proximal SB lesions are detected in a low proportion of CD patients (about 5%)[14-16]. However, these rates have been reported using radiologic techniques which show a low sensitivity for visualizing superficial lesions. Recently, WCE has been shown to visualize the inner SB surface, providing a high sensitivity in detecting minor lesions (i.e. erosions, aphthoid ulcers)[2-4]. Two independent studies reported that WCE visualizes lesions related to early CD recurrence in the SB[17,18]. As the frequency, natural history and clinical relevance of proximal SB lesions in CD is undefined, we investigated this issue in a prospective longitudinal study. A high frequency of WCE findings compatible with proximal SB lesions related to CD was observed. As WCE does not allow an histological characterization of the lesions, WCE findings in CD patients were compared with those observed in control patients requiring WCE for IDA or chronic diarrhea. No control patients showed aphthoid or deep ulcers, thus supporting the specificity of the upper SB lesions detected by WCE in our CD population. No correlations were observed between risk factors and proximal SB lesions, supporting the disease-specificity of our findings.

The frequency of WCE impaction was within the expected range (3%)[8]. The finding of WCE impaction within the "*cul the sac*" of a side-to-side ileo-ileal anastomosis may indicate a higher impaction risk in these patients, even in the absence of overt stenosis. In addition, a WCE examination allowed the detection of a previously unknown ulcerated substenosis in one additional patient with IDA associated with CD of the distal ileum. This observation further supports the role of WCE in identifying upper SB lesions not detected by conventional radiology.

No concordance was observed between proximal SB lesions at WCE and related signs/symptoms, even when patients were followed up for at least 12 mo. This observation provides additional evidence for a diffuse involvement of the SB in patients with CD of the distal ileum, even if not associated with overt symptoms. Present findings also suggest that no treatment changes may be required in CD patients showing upper SB lesions at WCE. The observed frequency of upper SB lesions is in agreement with previous findings in the early postoperative period (56%)[17].

When WCE and SICUS findings were compared, a small proportion of patients (3 of 16) showing upper SB lesions with WCE, also showed the same finding with SICUS. This discrepancy is in agreement with our previous studies[18,19] and may be related to the observation that WCE and SICUS provide a different view of the SB (i.e. intraluminal *vs* extraluminal). In addition, WCE allows the visualization of superficial lesions not detected by SICUS[18]. In the 3 patients showing upper SB lesions by both WCE and SICUS, lesions were represented by deep ulcers at WCE in 2, suggesting that discrepancies are mainly observed for superficial lesions. In contrast to the upper SB lesions, WCE and SICUS findings appeared comparable in the distal SB. This observation indicates that the characteristics of the SB lesions, including not only the severity (deep *vs* aphthoid ulcers) and number, but also the site (upper *vs* distal SB) may influence the sensitivity of ultrasonography. A good interobserver agreement was observed, supporting previous findings[17]. Although some patients were studied by SBFT, this technique was not included for ethical and economic reasons, in relation to both the high radiation exposure and to the known low sensitivity of SBFT in detecting superficial SB lesions. In addition, there was no clinical indication for SBFT in our population, including only 5 active patients with an established diagnosis of CD.

To our knowledge, no studies have investigated the role of WCE in comparison with SICUS in detecting the presence and clinical relevance of upper SB lesions in patients with CD involving the distal ileum, diagnosed by conventional radiological techniques. The present findings supports that WCE is a non-invasive technique which allows the visualization of superficial proximal SB lesions in a high proportion of patients with an established diagnosis of CD of the distal ileum. Despite no significant clinical relevance appearing to be associated with these findings even in the long term, the use of WCE in CD involving the distal SB may add clues in defining the extent of the lesions and its relation with clinical manifestations of the disease.

COMMENTS

Background

Wireless capsule endoscopy (WCE) is a non-invasive technique visualizing the

mucosal surface of the small bowel (SB). WCE showed a high sensitivity and specificity for detecting lesions related to SB Crohn's disease (CD). WCE has in particular been shown to be able to detect minor lesions, not visualized by conventional radiologic techniques, providing high radiation exposure. WCE has therefore been proposed as an alternative non-invasive technique for assessing CD lesions. Ultrasonography also is a non-invasive technique proposed for detecting SB lesions in CD. The use of an oral contrast (SICUS) significantly increases, in experienced hands, the sensitivity of ultrasonography for assessing SB lesions in CD (> 95%). Although several studies concordantly showed that WCE is able to visualize superficial lesions in the SB, its role in defining the extent of the lesions in CD is undefined.

Research frontiers

Proximal small bowel lesions are detected in a low proportion of CD patients (about 5%). However, these frequencies have been reported using radiologic techniques which have a low sensitivity for visualizing superficial lesions. WCE has been shown to visualize the inner SB surface, providing a high sensitivity in detecting minor lesions (i.e. erosions, aphthoid ulcers). Two independent studies reported that WCE visualizes lesions related to early CD recurrence in the SB. However, the frequency, natural history and clinical relevance of proximal SB lesions in CD is currently undefined.

Innovations and breakthroughs

The present study showed that WCE is a non-invasive technique allowing the visualization of superficial proximal small bowel lesions in a high proportion of patients with an established diagnosis of CD of the distal ileum.

Applications

Despite no significant clinical manifestations appearing to be associated with these findings even in the long term, the use of WCE in CD involving the distal SB may add clues in defining the extent of the lesions and the relationship with clinical symptoms of the disease.

Terminology

WCE is a non-invasive technique able to visualize the inner surface of the small intestine. SICUS is also a non invasive technique showing, in experienced hands, a high sensitivity and specificity in terms of assessment of small bowel lesions, including increased bowel wall thickness in ileal CD.

Peer review

This is a small (32 patients) prospective study, with a control population, that evaluates the diagnostic accuracy of WCE in CD, and compares it with different diagnostic tools. It is well presented and performed in an ethical manner.

Abstract

AIM: To describe patient characteristics and the results of surgical treatment for hepatic hydatidosis (HH) in the Hospital Hernán Henríquez Aravena from December 2001 to March 2005.

METHODS: Subjects older than 16 years with suspected HH were included based on the clinical picture and radiological studies. Variables examined included clinical and laboratory aspects, outcome, features of the parasite and surgical aspects. Descriptive statistics were used, calculating central tendency, dispersion and extreme tendency.

RESULTS: The series was comprised of 122 patients, with an average age of 44 ± 16.9 years. The most frequently used surgical technique was subtotal cystectomy in 90% of the patients, followed by hepatic resection (hepatectomy, segmentectomy and subsegmentectomy) in 5%. In 2%, a combination of subtotal cystectomy and segmentectomy was performed. In addition, 28% of the series presented complications in the postoperative period and mortality was 2%.

CONCLUSION: The most frequently used surgical technique for HH was subtotal cystectomy and the morbidity and mortality rates in this Chilean series are comparable to other national and international series.

Key words: Echinococcosis of liver; Surgery; Cases series; Mortality; Morbidity

Experience with the surgical treatment of hepatic hydatidosis: Case series with follow-up. *World J Gastroenterol* 2010; 16(26): 3305-3309 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i26/3305.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i26.3305

INTRODUCTION

Hepatic hydatidosis (HH) is a zoonosis produced by *Equinococcus granulosus* that presents a high prevalence and incidence in southern Chile, at a rate of 38 per 100 000[1-2]. There are many options for HH treatment. Based on World Health Organization guidelines and our experience, surgery is one of the most effective treatments for HH[3-5].

There is a wide range of surgical techniques for treating HH, from radical surgery with complete removal of

the cyst leaving no residual cavity (pericystectomy or regulated hepatic resection), to more conservative techniques with partial removal of the cyst and treatment of that part of the cyst remaining in the hepatic parenchyma: subtotal cystectomy plus epiploplasty, subtotal cystectomy plus capitonnage, cystostomy plus epiploplasty, among others[3-12]. Some reports show that epiploplasty decreases the incidence of deep abdominal abscess after surgical treatment[10-12].

The surgical technique preferred by our team is subtotal cystectomy, leaving the smallest amount of cyst in the hepatic parenchyma, accompanied by epiploplasty[11,12]. Performing complete dissection of the liver's ligamentous attachments we can thus provide even better exposure for resection of the cyst, only leaving the part close to vascular structures.

Our hypothesis is that morbidity and mortality rates associated with the surgical treatment of HH in the Hospital Hernán Henríquez Aravena, Temuco, Chile, are comparable to national and international figures. Our aim is to describe patient characteristics, the results of the surgical treatment and the morbidity and mortality associated with the surgical treatment of HH in the Hospital Hernán Henríquez Aravena from December 2001 to March 2005.

MATERIALS AND METHODS

Study design and population

Patients were subjects older than 16 years with suspected HH based on the clinical findings and radiological studies which were performed in Hospital Hernán Henríquez Aravena (Temuco, Chile) from December 2001 to March 2005. Our protocol did not include preoperative albendazole.

Definitions

Subtotal cystectomy: Surgical technique in which part of the adventitious membrane of the hydatid cyst is resected. In this technique, we only leave the part of the adventitia adjacent to the vascular structures. When possible, this part is covered by a vascularized omental flap (epiploplasty).

Pericystectomy: Total resection of the cyst's adventitious membrane, in which the plane between the adventitious membrane and hepatic parenchyma is dissected. This technique is used for peripheral cysts and is performed with afferent vascular control (Figure 1A).

Maneuver

The biliopancreatic surgery team prefers to treat HH *via* the abdomen no matter where the cysts are located. A subcostal laparotomy is used, either right or bilateral, depending on the location of the cysts; or a J laparotomy towards the right. The round ligament is sectioned and tied off and the liver is then moved to locate the cyst (Figure 1B). On some occasions, intraoperative echography is used when cysts are difficult to locate. Once a cyst has been located, we protect the surgical area with compresses containing either diluted povidone or 20% hypertonic saline solution as per the surgeon's choice (Figure 1C). The cyst is subsequently punctured and all the hydatid fluid and daughter vesicles are aspirated (Figure 1D and E). The germinative membrane is removed and the protection field withdrawn. Depending on the location, the subtotal cystectomy is planned, beginning the resection of the cyst wall with electrocoagulation, controlling the hemostasia, leaving only that part of the cyst which is adjacent to the vascular structures. This area is then reviewed in search of biliary communications, which are sutured with 3-0 resorbable material. Some team members perform a cholecystectomy and they inject physiological serum into the cystic duct through a nelaton probe to make small biliary communications visible (Figure 1F). Depending on the number of communications, satisfaction with the closing of the communications and the diameter of the bile duct, a choledochostomy is performed. The only absolute indication for a choledochostomy is a clinical picture compatible with cholangiohydatidosis, in which the bile duct is always drained. Nevertheless, in recent months, we have tried to drain the bile duct using endoscopic retrograde cholangiography. An epiploplasty is subsequently performed with a greater omentum pedicle flap. Drains are not positioned as a matter of course and are at the surgeon's discretion.

Study variables

Variables examined included clinical and laboratory features, clinical images and evolutionary complications, surgical and clinical evolution variables.

Variables examined included ultrasound (US) and computed tomography (CT) characteristics of the cyst, the number of cysts (continuous variable), location of the cysts (categorized into right hemi-liver, left hemiliver, bilateral or central liver), diameter of the lesion, evolutionary complications of the cyst (hepatic abscess of hydatid origin (HAH), hepatothoracic transit (HHT), rupture to the abdominal cavity and cholangiohydatidosis.

Surgical variables: The substance used to protect the surgical area is considered (povidone and/or hypertonic solution), as is the surgical technique (categorized into subtotal cystectomy, pericystectomy, segmentectomy and hepatectomy). The use of choledochostomy and/or drain (dichotomized: yes or no) is evaluated.

Clinical evolution variables: The duration of hospitalization is assessed, and the presence of postoperative complications (categorized into: residual cavity, infection of the operating site, atelectasis, pneumonia, hemoperitoneum, bilioperitoneum, evisceration and pneumothorax).

Abscess in the residual cavity is defined as any purulent collection in relation to the liver surgical bed that needs treatment (surgery or CT-guided drainage).

Postoperative follow-up was carried out by clinical assessment. For any abnormal finding US or CT was un-

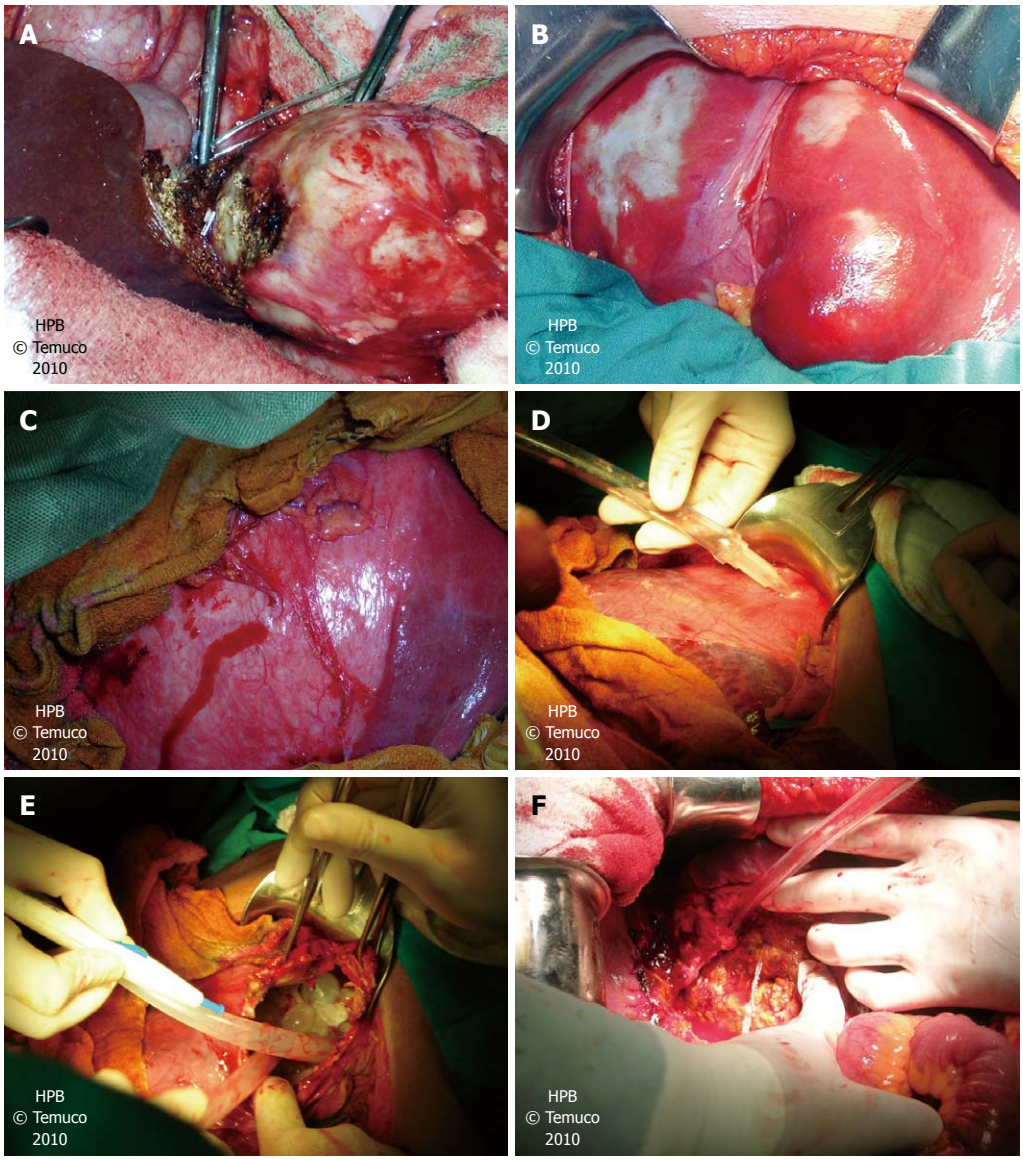

Figure 1 Surgical technique. A: Pericystectomy used for peripheral cyst; B: Subcostal laparotomy is used. Round ligament is sectioned and tied off and the liver is then moved to locate the cyst; C: Protection of the surgical area with compresses containing diluted povidone; D: Puncturing hydatid cyst with trocar; E: Aspirating daughter vesicles; F: Once the cystectomy has been performed, saline solution is injected *via* cyst duct or choledochostomy to locate the biliary communications.

dertaken. Liver recurrence was defined as any cyst image (such as hydatid cyst) with postoperative normal images.

Statistical analysis

Descriptive statistics were used, calculating measures of central tendency (mean, median) dispersion (SD) and extreme values. Database was analyzed using the program Stata® 8.0.

RESULTS

The series included 122 patients with a mean age of 44 ± 16.90 years; with a median of 44 years and range 17-85 years. The distribution by gender showed 73 (60%) male and 49 (40%) female. Forty-nine patients (40%) were admitted by the emergency service and 73 (60%) by the clinic. The mean number of cysts found by US was 1.57 ± 0.91 and the mean number found in surgery was 1.37 ± 0.63. The mean diameter of the main lesion was 10.77 ± 5.62 cm with a median of 10 cm and range 5-30 cm.

When describing the location of the largest cyst, we found that 73 (60%) were located in the right hemi-liver and 49 (40%) in the left hemi-liver. At the time of this study only 49 patients (40%) had undergone CT. Ninety-eight lesions (80%) were hypodense.

The most frequently used surgical technique was subtotal cystectomy in 110 (90%) cases (Table 1). In those patients who underwent a subtotal cystectomy, 90 (82%) also received epiploplasty.

There were evolutionary complications of HH in 20 patients (16%). Intraoperatively, evolutionary complications were found in 49 patients (40%), with the most frequent being cholangiohydatidosis in 38 (31%), followed by HHT in 24 (20%), HAH in 18 (15%) and rupture in 12 (10%).

The surgical area was protected with povidone in 107 patients (88%) and hypertonic solution in 15 (12%).

Table 1 Surgical techniques for HH in this patient series

Technique	*n* (%)
Subtotal cystectomy	110 (90)
Liver resection	6 (5)
Subtotal cystectomy + liver segmentectomy	2 (2)
Others	4 (3)
Total	122 (100)

HH: Hepatic hydatidosis.

The bile duct was explored *via* choledochostomy in 39 patients (32%), with the most common indication being suspected cholangiohydatidosis. Cholangiohydatidosis was treated by bile duct exploration and antibiotic treatment. A drain was left in the cystectomy site at the end of the surgery in 81 patients (66%). Twenty-eight per cent of the series (34 patients) presented postoperative complications. The most frequent was atelectasis and pneumonia in 28 patients (23%), surgical site infection in 6 (5%), hemorrhage in 6 (5%). Three patients presented abscess in the residual cavity. Two were solved surgically and 1 patient was treated by CT-guided drainage.

The clinical, evolutionary and laboratory variables according to the presence of complications are described in Table 2.

The mortality of the series was 3 patients (2%). Six patients (5%) received albendazole as a pharmacological therapy subsequent to the surgery, despite our protocol. Twenty-three patients (19%) were operated on for pulmonary hydatidosis at some point in the postoperative evolution, with the most frequent surgery being cystectomy in 111 patients (91%), followed by pulmonary lobectomy (9%).

With an average follow-up of 22.4 ± 8 mo, 13 patients (11%) presented recurrence. In 10 patients recurrence was in relation to a surgical site.

When the biopsies of the patients operated for suspected HH were reviewed, we found that HH was confirmed in 120 patients (98%). In only 3 patients did the biopsy show different results: in 2 patients the biopsy revealed a simple hepatic cyst with signs of inflammation and in 1 patient a primitive neuroectodermic tumor was discovered.

The mean hospital stay was 16.33 ± 8 d with a median of 13 d and range 3-62 d.

Table 2 Clinical, evolutionary and laboratory variables according to postoperative complications (mean ± SD)

Variables	Patients with postoperative complications (*n* = 25)	Patients without postoperative complications (*n* = 97)
Age (yr)	48.2 ± 15	43.63 ± 17
Sex (% male)	60	33
Evolutionary complications of the cyst (before surgery) (%) (HAH, HHT, rupture to the abdominal cavity and cholangiohydatidosis)	20	9
Protection of the surgical area (% povidone)	24	21
Number of cysts	1.56 ± 0.9	1.32 ± 0.5
Leukocyte count (cells/mm^3)	10245 ± 3955	9095 ± 4605
Total bilirubin (mg/dL)	2.03 ± 2.4	1.43 ± 3.7
Alkaline phosphatase (U/L)	616 ± 576	397 ± 440
AST (U/L)	85.8 ± 39	55.8 ± 91
ALT (U/L)	83.47 ± 94	73 ± 96

HAH: Hepatic abscess of hydatid origin; HHT: Hepatothoracic transit; AST: Aspartate transaminase; ALT: Alanine transaminase.

DISCUSSION

All the patients in our series had abdominal pain as the main symptom upon admittance. Our center does not run routine immunological exams for *Equinococcus* because several previous reports from our center question their diagnostic value[13]. Our diagnostic suspicion is based on epidemiological history, the study of images and the clinical presentation of the patient.

The mean age of the series (44 years) and the predominance of males are remarkable aspects in that these vary from what was recently reported by a Greek series where female gender was higher and patients were younger[14].

The average diameter of the main lesion (10.77 ± 5.62 cm) is less than that reported in a previous cohort conducted in our center (14.5 ± 6 cm). Predominant location in the right hemi-liver tallies with national and international series[11-15].

Among the evolutionary complications of HH, the most frequent was cholangiohydatidosis (31%), followed by hepatothoracic transit (20%). This contrasts with a previous cohort studied in our center, where the most frequent evolutionary complication was HAH (51.5%) followed by cholangiohydatidosis (10.6%)[11].

We have changed the preference of surgical area protection to diluted povidone, due to some cases of hypernatremia which occurred with use of hypertonic saline solution.

With respect to the surgical technique, our team prefers subtotal cystectomy with epiploplasty. We are emphatic about resecting most of the content of the cyst, leaving only the surface in contact with the vascular structures, which we would call an "almost total cystectomy". To this end, it is necessary to have a complete mobilization of the liver and to be familiar with the vascular structures of the hepatic segments.

Our service does not perform routine choledochostomies in HH surgery. This is demonstrated in the 32% of patients in the series who underwent this procedure, where the majority had suspected cholangiohydatidosis.

Unlike other centers[14], postoperative treatment with albendazole is not routine in our service; this is based on previous studies made in our center that showed a low concentration in the interior of the cyst and the non-existence of an association between the intracystic concentration of albendazole and the viability of the scolices[16].

The recurrence of abdominal hydatidosis (11%) is comparable to a recently published series carried out in Turkey with similar surgical approach[15].

The morbidity (28%) is comparable to that reported

by 2 recent international series and 1 cohort conducted in our center[11,12,14] and the mortality (2%) is comparable to that reported recently in a Greek series[14].

A greater prevalence of evolutionary complications and a greater alteration in hepatic test results can be seen in those patients who presented postoperative complications. This tendency must be corroborated in a cohort study designed for this purpose.

The median duration of the hospital stay (16.33 d) is comparable to that published by a previous Chilean series (17 d)[17].

In conclusion, in our Chilean series, subtotal cystectomy was the most common procedure undertaken for HH. The rates of morbidity and mortality are comparable to those reported by other national and international series.

COMMENTS

Background

Hepatic hydatidosis (HH) is a zoonosis produced by *Equinococcus granulosus* that presents a high prevalence and incidence in southern Chile. Based on World Health Organization guidelines and our experience, surgery is one of the most effective treatments for HH.

Research frontiers

Patient characteristics and the results of surgical treatment for HH in the Hospital Hernán Henríquez Aravena from December 2001 to March 2005 were described.

Applications

The authors are very experienced with the treatment of HH and the number of patients presented would allow for a meaningful analysis, which could help to improve the quality of care for these patients.

Peer review

The authors describe their surgical technique used in HH treating and compare morbidity and mortality with the available literature.

Abstract

AIM: To evaluate the prevalence of preoperative and postoperative malnutrition and the relationships between objective and subjective nutritional assessment of gastric cancer patients.

METHODS: From October 2005 to July 2006, we studied 80 patients with no evidence of recurrent disease and no loss to follow-up after curative surgery for gastric cancer. In this group, 9 patients underwent total gastrectomy and 71 patients subtotal gastrectomy. At admission, 6 and 12 mo after surgery, the patients were assessed on the subjective global assessment (SGA), nutritional risk screening (NRS-2002), nutritional risk index (NRI) and by anthropometric measurements and laboratory data. Differences between the independent groups were assessed with the Student's *t* test and one-way analysis of variance. Spearman's rank correlation coefficients were calculated to evaluate the association between the scores and variables.

RESULTS: The prevalence of malnutrition at admission was 31% by SGA and 43% by NRS-2002. At admission, the anthropometric data were lower in the malnourished groups defined by the SGA and NRS-2002 assessments, but did not differ between the groups using the NRI assessment. Body weight (BW), body mass index (BMI), triceps skin fold and midarm circumference were significantly reduced, but the total lymphocyte count, albumin, protein, cholesterol and serum iron levels did not decrease during the postoperative period. Six months after surgery, there was a good correlation between the nutritional assessment tools (SGA and NRS-2002) and the other nutritional measurement tools (BW, BMI, and anthropometric measurements). However, 12 mo after surgery, most patients who were assessed as malnourished by SGA and NRS-2002 had returned to their preoperative status, although their BW, BMI, and anthropometric measurements still indicated a malnourished status.

CONCLUSION: A combination of objective and subjective assessments is needed for the early detection of the nutritional status in case of gastric cancer patients after gastrectomy.

INTRODUCTION

We should pay special attention to the alarming report that 30%-50% of patients in general hospitals have some degree of malnutrition[1-5]. Malnutrition is defined as a state of deficiency in energy, protein or other specific nutrients, producing an appreciable change in body function[6]. Patients who have had gastrointestinal problems and who have undergone gastrointestinal surgery constitute an important risk group for malnutrition[7,8]. Malnutrition is an important factor, influencing both their morbidity and recovery after gastrectomy surgery including radical lymphadenectomy[9,10]. The early detection of nutritional risk would allow early intervention, which may prevent later complications.

The assessment of a patient's initial nutritional status and its evaluation during the disease and/or treatment plays an important role in tailoring nutritional support[11]. The goals of a formal nutrition assessment are: to identify patients who are malnourished or are at risk of malnutrition; to collect the information necessary to create a nutrition care plan; and to monitor the adequacy of nutritional therapy[12]. Studies have consistently revealed the inadequacy of any single method or tool in assessing a patient's nutritional status. The absence of a single gold-standard objective measure has led investigators to develop various nutritional indices that can be used to stratify patients at increased risk of poor outcomes[13]. As a result, combinations of diverse measurements have been developed into subjective scoring systems designed to increase the sensitivity and specificity of nutritional status determinations[14]. Traditionally, scoring systems have been based on objective measurements of nutritional status, such as oral energy intake, body weight, weight loss over time, loss of subcutaneous fat, muscle wasting, serum protein levels, and immune competence. These prognostic indices include the nutritional risk index (NRI)[15], which is based on mathematical equations, and the subjective global assessment (SGA)[16] and nutritional risk screening (NRS-2002), which are based on clinical and subjective assessments[17].

This study was performed to evaluate the prevalence of preoperative and postoperative malnutrition in patients with gastric cancer who underwent radical gastrectomy, and the relationships between the objective variables (anthropometric and laboratory measurements) and the subjective scoring systems in the assessment of nutritional status during the postoperative follow-up period.

MATERIALS AND METHODS

Patients

Between October 2005 and July 2006, 80 patients were studied following curative surgery for gastric cancer. Among this group, 9 patients underwent total gastrectomy and 71 patients underwent subtotal gastrectomy. We assessed the nutritional status and laboratory parameters of the patients on admission and at 6 and 12 mo after surgery. Patients with evidence of recurrent disease or who were lost to follow-up were excluded.

This study was approved by the research ethics committee of the institution, and informed consent was obtained from all patients.

Nutritional measurements

The patients were assessed on the following items: SGA, NRS-2002, NRI, anthropometric measurements and laboratory data. The nutritional assessments were performed by a trained nurse specializing in nutrition and a dietitian.

SGA questionnaire

The SGA is a screening tool to determine the nutritional status of patients and was developed by Detsky *et al*[16]. The SGA is a clinical technique with subjective elements and assesses nutritional status based on features of the patient's history and physical examination. During the SGA, two trained investigators used a standardized questionnaire concerning the patients' height and weight (current, before illness, and weight range during the previous 6 mo) and took a nutritional history (appetite, intake, gastrointestinal symptoms). In addition, the dietitian evaluated their physical appearances (subjective assessment of fat loss, muscle wasting, edema and ascites) and noted any existing medical conditions (e.g. encephalopathy, infection, renal insufficiency). Based on this evaluation, the patients were classified as being well nourished (SGA A), moderately malnourished (SGA B), or severely malnourished (SGA C). The SGA examiner was not aware of the laboratory test results at the time of the assessment.

Nutritional risk screening

The NRS-2002 was introduced by the European Society of Parenteral and Enteral Nutrition as the preferred method for screening and assessing hospital patients[17]. Its stated purpose was "Identification of those hospitalized patients, who are malnourished or at risk for malnourishment and who would gain benefit from the improvement of their nutritional situation." The NRS-2002 consists of a nutritional score and a severity of disease score and an age adjustment for patients aged > 70 years (+1). Nutritional score: weight loss > 5% in 3 mo or food intake below 50%-75% in the preceding week = 1; weight loss > 5% in 2 mo or BMI 18.5-20.5 kg/m^2 and impaired general condition or food intake 25%-60% in the preceding week = 2; weight loss > 5% in 1 mo or > 15% in 3 mo or BMI < 18.5 kg/m^2 and impaired general condition or food intake 0%-25% in the preceding week = 3. Severity of disease score: hip fracture, chronic patients with acute complications = 1; major abdominal surgery, stroke, severe pneumonia, hematological malignancies = 2; head injury, bone marrow transplantation, intensive care patients with APACHE > 10 = 3. The NRS-2002 score is the total of the nutritional score, severity of disease score and age adjustment. Patients are classified as no risk = 0, low risk = 0-1, medium risk = 3-4 and high risk = > 5.

Nutritional risk indicator

The NRI was developed by the Veteran's Affairs Total

Parenteral Nutrition group[15] in 1991 for use in the evaluation of the efficacy of perioperative total parenteral nutrition in patients undergoing thoracic or abdominal surgery. The NRI is a simple equation that uses serum albumin and recent weight loss: NRI = [1.519 × serum albumin (g/L)] + 0.417 × (present weight/usual weight × 100). An NRI score higher than 100 indicates that the patient is not malnourished, a score of 97.5 to 100 indicates mild malnourishment, a score of 83.5 to 97.5 indicates moderate malnourishment, and a score lower than 83.5 indicates severe malnourishment.

Anthropometric measurements

Body weight (BW; nearest 0.1 kg) and height (nearest cm) were measured while the patient was standing without shoes and in light clothes. Body mass index (BMI) was derived as weight (kg) divided by height (m) squared (kg/m^2). The triceps skinfold thickness (TSF), to the nearest mm, was measured at the midpoint between the acromion and olecranon processes on the nondominant side with a Holtain caliper (Holtain Ltd., Crymych, UK). The midarm circumference (MAC) was measured to the nearest 0.1 cm with a tape at the same point as the TSF. All anthropometric measurements were made at least three times by the same investigator, and the reported values are the means of the repeated measurements.

Serological measurements

Blood samples were taken from the cubital vein and tests included the measurement of serum protein, albumin, and cholesterol, and total lymphocyte counts (TLC). Laboratory data were collected using standard laboratory methods.

Statistical analysis

The data were analyzed with the statistical software "Statistical Package for Social Science (SPSS)" version 12.0 for Windows (SPSS, Inc., Chicago, IL, USA). Differences between the independent groups were assessed with Student's *t* test and one-way analysis of variance. Spearman's rank correlation coefficients were calculated to evaluate the association between the scores and variables. Data are presented as mean ± SD. Differences were considered to be statistically significant at $P < 0.05$. Agreement between two assessment methods was analyzed with the κ statistic. The value of κ varies from 0 to 1; a value of 0.4 or less indicates that chance alone can account for the observed agreement, and a value of 1 indicates perfect concordance.

RESULTS

Eighty patients who were treated with gastrectomy for gastric carcinoma were enrolled. The patients' characteristics are summarized in Table 1.

Preoperative nutritional status

We assessed the nutritional status and laboratory parameters of patients within 24 h of their hospital admission. The prevalence of malnutrition at admission was 31% when determined with the SGA (moderately and severely malnourished) or 43% when determined with the NRS-2002 (medium and high risk). The frequency of any degree of malnutrition at admission was 31% according to the NRI (mild, moderate, and severe malnutrition). There was no difference in age or TLC between malnourished and well-nourished groups defined according to the three assessments, but the percentage weight loss differed between the groups (Table 2). The anthropometric data were lower in the malnourished groups based on SGA and NRS-2002 assessments, but did not differ between the groups defined with the NRI assessment. Albumin, protein, and total cholesterol levels differed between the malnourished and well-nourished groups based on the NRI assessment, but there was no significant difference between the groups defined with the SGA and NRS-2002 techniques (Table 2).

P values were determined with the use of the Pearson χ^2 test and independent *t* test.

Malnutrition scores correlated significantly with the percentage weight loss according to the SGA and NRS-2002 groupings. BMI and anthropometric data correlated inversely in the SGA and NRS-2002 groupings, but did not correlate in the NRI grouping, which correlated inversely with the nutrition factors albumin, protein, and total cholesterol (Table 3). Concordance between the SGA and NRS-2002 assessments was observed in 68 of the 80 (85%) patients, but was not observed between the SGA and NRI assessments in 50 of the 80 (63%) patients (Table 4). Sensitivity was 80% with the NRS-2002 and 73% with the NRI. Specificity was 96% and 40% with the NRS-2002 and NRI, respectively. Agreement was higher between the SGA and NRS-2002 (κ = 0.685, $P = 0.000$) than between the SGA and NRI (κ = 0.127, $P = 0.255$) (Table 4).

Postoperative nutritional status

At 6 and 12 mo after surgery, BW, BMI, TSF and MAC were significantly reduced, whereas the TLC, and albumin, protein, cholesterol and serum iron levels did not decrease

P values were determined with the use of ANOVA or the Kruskal-Wallis nonparametric test.

during the postoperative period (Table 5). The nutritional status of the patients who had undergone subtotal gastrectomy stabilized 6 mo after surgery, but the total gastrectomy patients showed a significantly reduced nutritional status in terms of BW, BMI and anthropometric measurements 12 mo after surgery (Figure 1).

Relationship between the nutritional assessment tools and nutritional status after gastrectomy

At 6 mo after surgery, a good correlation was observed between the results of the nutritional assessment tools (SGA, and NRS-2002) and those of the other nutritional measurement tools (BW, BMI, and anthropometric measurements).

According to the SGA and NRS-2002, the proportion of malnourished patients was 80% and 83%, respectively, 6 mo after surgery. At 12 mo after surgery, most patients who had been assessed as malnourished by SGA and NRS-2002 had returned to their preoperative status (Figure 2), although the other nutritional measurement tools (BW, BMI, and anthropometric measurements) still showed a malnourished status.

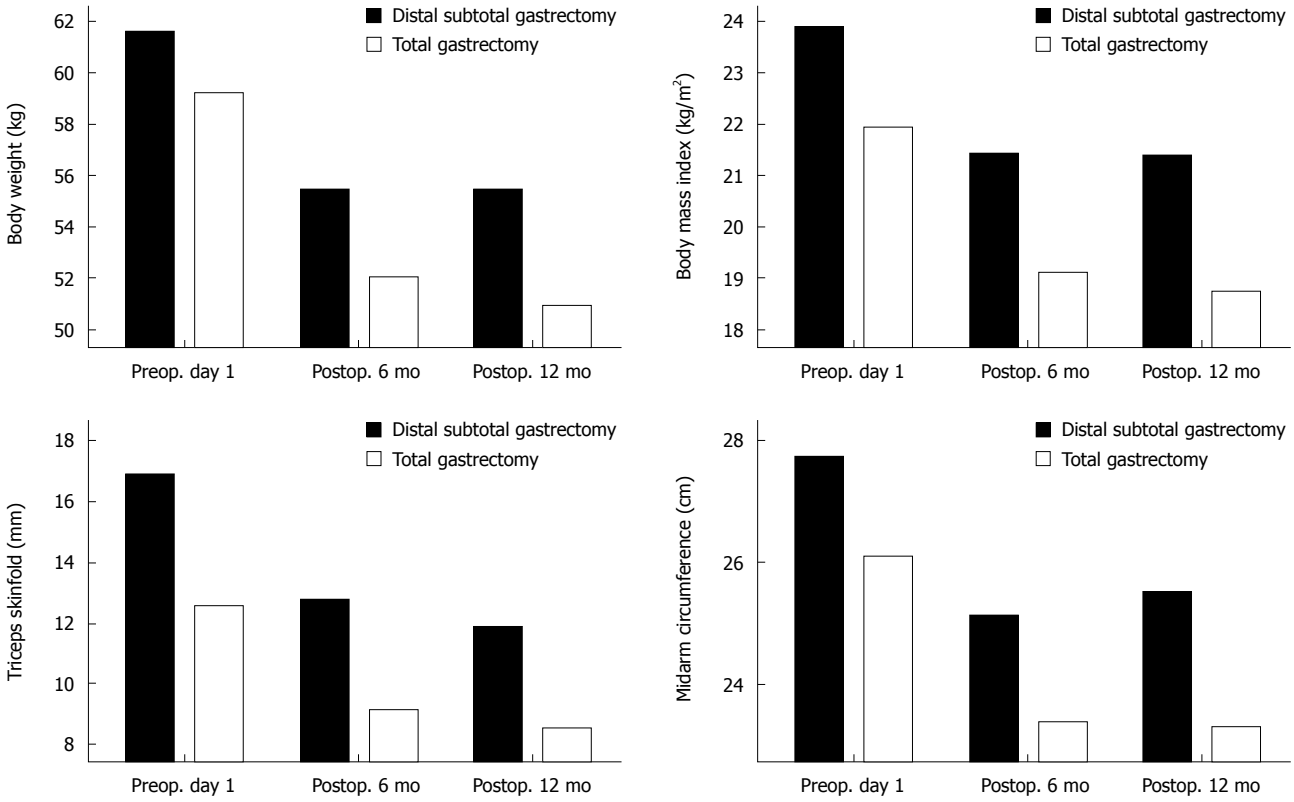

Figure 1 Postoperative nutritional status. Comparison of postoperative changes in objective nutritional parameters of patients undergoing distal subtotal gastrectomy and total gastrectomy from preoperative day 1 until 12 mo after surgery.

DISCUSSION

Nutritional depletion is a common problem in critically ill patients with cancer and is associated with a poor outcome. It is specifically reversible with nutritional support. Several studies have shown that patients with malignant gastrointestinal disease have a higher prevalence of weight loss before surgery, and during the first postoperative months, an additional weight loss of approximately 10% has been reported[7,18-21]. Plausible reasons for the development of malnutrition are a reduced food intake because of poor appetite, postprandial symptoms, and malabsorption[22,23]. Hospitalization, surgery, and chemo/radiotherapy can also cause malnutrition. In this study, the overall prevalence of malnutrition in patients with gastric cancer at admission was 31% according to the SGA and 43% according to the NRS-2002. Based on the objective assessment techniques, BW loss, BMI and anthropometric data were lower in the malnourished groups.

The purpose of nutritional screening is to identify those patients who are at nutritional risk and therefore at higher risk of complications. Malnutrition in hospitalized patients is a critical issue and has been associated with a significant increase in morbidity and mortality[9,10,24]. The detection of malnourished patients is possible if the importance of the issue is understood and the patient's nutritional status is evaluated on admission to hospital. Multiple clinical parameters are available to assess the nutritional status of critically ill patients, but no standard recommendation can be made at this time. Each method has its own advantages and disadvantages[25].

A traditional nutritional assessment often includes dietary and medical evaluations to identify significant weight loss over time, significantly low or high BW or BMI, reduction in MAC, SFT, serum protein levels, or immune competence, and functional measurements of muscle strength may be incorporated into the overall final assessment[26]. Individually, these measurements often have limited value in accurately determining a patient's nutritional risk. Studies have consistently revealed the inadequacy of any single assessment method or tool in evaluating a patient's nutritional status. An effective nutritional screening tool will generally combine both objective and subjective factors.

In this analysis of the preoperative and postoperative anthropometric p arameters of patients with gastric cancer, an interesting observation was that, although the mean BMI was within the normal range, malnutrition scores correlated significantly with the percentage weight loss according to the SGA and NRS-2002. This means that BMI alone is not sufficient to determine the real malnutrition rate. Aydin *et al*[27] reported that a patient can be malnourished even when the BMI is normal and that the SGA can detect malnutrition before the BMI drops below 20 kg/m^2. For this reason, it is very important to use several methods in combination to evaluate a patient's nutritional status.

Albumin is commonly considered a good marker of

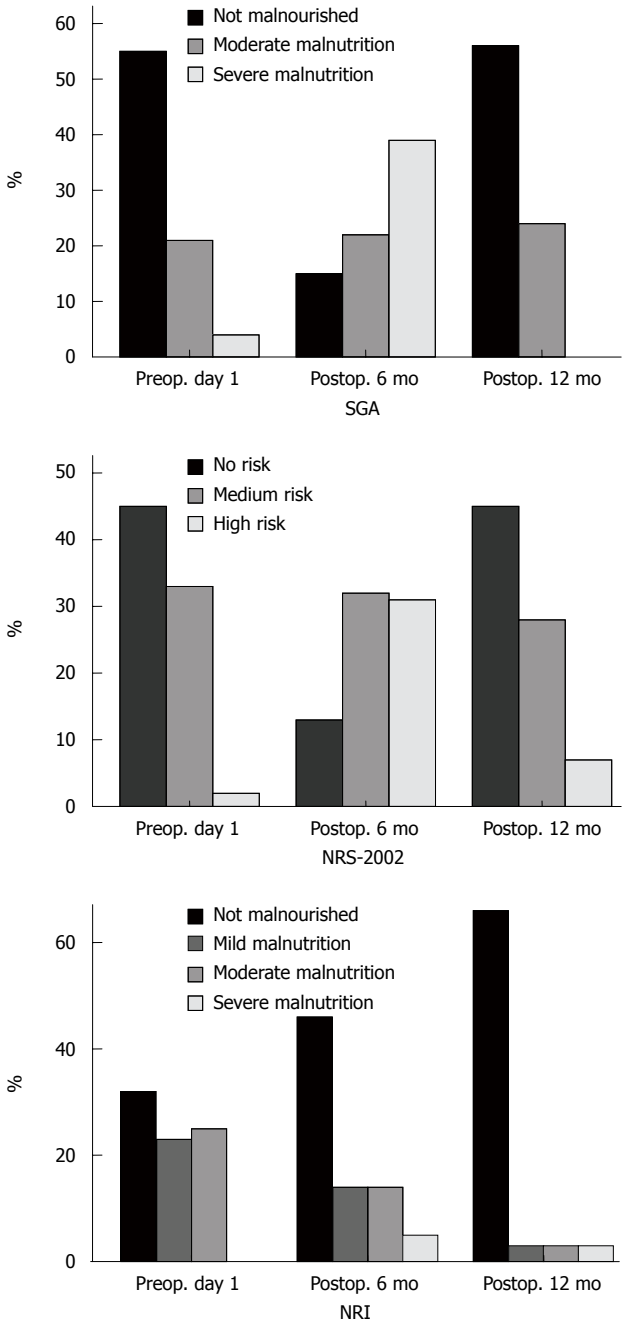

Figure 2 Malnutrition rate. Frequency of malnutrition during the postoperative period assessed with various subjective scoring techniques. SGA: Subjective global assessment; NRS-2002: Nutritional risk screening; NRI: Nutritional risk index.

nutritional status and visceral protein stores. The NRI is derived with an equation from the serum albumin concentration and the ratio of the actual to the usual weight. In this study, serum protein and albumin levels correlated statistically with the malnourished and well-nourished groups based on NRI assessment, but there was no statistical correlation with the groups defined by the SGA or NRS-2002. From this result, it can be inferred that albumin and serum protein parameters are not as sensitive as anthropometric measurements in the evaluation of nutritional status. Some studies have demonstrated that low serum albumin concentrations correlate with longer hospital stays, medical complications, and increased mortality[28,29], whereas other studies have reported that low serum protein levels do not always indicate malnutrition and malnutrition does not always accompany low serum protein levels[27,30,31]. Usually, many serum proteins and albumin are affected by the inflammatory response, liver disease, cancer, or idiopathically[32]. For these reasons, hypoalbuminemia has been reported to be a predictor of risk in a broad sense, rather than a parameter that indicates malnutrition[33]. Therefore, there are arguments for discounting hypoalbuminemia as a marker of malnutrition because patient populations differ. In this study, we evaluated only preoperative patients with gastric cancer who had no other serious medical problems. There was no good correlation between the NRI and objective assessments. The concordance and agreement were higher between the SGA and NRS-2002 than between the SGA and NRI. In this respect, the NRI may not be specific for the diagnosis of malnutrition in preoperative cancer patients.

Weight loss is a common problem after gastrectomy. The main mechanisms implicated include impaired food intake and malabsorption[34]. Patients who undergo gastrectomy consume fewer calories during the first 3-6 mo after surgery, after which their intake improves[20]. In this study, mean BW, BMI, TSF, and MAC were significantly reduced from the time of hospital discharge until 6 mo after surgery. Conversely, serum albumin levels, total protein, cholesterol, and TLC were similar between the groups before and 6 mo after surgery.

According to the subjective assessment of nutritional status 6 mo after surgery, 80% and 83% of the patients were malnourished according to the SGA and NRS-2002, respectively, compared with 31% and 43% of patients who were malnourished on preoperative day 1, respectively. In the group of patients who underwent subtotal gastrectomy, the patients' anthropometric parameters did not change between 6 and 12 mo after surgery. At 12 mo after surgery, their nutritional status was assessed as similar to its preoperative value according to the SGA, NRS-2002 and NRI, but their objective nutritional parameters were still low, especially mean BW, BMI, TSF, and MAC. Subjective assessment is a validated method of nutritional assessment when based on a medical history (weight change, dietary intake change, gastrointestinal symptoms, changes in functional capacity) and physical examination (loss of subcutaneous fat, muscle wasting). Therefore, according to the SGA and NRS-2002, the proportion of malnourished patients was high at 6 mo after surgery, but weight loss was not significant between 6 and 12 mo after surgery. Most of the patients who were assessed as malnourished had returned to their preoperative status, although the other nutritional measurement tools (BW, BMI, and anthropometric measurements) still indicated a malnourished status.

Patients with malignant gastrointestinal disease have a high prevalence of malnutrition. In cancer, reduced food intake and an increased energy gap result in the deterioration of nutritional status. It is very important to detect malnourished patients during the preoperative period and

postoperative follow-up. Not only objective nutritional parameters but also subjective assessments have some limitations in the accurate measurement of nutritional status. Therefore, measuring the nutritional status of patients who have undergone gastrectomy requires a combination of objective variables (anthropometric and laboratory measurements) and a subjective scoring system during the postoperative follow-up period.

COMMENTS

Background

Nutritional depletion is a common problem in critically ill patients with cancer and is associated with a poor outcome. The assessment of nutritional status and its evaluation plays an important role in tailoring nutritional support. Multiple clinical parameters are available to assess the nutritional status of gastric cancer patients, but no standard recommendation can be made at this time. This study would suggest that a specific tailored nutritional assessment is needed for the accurate measurement of nutritional status in patients.

Research frontiers

A traditional nutritional assessment often includes dietary and medical evaluations to identify significant weight loss over time, significantly low or high body weight, skinfold thickness, serum nutritional factor levels and functional measurements of muscle strength. Individually, these measurements often have limited value in accurately determining a patient's nutritional risk. As a result, combinations of diverse measurements have been developed into subjective scoring systems [subjective global assessment (SGA) and nutritional risk screening (NRS-2002)] designed to increase the sensitivity and specificity of nutritional status determinations. Scoring systems have been based on objective measurements of nutritional status, such as oral energy intake, body weight, weight loss over time, loss of subcutaneous fat, muscle wasting, serum protein levels, and immune competence.

Innovations and breakthroughs

When the authors analyzed the nutritional status in gastric cancer patients after gastrectomy surgery, body weight (BW), body mass index (BMI) and fat thickness were significantly reduced, but the total lymphocyte count, albumin, protein, cholesterol and serum iron levels did not decrease during the postoperative period. From this result, it can be inferred that albumin and serum protein parameters are not as sensitive as anthropometric measurements in the evaluation of nutritional status. Six months after surgery, there was a good correlation between the scoring nutritional assessment tools and the other general nutritional measurement tools (BW, BMI, and anthropometric measurements). However, 12 mo after surgery, most patients who were assessed as malnourished by the scoring nutritional assessment tool had returned to their preoperative normal nutritional status, although their BW, BMI, and anthropometric measurements still indicated a malnourished status.

Applications

The authors studied the prevalence of preoperative and postoperative malnutrition in patients with gastric cancer who underwent radical gastrectomy. This is the first study to report on the relationship between nutritional assessment tools and the nutritional status of gastric cancer patients after gastrectomy. From this study, not only objective nutritional parameters but also subjective scoring assessments have some limitations in the accurate measurement of nutritional status. Therefore, measuring the nutritional status of patients who have undergone gastrectomy requires a combination of objective variables (anthropometric and laboratory measurements) and a subjective scoring system during the postoperative follow-up period.

Peer review

This is a nicely written paper and well executed small study. There is enough presented to alert clinicians to both the problem of malnutrition in the sample studies and the problem of nutritional assessment tools used. The combination of assessment tools should allow for improvement in the identification of at risk patients.

Abstract

AIM: To explore the oncological outcomes of unresectable lung metastases without extrapulmonary metastases in colorectal cancer.

METHODS: Patients with unresectable isolated lung metastases from colorectal cancer were prospectively collected in a single institution during a 5-year period. All patients received either the fluorouracil/leucovorin plus oxaliplatin, fluorouracil/leucovorin plus irinotecan or capecitabine plus oxaliplatin regimen as first-line treatment. The resectability after preoperative chemotherapy was evaluated. Patients' outcome and predictive factors for overall survival were also investigated by univariate and multivariate analysis.

RESULTS: A total of 70 patients were included in the study. After standardized first-line chemotherapy, only 4 patients (5.7%) were converted to resectable disease. The median overall survival time in all patients was 19 mo (95% CI: 12.6-25.4), with a 2-year overall survival rate of 38.8%. No survival difference was found among different first-line chemotherapeutic regimens. Prognostic analysis demonstrated that only the first response assessment for first-line treatment was the independent factor for predicting overall survival. The median survival time in partial response, stable disease and progressive disease patients were 27 mo, 16 mo and 8 mo (P = 0.00001).

CONCLUSION: Pulmonary metastasectomy can only be performed in a small part of unresectable lung metastases patients after chemotherapy. Patients' first response assessment is an important prognostic factor.

Key words: Colorectal cancer; Lung; Metastases; Chemotherapy

INTRODUCTION

Colorectal cancer is the second leading cause of cancer death in the USA, and its frequency is increasing in China in recent years. In Shanghai, colorectal cancer has

become the third most prevalent malignancy[1]. Approximately 50%-60% of patients diagnosed with colorectal cancer will develop metastases[2,3]. The liver and lungs are the most common sites of metastases for colorectal cancers. Nearly 50% of patients with colorectal cancer will develop liver metastases, while only approximately 10%-15% of patients will develop lung metastases ultimately[4,5]. Commonly, metastases from colorectal cancer occur first in the liver and then later appear systemically, because of venous drainage *via* the portal system. However, lung metastases without extrapulmonary metastasis, also called isolated lung metastases, have been reported in several studies[4,6,7]. Through the bypass route of venous or lymphatic drainage, isolated lung metastases were only found in 2%-8% of all colorectal cancers[4,6].

Since the majority of metastases from colorectal cancer are considered initially unresectable disease, neoadjuvant chemotherapy has been applied in potentially resectable liver metastases for years. Studies demonstrated that 10%-15% of initially unresectable liver metastases could be converted to resectable disease after preoperative chemotherapy. However, the experience in unresectable isolated lung metastasis was rare. Current opinions consider that the recommendation in liver metastases may be reasonable to apply to the treatment of lung metastasis[8], but the evidence is weak and the result of this application is unknown, especially for initially unresectable isolated lung metastases.

In this current study, we prospectively collected data from all patients with unresectable isolated lung metastases from colorectal cancer at the first recurrence in a single institution during a 5-year period. The resectability after chemotherapy, outcomes of the patients, results with different chemotherapeutic regimens, and predictive factors for overall survival were all studied in the current cohort.

MATERIALS AND METHODS

Between May 2003 and January 2008, a prospective study was performed to collect data from all the colorectal cancer patients who developed unresectable lung metastasis without extrapulmonary lesions as the first recurrence from the outpatient and inpatient services of Fudan University Shanghai Cancer Center. All the unresectable patients had multiple lung metastastic lesions in two or more than two lobes and had no possibility of radical resection. According to the institutional protocol, all patients who were diagnosed with recurrence received intensive oncological assessment, including chest computed tomography (CT) scans, abdominopelvic CT or magnetic resonance imaging scans and serum carcinoembryonic antigen (CEA). Positron emission tomography-CT scans were performed in some patients, and digital rectal examinations were performed in all patients whose primary tumor was located in rectum.

For viable patients, core biopsy or fine needle biopsy was performed to confirm the diagnosis. For patients whose cytological or histological diagnosis was unavailable, the diagnoses of lung metastases were discussed by the colorectal cancer multidisciplinary treatment (MDT) team, which included a specialized radiologist. When there was doubt about the case, close follow-up without chemotherapy and dynamic change in CT scans were observed to confirm the diagnosis. The resectability of lung metastases was discussed by the colorectal MDT team and a specialized thoracic surgeon according to image study.

Patients with extrapulmonary metastasis or local recurrence were excluded from the current study. Patients, who refused to receive chemotherapy (3 cases) or sign the informed consent form (2 cases), were also excluded from the study. Besides concurrent chemotherapy, 4 patients received weekly administration of cetuximab 8, 8, 11 and 16 times, respectively, in the first line setting; they were excluded from the following outcome analysis because of the small number of cases. After screening, a total of 70 colorectal cancer patients who developed synchronous or metachronous unresectable isolated lung metastasis were included in the study.

Chemotherapeutic regimens and response assessment

According to the medical oncologists' preference, either the fluorouracil/leucovorin plus oxaliplatin (FOLFOX), fluorouracil/leucovorin plus irinotecan (FOLFIRI) or capecitabine plus oxaliplatin (XELOX) regimen was used as first-line treatment for patients who never received chemotherapy or who had received adjuvant chemotherapy over 12 mo ago. For patients who received adjuvant chemotherapy within 12 mo, a different regimen from their original first-line treatment was used. Second-line or third-line treatment regimens were determined by considering the first-line regimen, adjuvant regimen and patients' consent. The "stop-and-go" strategy using a modified FOLFOX6 regimen with maintenance capecitabine during the interval period was applied to 5 patients in our cohort, and they were considered to have received first-line treatment of FOLFOX in the following analysis.

Physical examination, chest CT scans, abdominopelvic ultrasound or CT scans, and serum CEA were used according to the institutional routine assessment for metastatic colorectal cancers. During chemotherapy, response assessment was performed after the first 3 (XELOX regimen) or 4 cycles (FOLFOX or FOLFIRI regimen) and then repeated every 2 to 3 mo. In patients who stopped treatment, similar oncological assessments were asked to be performed every 3 to 6 mo. The response to treatment was defined based on Response Assessment Criteria in Solid Tumors (RECIST)[9].

Statistical analysis

All surviving patients were followed up between January and March 2009 for the purpose of this project. Progression free survival (PFS) was calculated from the start of first-line treatment to the time when disease progression was determined by response assessment. In patients with metachronous metastasis, the time from resection of the primary lesion to occurrence of metastases in the lung was defined as time to metastasis in the current study. The

prognostic value of the first response assessment, which was performed after the first 3 (XELOX regimen) or 4 cycles (FOLFOX or FOLFIRI regimen) of chemotherapy, was analyzed as an independent factor.

The distribution of PFS and overall survival (OS) was calculated by the Kaplan-Meier method, and a log-rank test was used to compare the differences among curves in univariate analyses. Cox regression was used in multivariate analyses, and hazard ratios were calculated including 95% confidence interval (CI). $P < 0.05$ was considered statistically significant.

RESULTS

Basic clinical characteristics

Of the 70 patients who had unresectable lung metastases, 19 patients (27.1%) had synchronous lung metastases with primary colorectal cancers, while the other 51 patients (72.9%) had metachronous metastatic disease. All the patients with synchronous metastases in our series underwent resection of primary colorectal cancer first, and chemotherapy started within 2 mo of the surgery. All 70 patients received first-line treatment with a regimen of FOLFOX, FOLFIRI or XELOX. The detailed clinicopathological features are summarized in Table 1. In 51 patients who had metachronous lung metastasis, the median time to metastasis was 17 mo (range: 3-67 mo). The cumulative proportions of time to metastasis within 1, 2 and 3 years were 29.4%, 70.6% and 84.3%, respectively.

Table 1 The clinicopathological characteristics and survival time of all the unresectable pulmonary metastases patients

Characteristics	Number (%)	Median OS (mo)	95% CI	*P* value

FOLFOX: Fluorouracil/leucovorin plus oxaliplatin; XELOX: Capecitabine plus oxaliplatin; FOLFIRI: Fluorouracil/leucovorin plus irinotecan; PR: Partial response; SD: Stable disease; PD: Progressive disease.

Treatment outcomes

With a median follow-up time of 17 mo (range: 5-44 mo), 81.4% of patients (57 cases) had disease progression, and 26 patients were still alive (37.1%). The median PFS for first-line treatment was 8 mo (95% CI: 6.4-9.6 mo, range: 1-32 mo, Figure 1A). The median PFS for FOLFOX, XELOX and FOLFIRI regimens in the first-line setting were 10, 8 and 8 mo, respectively ($P = 0.693$). The median overall survival time was 19 mo (95% CI: 12.6-25.4 mo, range: 5-44 mo), with a 2 years OS rate of 38.8% (Figure 1B). At the patients' first response assessment, none of the patients had complete response; partial response (PR), stable disease (SD) and progressive disease (PD) were observed in 35.7%, 51.4% and 12.9% of patients, respectively. Four patients (5.7%) in our cohort underwent pulmonary resection of metastases for curative intent after first-line chemotherapy. We analyzed the 4 patients whose pulmonary metastatic lesions converted to resection in more detail: all 4 patients had multiple lesions in bilateral lungs. Two patients received preoperative chemotherapy with a regimen of modified FOLFOX6, while the other two received FOLFIRI. All 4 patients had a PR after first-line chemotherapy. The decision to perform metastatectomy in the 4 patients was made on the basis of the disappearance of lesions in one side of lung and stillness of residual disease in the other side of lung during ongoing chemotherapy. One patient underwent thoracoscopic surgery and the other three underwent open surgery. Wedge resections were performed and postoperative chemotherapy was applied using the same regimen before resection in all 4 patients. However, 1 patient developed disseminated liver and pelvic metastases later and died of cancer 7 mo after surgery; 1 patient had lung metastasis recurrence in the place where lesions disappeared after first-line chemotherapy. The other two patients were still free of recurrence until the last follow-up.

Clinical characteristics, including patients' gender, age, location of primary lesion, stage of primary lesion, metachronous or synchronous lung metastasis, unilateral or bilateral lung metastases, first-line chemotherapeutic regimens and first response assessment, were analyzed in univariate analyses to find potential predictive factors for patients' OS. The time to metastasis (continuous variable) in 51 patients with metachronous lung metastases was also studied using univariate Cox regression. Univariate analysis revealed that only the first response assessment was related to overall survival. Using Cox regression, multivariate analyses also demonstrated that first response assessment was the only independent factor for predicting OS. The risks of death within 2 years in SD and PD patients at their first response assessment were 3.5 times (95% CI: 1.4-8.7, $P = 0.007$) and 18.2 times (95% CI: 6.1-54.5, $P = 2 \times 10^{-8}$) higher than that of PR patients at the first response assessment. The median survival time in PR, SD and PD patients was 27 mo, 16 mo and 8 mo ($P = 0.00001$, Figure 1C).

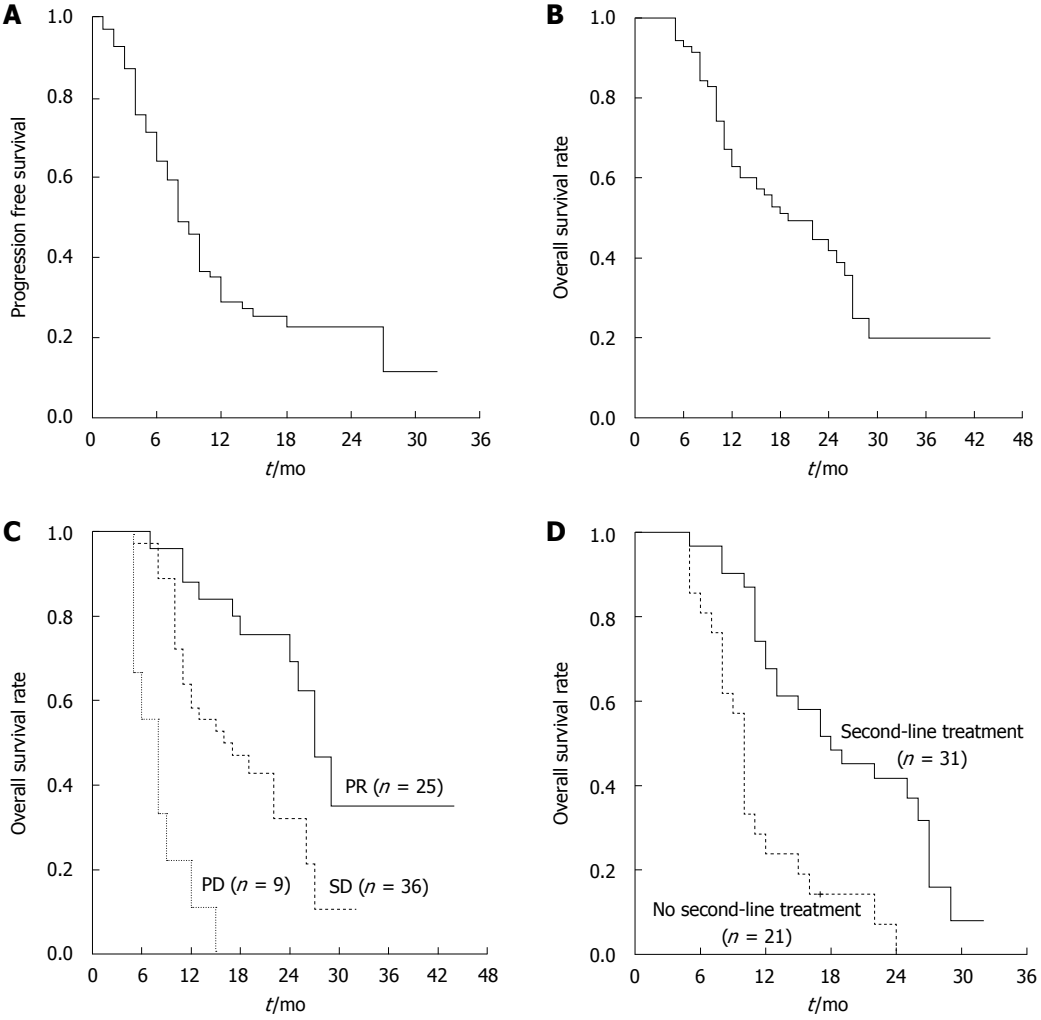

Figure 1 The median progression free survival and overall survival time. A: Progression free survival time of first-line chemotherapy; B: Overall survival rate for colorectal cancer patients with unresectable pulmonary metastases; C: Kaplan and Meier plots for median survival time according to chemotherapy efficacy; D: Kaplan and Meier plots for median survival time according to whether the second-line treatment was received. PR: Partial response; SD: Stable disease; PD: Progressive disease.

Second-line treatment

None of the patients without disease progression received second-line treatment. A total of 52 patients (74.3%) had disease progression during first-line chemotherapy. Thirty-one patients (59.2% of all first-line PD patients) underwent second-line chemotherapy. Unlike the first-line regimens, the chemotherapeutic regimens in the second-line were varied. Three patients only had a single agent regimen with 5-FU/leucovorin or capecitabine; 8 patients received FOLFOX or XELOX regimen; 16 patients received FOLFIRI or XELIRI regimen; 4 patients received a combination of chemotherapy and cetuximab. In 52 first-line PD patients, the median survival time was 18 mo for those receiving any of the above second-line regimens, compared with 10 mo for patients without any further chemotherapy ($P = 0.0004$, Figure 1D) .

DISCUSSION

In the current study, we focused on a typical group of patients with isolated lung metastasis. Lung metastases in all of our patients were the first and the only site of metastasis after diagnosing the primary tumor in the colon or rectum. Isolated lung metastasis is considered uncommon in colorectal cancers, as the major venous drainage is through the portal vein system and metastases in lungs usually occur along with concomitant systemic metastases. Pihl *et al*[4] reported 8.6% of 1578 patients with colorectal cancer who had undergone curative resection developed lung metastases, and that 11.5% of lung metastases were found in patients with rectal cancer, compared with 3.5% in colon cancer. Tan *et al*[6] reported 56 cases (7.4%) of isolated lung metastasis in 754 patients with colorectal cancer, and 13.3% of lung metastases were found in patients with primary rectal cancer *vs* 6.3% with primary colon cancer ($P = 0.011$). In our series, we also observed more isolated lung metastases in patients with primary rectal cancer. This result may partly be attributed to the bypass route of spreading into systemic circulation *via* the hemorrhoidal veins. However, the precise mechanism for this phenomenon of skip metastasis bypassing the first venous or lymphatic draining route is unclear. Differences in tumor biology among various patients, tumor types, or even within a given tumor, may also be related to this result[10,11].

Most of the lung metastases from colorectal cancer were unresectable disease because of synchronous metastases in other organs or multiple unilateral or bilateral lesions. Although resection of synchronous liver and lung metastases was performed in selected patients in several studies, a favorable outcome was only observed in a study with a small number of patients with limited metastases in liver and lung[12-14]. Different from the situation in the liver, lung metastases are more prone to disseminating to the lungs bilaterally, making the resection rate lower than that of liver metastasis[15,16]. The use of CT scans in diagnosing multiple lesions and thoracoscopic resection in the management of metastatic disease were also questioned[17-19]. Most of the patients selected for pulmonary metastasectomy presented with a single lesion in lung, and patients with a single metastasis were proven to have a better outcome compared with patients with multiple metastases[20-22]. The effectiveness of pulmonary resection in patients with multiple lesions is still unclear, and no consensus has been obtained for the indication of resection concerning the number of metastases[8,22-25]. Multiple lesions in bilateral lungs were usually considered unresectable disease. In our study, after discussing the resectability of isolated lung metastases, all cases with unresectable metastases were treated with first line chemotherapy. We reported the possibility of converting to resection in patients with multiple bilateral lesions by preoperative chemotherapy for the first time. Four cases (5.7%) were converted to resectable disease after first line treatment. To our knowledge, this is the first study reporting the resectability of initially unresectable lung metastases after preoperative chemotherapy. The proportion of resection seems lower than that of inoperable liver metastases[26], suggesting a different strategy might be used when considering preoperative chemotherapy for initially unresectable lung metastases. However, there are still other reasons which may be responsible for the low rate of conversion to resection, including the undetermined surgical indication, doubtful nodules in other areas, multiple lobular lesions after chemotherapy, and patients' consent.

In our study, the median PFS for first-line treatment and OS was similar to other studies in stage Ⅳ colorectal cancer, which combined all metastatic disease together[27,28]. Different chemotherapeutic regimens in the first-line setting, including FOLFOX, FOLFIRI and XELOX, resulted in a similar PFS and response rate. The National Comprehensive Cancer Network (NCCN) guidelines recommended that the practice in liver metastases can be applied to lung metastases[29]. However, few data were focused on this group of patients with unresectable isolated lung metastases. Our data confirmed the similar oncological results in the management of isolated lung metastases. Although the second-line chemotherapy regimens varied in progressed patients, we confirmed the benefit of continuing chemotherapy for patients with isolated lung metastases who progressed after first-line treatment. However, which regimen would be better and whether a monoclonal antibody should be used were unknown according to our study.

During first-line chemotherapy, the first response assessment is usually performed after the second month of treatment in most clinical trials of metastatic colorectal cancer. In our cohort, multivariate analysis demonstrated that the first response assessment was the independent factor predicting patients' overall survival. The risk of death within 2 years was found to be 3.5 times higher in SD patients than that in PR patients. This result raised doubts about whether we should continue first-line treatment in SD patients. In our study, the response assessment was performed according to RECIST guidelines. Patients assessed to have SD included patients whose targeted lesions showed less than 20% increase to less than 30% decrease in the sum of the longest diameter. Changing of chemotherapeutic regimens might be reasonable in selected SD patients, such as patients with increased lesions. For patients with metachronous lung metastases, the time to relapse was considered a risk factor predicting survival in several studies[30], but most other studies did not find the time to relapse a significant risk factor[31-33]. In 906 patients who relapsed after curative treatment of colorectal cancer, Kobayashi *et al*[16] found that the time to relapse was only related to the survival of liver metastases and local recurrence, but no survival difference was found in patients with lung metastases.

Novel treatment approaches have been introduced into the local treatment of unresectable lung metastases. Radiofrequency ablation was studied for patients with unresectable lung metastases in several studies. Marginal survival benefit and improvement in quality of life were observed in selected cases[34-36], and it is only used as an adjunct to resection or as an alternative for unresectable lesions. Transpulmonary chemoembolization is another new technique used for the local treatment of inoperable lung metastases. Preliminary results found this technique was a well-tolerated procedure for palliative treatment, but the benefit of survival was still unknown[37-39].

In conclusion, isolated lung metastases were relatively rare in metastatic colorectal cancer. The outcomes of chemotherapy in unresectable lung metastases patients were similar to the results of liver metastases, and first response assessment was an important risk factor to predict survival. Pulmonary metastasectomy can only be performed in a small group of patients with initially unresectable lung metastases after preoperative chemotherapy. Further studies are needed to validate our results and evaluate the rate of resectability after chemotherapy.

COMMENTS

Background

Approximately 50%-60% of colorectal cancer patients will develop metastases. Nearly half of patients with colorectal cancer will develop liver metastases, while only approximately 10%-15% of patients will develop lung metastases ultimately. Studies demonstrated that 10%-15% of initially unresectable liver metastases could be converted to resectable disease after preoperative chemotherapy. However, there was little experience in unresectable isolated lung metastasis.

Research frontiers

Current opinions consider that it may be reasonable to apply the recommendations for treatment of liver metastases to the treatment of lung metastasis, but

the evidence is weak and the result of this application is unknown, especially for initially unresectable isolated lung metastases.

Innovations and breakthroughs

This study prospectively collected data from all patients with unresectable isolated lung metastases from colorectal cancer as the first recurrence in a single institution during a 5-year period. The outcomes of chemotherapy were similar to the results of liver metastases, and first response assessment was an important risk factor to predict survival. Furthermore, only 5.7% of patients were converted to resectable disease after preoperative chemotherapy, which was obviously lower than the conversion rate in liver metastasis. It is the first study reporting the resectability of initially unresectable lung metastases after preoperative chemotherapy.

Applications

The results of this study suggested that a different strategy might be used when considering the preoperative chemotherapy for initially unresectable lung metastases.

Peer review

This is an interesting and novel paper looking at isolated lung metastases in colorectal cancer.

Abstract

AIM: To investigate let-7a expression and analyze the correlation between let-7a and progression of gastric mucosa cancerization.

METHODS: The tissue microarray was constructed previously in 52 cases of human gastric carcinoma, 17 cases of chronic atrophic gastritis (atypical hyperplasia) and 11 cases of normal gastric tissue, and tissue microarrays combined with *in situ* hybridization were used to detect the expression of let-7a.

RESULTS: The positive rates of let-7a in normal gastric tissue, chronic atrophic gastritis and gastric carcinoma were 90.9%, 88.2% and 86.5%, respectively, without significant differences among the groups ($P > 0.05$). However, an intense signal of let-7a was observed in gastric epithelial cells, whereas a less intense signal was found in gastric atypical hyperplasia epithelial cells and a weak signal in gastric carcinoma epithelial cells. The expression of let-7a decreased along with the progression of gastric mucosa cancerization ($P < 0.05$). In the group of gastric carcinoma, the expression of let-7a was even significantly lower in gastric carcinomas with lymph node metastasis than in those without metastasis ($P < 0.05$).

CONCLUSION: Gastric carcinoma has relatively lower expression of let-7a. Reduced let-7a may be a fundamental factor in the formation and lymph node metastasis of gastric carcinoma.

Key words: Tissue microarray; *In situ* hybridization; MicroRNA; Gastric carcinoma; Precancerous lesions

INTRODUCTION

MicroRNAs (miRNAs) are a recently discovered class of short noncoding RNA genes that act post-transcriptionally as negative regulators of gene expression[1,2]. A large body of research shows that animal miRNAs play a fundamental role in many biological processes, including cell growth and apoptosis, hematopoietic lineage differentiation, insulin secretion, brain morphogenesis, and muscle

cell proliferation and differentiation[3]. About 1000 miRNA genes are thought to be encoded in the human genome[4,5]. Although it is still difficult to identify accurately individual miRNA/target interactions[6], computational predictions of miRNA target genes indicate that as many as one-third of all human protein-encoding genes may be regulated by miRNAs[7]. This suggests that miRNAs could be involved in a wide variety of human diseases, including cancer. As a result of in-depth researches over the last 5 years, miRNA-mediated regulation of tumorigenesis is emerging as a new paradigm in the field of cancer biology[8,9]. It has also been reported that these miRNA signatures may be a more robust tool than expression patterns of protein-encoding genes for distinguishing normal from tumor tissues[10,11]. One particular miRNA, let-7, was discovered in the early 1990s in humans and mice. It has been reported that let-7 as a novel candidate of tumor suppressor gene is involved in several cancers such as lung carcinoma and colon carcinoma.

Gastric carcinoma is one of the most frequent cancers and one of the most common causes of cancer-related mortality in China, with an incidence of 0.4 million new cases and 0.3 million deaths annually. Gastric carcinoma is also an inadequately understood, and often fatal disease when not detected at early stages. Atypical hyperplasia is generally accepted as a precancerous lesion. Cancerization from normal gastric mucosa, chronic atrophic gastritis to gastric carcinoma has been well acknowledged. In this study, the expression of let-7a in normal gastric tissue, chronic atrophic gastritis (atypical hyperplasia) and gastric carcinoma was detected by *in situ* hybridization (ISH) using a locked nucleic acid (LNA) probe and gastric mucosa cancerizing tissue microarrays; the relation between expression level of let-7a and the progression of gastric mucosa cancerization was discussed.

MATERIALS AND METHODS

Tissue microarray and probe

The tissue bank at Shanxi Chaoying Biotechnology Company maintains a series of formalin-fixed, paraffin-embedded (FFPE) tissue blocks of patients with gastric carcinoma, chronic atrophic gastritis (atypical hyperplasia) and normal gastric tissue. Information on tumor histologic grade, patient's age and sex was collected and anonymized in a secure database. We generated a tissue microarray (TMA) from archived FFPE blocks of 80 cases, including 11 cases of normal gastric tissue, 17 cases of chronic atrophic gastritis with atypical hyperplasia (incomplete intestinal metaplasia) and 52 cases of gastric carcinoma (intestinal type). In the gastric carcinoma group, there were 10 cases with lymph node metastasis and 42 cases without lymph node metastasis. This study complied with the rules and regulations of the Ethics Committee of the hospital. Informed consent was obtained from all subjects. All FFPE blocks were reviewed and tissue cores were selected by a board-certified pathologist. The 5'Digoxin-labeled, LNA-modified oligonucleotide probe (sequence 5'-3': aactatacaacctactacctca) complementary to the entire mature sequence of let-7a, was synthesized by Exiqon DNA technologies.

Detection of miRNAs by ISH in FFPE sections

The experiment was conducted at a laboratory of Shanxi Chaoying Biotechnology Company in November 2009. Sections (5 μm) of archived paraffin-embedded specimens were deparaffinized in xylenes and then rehydrated through an ethanol dilution series (from 100% to 25%). Slides were submerged in diethyl pyrocarbonate-treated water and subjected to proteinase K digestion (5-10 μg/mL) and 0.2% glycine treatment, refixed in 4% paraformaldehyde, and treated with acetylation solution [66 mmol/L HCl, 0.66% (v/v) acetic anhydride, and 1.5% (v/v) triethanolamine]; slides were rinsed thrice with 1 × PBS between the treatment. Slides were prehybridized in hybridization solution (50% formamide, 5 × SSC, 500 Ag/mL yeast tRNA, and 1 × Denhardt's solution) at 50℃ for 30 min. Then 5-10 pmol of Digoxin-labeled, LNA-modified probe, was added to 150 μL hybridization solution and hybridized for 18 h at a temperature of 42℃ below the calculated Tm of the LNA probe. Subsequently, the samples were incubated at 37℃ for 90 min with 50 μL biotin-labeled anti-digoxin antibody, rinsed with 0.5 × SSC four times for 5 min, incubated at 37℃ for 30 min with 50 μL SABC solution, and rinsed with 0.5 × SSC solution three times for 5 min. After added 50 μL biotin-labeled peroxidase and incubated at 37℃ for 30 min, the samples were rinsed five times with 0.5 × SSC for 5 min, then stained with Nitro-Blue-Tetrazolium/5-bromo-4-chloro-3-indolyl-phosphate. Finally, the sections were restained with eosin before covering. For a negative control, the hybridization solution was replaced with pre-hybridization solution. Likewise, β-actin was used as the probe of positive control.

Determination of results

Signals were visually quantified by a pathologist according to the reference of Frantz *et al*[12]. A total of 100 × 10 cells were counted randomly. Then, tissue sections were blindly examined by a second individual for an agreement with the initial quantifications. If there was no positive cell, the sample was scored as 0 point. If the percentage of positive cells was less than or equal to 30%, the sample was scored as 1 point; less than or equal to 70% as 2 points; and more than 70% as 3 points. The staining intensity was recorded as negative, light, moderate, or strong, and scored as 0, 1, 2 or 3 points, respectively. The two values were multiplied, and a sum of 0 point represented negative expression, and 1-9 points represented positive expression. Points 1-2 were marked ±, 3-4 marked +, 6 marked ++, and 9 marked +++.

Statistical analysis

Statistical analysis was performed using SPSS 11.5 Package. The χ^2 and correlation tests were used in this study. A difference was considered significant when *P* value was less than 0.05.

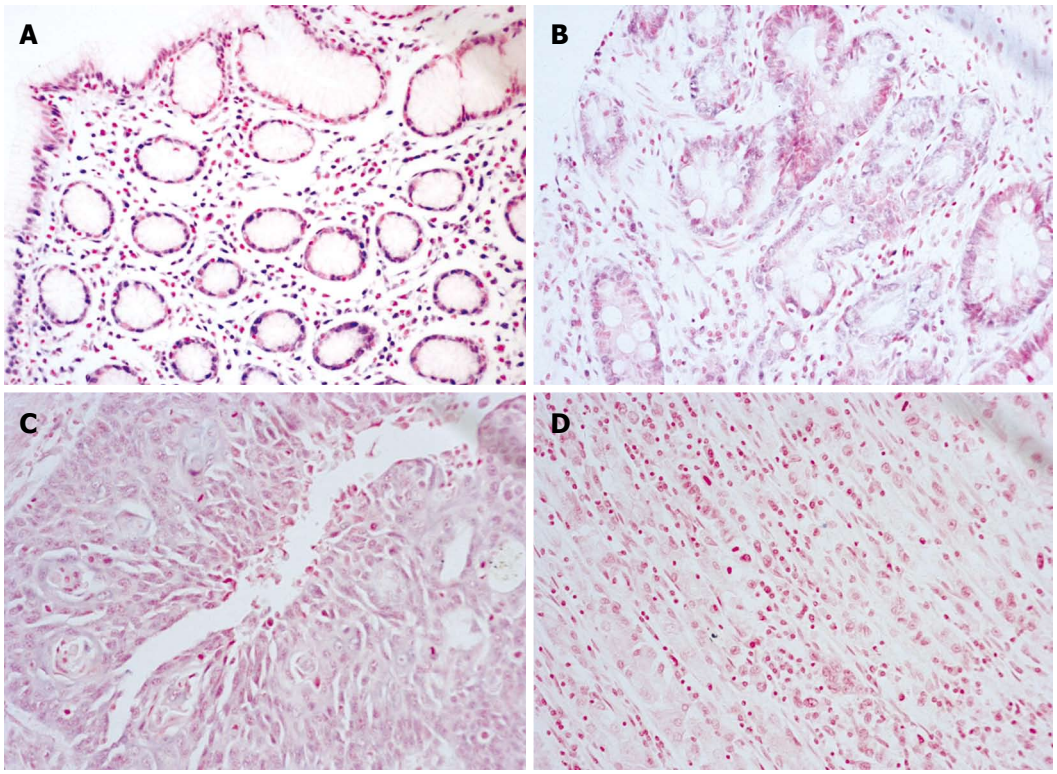

Figure 1 Expression let-7a in stomach cancer progression tissue array (*in situ* hybridization, Nitro-Blue-Tetrazolium/5-bromo-4-chloro-3-indolyl-phosphate staining, original magnification × 200). A: Positive expression (++) of let-7a in gastric tissue; B: Positive expression (+) of let-7a in chronic atrophic gastritis; C: Positive expression (±) of let-7a in gastric carcinoma; D: Negative expression of let-7a in gastric carcinoma.

Table 1 Expression of let-7a in gastric mucosa cancerization tissue array

	Cases (*n*)	Results					Positive rate (%)
		-	±	+	++	+++	
Normal gastric mucosa	11	1	0	2	8	0	90.9
Chronic atrophic gastritis	17	2	2	7	5	1	88.2
Gastric carcinoma	52	7	18	18	7	2	86.5

Table 2 Expression of let-7a in gastric carcinomas

Lymph node metastasis	Cases (*n*)	Results					*P* value
		-	±	+	++	+++	0.043
Negative	42	4	11	18	7	2	
Positive	10	3	6	1	0	0	

RESULTS

Expression of let-7a was determined on 5-μm sections obtained from each of the TMA blocks. Generally, let-7a appeared as blue-purple particles in the cytoplasm or nucleus after staining, and predominantly expressed in normal gastric mucosa epithelia and its expression was down-regulated in atypical hyperplasia epithelia, especially in malignant cells. The let-7a probe revealed an intense cytoplasmic signal in gastric epithelial cells, whereas a less intense signal was observed in gastric atypical hyperplasia epithelial cells and a weak signal in gastric carcinoma epithelial cells (Figure 1). Let-7a was also detected in endothelial cells lining blood vessels and in fibroblasts (data not shown). The classification of let-7a expression grade in each group is shown in Table 1. There was no significant difference in the positive rates of let-7a among gastric carcinoma, chronic atrophic gastritis and normal gastric tissues ($P > 0.05$). However, by analysis of the signal levels of let-7a in each group, the levels of let-7a expression were reversely related to the progression of gastric mucosa cancerization ($P = 0.008$). The expression of let-7a decreased along with the progression of gastric mucosa cancerization. In the gastric carcinoma group, the expression of let-7a in the 10 cases with lymph node metastasis was even lower than in the 42 cases without lymph node metastasis ($P = 0.043$) as shown in Table 2. In this study, β-actin showed an intense cytoplasmic signal in each of the TMA blocks in positive control while no blue-purple staining was found in blocks of negative control.

DISCUSSION

The let-7 family consists of 12 genes encoding for nine distinct miRNAs (let-7a to let-7i). Historically, let-7 was found to bind to the 3' UTR of lin-41 and hbl-1 (lin-57)

to inhibit their translation in nematodes[13], and control the developmental transition from the L4 stage into the adult stage[14-16]. An evolutionarily conserved regulation of the RAS family of growth control proteins by let-7 from nematodes to human cancer cells has also been demonstrated. Recently, let-7 implication in cancerogenesis has been extended to the repression of high mobility group A2, thus preventing oncogenic transformation in many tumors[17]. Johnson *et al*[18] showed that let-7 miRNA expression was lower in lung tumors than in normal lung tissues. The detection of mature miRNAs by ISH is technically challenging because of their small size. LNAs are a class of bicyclic high-affinity RNA analogues, in which the furanose ring in the sugar-phosphate backbone is chemically locked in a conformation mimicking the North-type (C3'-endo) conformation of RNA[19,20]. This results in an unprecedented hybridization affinity of LNA toward complementary single-stranded RNA molecules. A limitation to identifying and validating potential biomarkers makes it difficult to conduct retrospective studies with archived tumor specimens due in part to protein and RNA degradation[21]. Hence, the very small size of miRNAs offers a unique advantage because short RNA molecules are substantially less susceptible than mRNAs to enzymatic and mechanical degradation. In this study, we used a method for detection of miRNAs in gastric carcinoma specimens, LNA-ISH, which offers a spatial resolution of miRNA expression unsurpassed by other available techniques. Zhang *at al*[22] established an accurate and rapid stem-loop reverse transcriptional real-time PCR (RT-PCR) method to quantify human let-7a miRNA in gastric cancer. It was found that the expression level of let-7a miRNA in gastric tumor tissues was significantly lower than in normal tissues of 14 samples from 32 patients. There might be a discordance between ISH and RT-PCR results, which could be explained by the overrepresentation of epithelial cells in tumor lesions, resulting in a high let-7 signal in gross tissue biopsies. However, let-7a expression is diminished within individual cancer cells, which can be determined only by the ISH approach. We noticed that long fixation periods in 10% formalin (more than 12-18 h) can affect negatively the intensity of the miRNA *in situ* signal. There is no significant difference of the positive rates of let-7a expression among gastric carcinoma, chronic atrophic gastritis and normal gastric tissue, which may be partly due to the limitation of normal gastric tissue cases in the TMA. Decrease of let-7a expression is already apparent in hyperplasia (possibly preneoplastic). Its further decrease in gastric carcinoma is reminiscent of reduction of let-7a related to the gastric mucosa cancerization progression. Hence, this suggests that reduction of let-7a is an early event during intestinal-type gastric carcinoma formation. The most essential behavior of the malignant tumor is metastasis. Lymph nodes metastasis is an important index for clinical stages of gastric carcinoma before surgery and it is also an important prognosis factor for gastric carcinoma patients. Our study showed that the expression of let-7a was even lower in gastric carcinoma with lymph nodes metastasis than in those without lymph nodes metastasis. Decreased expression or absence of let-7a may determine initially the occurrence, development, metastasis and prognosis of gastric carcinoma. Using combined LNA-ISH and RT-PCR, quantitative detection of let-7a may have a potential clinical application as a novel biomarker for early diagnosis and prognosis of gastric carcinoma. Infecting breast tumor-initiating cells with let-7-lentivirus reduced proliferation, mammosphere formation, and the proportion of undifferentiated cells *in vitro* and tumor formation and metastasis in NOD/SCID mice[23]. Thus, the reason why let-7a in human gastric carcinoma has generated great interest is that it not only has a potency in diagnosis, but also can shed light on the molecular mechanisms of the tumorigenic process and has a high potential as novel targets for therapeutic intervention using synthetic oligonucleotide technologies. Further studies are being carried out on the relationship between gastric carcinoma and let-7a in our laboratory.

COMMENTS

Background

Gastric carcinoma is one of the malignancies with highest incidence and mortality rates and it is of great significance to investigate the mechanisms behind the occurrence and development of gastric carcinoma. Down-regulated expression let-7a has been shown to play an important role in the tumorigenesis and cancer progression. Therefore, the exploration into the expression of let-7a in gastric carcinoma and precancerous lesions may shed a new light on early detection and therapy of gastric carcinoma.

Research frontiers

Let-7a has been shown to exert tumor suppressor gene effects in various human neoplasms. In this study, the author investigated the expression of let-7a in normal gastric mucosa, chronic atrophic gastritis and gastric carcinoma to explore its correlation with gastric carcinogenesis and metastasis. They found that reduced expression of let-7a may take part in early carcinogenesis and metastasis of gastric carcinoma.

Innovations and breakthroughs

Let-7a is down-regulated in a wide range of human cancers such as gastric, colorectal and breast carcinomas, and may play a key role in cancer pathogenesis. Down-regulated let-7a increases cancer cell proliferation, migration and invasion. This is the first study to report that expression of let-7a has a reverse correlation with gastric cancerization.

Applications

The expression level of let-7a was significantly lower in gastric carcinoma than in chronic atrophic gastritis and normal gastric mucosa. In the malignant tumor group, the expression level of let-7a was even significantly lower in gastric carcinoma with lymph node metastasis than in those without metastasis. Detection of let-7a expression might be helpful in early detection and prognosis judgment of gastric carcinoma patients. In addition, let-7a may serve as a potential therapeutic tool for gastric carcinoma.

Peer review

In this descriptive study, let-7a miRNA expression is analyzed in human gastric mucosa, chronic atrophic gastritis, and gastric cancer with *in situ* hybridization technique on tissue microarray. The study confirms the results by Zhang *et al* demonstrating a decrease of let-7a in gastric carcinogenesis.

Abstract

AIM: To investigated if paclitaxel can attenuate hepatic fibrosis in rat hepatic stellate cells (RHSCs).

METHODS: RHSCs were cultured *in vitro* and randomly assigned to four groups: normal control group (treated only with Dulbecco's Modified Eagle's Medium), Taxol group (200 nmol/L paclitaxel was added to the cell culture), transforming growth factor (TGF)-β group (5 ng/mL recombinant human TGF-β1 was added to the cell culture), and TGF-β + Taxol group. TGF-β signaling cascade and status of various extracellular matrix proteins were evaluated by real time reverse transcriptase polymerase chain reaction and Western blotting.

RESULTS: The paclitaxel treatment markedly suppressed Smad2/3 phosphorylation. This was associated with attenuated expression of collagen Ⅰ and Ⅲ and fibronectin in RHSCs.

CONCLUSION: These data indicate that 200 nmol/L paclitaxel ameliorates hepatic fibrosis *via* modulating TGF-β signaling, and that paclitaxel may have some therapeutic value in humans with hepatic fibrosis.

INTRODUCTION

Hepatic fibrosis is the key stage in the pathological process from hepatic injury to cirrhosis or even to tumor. Transforming growth factor (TGF)-β1 is widely acknowledged as a key factor in acceleration of the hepatic fibrosis process. TGF-β1 mainly activates hepatic stellate cells (HSCs) through the TGF-β1/Smad signaling pathway, thus causing hepatic fibrosis[1-5]. TGF-β evokes diverse cellular responses by binding to and activating specific cell-surface receptors that have intrinsic serine/threonine kinase activity. The activated TGF-β receptors stimulate the phosphorylation of receptor-regulated Smad2 and Smad3 proteins (R-Smads), which in turn form complexes with Smad4. This complex translocates from the cytoplasm into the nucleus, where the Smads regulate the transcription of target genes. Inhibitory Smad7 acts in an opposing manner to the R-Smads, and downregulates TGF-β signaling[6].

Some studies have previously demonstrated that endogenous Smad-2, 3 and 4 bind to microtubules in several cell lines, and the binding provides a negative regulatory mechanism to modulate TGF-β activity. Disruption of the microtubule network by chemical agents, such as nocodazole and colchicine, leads to ligand-independent Smad nuclear accumulation and transcription of TGF-β-responsive genes, which in turn increases TGF-β-induced Smad activity[7].

The aim of this study was to assess if microtubule stabilization with low-dose paclitaxel (Taxol) could inhibit TGF-β/Smad signaling and ameliorate hepatic fibrosis in HSCs.

MATERIALS AND METHODS

Cell culture and grouping

HSCs (supplied by the Institute of Liver Diseases, the Second Xiangya Hospital, Hunan, China) were seeded in 24-hole plastic culture plates with a density of 1×10^6/mL. The cell viability was > 95% and purity was > 90%. After cell culture for 2 wk, nearly all HSCs were activated. These cells were first cultured for 3 d, followed by a cell cycle of synchronous culture for 48 h, then the HSCs were randomly divided into four groups: normal control group (treated only with Dulbecco's Modified Eagle's Medium), normal + Taxol group [200 nmol/L paclitaxel (Taxol; Sigma, St. Louis, MO, USA) was added to the cell culture], TGF-β group [5 ng/mL recombinant human TGF-β1 (R&D Systems, Minneapolis, MN, USA) was added to the cell culture], and TGF-β + Taxol group. The examinations were carried out after 48 h of culture. All the examinations were repeated three times for accuracy and consistency.

Real-time reverse transcriptase polymerase chain reaction

Total RNA was isolated using the High Pure RNA Isolation Kit according to the manufacturer's instructions (Roche, Switzerland). Contaminated DNA was removed by treating the samples with RNase-free DNase I (Promega, Madison, WI, USA). Real-time polymerase chain reaction (PCR) was performed using Bio-Rad (Hercules, CA, USA) iQ SYBR Green supermix with Opticon (MJ Research Inc., Waltham, MA, USA) by following the vendor's instructions. One hundred micrograms of total RNA was reverse-transcribed and subjected to PCR as follows: 94℃ for 2 min followed by 40 cycles of: 94℃ for 15 s, 58℃ for 30 s and 72℃ for 30 s, and a final extension at 72℃ for 10 min. The primers used were as follows. Rat Smad2, forward: 5'-TCACAGCCATCATGAGCTCAAGG-3', reverse: 5'-TGTGACGCATGGAAGGTCTCTC-3'; Smad3, forward: 5'-AGCACACAATAACTTGGACC-3', reverse: 5'-TAAGACACACTGGAACAGCGGATG-3'; collagen Ⅰ, forward: 5'-GAGCGGAGAGTACTGGATCG-3', reverse: 5'-TACTCGAACGGGAATCCATC-3'; collagen Ⅲ, forward: 5'-GTGCGGTTTGTGAAGCACCG-3', reverse: 5'-GTTCTTCTCATGCACACTT-3'; fibronectin, forward: 5'-TGACTCGCTTTGACTTCACCAC-3', reverse: 5'-TCTCCTTCCTCGCTCAGTTCGT-3'. All samples were subjected to reverse transcriptase (RT)-PCR along with the housekeeping gene GAPDH with the following primer sequences: forward: 5'-TGCTGAGTATGTCGTGGAGTCTA-3', reverse: 5'-AGTGGGAGTTGCTGTTGAAATC-3' as an internal standard. Reaction specificity was confirmed by gel electrophoresis of products after real-time PCR and melting curve analysis. Ratios for Smad2/GAPDH, Smad3/GAPDH, collagen Ⅲ/GAPDH, fibronectin/GAPDH and collagen Ⅰ/GAPDH mRNA were calculated for each sample and expressed as the mean ± SD.

Western blotting

Total protein was extracted from cells and analyzed with bicinchoninic acid protein concentration assay kit (Beijing Biosea Biotechnology Co. Ltd., China). Samples (20 μg) were fractionated by SDS-PAGE. After transfer onto nitrocellulose membrane (Amersham International, Bucks, UK), the blots were probed with a mouse monoclonal antibody to p-Smad3 (Cell Signaling Technology, Beverly, MA, USA 1:1000 dilution), a goat polyclonal antibody to p-Smad2 (Upstate Biotechnology, Billerica, MA, USA 1:1000 dilution) and rabbit polyclonal antibodies to collagen Ⅰ (Santa Cruz Biotechnology, Santa Cruz, CA, USA, 1:2000 dilution), collagen Ⅲ (Abcam, Cambridge, MA, USA 1:2000 dilution), and fibronectin (Santa Cruz Biotechnology, 1:1000 dilution). The second antibodies were peroxidase-conjugated goat anti-mouse IgG (1:20 000 dilution)and the swine anti-rabbit IgG or rabbit anti-goat IgG , which be diluited in PBS that contained 1% normal goat serum or 1% fetal calf serum. β-actin was used as an internal control.

Statistical analysis

Data were calculated as the mean ± SD and the groups were compared using one-way ANOVA. Statistical significance was set at $P < 0.05$.

RESULTS

Paclitaxel inhibits extracellular matrix expression in rat HSCs

The suppressive effects of paclitaxel on mRNA and protein expression of fibronectin and collagen Ⅰ and Ⅲ were assessed by real-time RT-PCR and Western blotting. Figure 1A shows RT-PCR analysis that indicated that paclitaxel had no effect on basal mRNA expression for fibronectin and collagen Ⅰ and Ⅲ in rat HSCs. The expression of integrin-linked kinase, α-smooth muscle actin and collagen Ⅰ was reduced in cells treated with paclitaxel and TGF-β at 48 h ($P < 0.01$). Western blotting analyses revealed similar trends in mRNA expression ($P < 0.05$, $n = 6$) (Figure 2A).

Blockade of Smad2/3 activation is a key mechanism by which paclitaxel prevents hepatic fibrosis in rat HSCs

The effects of paclitaxel on expression of Smad2 and Smad3 mRNA were assessed by real-time RT-PCR. The analysis showed that paclitaxel had no effect on Smad2

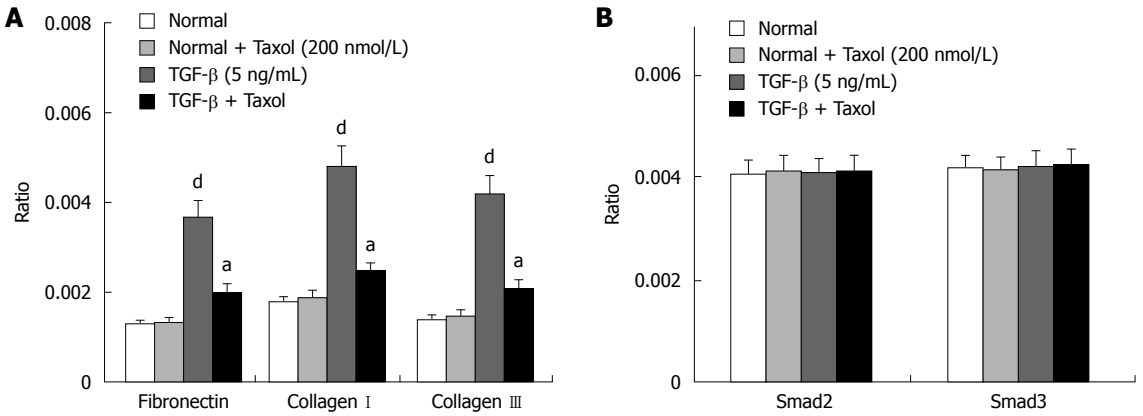

Figure 1 The mRNA levels changes *in vitro* after treatment. A: Real-time PCR depicting fibronectin and collagen Ⅰ and Ⅲ mRNA expression *in vitro* following paclitaxel treatment of hepatic stellate cells (HSCs). Fibronectin and collagen Ⅰ and Ⅲ expression was significantly higher in the TGF-β group at 48 h compared with the normal or Taxol groups ($P < 0.05$, $n = 6$). Treatment with paclitaxel resulted in a decrease in fibronection and collagen Ⅰ and Ⅲ expression ($P < 0.05$, $n = 6$). $^{a}P < 0.05$ *vs* TGF-β group; $^{d}P < 0.01$ *vs* normal or Taxol group ($n = 6$); B: Real-time PCR showing Smad2 (left) and Smad3 (right) mRNA expression *in vitro* following treatment with paclitaxel in HSCs. Smad2 and Smad3 mRNA expression was more or less similar in the normal and Taxol groups at 48 h ($P < 0.05$, $n = 6$). Densitometric analyses were performed from six independent experiments. Each bar represents the mean ± SD for six animals. PCR: Polymerase chain reaction; TGF-β: Transforming growth factor β.

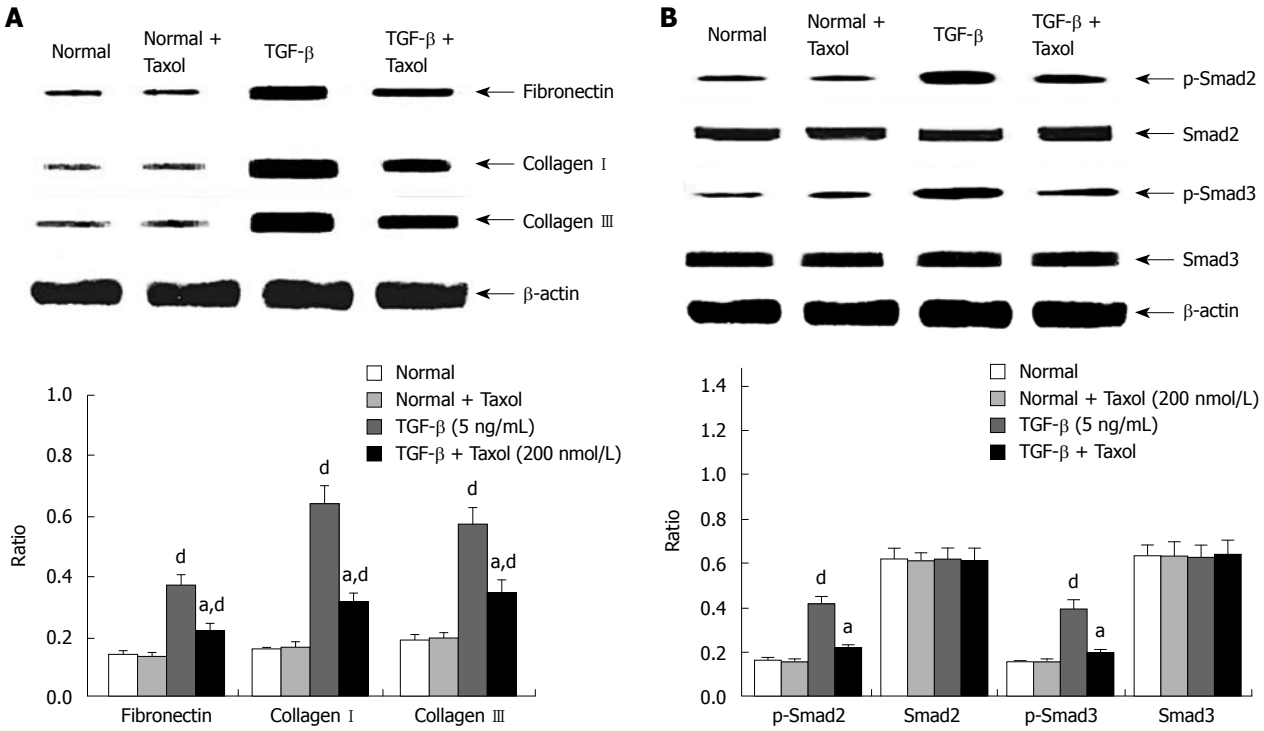

Figure 2 The protein levels changes *in vitro* after treatment. A: Western blotting analyses depicting fibronectin and collagen Ⅰ and Ⅲ mRNA expression *in vitro* following paclitaxel treatment in HSCs. Whole hepatic cell extracts were immunoblotted with the indicated antibodies. Fibronectin and collagen Ⅰ and Ⅲ expression was significantly higher in the TGF-β group at 48 h compared with the normal or Taxol group ($P < 0.05$, $n = 6$). Treatment with paclitaxel resulted in a decrease in fibronectin and collagen Ⅰ and Ⅲ expression ($P < 0.05$, $n = 6$); B: Western blotting analysis showing Smad2/3 protein expression *in vitro* following treatment with paclitaxel in HSCs. Phosphorylated Smad2 and Smad3 but not total Smad2 or Smad3 expression was significantly higher in the TGF-β group at 48 h compared with the normal or Taxol group ($P < 0.05$, $n = 6$). Treatment with paclitaxel resulted in a decrease in phosphorylation of Smad2 and Smad3 ($P < 0.05$, $n = 6$). Densitometric analyses were performed from six independent experiments. Each bar represents the mean ± SD for six animals. $^{a}P < 0.05$ *vs* TGF-β group; $^{d}P < 0.01$ *vs* normal or Taxol group ($n = 6$).

and Smad3 mRNA expression in the normal, Taxol and TGF-β + Taxol groups at 48 h (Figure 1B). Western blotting analysis showed that phosphorylated Smad2/3 but not total Smad2/3 expression was markedly reduced in HSCs treated with paclitaxel and TGF-β at 48 h ($P < 0.01$). In contrast, paclitaxel had no effect on expression and phosphorylation of Smad2/3 in the Taxol group (Figure 2B).

DISCUSSION

In the present study, we observed that fibrosis in HSCs was substantially decreased by paclitaxel, a microtubule-stabilizing agent, thus suggesting that low-dose paclitaxel has therapeutic benefits in the amelioration of hepatic fibrosis.

The TGF-β/Smad signaling pathway plays an impor-

tant role in hepatic fibrosis. In chronic hepatic injury, after HSCs are transformed into myofibroblasts, Smad2 and Smad3 are continuously phosphorylated and the inhibitory expression of Smad7 is at a low level. As a result, TGF-β1 signal transduction cannot be effectively inhibited. This might be one of the mechanisms for progression from chronic hepatic injury to hepatic fibrosis[8,9]. The worse the hepatic fibrosis and the higher the expression of TGF-β1, the higher is the Smad3 protein expression. Therefore, whatever is transferred by Smad3 might be the signal that can induce hepatic fibrosis[10-12]. Currently, TGF-β1 is the most effective fibrosis-promoting known, and it can promote activation of HSCs, and increase synthesis of extracellular matrix (ECM)[4,5]. Furthermore, it has been previously shown in several different cell lines that microtubules serve as a negative regulator for TGF-β/Smad signaling by forming a complex with endogenous Smad2, 3 and 4, thus sequestering the R-Smads away from the TGF-β receptor[7]. Therefore, it is conceivable that stabilization of microtubules by low-dose paclitaxel can dampen the exacerbated TGF-β signaling, as reported in TGF-β-induced inhibition of myogenesis in C2C12 myoblasts[13]. Similarly, in an earlier study, Liu *et al*[14] also have found that paclitaxel can significantly suppress TGF-β/Smad activity in SCID mice. In the present study, we provided evidence that low-dose paclitaxel suppressed phosphorylation of Smad2 and Smad3, two homologous Smad proteins that transduce signals from TGF-β and activin, in rat HSCs. These data support the notion that TGF-β/Smad signaling is regulated by the dynamic stability/instability of microtubules that are sensitive to low-dose microtubule-stabilizing agents, like paclitaxel.

Paclitaxel is an anticancer agent[15], which by stabilizing polymerized microtubules and enhancing microtubule assembly, arrests the cell cycle in the G0/G1 and G2/M phases, thus leading to cell death[16,17]. Prolonged treatment with paclitaxel has been associated with scleroderma-like changes or pulmonary fibrosis, albeit in only a small fraction of patients. It is noteworthy that inhibition of tumor cell proliferation can be achieved by much higher doses of paclitaxel. The inhibition of TGF-β/Smad signaling, however, can be attained with very low doses of paclitaxel. However, some of the recent studies have indicated that low-dose paclitaxel has minimal, if any, detectable effects on cell proliferation and other cellular activities, including fibrosis. Intriguingly, low-dose paclitaxel has been shown to inhibit collagen-induced arthritis and fibrosis associated with systemic sclerosis in SCID mice[14,18,19]. Type I collagen, the major ECM component of fibrotic tissue, is a heterotrimer composed of two α1 chains and one α2 chain. Increased production of type I collagen is a common hallmark of fibrotic diseases in various organs including the liver. Once stimulated by fibrogenic stimuli, HSCs are the only cells that respond by expressing increased amounts of all three different isoforms of TGF-β. As activated HSCs are the principal cells to produce type I collagen in fibrotic liver, they contribute to the development of liver fibrosis through autocrine and paracrine loops of TGF-β-stimulated collagen production[4]. In the present study, low-dose paclitaxel treatment effectively reduced expression of type I and Ⅲ collagen and fibronectin in rat HSCs.

In conclusion, we demonstrated that low-dose paclitaxel significantly suppressed the exacerbated TGF-β/Smad signaling and decreased interstitial fibrosis in rat HSCs. It is hoped that the current results will give an impetus to future investigations to explore the therapeutic potential of paclitaxel in the amelioration of hepatic fibrosis.

COMMENTS

Background

Hepatic fibrosis is the key stage in the pathological progress from hepatic injury to cirrhosis. Transforming growth factor (TGF)-β is widely acknowledged as a key factor in accelerating hepatic fibrosis. Smad proteins have been identified to play an important role in regulating the expression of extracellular matrix (ECM) proteins *via* the TGF-β signaling pathway. Aberrant TGF-β/Smad signaling can be modulated by stabilization of microtubules with paclitaxel.

Innovations and breakthroughs

In this study, the authors' research group for the first time reported that 200 nmol/L paclitaxel ameliorated fibrosis in rat hepatic stellate cells (HSCs) *via* inhibition of TGF-β/Smad activity.

Applications

In future experiments, the authors will use the hepatic fibrosis model to observe the treatment effect of paclitaxel *in vivo*.

Terminology

Paclitaxel is an anticancer agent. It is noteworthy that the inhibition of tumor cell proliferation can be achieved by much higher doses of paclitaxel. The inhibition of TGF-β/Smad signaling, however, can be attained with very low doses of paclitaxel.

Peer review

The findings that low-dose paclitaxel significantly suppressed the exacerbated TGF-β/Smad signaling and decreased interstitial fibrosis in rat HSCs are interesting and important.

Abstract

Vanishing bile duct syndrome (VBDS) refers to a group of disorders characterized by prolonged cholestasis as a result of destruction and disappearance of intrahepatic bile ducts. Multiple etiologies have been indentified including infections, neoplastic disorders, autoimmune conditions and drugs. The natural history of this condition is variable and may involve resolution of cholestasis or progression with irreversible damage. VBDS is extremely rare in human immunodeficiency virus (HIV)-infected patients and anti-retroviral therapy has never been implicated as a cause. We encountered a young pregnant female with HIV and VBDS secondary to anti-retroviral therapy. Here, we report her clinical course and outcome.

INTRODUCTION

The destruction and disappearance of intrahepatic bile ducts leading to "ductopenia" and cholestasis is termed "vanishing bile duct syndrome (VBDS)". The exact mechanism underlying this syndrome is unknown; however, common causes include autoimmune disorders such as primary biliary cirrhosis (PBC), neoplasms, infections and drug toxicities[1-7]. Several patients with VBDS respond to treatment of the underlying condition and/or removal of the offending agent. However, other patients progress to biliary cirrhosis and end stage liver disease. VBDS is rare in the human immunodeficiency virus (HIV)-infected population and to date, only one case has been reported in the literature[8]. In addition, none of the anti-retroviral medications have been implicated as a cause of ductopenia. We report the case of a young female with HIV and VBDS secondary to anti-retroviral therapy.

CASE REPORT

In August, 2009, a 28-year-old African American female in the 3rd trimester of pregnancy (G1P0, 31 wk) presented to the emergency room with jaundice for 3 d. She also complained of pruritus, light-colored stools and dark urine. She denied any abdominal pain, fever,

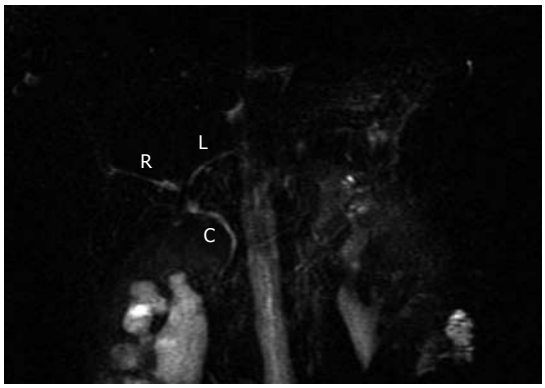

Figure 1 Magnetic resonance cholangiopancreatography. Patent biliary system without evidence of strictures or obstruction with normal caliber common bile duct (C), right hepatic duct (R), and left hepatic duct (L).

chills, vomiting or diarrhea. The patient had a history of heavy alcohol use (approximately 5 drinks/d) for 3 years discontinued at the beginning of her pregnancy. She reported no history of intravenous drug use or unprotected sexual exposure. She had no history of taking herbal supplements or over-the-counter medications. Her past medical history was significant for HIV infection diagnosed in 2000. She had not been on highly active antiretroviral therapy (HAART) since 2003 but recently started triple drug therapy to minimize risk of vertical transmission, with zidovudine, lamivudine and nevirapine 4 wk prior to presentation. She had no history of any opportunistic infections and was not taking any prophylactic medications. Her only other medications included folic acid and multivitamins. Her CD4 count and viral load prior to initiating therapy were 234 cells/μL (normal range: 410 to 1590 cells/μL) and 35 853 copies/mL [reverse transcriptase polymerase chain reaction (RT-PCR) lower limit of detection: 48 copies/mL], respectively.

Physical examination revealed icterus and gravid uterus consistent with duration of pregnancy. There were no stigmata of chronic liver disease. Abdomen was nontender and without hepatosplenomegaly or ascites. Fetal exam was normal. Her liver tests revealed total bilirubin of 10.5 mg/dL (normal range: 0.2-1.3 mg/dL), direct bilirubin 6.7 mg/dL, aspartate aminotransferase 103 U/L (normal range: 0-37 U/L), alanine aminotransferase 179 U/L (normal range: 0-40 U/L), and alkaline phosphatase 496 U/L (normal range: 39-117 U/L). Hematologic and electrolyte values were within normal range, and serum ethanol and urine drug screen were negative. Serologic testing was negative for viral and autoimmune hepatitis including hepatitis E IgM, Epstein Barr virus PCR and cytomegalovirus PCR (CMV-PCR), antinuclear antibody, antismooth muscle antibody, and antimitochondrial antibody. Her CD4 cell count and HIV-1 RNA viral load were measured as 224 cells/μL and 304 copies/mL, respectively. Fungal, mycobacterial, CMV, aerobic and anaerobic blood cultures as well as tests for *Cryptosporidium parvum*, *Microsporidium* and *Toxoplasma* were negative.

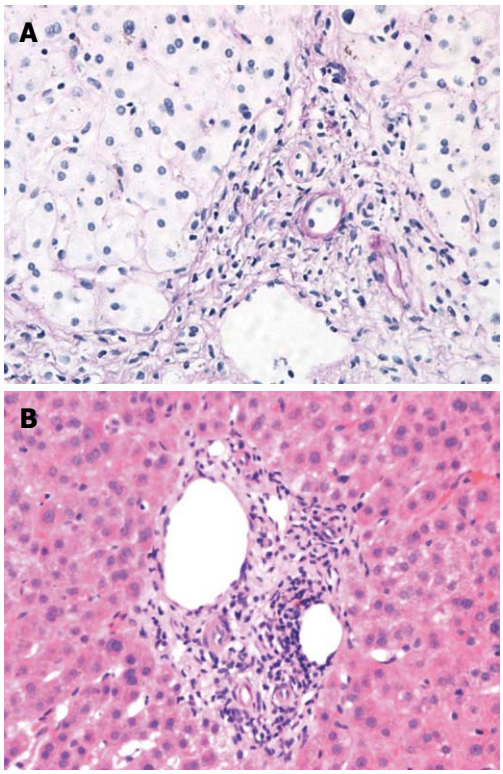

Figure 2 Liver biopsy showing portal tract with normal appearing hepatic vein and hepatic artery, and absence of bile ducts. A: PAS-D stain, × 200 magnification; B: Hematoxylin and eosin stain, × 200 magnification.

Right upper quadrant ultrasound revealed normal size liver with normal echogenicity and no focal lesions, cholelithiasis or biliary tract obstruction. Magnetic resonance cholangiopancreatography (MRCP) was performed. There was no cholangiographic evidence of extra- or intra-hepatic biliary duct dilatation (Figure 1), sclerosing cholangitis or discrete liver mass. A liver biopsy was performed which revealed marked ductopenia with cholestasis (Figure 2). Cytokeratin immunostain confirmed ductopenia and showed one irregular bile duct and scattered ductular proliferation among 11 visualized portal tracts (Figure 3). There was mild lymphocytic portal inflammation and CMV, AFB and GMS stains were negative. A diagnosis of VBDS was made.

HAART medications were withdrawn and the patient was started on ursodeoxycholic acid at 15 mg/kg per day to treat cholestasis and provide symptomatic relief. Over the next few weeks, the patient continued to have severe pruritus and worsening jaundice. Her liver tests deteriorated further with peak levels as shown in Figure 4. A second liver biopsy was performed 8 wk later which showed worsening cholestasis and persistent ductopenia. Owing to the progressive nature of her disease course, liver transplant evaluation was initiated for the patient.

DISCUSSION

VBDS refers to a group of disorders resulting in cholestasis as a consequence of progressive destruction and

A: No bile ducts are seen, minimal ductular proliferation is apparent at the edges of the portal tract (long arrows); B: Solitary portal tract with presence of irregular bile ducts (long arrows) and ductular proliferation (short arrows).

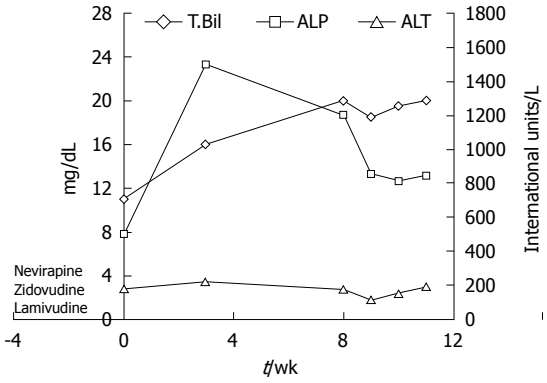

Figure 4 Trend of liver enzymes and bilirubin during the patient's clinical course.

disappearance of intrahepatic bile ducts. This condition was first described in 1988 in a case series of 3 patients by Ludwig *et al*[1] as "idiopathic adulthood ductopenia". Ductopenia is defined as the absence of interlobular bile ducts in greater than 50% of small portal tracts in a liver biopsy specimen.

Several causes of VBDS have been identified with varying mechanisms of duct injury and loss. PBC is one of the most common causes of ductopenia and is likely secondary to T-cell mediated bile duct injury[1,2]. Small duct primary sclerosing cholangitis, acute and chronic hepatic cellular rejection and sarcoidosis are other causes of VBDS with an underlying immune mechanism[3,4]. Infections and neoplastic disorders commonly implicated include CMV, reovirus 3, syphilis, cryptosporidium, Hodgkin's disease and histiocytosis X[5-7]. In addition, several drugs have been reported to cause VBDS, the most frequent ones include antibiotics and psychiatric medications (Table 1)[7].

Intrahepatic cholestasis of pregnancy was considered upon presentation as a possibility in our patient. However, this is a physiologic response to hormonal fluctuation during pregnancy and usually resolves spontaneously after delivery without persistent hyperbilirubinemia and ductopenia as seen in our patient[9]. There is no known association between pregnancy and VBDS, and the few existing case reports have been ascribed to medications such as chlorpromazine[10,11]. VBDS is even rarer in patients with HIV infection and has not been well described. Only a single case has been reported in the literature, in a patient with advanced AIDS (CD4 cell count: 7 cells/μL) and cholestasis with ductopenia presumably due to CMV infection[8]. A second case with HIV infection, low CD4 count (108 cells/μL) and idiopathic ductopenia has been reported, but does not fit the definition of VBDS since bile ducts were absent only in 6 of 15 portal tracts[12]. Cholestasis in patients with HIV infection is commonly due to sclerosing cholangitis and AIDS cholangiopathy which involves obstruction of the biliary tract due to infection-related strictures. Other causes include drug toxicity from HAART medications

and antimicrobials, neoplasms (Kaposi sarcoma and lymphoma) and opportunistic infections[13]. Our patient did not have biliary obstruction on ultrasound or MRCP, and had significantly higher levels of serum bilirubin than is commonly seen in AIDS cholangiopathy. Liver biopsy was negative for malignancy and did not show any features of sclerosing cholangitis or PBC. No strictures were seen on MRCP and tests for specific opportunistic pathogens were negative, ruling out AIDS cholangiopathy and infection.

The most likely cause of cholestasis in our patient was drug-induced liver injury. Medications used by our patient prior to onset of jaundice included zidovudine, lamivudine, nevirapine, multivitamins and folic acid. Zidovudine or lamivudine toxicity is associated with lactic acidosis, elevated lactate dehydrogenase, amylase and lipase along with abnormal liver tests[14]. None of these findings were seen in our patient. In addition, these two drugs were less likely to be the culprits since their toxic effects on the liver usually manifest after 6 mo of use. Nevirapine, a non-nucleoside reverse transcriptase inhibitor, is being increasingly used in pregnant patients owing to its favorable side effect profile and lower teratogenicity compared to protease inhibitors[14]. However, hepatotoxicity is the major adverse effect of nevirapine (5%) and most often manifests as a hypersensitivity reaction with fever, rash and elevated liver tests within the first few weeks of therapy. Late onset hepatotoxicity after several weeks of nevirapine use has also been described in several cases and may be an idiosyncratic reaction to the drug[14]. Although several case reports have demonstrated a cholestatic pattern of nevirapine toxicity, VBDS has never been reported[15,16]. Our patient did not have fever and rash, but had evidence of cholestatic hepatitis and a temporal association between nevirapine use and development of biochemical abnormalities. Therefore, nevirapine toxicity was felt to be the most likely cause of cholestasis and VBDS in our patient.

In summary, VBDS can result from multiple etiologies including autoimmune disorders, infections, neoplastic disorders, genetic abnormalities and medications. The diagnosis is suggested by abnormal liver tests and paucity of interlobular bile ducts on liver biopsy. To the best of our knowledge, this is the first reported case of nevirapine-induced cholestatic hepatitis in a patient with HIV leading to severe ductopenia and VBDS. VBDS should be considered in all HIV patients with chronic cholestasis, especially those with a history of nevirapine use.

Abstract

We report a case of 71-year-old man who developed a hypersensitivity syndrome associated with terbinafine. He was placed on terbinafine (250 mg/d) for the treatment of tinea pedis due to diabetes mellitus. Following the treatment with terbinafine, he developed drug-induced hypersensitivity syndrome (DIHS). Systemic corticosteroid led to transient improvement of his clinical manifestations. Three months after disease onset, he presented with panperitonitis due to ileal perforation, and underwent an emergency operation. The affected ileum was resected and ileostomy was performed in the terminal ileum. Cytomegalovirus (CMV)-specific IgG antibodies were significantly increased, high-titer CMV antigenemia was detected, and pathological examination of the resected ileum confirmed CMV infection. Based on these observations, we strongly recommend that physicians monitor reactivation of the family of herpesvirus other than herpesvirus 6, to manage DIHS properly.

INTRODUCTION

Terbinafine has become established as a drug of choice to treat onychomycosis and other dermatomycoses. Although previously reported cases of drug-induced hypersensitivity syndrome (DIHS) are notably uncommon (anticonvulsants, salazosulfapyridine, allopurinol, minocycline, and mexiletine), the number of reported cases of DIHS induced by terbinafine has been increasing.

It is true human herpesvirus 6 (HHV-6) reactivation has been the most frequently described infection associated with this syndrome, but recent articles have suggested that certain herpesviruses other than HHV-6 might be reactivated in a sequential manner in the development of DIHS (multiple and sequential herpesvirus reactivation)[1-7].

Although rare, cytomegalovirus (CMV) is known to cause ileal perforation, not only in immunocompromised

patients such as those with the acquired immunodeficiency syndrome (AIDS) but also immunocompetent patients[8-11]. To the best of our knowledge, especially in the English-language literature, isolated cases of ileal perforation due to CMV infection have never been reported in patients with DHIS.

Here, we report a case of isolated ileal perforation due to CMV in a case of DIHS due to terbinafine, in whom reactivation of HHV-6, Epstein-Barr virus (EBV) and CMV was detected.

CASE REPORT

A 71-year-old Japanese man with diabetes mellitus with onychomycosis was treated with oral terbinafine. Other medical history was not remarkable: any anticonvulsants, mexiletine, and antibiotics such as minocycline and salazosulfapyridine, were not prescribed. One week after taking terbinafine, he developed a high fever, erythema covering the whole body, and superficial lymph node swelling. Laboratory data at that time showed leukocytosis (16 670/mm^3) with 30.2% eosinophils. Atypical lymphocytes were not present. Liver enzymes were slightly elevated: 47 IU/L alanine aminotransferase and 78 IU/L aspartate aminotransferase. DIHS was suspected and terbinafine administration was discontinued soon after the onset of illness. As a result of sustained fever and erythroderma for 1 mo, 30 mg/d systemic corticosteroid was started. After 7 d, his symptoms improved temporarily. However, tapering the corticosteroid dose to 25 mg/d led to recrudescence of his fever and generalized rash (on day 50). Other results of systemic corticosteroids were not remarkable. Retrospectively, seroconversion of anti-HHV-6 antibody was detected; the titer increased from < 10 (on day 14) to 40 (on day 90). Judging from his drug history, characteristic generalized erythematous rash and laboratory data, the diagnosis of DIHS was confirmed. He was again administrated 30 mg/d prednisolone from day 50. Then, the patient was referred to our hospital (Osaka City General Hospital).

Examination on admission revealed erythematous rash over his entire body, with partially exfoliated lesions and superficial lymphadenopathy. Laboratory data included a normal count of white blood cells without eosinophilia and normal liver enzymes. Antinuclear and antineutrophil cytoplasmic antibodies were negative. The patient was negative for human immunodeficiency virus (HIV). Histological examination of the skin was not performed. Seventy days after the onset of DIHS, the patient complained of abdominal discomfort, and occult blood tests were positive on two occasions. On day 80, colonoscopic examination was performed and no abnormality around the whole colon and terminal ileum was revealed. At that time, CMV antigenemia was strongly suggested by the direct detection of viral antigen in the peripheral blood: CMV antigenemia-1, 56 and antigenemia-2, 89. CMV IgG titer increased to 128 and IgM titer was negative (< 0.8). Intravenous administration of 500 mg/d ganciclovir was started. However, fever with abdominal pain was present on day 82, and physical examination showed muscular defense in the entire abdomen. Abdominal computed tomography (CT) revealed free air, ascites, and swelling of the ileal loop (Figure 1). He was diagnosed as having panperitonitis due to ileal perforation, and underwent an emergency operation. The affected ileum was resected and ileostomy was performed. Pathological examination of the resected ileum revealed acute inflammation with vasculitis and CMV inclusions in the macrophages and endothelial cells, and evidence of CMV on immunostaining (Figure 2). There was no evidence of cancer cells or any other pathogens. Administration of 500 mg/d ganciclovir was continued, and CMV antigenemia was not detected on day 89. Unfortunately, the patient died from pneumonia.

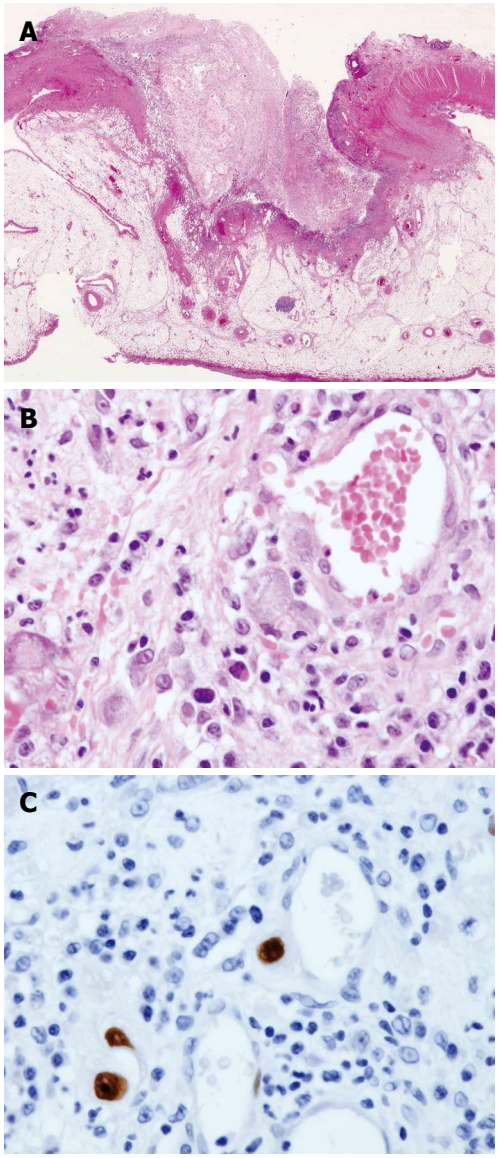

Figure 1 Histological examination of perforated ileum. A: Perforated ileal lesion (hematoxylin and eosin stain) × 40; B: × 400; C: Cytomegalovirus infection was evident in the same lesion, by immunohistochemical staining with anti-cytomegalovirus antibody (× 200).

DISCUSSION

Terbinafine has become established as a drug of choice

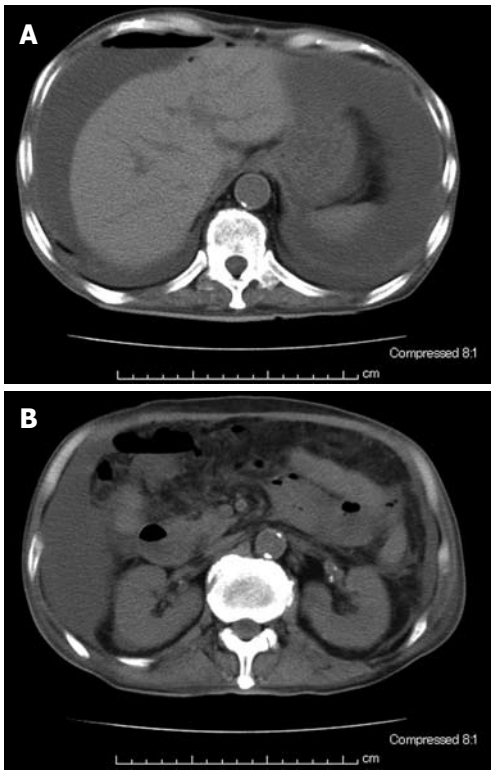

Figure 2 Abdominal computed tomography. A: Free-air, ascites; B: Swelling of the ileal loop.

to treat onychomycosis and other dermatomycoses. Although previously reported cases of DIHS are notably uncommon (anticonvulsants, salazosulfapyridine, allopurinol, minocycline, and mexiletine), the number of reported cases of DIHS induced by terbinafine has been increasing. It was thought that the present case met the criteria for DIHS because the patient had clear exposure to a given drug (in this case, terbinafine), high fever (> 39℃); erythroderma followed by exfoliative dermatitis; diffuse lymphadenopathy; and hypereosinophilia (absolute eosinophil count, 5032/mm^3). The results of a lymphocyte-stimulating test for terbinafine performed in our hospital were negative, and it was thought that treatment with prednisolone may have affected the results.

Since Aihara *et al*[2] in 2001, it has been recognized that CMV is associated with hypersensitivity syndrome. Recent studies have suggested that reactivation of members of the herpesvirus family other than HHV-6 could be associated with DIHS. Moreover, multiple herpesvirus reactivations and sequential reactivation have been reported in the case of DIHS. The list of viruses that have been documented to be reactivated include HHV-6, HHV-7, EBV and CMV[2-7]. In the present case, reactivation of HHV-6, EBV and CMV was confirmed on the basis of serological tests on paired serum samples for HHV-6 and EBV, and polymerase chain reaction for CMV. EBV reactivation was asymptomatic, which might have been due to administration of corticosteroids.

The clinical course of this patient can be divided in three phases: (1) hypersensitivity reaction with eosinophilia; (2) relapse of fever and rash due to HHV-6 reactivation; and (3) ileal perforation due to CMV reactivation. Retrospectively, the worsening of exanthema and poor control of second fever in spite of treatment with prednisolone reflect virus reactivation. We speculate that the virus responsible for this phase was HHV-6, although we could not confirm the absence of CMV infection in this period. The following abdominal pain and ileal perforation was due to CMV reactivation, as confirmed by pathological examination of the resected ileum.

Table 1 Previously reported causes of isolated ileal perforation due to CMV

AIDS
Non-Hodgkin's lymphoma with chemotherapy
Systemic lupus erythematosus
Liver transplantation
Ulcerative colitis
Recurrent gastric cancer
Blood transfusion associated with trauma
Immunocompetent elderly/neonatal
DIHS (present case)

CMV: Cytomegalovirus; AIDS: Acquired immunodeficiency syndrome; DIHS: Drug-induced hypersensitivity syndrome.

Our patient was unique in that CMV reactivation resulted in ileal perforation during the course of DIHS. Although rare, CMV is known to cause ileal perforation, especially in immunocompromised patients, such as those with AIDS. To the best of our knowledge, isolated cases of ileal perforation due to CMV infection have never been reported in a patient with DIHS (Table 1)[8-11]. Although it remains possible that systemic corticosteroid administration precipitated CMV reactivation, there is also a case report that demonstrated that a patient without any corticosteroids showed reactivation of HHV-6, HHV-7 and CMV[3]. Based on these observations, it is important for physicians to be aware of the possible reactivation of CMV and other herpesviruses in every patient with DIHS, to avoid awkward small intestinal ulcer and perforation.

In summary, we have reported a case of isolated ileal perforation due to CMV reactivation during the management of terbinafine hypersensitivity. Although the prognosis in bowel perforation related to CMV infection is extremely poor, emergency surgery saved our patient's life. However, earlier diagnosis and prompt administration of antiviral drugs could have avoided surgical treatment. Although CMV could affect multiple organ functions and might be the direct cause of death, effective medication such as ganciclovir is available. Therefore, it is strongly recommended that physicians monitor reactivation of herpesviruses other than HHV-6, to manage DIHS properly.

Abstract

We report a male patient with prolonged post-prandial abdominal distension and a sudden onset of epigastric pain initially diagnosed as acute abdomen. The patient had no history of surgery. Physical examination revealed peritonitis and abdominal computed tomography scan showed upper abdominal mesentery intorsion. The patient then underwent surgical intervention. It was found that the descending mesocolon dorsal root was connected to the ascending colon and formed a membrane encapsulating the small intestine. The membrane also formed an orifice in the ileal pars caeca, from which a 30 cm herniated ileum formed a "C"-shaped loop which was strangulated by the orifice. An abdominal separation was diagnosed after surgery. We liberated the membranous peritoneum which incarcerated the intestinal canal from the root of ileocecal junction to Treitz ligament, and reduced the small intestinal malrotation. The patient had an uneventful recovery after operation with his abdominal distention disappeared during the follow-up. Abdominal separation is a rare situation, which may be related with embryo development. Surgery is a choice of treatment for it.

INTRODUCTION

Acute abdominal pain, a common chief complaint encountered in emergency department, accounts for about 5% of all emergency department visits[1] and can be caused by a variety of conditions[2]. Many factors can result in acute abdominal pain, such as appendicitis, bowel obstruction, and cholecystitis[3]. This report describes a rare case of abdominal separation in an adult male patient with strangulated internal hernia of the terminal ileum complicating malrotation of intestine, which has not been reported in the literature.

CASE REPORT

A 43-year-old man visited the emergency department of our hospital on December 31, 2007 for a sudden onset of persistent epigastric pain for 10 h. He had a history

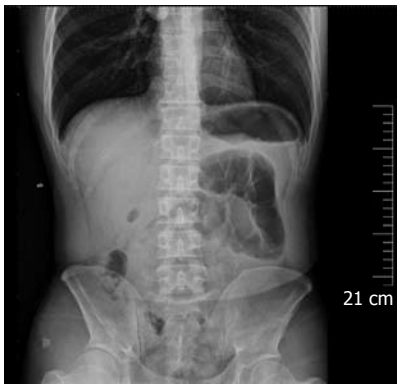

Figure 1 Plain abdominal X-ray. Mildly dilated pneumatic intestinal canal loops but no typical air-fluid level shadow in the left upper quadrant of abdomen.

of prolonged episodes of postprandial abdominal distension. The pain was associated with nausea and vomiting without any clear inducing factors, and did not radiate to the back and shoulders. The symptoms included anorexia, constipation, obstipation and poor sleep. Furthermore, he had no history of abdominal surgery or trauma. On admission, his temperature was 36.5℃, blood pressure was 127/72 mmHg, respiratory rate and pulse rate were 17 breaths/min and 70 beats/min, respectively. Physical examination showed tenderness, rebound tenderness and slight muscular rigidity in the right lower quadrant of abdomen. Laboratory findings included 86.8% of neutrophils and 116.0 U/L of hemoglobin. Plain abdominal X-ray revealed mildly dilated pneumatic intestinal canal loops but no typical air-fluid level shadow in the left upper quadrant of abdomen (Figure 1). The patient was initially diagnosed as localized peritonitis which was differentially diagnosed from acute appendicitis and intestinal mesentery intorsion.

The patient had no significant improvement after initial treatment with fluid replacement, antibiotics and gastrointestinal decompression. He developed peritonitis with the pain exacerbated. Computed tomography (CT) scan revealed suspicious upper abdominal mesentery intorsion (Figure 2). Exploratory laparoscopy demonstrated appendix in the retroileal position, descending mesocolon dorsal root that was connected to the ascending colon encapsulating the small intestine, an orifice in the ileal pars caeca from which a 30 cm herniated ileum formed a "C"-shaped loop at the root of ileocecal junction strangulating at the orifice, and a purple incarcerated intestinal canal.

We liberated the incarcerated intestinal canal by opening the membrane at the mesentery root from the ileocecal junction to Treitz ligament and reduced the mesoileal malrotation. The strangulated intestine was about 50 cm from the ileocecal junction. After liberation, the intestinal canal was recovered with its color changed from purple to pink, and vascular pulsation was obvious and peristalsis was resumed.

The patient had an uneventful recovery and was discharged on January 8, 2008. The patient was diagnosed as localized peritonitis, small intestinal malrotation, internal herniation, strangulation of small bowel and abdominal separation after operation, and followed up for 18 mo during which no complications and post prandial abdominal distention occurred.

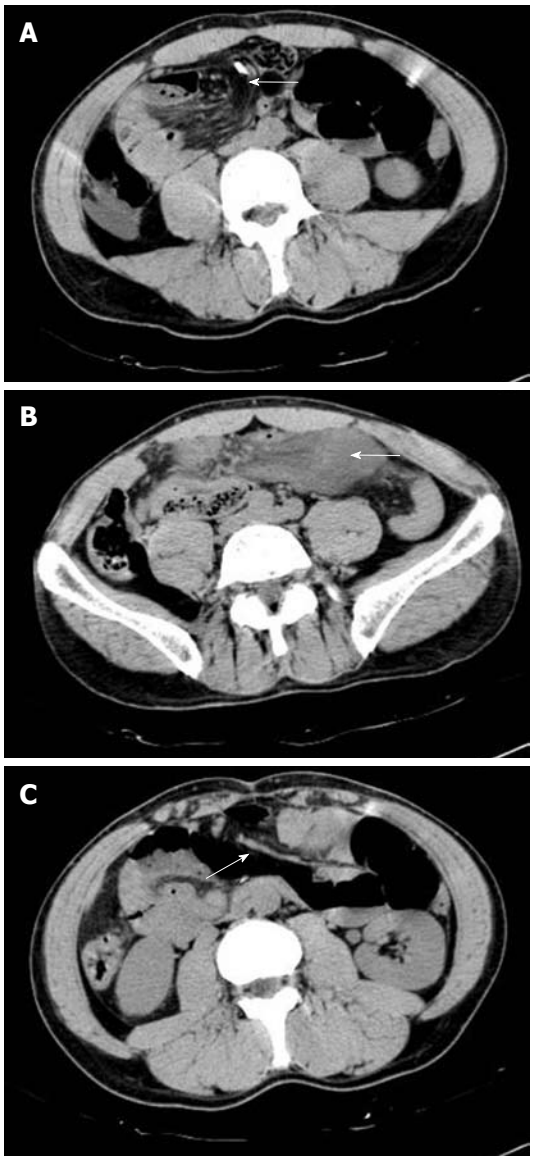

Figure 2 Computed tomography scan. Suspicious upper abdominal mesentery intorsion (A, arrow), right lower quadrant intestinal loop (B, arrow), middle abdominal line separation (C, arrow).

DISCUSSION

Since a large number of patients visiting emergency department complain of acute abdominal pain and most of them have typical symptoms and signs, appropriate evaluation can be accomplished with the aid of relevant auxiliary investigations[3]. The complaints are usually relieved after symptomatic treatment. In some rare cases, its initial diagnosis may be difficult as in our case. The incidence of internal hernia is low, accounting for less than 1% of all acute abdomen cases[4-6]. However, the overall mortality may be higher than 50% if it is not ap-

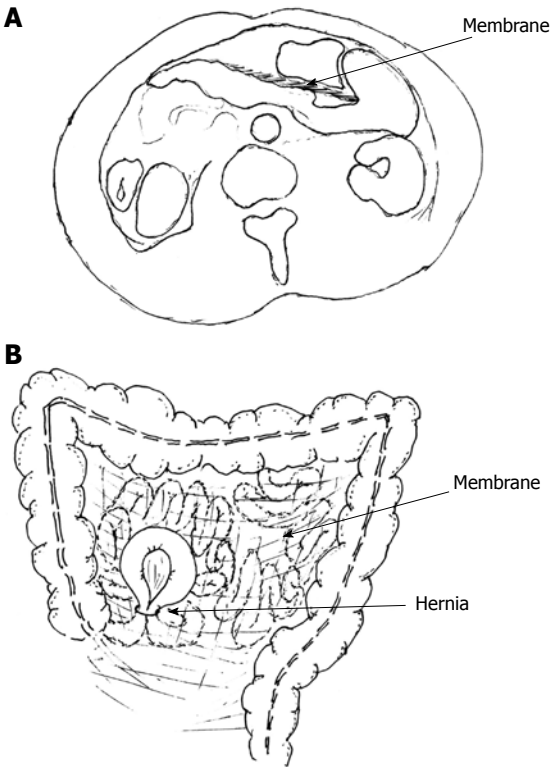

Figure 3 Schema showing a membrane separating the peritoneal cavity into two compartments (A) and descending mesocolon dorsal root connecting with the ascending colon (B).

propriately treated, especially when strangulation occurs. A fast and correct diagnosis is therefore necessary.

Our patient suffered from abdominal pain which exacerbated although it was treated with fluid resuscitation and antibiotics. Nasogastric tube decompression did not produce desirable effect and vomiting continued. Since the condition was nonspecific, its differential diagnosis was difficult from acute abdomen caused by factors such as mechanical intestinal obstruction. Plain abdominal X-ray has been recommended for patients with highly suspected obstruction[7-9] according to The Royal College of Radiologists Guidelines[10]. A single plain abdominal X-ray is not adequate to make a definitive judgment of suspected obstruction[9], and CT scan is the reasonable next step for further investigation of abdomen[2,11]. Abdominal CT scan has a good inter-observer agreement in unselected patients with acute abdominal pain at emergency department and plays an important role in diagnosis of acute intestinal obstruction and in planning of surgical treatment. Although internal hernias are uncommon, they should be included in the differential diagnosis from intestinal obstruction, especially in the absence of abdominal surgery or trauma. Recognition of the characteristic findings on CT scan may assist in identification of internal hernias in most cases of small bowel obstruction. Since the general condition of this patient deteriorated very quickly and CT revealed a mesentery intorsion, surgery was performed. The function of strangulated bowel was recovered after its loop was released and the mesenteric malrotation was reduced.

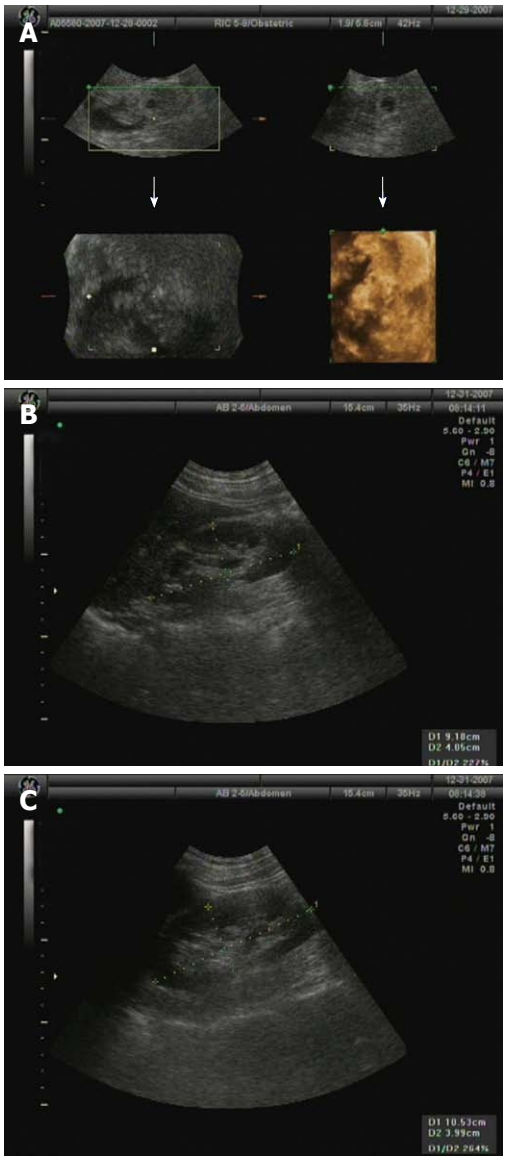

Figure 4 Abdominal and kidney ultrasonography showing no mass and fluid collection (A), left (B) and right (C) normal kidney structure.

Although abdominal separation in our case could not be definitely diagnosed before operation by the radiologist and clinician[8] due to the presence of peritonitis, surgery was performed during which the otherwise rare phenomenon of abdominal separation was discovered, namely a membrane divides the abdominal cavity into two compartments. The anterior compartment contains the colon, while the posterior compartment encapsulates the small intestine, forming an orifice at the end of ileocecal junction. It is at this orifice that a 30 cm ileum is protruded and strangulates the anterior compartment, causing abdominal pain. A CT scan showed an intra-abdominal membrane-like line dividing the two compartments (Figures 2 and 3). Ultrasonography did not show specific intraabdominal evidence (Figure 4). This patient experienced episodes of post prandial abdominal distension, which supported the findings on abdominal CT scan and at operation. His symptoms were relieved after operation. We therefore recommend that abdominal sep-

aration should be differentially diagnosed from acute abdomen. Early diagnosis and operation will greatly reduce the morbidity and mortality of intestinal strangulation.

The intestine has returned to the abdominal cavity and the midgut consisting mainly of the duodenum, jejunum, ileum, ascending colon, and transverse colon has completed its 270-degree loop by weeks 10 and 20 of embryo development, respectively. With the growth of small intestine, the ascending and descending colon are pushing against the body wall in a secondary retroperitoneal location like the pancreas and duodenum[12,13]. Whether the mesentery separates abdomen into two parts of peritonum during the development is not well known. Whether there is any genetic change needs to be further investigated.

In conclusion, abdominal separation with internal hernias is a rare condition that can present as acute abdomen. Such patients can recover if they are properly treated. We strongly recommend that abdominal separation should be differentially diagnosed from acute abdomen.

ACKNOWLEDGMENTS

The authors thank Sangeeta Sharma for the help in manuscript preparation and Jin Xu for preparation of the schema.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Electronic journal (list all authors)

15 Morse SS. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Patent (list all authors)

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology

A peer-reviewed, online, open-access journal of gastroenterology and hepatology

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1144 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 60 countries, including Albania (1), Argentina (8), Australia (29), Austria (14), Belgium (12), Brazil (10), Brunei Darussalam (1), Bulgaria (2), Canada (20), Chile (3), China (69), Colombia (1), Croatia (2), Cuba (1), Czech (4), Denmark (8), Ecuador (1), Egypt (2), Estonia (2), Finland (8), France (24), Germany (75), Greece (14), Hungary (10), India (26), Iran (6), Ireland (7), Israel (12), Italy (101), Japan (112), Jordan (1), Kuwait (1), Lebanon (3), Lithuania (2), Malaysia (1), Mexico (10), Moldova (1), Netherlands (29), New Zealand (2), Norway (11), Pakistan (2), Poland (11), Portugal (4), Romania (3), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (10), South Africa (2), South Korea (32), Spain (38), Sweden (18), Switzerland (11), Thailand (1), Trinidad and Tobago (1), Turkey (24), United Arab Emirates (2), United Kingdom (82), United States (249), and Uruguay (1).

WJG World Journal of Gastroenterology

Contents

Weekly Volume 16 Number 27 July 21, 2010

EDITORIAL

3347 Changing face of hepatic encephalopathy: Role of inflammation and oxidative stress
Seyan AS, Hughes RD, Shawcross DL

3358 R0 resection in the treatment of gastric cancer: Room for improvement
Biondi A, Persiani R, Cananzi F, Zoccali M, Vigorita V, Tufo A, D'Ugo D

ORIGINAL ARTICLE

3371 Effect of soy saponin on the growth of human colon cancer cells
Tsai CY, Chen YH, Chien YW, Huang WH, Lin SH

3377 Galangin induces apoptosis of hepatocellular carcinoma cells *via* the mitochondrial pathway
Zhang HT, Luo H, Wu J, Lan LB, Fan DH, Zhu KD, Chen XY, Wen M, Liu HM

3385 8-bromo-7-methoxychrysin-induced apoptosis of hepatocellular carcinoma cells involves ROS and JNK
Yang XH, Zheng X, Cao JG, Xiang HL, Liu F, Lv Y

3394 Effects of four *Bifidobacteria* on obesity in high-fat diet induced rats
Yin YN, Yu QF, Fu N, Liu XW, Lu FG

BRIEF ARTICLE

3402 Sessile serrated adenomas: Demographic, endoscopic and pathological characteristics
Gurudu SR, Heigh RI, De Petris G, Heigh EG, Leighton JA, Pasha SF, Malagon IB, Das A

3406 Can chronic gastritis cause an increase in fecal calprotectin concentrations?
Montalto M, Gallo A, Ianiro G, Santoro L, D'Onofrio F, Ricci R, Cammarota G, Covino M, Vastola M, Gasbarrini A, Gasbarrini G

3411 Pancreatic and pulmonary mast cells activation during experimental acute pancreatitis
Lopez-Font I, Gea-Sorlí S, de-Madaria E, Gutiérrez LM, Pérez-Mateo M, Closa D

3418 Double balloon enteroscopy examinations in general anesthesia
Zubek L, Szabo L, Lakatos PL, Papp J, Gal J, Elo G

3423 Does bilioenteric anastomosis impair results of liver resection in primary intrahepatic lithiasis?
Herman P, Perini MV, Pugliese V, Pereira JC, Machado MAC, Saad WA, D'Albuquerque LAC, Cecconello I

3427 Prevalence of type 2 diabetes in Algerian patients with hepatitis C virus infection
Rouabhia S, Malek R, Bounecer H, Dekaken A, Bendali Amor F, Sadelaoud M, Benouar A

3432 Association of *E-cadherin* (*CDH1*) gene polymorphisms and gastric cancer risk
Al-Moundhri MS, Al-Khanbashi M, Al-Kindi M, Al-Nabhani M, Burney IA, Al-Farsi A, Al-Bahrani B

3437 Transcatheter arterial chemoembolization with a fine-powder formulation of cisplatin for hepatocellular carcinoma
Kasai K, Ushio A, Sawara K, Miyamoto Y, Kasai Y, Oikawa K, Kuroda H, Takikawa Y, Suzuki K

3445 Association of genetic polymorphisms of aldehyde dehydrogenase-2 with esophageal squamous cell dysplasia
Zhou YZ, Diao YT, Li H, Li HQ, Ma Q, Cui J

3450 Radiofrequency ablation in the treatment of small hepatocellular carcinoma: A meta analysis
Liu JG, Wang YJ, Du Z

3457 Impact of human leukocyte antigen mismatching on outcomes of liver transplantation: A meta-analysis
Lan X, Zhang MM, Pu CL, Guo CB, Kang Q, Li YC, Dai XK, Deng YH, Xiong Q, Ren ZM

3465 Precise prediction model and simplified scoring system for sustained combined response to interferon-α
Mao QG, Pan JS, Fang KN, Zhang RM, Hong QY, Song MN, Zhu JP, Huang WQ, Chen LM, Hong MZ

CASE REPORT

3472 Anterograde jejunojejunal intussusception resulted in acute efferent loop syndrome after subtotal gastrectomy
Kwak JM, Kim J, Suh SO

Abstract

The face of hepatic encephalopathy (HE) is changing. This review explores how this neurocognitive disorder, which is associated with both acute and chronic liver injury, has grown to become a dynamic syndrome that spans a spectrum of neuropsychological impairment, from normal performance to coma. The central role of ammonia in the pathogenesis of HE remains incontrovertible. However, over the past 10 years, the HE community has begun to characterise the key roles of inflammation, infection, and oxidative/nitrosative stress in modulating the pathophysiological effects of ammonia on the astrocyte. This review explores the current thoughts and evidence base in this area and discusses the potential role of existing and novel therapies that might abrogate the oxidative and nitrosative stresses inflicted on the brain in patients with, or at risk of developing, HE.

Key words: Hepatic encephalopathy; Ammonia; Inflammation; Oxidative stress; Astrocyte

INTRODUCTION

Hepatic encephalopathy (HE) is a neurocognitive disorder in which brain function is impaired and is associated with both acute and chronic liver dysfunction. HE occurs in the presence of liver injury or when the liver is bypassed in the presence of a portosystemic shunt. In acute liver failure, patients may develop cerebral oedema and increased intracranial pressure. However, recent studies suggest that intracranial hypertension is less frequent than previously described, complicating 25% of acute cases and only 9% of those with sub-acute liver failure[1]. In cirrhosis, it causes a range of neuropsychiatric and motor disturbances spanning a spectrum of abnormalities, which encompass short-term memory impairment, slowing of reaction time, poor concentration, psychomotor retardation, and sensory dysfunction, through to more clinically apparent neurological signs and symptoms. In its most severe form, patients can develop confusion, stupor, and coma[2]. However, abnormalities can be subtle and only become apparent on formal psychometric testing (minimal HE). Minimal HE is thought to be a disorder of executive functioning, primarily leading to impairments in selective atten-

tion, response inhibition, and working memory. This frequently impacts on quality of life[3] and specifically impairs navigation skills[4], which can be demonstrated utilising a driving simulator that correlates impairment with response inhibition and attention[5]. HE has generally been considered to be a reversible process following liver transplantation, although recent studies have suggested that this may not always be the case[6].

The "World Congress of Gastroenterology" in 2002 developed a set of consensus definitions, which has led to the classification of HE into three different types, A-C. (Table 1)[2]. In addition, the clinical presentation of HE was categorised into four main subtypes (Table 2). The heterogeneous nature of the presentation of HE has been the cause of great consternation, and has made the interpretation of comparative studies problematic. The staging of overt HE remains an imprecise art, which is often hampered by its fluctuant course. Thus, more objective methods using electroencephalographic techniques have been developed to assess HE. The effectiveness of using the bispectral index to grade and monitor the course of HE has high discriminative power in patients with both low and high grades of HE, and can be utilised as a simple and objective method of grading HE[7]. It has recently been suggested that we should consider HE as a spectrum of neurocognitive impairment in patients with cirrhosis; the spectrum spanning normal performance to coma[8].

Table 1 Classification of hepatic encephalopathy[2]

Type	Definition
A	Acute and hyperacute liver failure
B	Portosystemic bypass without intrinsic hepatocellular disease
C	Cirrhosis and portal hypertension with portosystemic shunts

A: Acute; B: Bypass; C: Cirrhosis.

Table 2 Clinical presentation of hepatic encephalopathy[2]

Encephalopathy	Definition
Acute	Acute liver dysfunction
Recurrent or episodic	Episodes of mental alteration in a patient with cirrhosis, even in the absence of a known precipitating factor
Persistent	Neurological deficit that persists despite the reversal of liver injury, such as following liver transplantation or the removal of a precipitating factor
Minimal (previously known as subclinical)	No evidence of overt encephalopathy, but subtle cognitive deficits might be detected with a neuropsychological function test battery

THE AMMONIA HYPOTHESIS

Ammonia was first thought to play a major role in the development of HE when studies by Hahn *et al*[9], Nencki *et al*[10] and Nencki *et al*[11] in the 1890s described the "meat intoxification syndrome". By diverting blood away from the liver utilising a surgical shunt from the portal vein into the vena cava of dogs, within 6 wk of the portocaval shunt being constructed, it was observed that the dogs developed symptoms such as aggression, irritability, and convulsions, similar to the symptoms exhibited by patients with cirrhosis and overt HE. The portocaval shunt allows blood to bypass the liver, resulting in a lack of urea metabolism, and arterial ammonia levels were found to be increased. When ammonium salts were administered to the dogs, they rapidly fell into a coma and died[9]. Ammonia was later confirmed as the main causative factor of the "meat intoxification syndrome" in portocaval shunted dogs in 1922[12]. The role of ammonia became increasingly recognised as being important when Gabuzda *et al*[13] and Phillips *et al*[14] attempted to treat patients with ascites with cation exchange resins that absorbed sodium but released ammonium ions, leading to the adverse effect of significant reversible neurological dysfunction, which was indistinguishable from the syndrome we now know as HE. Blood ammonia concentration was subsequently noted to be elevated in patients with liver disease and hepatic coma[15]; the highest values being found in those patients who were comatose[16].

Subsequently, other investigators have shown that ammonia plays a definitive role in the development of HE. Bessman *et al*[17] demonstrated a positive arteriovenous difference in ammonia levels in patients with cirrhosis, suggesting an uptake of free ammonia into the brain. More recently, Ehrlich *et al*[18] demonstrated that by constructing an end-to-side portocaval anastomosis in rats and injecting them with ammonium acetate, the rats demonstrated typical characteristics of HE, such as drowsiness, seizures, and coma in association with elevated blood and brain ammonia concentrations, compared to control rats. Lockwood *et al*[19] were then able to demonstrate the first evidence linking ammonia to HE in humans, using positron emission tomography (PET). A ^{13}N tracer demonstrated that the rate of uptake of ammonia in the brains of patients was greater in those with HE than without. It was postulated that an increased ammonia uptake in the brain was linked to an increased permeability of the blood-brain barrier to ammonia[20]. In acute liver failure, arterial ammonia concentrations of > 150 μmol/L predict a greater likelihood of dying from brain herniation[21], and intracranial hypertension develops in 55% of cases with an arterial ammonia concentration > 200 μmol/L[1]. In cirrhosis, there is no doubt that blood ammonia concentrations are elevated, but there is conflicting evidence regarding the relationship between ammonia concentration and HE severity. Moreover, it is not unusual in clinical practice to see patients with cirrhosis presenting with symptoms of overt HE who have normal or only mildly elevated arterial ammonia concentrations. Indeed, numerous studies have shown that a single test for blood ammonia concentration is a poor method for assessing HE[22]. Furthermore, Ong *et al*[23] studied the blood ammonia levels of patients with chronic liver disease and compared these to their mental states. In patients considered not to have any sign of HE, 60% had ammonia levels higher than normal, whereas there was a high proportion of those with grade 3 or 4

HE with normal or only mildly elevated blood ammonia levels. Whilst there is no denying the involvement of ammonia in the pathogenesis of HE, it seems that there might be other factors involved which are as, if not more, important.

THE ASTROCYTE IN HE

Astrocytes are a type of glial cell found within the central nervous system (CNS), which are involved in maintaining cells within the CNS, including providing nutrients for neurones. Astrocytes are particularly vulnerable to the effects of ammonia in the brain. One reason for this is that the enzyme glutamine synthetase is mainly located within astrocytes. Norenberg *et al*[24] found glutamine synthetase exclusively within astrocytes in rat brains, and none within neurones or other glial cells. It is also important to note that the end-processes of astrocytes surround the capillaries in the CNS. Theoretically, this would ensure that any toxin entering the brain, such as ammonia, is immediately metabolised, protecting other CNS cells from its damaging effects[25]. This theory was tested by Rao *et al*[26], who investigated the effects of ammonia exposure on purely neuronal cultures and co-cultures of neurons and astrocytes. The cultures containing neurons alone showed significant increases in cell death, apoptotic cells, degeneration of neuronal processes, and free radical levels. However, these changes were not detected in the co-cultures, indicating a protective function of astrocytes.

The blood brain barrier remains anatomically intact in HE[27]; however, PET studies have demonstrated an increased permeability-surface area to ammonia with increasing severity of disease[20].

HE in patients with chronic liver disease is characterised neuropathologically by Alzheimer type Ⅱ astrocytosis. This describes morphological changes to astrocytes, which include a large swollen nucleus, prominent nucleolus, and margination of the chromatin pattern. These neuropathological findings have been replicated in the brains of patients with congenital abnormalities of urea cycle enzymes[28], in experimental animal models[29,30], and astrocyte cultures exposed chronically to ammonia[31]. Therefore, it is likely that ammonia taken up into the brain interacts with astrocytes, eventually leading to these characteristic changes.

In acute liver failure, an increased brain ammonia concentration causes astrocyte swelling and patients develop cytotoxic brain oedema[32]. Kato *et al*[32] used electron microscopy to study the cells of patients who died of fulminant hepatic failure. They found brain oedema to be present, with pronounced swelling of astrocytes. Glutamine synthetase catalyses the conversion of ammonia and glutamate to glutamine. As a result, hyperammonemia can lead to excessive levels of glutamine within astrocytes, causing the cells to swell, and therefore explaining the oedema and intracranial hypertension seen with fulminant hepatic failure. Willard-Mack *et al*[33] used rats to investigate whether inducing an acute onset of hyperammonemia caused astrocytes to swell and if inhibiting the action of glutamine synthetase prevented these astrocytic changes. The study found that 8 h after inducing plasma hyperammonemia, changes in astrocyte morphology could be identified. These changes included an increased number of organelles, increased cytoplasmic volume, and an increased nuclear volume. They also found that inhibiting glutamine synthetase attenuated the enlargement of the nuclei and prevented the increase in astrocyte water content seen with hyperammonemia. The results of this study suggest that the production of glutamine by ammonia detoxification, results in water being drawn into astrocytes through osmotic pressure.

There might also be a potential role for vasogenic brain oedema in acute liver failure. This is believed to result from damage to the blood-brain barrier, leading to uncontrolled movement of plasma components and water to extracellular areas of the brain[34]. Consistent with this, animal studies have shown an increased permeability of the blood brain barrier to substances that are normally unable to cross it[35,36]. It has been suggested that perhaps in the early stages of HE, cytotoxic brain oedema predominates, and is enhanced in the later stages by vasogenic brain oedema following damage to the blood brain barrier[37]; however, the ability of mannitol to reduce intracranial hypertension in patients with fulminant hepatic failure indicates that the blood brain barrier remains largely intact[38].

The presence of low-grade astrocyte swelling has been further investigated in human patients with cirrhosis. Córdoba *et al*[39] used magnetic resonance spectroscopy and the magnetisation transfer ratio (a measure of free water in the brain) to assess cirrhotic patients before and after liver transplantation. The results showed a high level of free water in the brain before liver transplantation, which then reduced after transplantation. This correlated with changes in neuropsychological function, suggesting that brain oedema plays a direct role in the changes observed in HE. A further finding of the study was that brain glutamine levels also correlated with the changes in brain water and neuropsychological function, providing further evidence to the theory that hyperammonemia plays an important role in the pathophysiology of HE. Balata *et al*[40] showed that inducing hyperammonemia in patients with cirrhosis leads to an increase in brain glutamine, which results in an increase in brain water, and deterioration in neuropsychological function.

Interestingly, brain oedema and the consequent risk of intracranial hypertension are rarely complications of chronic liver failure, and are more often associated with fulminant hepatic failure. One possible suggestion for this is that in chronic liver disease, cells have more time to use compensatory mechanisms to adapt to the osmotic changes taking place[41].

Ammonia is directly toxic to the brain, and in acute liver failure causes disarray of inhibitory and excitatory neurotransmission[42], impairs brain energy metabolism[43-46], alters expression of several genes that code for important proteins involved in brain function[47,48], and impairs autoregulation of cerebral blood flow[49]. In patients with cirrhosis, there appears to be a shift in the balance between

inhibitory and excitatory neurotransmission towards a net increase in inhibitory neurotransmission.

THE CHANGING FACE OF HE

Although it is widely accepted that ammonia has a key role to play in the pathophysiology of HE, the clinical picture is not always so straightforward. Frequently, the arterial concentration of ammonia can be elevated in the absence of symptoms of HE, and the correlation between the severity of HE and ammonia concentration in patients with cirrhosis can be poor. The theory that several factors could contribute together to the clinical picture of HE was first suggested by Zieve *et al*[50] in 1974, who described the possible synergistic effects of several toxins, with ammonia. Since this first suggestion, it has become increasingly apparent that aspects of the inflammatory response (such as elevation of pro-inflammatory cytokines) in response to infection and/or systemic inflammation, and oxidative stress, participate in a synergistic relationship with ammonia in the pathogenesis of HE[51-53].

THE ROLE OF INFECTION AND INFLAMMATION IN HE

Acute liver failure

Studies in patients with acute liver failure have shown a more rapid progression to severe HE in those patients with evidence of a systemic inflammatory response, supporting a link between inflammation and HE[51]. In addition, in patients with acetaminophen-induced acute liver failure, infection and/or the resulting systemic inflammatory response were shown to be important factors contributing to an increase in the severity of HE[52]. Furthermore, in the advanced stages of HE in acute liver failure, the brain produces a number of pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α), interleukin (IL)-1β and IL-6[54,55]. This relationship is supported by evidence derived from therapeutic interventions, such as moderate hypothermia, that reduce cerebral oedema by reducing cerebral blood flow and inflammatory responses[56,57].

Cirrhosis

In patients with cirrhosis, there is mounting evidence for the role of inflammation in exacerbating the symptoms of HE, thus reinforcing the potential synergistic effects of ammonia and inflammation. Studies have shown this to be the case in patients with minimal HE, and across the whole spectrum of patients with varying degrees of overt HE (Westhaven grades 0-4)[53,58,59]. A recent study confirmed that the presence and severity of minimal HE in cirrhosis is independent of the severity of liver disease and plasma ammonia concentration, but markers of inflammation are significantly higher in those with minimal HE compared to those without[59]. In a further study, significant deterioration of neuropsychological test scores in patients with cirrhosis following induced hyperammonemia during the inflammatory state, but not after its resolution, suggested that inflammation might be important in modulating the cerebral effect of ammonia in liver disease, supporting an inflammatory hypothesis[53].

Synergy with ammonia

As inflammation, infection, and ammonia have been shown to be important in the pathogenesis of HE in cirrhosis, the question has to be raised as to whether infection and inflammation have a synergistic relationship with ammonia[60]. Marini and Broussard used mice with a deficiency in a critical urea cycle enzyme conferring chronic hyperammonemia, to demonstrate an increased sensitivity to inflammation. Furthermore, the hyperammonemic mice developed longer lasting and stronger cognitive defects when exposed to an inflammatory stimulus[61]. In a bile duct ligated (BDL) rat model, Jover *et al*[62] fed an ammonia-containing diet for 2 wk following ligation and compared animals sacrificed 7 d later to those fed a normal chow diet. Ammonia-fed BDL rats had increased cerebral ammonia and demonstrated the presence of type II Alzheimer astrocytosis analogous to patients with cirrhosis presenting with episodic HE. Both BDL groups had evidence of systemic inflammation, but the ammonia-fed BDL rats had increased brain glutamine, decreased brain myoinositol, and a significant increase in brain water compared to BDL controls, alluding to a potential synergistic relationship between ammonia and systemic inflammation. Wright *et al*[27] went on to explore the hypothesis that the inflammatory response induced by lipopolysaccharide (LPS) exacerbates brain oedema in BDL rats. LPS administration increased brain water in ammonia-fed, BDL, and sham-operated animals significantly, but this was associated with the progression to pre-coma only in the BDL animals. LPS induced cytotoxic brain swelling, but the anatomical integrity of the blood brain barrier was maintained. There was evidence of brain and systemic inflammation in BDL rats, which was significantly increased in LPS-treated animals. Nitrosation of proteins in the frontal cortex of BDL and LPS-treated animals was demonstrated. These data provide further evidence that in a background of cirrhosis and hyperammonemia, superimposed inflammation has an important role in the development of HE.

The ammonia-induced nitrosation of astrocytic proteins shown by Wright *et al*[27] has also been demonstrated in isolated astrocytes and astroglial tissue in brain sections of portocaval shunted rats[63]. However, ammonia alone cannot be responsible, because protein nitrosation was not demonstrated in ammonia fed sham-operated and ammonia-fed BDL rats in the absence of an inflammatory stimulus. Therefore, both ammonia and an additional inflammatory insult might need to be present for nitrosation of brain proteins to occur in animals with "subliminal" inflammation, such as that which has been observed in the BDL model[27]. This is further supported by recent work that demonstrated the presence of tyrosine nitration in astrocyte cultures in the presence of concentrations of TNF-α typically observed in patients with acute liver failure[64].

Inflammation and the brain

During an episode of infection, cytokines cannot directly cross the blood brain barrier and are unable to have a direct effect. Nevertheless, the peripheral immune system can still signal the brain to elicit a response during infection and inflammation through the expression of pro-inflammatory cytokines such as IL-1β, TNF-α and IL-6, both in the periphery and in the brain. Brain signalling may occur by direct transport of the cytokine across the blood brain barrier *via* an active transport mechanism, the interaction of the cytokine with circumventricular organs and activation of afferent neurons of the vagus nerve[65]. Endothelial cells, along with the astrocyte, are major constituents of the blood brain barrier. Endothelial cells are activated during infection, resulting in the release of various mediators into the brain. Activated microglial cells and astrocytes have the ability to produce a full repertoire of cytokines in response to inflammation and injury. One such cytokine is IL-1β, which has been shown *in vitro* to compromise the integrity of the blood brain barrier. This is mediated through the cyclo-oxygenase (COX) pathway within the endothelial cell[66]. In a portocaval shunted rat model that is more akin to a model of minimal HE, Cauli *et al*[67] demonstrated an improved learning ability following the administration of supra-therapeutic doses of the non-steroidal anti-inflammatory drug (NSAID), ibuprofen. This was accompanied by normalisation of COX and inducible NO activity within the cerebral cortex but interestingly also an increase in TNF-α. It is unclear however, how this NSAID specifically interacts with the glutamate-nitric oxide-cGMP pathway and how COX plays a role in the pathogenesis of minimal HE without identification of the specific COX isoform involved and in the absence of neuroanatomical, proteomic and genomic data. Nevertheless, the therapeutic use of NSAID in HE is not novel. Indomethacin (non-selective COX inhibitor) has been shown in patients with acute liver failure[68], and in a portocaval shunted rat model[69], to improve intracranial hypertension and cerebral oedema. Unfortunately, NSAID use is associated with a number of systemic complications, including cardiovascular/renal compromise and cellular prostaglandin metabolism, which impact greatly on not only astroglial function, but also on the development of organ dysfunction, particularly in the context of patients with longstanding liver disease.

TNF-α is released early during infection and can also influence the permeability of the blood brain barrier[70]. Moreover, an association between circulating TNF-α levels in patients with acute[71] and chronic liver failure[72] and the severity of HE, regardless of aetiology, has been recognised. Endothelial cells have receptors for IL-1β and TNF-α which can transduce signals which ultimately culminate in the intracerebral synthesis of NO and prostanoids[73]. Bémeur *et al*[74] investigated the effect of *IL-1β*, *TNF-α* and interferon-α (*IFN-α*) gene deletions on the onset of HE. Deletion of the *IFN-γ* gene had no effect on brain water levels or neuropsychiatric status. On the other hand, *IL-1β* and *TNF-α* gene deletions significantly delayed the onset of HE and brain oedema.

The relationship between the brain and inflammation is not one way. Molecular and neurophysiological studies during the past decade have suggested that pro-inflammatory responses are controlled by evolutionary neural circuits that operate reflexively[75,76]. The afferent arc of the reflex consists of nerves that sense injury and infection. This activates efferent neural circuits including the cholinergic anti-inflammatory pathway, which modulate immune responses and the progression of inflammatory disease. It might therefore be possible to target neural networks for the treatment of inflammation. This novel and fascinating body of work has recently been reviewed by Tracey[77].

Innate immune dysfunction

Innate immune dysfunction occurs in both acute and chronic liver failure, and up to 50% of admissions to hospital in patients with cirrhosis are likely to be related to the development of infection. In response to infection, the body initiates the innate immune response with phagocytic cells, such as monocytes and neutrophils. This response is particularly relevant to the liver, as the liver is the first organ to encounter bacteria or other toxins absorbed in the gut from the portal vein. Bacterial translocation of organisms from the gut in patients with cirrhosis and portal hypertension results in chronic endotoxemia. This culminates in a local milieu of pro-inflammatory cytokines/chemokines which can upregulate adhesion receptors and activate neutrophils[78]. There is significant literature on the immune response to infection in liver disease, which involves an important role of phagocytes and release of inflammatory cytokines. Patients with cirrhosis are functionally immunosuppressed and have impairment of several host defence mechanisms. The hemodynamic derangement of cirrhosis resembles that produced by endotoxin, and bacteremia can greatly exacerbate this state[79].

Neutrophils are a key component of the innate immune response. Ammonia has been shown to induce neutrophil dysfunction by inducing cell swelling, impaired phagocytosis, and increased oxidative burst in normal neutrophils *ex vivo*, in ammonia-fed rats and in patients with cirrhosis given an ammonia load[80]. Not only does this make patients potentially vulnerable to developing bacterial and fungal infections, but induces oxidative stress, and may ultimately culminate in a "sepsis-like" immune paralysis[81] and a reduction in monocyte HLA-DR expression[82].

OXIDATIVE STRESS

The evidence for the role of oxidative stress in the pathogenesis of HE is incontrovertible. Animal studies have shown significant reductions in the activities of glutathione peroxidase and superoxide dismutase enzymes, both in the liver and brain of rats exposed to ammonium acetate. Superoxide levels, in submitochondrial particles, were found to be elevated in ammonia-exposed rats[83] and lipid peroxidation has been shown to be increased, further demonstrating that hyperammonemia induces oxidative stress[84].

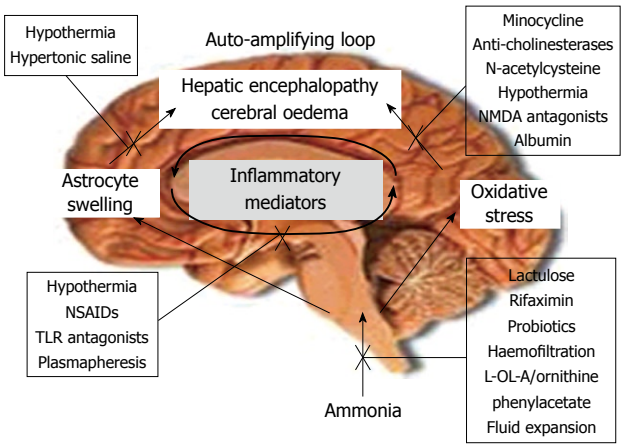

Figure 1 The "Two-hit" hypothesis. In a background of liver injury and hyperammonemia, a second "hit", such as an ammonia load following an upper gastrointestinal bleed, systemic inflammation/infection, or the development of hyponatremia can drive further astrocyte swelling, oxidative stress and lead to a rapid deterioration in neurocognitive function. The close relationship between astrocyte swelling and oxidative stress leads to an "auto-amplifying signalling loop". The sites of action of potential therapies are indicated on the Figure. L-OL-A: L-ornithine L aspartate; NMDA: N-methyl D-aspartate; NSAID: Non-steroidal anti-inflammatory; TLR: Toll-like receptor.

N-methyl D-aspartate (NMDA) receptors play a key role in the production of free radicals and an NMDA antagonist can prevent the calcium-mediated increase in oxidative stress[85]. *In vivo* excessive ammonia-induced NMDA receptor activation reduces antioxidant enzyme activity and results in increased production of superoxide anions[86]. It is, however, extremely difficult to differentiate whether it is oxidative stress that influences astrocyte swelling or whether astrocyte swelling itself induces oxidative stress through NMDA receptor and calcium-dependent mechanisms[87]. Either way, whether one considers that "the chicken came before the egg or vice versa", it would imply that the close relationship between astrocyte swelling and oxidative stress leads to an "auto-amplifying signalling loop" which promotes the development of HE[88] (Figure 1).

The production of reactive oxygen species (ROS) can arise in a number of different ways. Aside from ROS arising from neutrophil activation[80] and local and systemic inflammation/infection, ammonia and hypo-osmotic swelling-induced nitric oxide synthesis, the activation of NADPH oxidase[89], and mitochondrial glutamine uptake all generate ROS[90-92]. From these data we can propose a "two-hit hypothesis" in the pathogenesis of HE. Liver dysfunction leads invariably to hyperammonemia, which leads to astrocyte swelling, and in the longer term, structural changes to astrocytes (Alzheimer's type II astrocytosis). After this initial "hit", a second "hit", such as an ammonia load following an upper gastrointestinal bleed, systemic inflammation/infection, or the development of hyponatremia in a patient with cirrhosis can drive further astrocyte swelling, oxidative stress, and lead to a rapid deterioration in neuropsychological function (Figure 1 and Table 3).

Table 3 Factors precipitating hepatic encephalopathy[2]

Precipitating factors	Ammonia load e.g. upper gastrointestinal bleed or portocaval shunt
	Inflammation/oxidative stress
	Infection
	Dehydration
	Hyponatremia
	Sedative drugs e.g. benzodiazepines

Uptake of ammonia by astrocytes leads to the production of glutamine through the action of glutamine synthetase. Glutamine exposure in cultured astrocytes increases oxidative stress[91]. Mitochondrial glutamine uptake and subsequent cleavage of glutamine by phosphate-activated glutaminase elevates mitochondrial ammonia, which stimulates ROS production *via* induction of the mitochondrial permeability transition (MPT)[93]. However, cultured astrocytes exposed to ammonia produce ROS and begin swelling almost immediately, whereas MPT induction and glutamine accumulation occur thereafter.

Although astrocytes are relatively resistant to oxidative and nitrosative stress, neighbouring neurones are vulnerable to free radical attack. This can compromise brain energy metabolism and neurotransmission in patients with HE. Furthermore, ammonia, TNF-α, benzodiazepines, and hyponatremia can all trigger nitric oxide-dependent mobilisation of zinc which can augment GABAergic neurotransmission[94].

The mechanism through which free radical production is increased is currently not fully understood. One suggestion is based on findings that link an increase in calcium release to hyperammonemia. Rose *et al*[95] exposed cultured mice astrocytes to ammonium chloride. They observed a transient increase in the concentration of calcium ions from intracellular stores. The use of a calcium chelator (BAPTA) prevented the ammonia-induced production of free radicals[25]. Another possibility is that ROS are produced through activation of NMDA receptors[96].

One other area of research interest involves oxidation of RNA. It has been shown that in patients with Alzheimer's disease, there is significant RNA oxidation, which might result in impairments in protein synthesis and, consequently, cognitive function in patients[97]. Görg *et al*[98] reported the effects on cultured rat astrocytes and rat brain *in vivo* of ammonia exposure. Ammonia exposure was associated with a rapid, reversible oxidation of RNA (thought to involve NMDA receptor activation and calcium release). Consistent with this theory is the fact that some substrates required for learning and memory require protein synthesis[96]. Disruption of this protein synthesis *via* RNA oxidation might therefore interfere with cognitive function.

THERAPEUTIC STRATEGIES IN HE

To date, most therapeutic strategies in HE have been focused on lowering arterial concentrations of ammonia

and modulating inter-organ ammonia metabolism, but these remain largely ineffective. Treatments based on the hypothesis that the colon is the primary organ responsible for the generation of ammonia have ranged from dietary protein restriction, to the use of non-absorbable disaccharides, non-absorbable antibiotics, and colectomy[99]. However, Córdoba *et al*[100] showed that diets with normal protein content can be administered safely to patients with cirrhosis with episodic HE and that protein restriction does not have any beneficial effect for cirrhotic patients during an episode of HE and indeed, might even be detrimental in a patient with an underlying catabolic state.

It has been demonstrated that lactulose administered to patients with minimal HE in an unblinded open label study[101] might be of benefit and another open label randomised placebo controlled study in patients with a previous history of overt HE suggested that lactulose might delay the onset of a recurrent episode of HE[102]. However, in a recently published systematic review[103], which had very few high quality studies to base its findings on, lactulose was not found to have any impact on mortality in patients with cirrhosis presenting acutely with overt HE.

The use of non-absorbable antibiotics had been largely abandoned after concern that long-term administration of neomycin might lead to problems with nephrotoxicity and ototoxicity, and with metronidazole might lead to peripheral neuropathy. However, support for this strategy has been recently reinvigorated with the publication of the largest double blind placebo controlled study (n = 299) by Bass *et al*[104], which compared rifaximin (which has no known long term toxicity) favourably with placebo for the secondary prophylaxis of HE.

Benzodiazepine antagonists such as flumazenil also emerged as a potential therapy for HE patients. An analysis of six randomised controlled trials showed that 27% patients treated with flumazenil showed a clinical improvement, whilst 19% of treated patients showed an electroencephalographic improvement[105].

In the sickest cohorts, direct ammonia removal by hemofiltration in the intensive care unit is effective, but unfortunately by this stage multiorgan dysfunction and bacteremia might have superseded. Likewise, albumin dialysis in patients with acute-on-chronic liver failure improves HE grade[106], but the improvement is independent of changes in ammonia or cytokines[107] and remains controversial[108].

To address the issue of inter-organ ammonia metabolism, recent studies in patients with cirrhosis have shown that other than the gut, kidneys and muscle might be important targets[99]. Volume expansion produces significant increases in renal ammonia excretion resulting in a reduction in plasma ammonia concentration. This was shown to improve mental state, supporting the notion that the kidneys can be manipulated favourably[109]. During the hyperammonemic state, muscle detoxifies ammonia through conversion to glutamine[110,111]. L-ornithine L-aspartate (LOLA), which is a mixture of two amino acids, provides intermediates that increase glutamate availability for synthesis of glutamine and illustrates the concept that muscle can detoxify ammonia. Administration to animals with acute liver failure resulted in reduced brain water[112], but a recent study in patients with acute liver failure did not have any impact on brain dysfunction or survival[113]. When given to patients with cirrhosis and HE, administration of LOLA resulted in an improvement in HE compared with placebo-treated controls[114], although a recent meta-analysis concluded that it had little effect in patients with minimal HE[115]. Jalan *et al*[116] have hypothesised that this inefficacy might result from an accumulation of glutamine resulting in a rebound rise in circulating ammonia. By utilising a strategy which enables the excretion of glutamine, Davies *et al*[117] have demonstrated a synergy between L-ornithine and phenylacetate in reducing arterial ammonia in BDL rats.

However, in this review we have already convincingly demonstrated that ammonia, although central in the development of HE, is not solely responsible for its development. Infection/inflammation and oxidative stress are key determinants and indeed act synergistically with ammonia. Although ammonia could potentially be responsible for the development of neutrophil dysfunction, a patient with cirrhosis presents independently as a model of chronic endotoxemia that has direct implications on the innate and adaptive immune systems. We must therefore also look to therapies that directly or indirectly target the proinflammatory milieu.

Potential therapeutic strategies might include NMDA antagonists[84], leukodepletion[118], antagonism of pro-inflammatory cytokines[119], antioxidants [N-acetylcysteine (NAC)[120] and albumin[107,121]], anti-inflammatories (COX inhibitors[67] and minocycline[122,123]), probiotics[124] and hypothermia[125]. Excitement surrounds the prospect of small molecules that modulate toll-like receptor (TLR)-4 signalling, which can potentially down regulate neutrophil activation and other cellular responses. Early data indicate that TLR-4 antagonists can reduce LPS-stimulated cytokine release in healthy volunteers and results from phase 3 clinical trials are awaited. Inhibition of TLR-2, 4, and 9 prevented the increase in neutrophil oxidative burst induced from plasma from patients with alcoholic hepatitis. Furthermore, albumin, an endotoxin scavenger, prevented the deleterious effect of patients' plasma on neutrophil phagocytosis, spontaneous oxidative burst, and TLR expression[121]. This might also explain the beneficial role of albumin dialysis on HE[107,126].

When administered early after an overdose of acetaminophen, intravenous NAC prevents hepatic necrosis by replenishing stores of glutathione[127]. In patients with acute liver failure secondary to an overdose of acetaminophen, and in patients with acute liver failure secondary to other causes, NAC has been shown to increase oxygen delivery and consumption associated with increases in mean arterial pressure, cardiac index[128], and cerebral perfusion pressure[120]. These beneficial hemodynamic effects have been shown to be mediated by enhanced activity of the nitric oxide/soluble cGMP system[129] and suggest that NAC could have a beneficial role in the treatment of patients with cirrhosis who have developed overt HE.

As the role of central pro-inflammatory mechanisms are believed to be important in the pathogenesis of HE, then another novel therapeutic candidate drug to be considered is minocycline, which has been shown in two very recent studies by Jiang *et al*[122,123] to have anti-inflammatory effects in rats with acute liver failure. Minocyline treatment prevented both microglial activation [CD11b/c (OX-42) expression on immunohistochemistry] as well as the upregulation of IL-1β, IL-6, TNF-α, heme-oxygenase-1, eNOS, iNOS mRNA and protein expression with a concomitant attenuation of the progression of HE and brain edema, and at least in part, by reduction of oxidative/nitrosative stress. Thus, minocycline might also have promise in patients with acute and chronic liver failure cirrhosis and HE, and could be taken forward into randomised placebo controlled trials.

Modulation of intestinal microbiota is an emerging strategy to reduce the bacterial translocation of LPS and other bacterial activators of TLRs. Probiotics have been shown to reduce bacterial translocation and were shown to improve liver function and prevent the development of infection and HE in patients with cirrhosis[124]. Furthermore, probiotics have been shown to restore neutrophil phagocytic capacity in patients with alcoholic cirrhosis, possibly by reducing endogenous levels of IL-10 and TLR-4 expression[130].

Recent studies show that hypothermia is efficacious in patients with uncontrolled intracranial hypertension that are undergoing liver transplantation[56,125]. Hypothermia displays many beneficial effects on brain water and intracranial hypertension relating to decreased brain ammonia, cerebral blood flow, mediators of inflammation, and oxidative stress[131]. The sites of action of potential therapies for HE is shown in Figure 1.

CONCLUSION

HE is a dynamic neuropsychological spectral disorder that develops after liver injury. The pathophysiological mechanisms behind the development of HE are still not fully understood, but ammonia and the downstream consequences of ammonia uptake by astrocytes remain fundamental to the process. Ammonia not only leads to astrocyte swelling, but also alters neurotransmission, mitochondrial function, and induces oxidative stress. Astrocyte swelling and oxidative stress are closely related and result in "an auto-amplifying" loop. The presence of local and systemic inflammation and the release of ROS further exacerbate the cerebral effects of ammonia. Anti-inflammatory and anti-oxidative strategies may abrogate these effects and offer real treatment options to patients with HE in the future.

Abstract

Gastric carcinoma is one of the most frequent malignancies in the world and its clinical behavior especially depends on the metastatic potential of the tumor. In particular, lymphatic metastasis is one of the main predictors of tumor recurrence and survival, and current pathological staging systems reflect the concept that lymphatic spread is the most relevant prognostic factor in patients undergoing curative resection. This is compounded by the observation that two-thirds of gastric cancer in the Western world presents at an advanced stage, with lymph node metastasis at diagnosis. All current therapeutic efforts in gastric cancer are directed toward individualization of therapeutic protocols, tailoring the extent of resection and the administration of preoperative and postoperative treatment. The goals of all these strategies are to improve prognosis towards the achievement of a curative resection (R0 resection) with minimal morbidity and mortality, and better postoperative quality of life.

Key words: Gastric cancer; R0 resection; Total gastrectomy; Lymph node dissection; Adjuvant therapy; Preoperative therapy

INTRODUCTION

Despite an incidence rate that has steadily declined over the past few decades, gastric carcinoma is one of the most frequent malignancies worldwide. An estimated 934 000 new cases are diagnosed each year, with the highest incidence rate in Northeast Asia, intermediate incidence rates in Europe and South America, and the lowest incidence rates in North America, Africa, South Asia, and Oceania[1,2].

Early dissemination of the disease through the lymphatic system, blood, and peritoneum has limited optimal surgery as a cure, except in patients with early-stage cancers. In Japan and Korea, the introduction of screening for gastric cancer has been shown to improve early detection, and almost half of newly diagnosed patients are detected at an early stage[3-6]. Due to the lower disease incidence rate, this strategy has not been deemed cost-

effective in Europe or North America. Consequently, two-thirds of gastric cancers in the Western world present at an advanced stage, with lymph node metastasis at the time of diagnosis[7].

The mainstay of treatment is radical surgery, but even with optimal surgical resection, the prognosis remains dismal in Western countries. Numerous attempts have been undertaken to improve clinical outcomes. To date, most therapeutic efforts are directed toward an individualization of therapeutic protocols, tailoring the extent of surgery and integrating it with the administration of preoperative and/or postoperative treatment. The goal of such strategies is to improve prognosis towards the achievement of a curative resection with minimal morbidity and mortality and better postoperative quality of life.

R0 RESECTION: DEFINITIONS

Curative resection refers to the absence of tumor after surgical treatment, and in the Western world, it meets the R0 resection definition provided by Hermanek *et al*[8] more than 15 years ago. R0 resection indicates a microscopically margin-negative resection, in which no gross or microscopic tumor remains in the primary tumor bed. R1 resection indicates the removal of all macroscopic disease, but microscopic margins are positive for tumor. R2 indicates gross residual disease with gross residual tumor that was not resected (primary tumor, regional nodes, and macroscopic margin involvement).

If this definition holds, R0 resection should represent a surgical cure, with a high survival rate and low recurrence. Considering the low survival rate after R0 surgical treatment in the Western case-mix, it is clear that the R0 definition needs to be revised, especially in locally advanced cases[9-11]. It is likely that there is a tendency to misclassify a number of cases as R0 resection, which inexorably will recur, which suggests that a curative treatment was not actually achieved.

The reason that the definition of Hermaneck is not in accordance with this scenario may be because it is mainly concerned with the primary tumor site, and not examining in detail the three pathways of tumor dissemination: portal blood stream to the liver, peritoneal surfaces and lymphatic dissemination. With these methods of dissemination, it is often beyond the surgeon's ability to achieve loco-regional control of the cancer. It may be difficult or impossible for the surgeon to reduce the incidence of metastases to the liver, as well as to contain the peritoneal seeding of cancer cells, or the removal of all extra-regional metastatic lymph nodes.

In the eastern world, Japanese guidelines have given a different definition to the curative gastric resection based on both surgical and histopathological details[12]. Resection A: no residual disease, with a high cure probability. It implies resections satisfying all of the following conditions: tumor without serosal invasion; N0 treated by D1, D2, or D3 lymph node dissections, or tumor with first-level lymph node treated by D2 or D3 resection; no distant, peritoneal or liver metastases, negative cytological examination of peritoneal fluid and proximal and distal margins > 10 mm. Resection B: no histopathologic residual disease but not fulfilling criteria for resection A. Resection C: definite residual disease.

These strict criteria emphasize that once the tumor penetrates the serosa or invades adjacent organs, it begins to spread by routes other than the regional lymphatic system. Specifically, tumor metastasis can occur through the peritoneum, extra-regional lymph nodes and the portal-hepatic blood, which consequently diminishes the probability of a cure. Such a definition would imply that more than two-thirds of patients are considered non-curatively treated by surgery in the Western world, which underestimates the role of surgery at these stages.

Today, both definitions seem inadequate: they merely indicate the absence or presence of residual tumor cells in the tumor bed after surgical treatments or provide an estimation of the probability of cure with surgery. In reality, the surgeons must consider themselves responsible not only for resection of the large mass of the primary cancer and overt lymph node metastases in the tumor bed, but also for dealing with microscopic and distant residual disease.

R0 RESECTION AND PREOPERATIVE IMAGING: WHAT CAN WE ANTICIPATE?

Although surgical pathology provides the most accurate information on tumor extent, clinical preoperative staging is crucial to select the appropriate treatment strategy. Today, clinical staging has been improved by technical enhancement in endoscopic ultrasound (EUS), computed tomography (CT), positron emission tomography (PET), combined PET-CT scan, magnetic resonance imaging (MRI) and laparoscopic staging. Presently, EUS and CT are widely used for preoperative staging[13].

Although the accuracy of T staging has been much improved for EUS (current range: 78%-92%)[14-20] and CT (current range: 69%-89%)[17,21-27], N staging accuracy is still poor (63%-78% in EUS[14-20], 51%-78% in CT[17,21-27]). MRI has had limited use in the staging of gastric cancer, primarily as a result of difficulties with motion artifacts, cost, time required for examination, and lack of an appropriate oral contrast agent[28,29]. However, in recent studies, overall T staging accuracy has been reported to be between 71.4% and 82%, which is similar to CT[29]. In N staging, several studies have shown that the accuracy of MRI nodal staging is inferior to CT staging with both techniques tending to understage nodal status[28,29]. Moreover, MRI has showed a greater sensitivity than CT in detecting liver, bone, and peritoneal dissemination[29].

Generally, PET is not routinely performed in the clinical staging of gastric cancer. From clinical studies focusing on PET, it is concluded that, for N staging, PET has a significantly higher specificity (92%) but lower sensibility (56%) compared to CT in the detection of local lymph node involvement[30-32]. Recent reports have confirmed the limited role of PET in the preoperative staging of gastric cancer, but it must be pointed out

that combined PET-CT can significantly improve overall staging accuracy compared to PET and CT alone[33,34].

Due to the inaccuracy of CT for the detection of ≤ 5 mm macrometastases on the peritoneal surface or liver, staging laparoscopy is recommended as the next step in the evaluation of patients with locoregional disease. Staging laparoscopy can detect metastatic disease or modified preoperative therapeutic strategy in 23%-54% of patients, thus confirming its crucial role in staging gastric carcinoma[35-37]. Moreover, there is some evidence that laparoscopy permits a more accurate staging of extraserosal tumors, whereas EUS might sometimes lead to misinterpretation of T3 invasion, when edema distorts the interface between the stomach and adjacent tissues[18,38,39].

In addition, staging laparoscopy facilitates cytological examination of abdominal lavage fluid. Cytology of peritoneal fluid or lavage may reveal the presence of free intraperitoneal gastric cancer cells, which identifies patients with an otherwise occult microscopic carcinomatosis. Recent evidence has suggested that patients with positive findings on peritoneal cytology have a poor prognosis, similar to that of patients with macroscopic stage Ⅳ disease[40].

SURGICAL DEBATES OF R0 RESECTION

R0 resection: Total vs subtotal gastrectomy, what else?

Some issues about the extent of gastric resection seem to have been settled. Total gastrectomy should be avoided if adequate free resection margins can be obtained with subtotal gastrectomy: a gross surgical margin of at least 5 cm for the intestinal type or 8-10 cm for the diffuse type[41-44]. Many authors agree on the necessity of total gastrectomy if the cancer encroaches on an imaginary line between the angula incisura of the lesser curvature and the "bare" area on the greater curvature between the gastroepiploic vessels and the short gastric vessels[44]. This is because the lymph drainage from such a tumor feeds into the splenic hilum and flows along the splenic artery, as well as passing proximally and distally.

Proximal tumors and tumors of the gastroesophageal junction (GEJ) deserve different considerations. These tumors are traditionally classified according to the Siewert classification system, which takes into account the center of the tumor and the variable involvement of the esophagus and stomach: type Ⅰ, esophageal adenocarcinoma of the distal esophagus, with the center located between 1 and 5 cm above the GEJ; type Ⅱ, true adenocarcinoma of the cardia located within 1 cm above and 2 cm below the GEJ; and type Ⅲ, subcardial adenocarcinoma located between 2 and 5 cm below the GEJ. Surgical treatment of these tumors usually requires an extended total gastrectomy with resection of variable portions of the distal esophagus. The extent of resection of the distal esophagus depends on the extent of the tumor spread[45].

Generally, patients with type Ⅰ tumors are best treated by esophagectomy with gastric pull-up to the neck or by esophagogastrectomy (transthoracic or transhiatal). Type Ⅱ and Ⅲ tumors can be resected by gastrectomy with frozen-section-guided resection of the distal esophagus (transhiatally extended gastrectomy)[46]. Although total gastrectomy has been the procedure of choice in these tumors, some authors have advocated proximal gastrectomy as a surgical option, and in a retrospective study conducted by the Memorial Sloan Kettering Cancer Center, proximal gastrectomy has been reported to have similar mortality rate, hospital stay, and recurrence and survival rates[47]. Even if the R0 resection rate does not differ between groups, other authors have reported poor functional and quality of life results in patients undergoing proximal resection[48-50]. Although it is difficult to make definitive conclusions in the absence of a prospective randomized trial, it does appear that total gastrectomy remains the procedure of choice in these patients.

R0 resection: The "circumferential/lateral" margin

The progression of the cancer through the stomach wall to the adjacent structures makes one aware of the concept of circumferential/lateral margins and provides the rationale for conservative and extended surgery.

If diagnosed at an early stage, it may be possible to obtain a margin-negative resection without traditional gastrectomy (subtotal, proximal or total gastrectomy). When margin-free resection is warranted, the only limiting factor is the risk of lymph node metastasis. For patients with a well- to moderately well-differentiated tumor of less than 2 cm in size, with no submucosal invasion or lymphangioinvasion, local excision by endoscopic mucosal resection (EMR) has been the preferred treatment in Japan for the past 15 years, since the risk of lymph node metastases is thought to be very low[51].

Although a prospective randomized trial is lacking in the literature, results of a systematic review of cohort studies have shown that EMR has favorable disease-specific survival, incidence of local recurrence and complications, compared with surgery[52,53]. Endoscopic submucosal dissection (ESD) is a newly developed technique that can remove large tumors in one piece. In a comparison with EMR, resection that removes tumors in one piece was more frequent in an ESD group and resulted in a better 3-year recurrence-free rate, despite a higher complication rate[54,55].

Currently, indications for ESD, according to Japanese guidelines, are only for well-differentiated intramucosal (T1a) tumors. However, a large-scale study analyzing lymph node metastasis of early cancer has expanded the criteria for endoscopic treatment of early gastric cancer, which is based on tumor characteristics with a very low risk of lymph node metastasis[56]. This study showed that patients with intramucosally or submucosally well-differentiated tumors of less than 3 cm and poorly intramucosally differentiated tumors of less than 2 cm have a very low risk of lymph node metastasis.

The results of both the United Kingdom Medical Research Council and the Dutch trials, along with more recently randomized controlled trials, large retrospective series and meta-analysis[57-63] have reported a significantly worse prognosis, higher mortality, higher complication

rate, and longer hospital stay in patients who have undergone gastrectomy with prophylactic splenectomy or pancreaticosplenectomy.

Theoretically, in patients with T4 gastric adenocarcinoma, extended resection is required to improve the R0 resection rate. With careful patient selection, gastrectomy with additional organ resection can be done with acceptable morbidity and low mortality. Improvements in preoperative evaluation to confirm T3 and T4 disease are needed because postoperative histopathological examination has revealed that multi-organ resections are often performed for pT3 tumors, with a relatively small proportion of pT4 tumors[64,65]. Independent factors of a worse prognosis, such as N3 tumors and large diameter tumors (> 10 cm), have to be excluded before performing extended resection[66,67]. Based upon these issues, the cautious clinical behavior is to reconsider any clinically defined T4 tumor on a case by case basis before planning extended multi-organ resection.

R0-resection: When can the lymph node dissection be considered margin-negative?

The extent of lymphadenectomy continues to represent the main area for surgical research in gastric cancer, and the surgical strategy of choice is still a matter for debate. Lymphatic metastasis is one of the main predictors of tumor recurrence, and survival and current pathological staging systems reflect the concept that lymphatic spread is the most relevant prognostic factor in patients resected with curative intent[68-73]. Recurrence rates attributed to residual lymph node metastasis around the celiac artery have led to the concept that complete clearance of the metastatic lymph nodes by extended dissection (D2) may prolong survival. In Japan, where gastric cancer is far more common than in Western countries, a standardized lymph node dissection has been developed over the past 40 years and is used nationwide with therapeutic benefit and long-term survival rates of $\geqslant$ 60% after 5 years. Retrospective studies from Japan, and later from Korea[74], involving more than 10 000 patients, have suggested that extended lymph node dissection combined with gastrectomy increases 5-year survival rate from 50% to 62%, compared to a 5-year survival rate of 15%-30%, as a result of limited resections in the United States[75-79].

The importance of adequate lymph node dissection as part of a potentially curative resection has led to the development and publication of "The General Rules for the Gastric Cancer Study in Surgery and Pathology", which was definitively published in English in 1996[12]. Several Western reports have confirmed that extended lymphadenectomy, similar to that recommended in the General Rules, can be safely performed with improvements in survival[80-85].

In the Western world, the challenge has been to show whether these results could be generalized for unselected patients. To date, four prospective randomized trials of Japanese-defined D1 *vs* D2 lymph node dissection and two meta-analysis studies have been conducted[86-92].

All of these studies have documented limited survival benefits with unacceptable morbidity and mortality that is probably associated with pancreaticosplenectomy, low case volume, and a lack of specialist training[93,94]. Moreover, some authors have suggested that extended lymph node dissection combined with rigorous pathological evaluation results in improved staging rather than therapeutic benefit. Through accurate staging, patients with advanced stage cancer are well categorized, and any comparisons with series of non-standardized lymph node dissection, or under-staged patients, are therefore inaccurate. These results have made many Western surgeons reluctant to perform extended lymph node dissection routinely in an effort to obtain better regional disease control, and possibly, some survival advantage. Nevertheless, there is some evidence that extended lymph node dissection may offer a definite chance for a cure in a subset of patients with pN2 disease[88], even if these patients cannot be distinguished preoperatively.

At the same time, in the eastern World, where D2 lymph node dissection is not a matter of debate, the challenge has been to demonstrate that super-extended lymph node dissection offers a better chance of a cure in gastric cancer treated with curative intent. The Taipei single-institution study that has compared D1 and D3 dissection has demonstrated a significant overall survival benefit in extended lymph node dissection, but no significant improvements in disease-free survival or in per-protocol analysis[90]. Moreover, the study showed that the morbidity of extended lymphadenectomy, although not lethal, is substantial even in experienced hands[95]. Finally, a multi-institutional, randomized and controlled trial by the Japan Clinical Oncology Group (JCOG-9501) has failed to demonstrate a survival benefit when super-extended (D2 + para-aortic node) lymph node dissection was performed. Moreover, in this randomized trial, the rate of postoperative morbidity in patients with a body mass index of $\geqslant$ 25 kg/m^2 and age > 65 years was a notable concern[96].

Geographical differences notwithstanding, all of these results agree with Cady's paradigm "...the therapeutic effect of cancer surgery is akin to that of a drug with a threshold or plateau effect: dose response up to a certain plateau, and then no further therapeutic effect beyond this point, only more complications"[97].

From a practical point of view, it is hard to believe that unresected overt nodal metastases in the tumor bed will not worsen prognosis. Likewise, it is hard to believe that resection of more negative lymph nodes will improve it. Tailoring lymph node dissection on the basis of actual lymph node involvement could be a key point for performing appropriate lymph node dissection and avoiding high rates of postoperative morbidity.

In the late 1980s, Kampschöer *et al*[98] developed software that was designed to match cases with characteristics similar to a given case. With seven demographic and clinical inputs, all identifiable preoperatively or intraoperatively, the program was able to predict the statistical likelihood of nodal disease for each of the 16 main nodal stations around the stomach[98-100]. The so-called "Maruyama Index of Unresected Disease" (MI), when retrospectively

used, was able to quantify the adequacy of lymphadenectomy. Such a novel measure was defined as the sum of Maruyama Program predictions for lymph node stations (Japanese stations 1-12) left *in situ* by the surgeon[101,102]. In a large United States adjuvant chemoradiation study, MI proved to be a strong predictor of survival that was independent from the level of lymph node dissection[103]. Furthermore, a blinded retrospective analysis of Dutch D1 *vs* D2 trial data has suggested that low-MI surgery is associated with significantly increased survival, regardless of lymph node dissection[104]. The MI aims to define an R+ lymph node dissection, and it appears that surgeons might have a better impact on single patient survival by pursuing a low MI operation (low probability of lymph node metastases left *in situ*) instead of relying exclusively on D-level guidance.

When the probability of lymph node metastasis is considered low, sentinel node dissection can be considered as another approach to customize lymph node dissection[105-107]. The sentinel nodes are the first sites of lymph node metastasis from a primary tumor and theoretically predict the involvement of more distant lymph nodes. To date, selective sentinel node dissection, detectable using the injection of either dyes or radioactive tracers, represents a standard procedure for melanoma and breast cancer with low probability of lymph node metastasis. In early gastric cancer, the risk of lymph node metastases is 2%-5% for patients with mucosal cancer and 11%-20% for those with submucosal cancer[108]. Sentinel node mapping results in gastric cancer have been variable since the lymphatic drainage from the stomach is very complicated and multidirectional, with an incidence of skip metastasis ranging from 5% to 10%[109]. Moreover, early reports have demonstrated that the loco-regional lymph node station contains truly positive nodes, even when the sentinel biopsy is negative. These anatomical peculiarities have led to the concept of a "sentinel lymphatic basin"[110], which indicates the lymph node stations to which sentinel nodes belong. Dissection of these stations can provide an acceptable safety net for the clinical application of these procedures, and minimize the possibility of leaving metastasis behind. Preliminary studies have shown that these sentinel node techniques are an acceptable procedure for pathological T1 tumors with a diameter of < 40 mm, although long-term follow-up data are still required[111-114].

R0 RESECTION: IS IT MERELY A SURGICAL TARGET?

Along with these classical surgical topics, in the past 20 years, three different modalities of adjuvant (pre- and postoperative) therapy have been proven to be effective by large-scale randomized trials. These include postoperative chemoradiation therapy (Unites States INT-0116 trial)[115], postoperative single-drug chemotherapy (Japanese ACTS-GC trial)[116] and perioperative three-drug combination chemotherapy (European MAGIC trial)[117]. Since the publication of these trials, surgery alone is no longer considered the standard treatment for patients with resectable locally advanced forms of gastric cancer, and the concept of radical resection needs to take into account the fact that R0 resection is not an exclusively surgical target.

Postoperative therapy: Recovery of R0 resection

Many studies and several meta-analyses with a focus on adjuvant postoperative chemotherapy have been conducted[118-127]. Summarizing their results, we can state that there is insufficient evidence, at present, to recommend postoperative chemotherapy as standard adjuvant treatment in Western patients. At present, these results should be cautiously managed, since these studies included very different patient populations, surgical procedures, and non-standardized timing and regimens of adjuvant therapy that are now considered as outdated[128]. At the same time, results from pivotal studies on postoperative chemoradiotherapy are inconclusive and conflicting because of the relatively small number of patients recruited[129-133].

In the United States, between 1991 and 1998, a study from the SWOG-Intergroup 0116 trial randomly assigned 556 patients to surgery only and surgery plus postoperative chemoradiotherapy: 45 Gy radiotherapy at 1.8 Gy/d, given 5 d/wk for 5 wk, with modified doses of fluorouracil and leucovorin on the first 4 d and last 3 d of radiotherapy. Two 5-d cycles of fluorouracil and leucovorin were given after, and one cycle was given before chemoradiotherapy[115]. Although clinically significant toxicity was recorded after chemoradiotherapy, the overall and relapse-free survival results of the surgery-alone arm were significantly worse than those of the adjuvant chemoradiotherapy arm. Chemoradiotherapy significantly improved median survival from 27 to 36 mo. Distant relapse was the most common pattern of recurrence in the adjuvant group (33% *vs* 18%), whereas local recurrence was more common in the surgery-only group (29% *vs* 19%). In this trial, < 10% of patients received formal D2 dissection, whereas 54% underwent D0 dissection. A common interpretation of these results is that adjuvant therapy may be useful in high-risk patients treated with inadequate lymph node dissection, because, through radiotherapy, it can eliminate residual lymph node metastasis, which would have been removed by D2 resection. A Korean non-randomized study[134] recently has shown that chemoradiotherapy after Japanese D2 resection improves survival. Currently, promising results from a randomized study conducted by the same group (SMC-IRB 2004-08-10 trial) are anticipated[135].

In 2007, the most convincing evidence on the benefits of adjuvant therapy was reported by the Japanese ACTS-GC trial (Adjuvant Chemotherapy Trial of TS-1 for Gastric Cancer)[116]. In this trial, 1059 patients with stage Ⅱ or Ⅲ gastric cancer who had undergone curative D2 gastrectomy were randomized to observation or 1-year administration of oral S-1. The study was terminated at the first interim analysis due to a highly significant difference in survival that favored chemotherapy. The incidence rate of loco-regional, lymphatic and peritoneal relapse was significantly lower in the chemotherapy arm than in the surgery-alone arm, although the rate of distant metastases

did not differ between the two arms. This study reported a survival-associated advantage with adjuvant chemotherapy within the context of surgery performed according to Japanese standards.

New ongoing trials investigating adjuvant therapy (CLASSIC trial, SMC-IRB 2004-08-10, CALGB-80101) are expected to show the true efficacy and survival benefits in the near future[135-137].

In the past 30 years, Japanese and Korean researchers have performed a number of trials that have investigated the use of immunochemotherapy as adjuvant treatment after curative resection of gastric cancer. A variety of immunotherapeutic agents, such as protein-bound polysaccharide (polysaccharide K extracted from mycelia of *Coriolus versicolor*; PSK)[138,139], *Streptococcus pyogenes* preparation (OK-432)[140,141], polysaccharide sizofiran[142], *Nocardia rubra* cell wall skeleton[143], Bacillus Calmette-Guerin (BCG)[144] and polyadenylic-polyuridylic acid[145] have been used in addition to chemotherapy.

Results from randomized trials that have compared adjuvant chemo-immunotherapy with surgery alone or with other chemotherapeutic schedules have been contradictory because of a lack of robust evidence in clinical practice[146]. However, interesting results have been derived from two recent meta-analyses about OK-432 and PSK[147,148].

The benefit of combined adjuvant chemotherapy and immunotherapy with OK-432 (a lyophilized preparation of a low virulence group A *S. pyogenes*), in patients with curatively resected gastric cancer was assessed by Sakamoto *et al*[147] in a meta-analysis of data derived from 1522 patients enrolled in six randomized clinical trials. In these trials, adjuvant chemotherapy, usually consisting of induction with mitomycin C plus long-term oral fluordinated pyrimidines, was compared with the same chemotherapy plus OK-432. The 3-year survival rate for all eligible patients in the six trials was 67.5% in the chemo-immunotherapy group *vs* 62.6% in the chemotherapy-only group. The 3-year overall survival odds ratio was 0.81 (95% CI: 0.65-0.99). The beneficial treatment effect was shown to be statistically significant ($P < 0.044$). The results of this meta-analysis were interpreted by the authors to suggest that chemo-immunotherapy after surgery with OK-432 can improve the survival of patients with successfully resected gastric cancer.

The effect of adjuvant immunochemotherapy with PSK after curative resection of gastric cancer by means of a meta-analysis of eight randomized trials has been assessed by Oba *et al*[148]. In this analysis, the estimated overall HR was 0.88 (95% CI: 0.79-0.98, $P = 0.018$) with no significant heterogeneity between the treatment effects observed in different studies. The authors have concluded that the addition of PSK to standard chemotherapy offers significant advantages in survival over chemotherapy alone for patients with curative resections of gastric cancer.

Also for postoperative chemo-immunotherapy, there is a necessity for clear evidence in future studies; particularly, the clinical use of immunostimulating factors should be tested in large randomized trials.

Pre-/perioperative therapy: Induction of R0 resection

The rationale for preoperative therapy is based on several theoretical assumptions. Preoperative antiblastic therapy might reduce the risk of proliferation and allow for *in vivo* chemosensitivity tests, thus facilitating the choice of the most appropriate postoperative regimen. Furthermore, the preoperative approach has two distinct advantages: increased compliance due to an undoubtedly better performance status in patients who are not burdened with surgical complications, nutritional impairment, or damaged vascularization of the tumor bed. The twofold goal of eliminating hidden micrometastases along with tumor down-staging might increase the probability of a truly curative complete resection with delayed surgery.

Investigation of the efficacy and possible uses of chemotherapy in patients with advanced gastric cancer began in the late 1970s[149-151]. Encouraging results, however, were not reported until the early 1990s, when two independent studies in patients with non-resectable disease found that chemotherapy led to subsequent resection in 40%-50% of patients, with an increase in total median survival of 18 mo, compared with unresected patients[152,153]. These preliminary observations encouraged the introduction of preoperative chemotherapy protocols for potentially resectable, locally advanced gastric cancer (Table 1)[117,154-166]. However, the results of these first trials are questionable, mainly because of their methodological limitations. By following an inaccurate preoperative staging process, several authors have recruited patients on non-homogeneous criteria, commonly recruiting patients with locally advanced gastric cancer and others with disease of unclear stages, without a fixed distinction between resectable and non-resectable tumors. In addition to non-homogeneous methods of recruitment, other sources of bias in early trials included the use of different chemotherapeutic regimens, non-standardized surgery or surgery of questionable quality, and missing or poorly detailed response criteria.

In 1993, the Dutch Gastric Cancer Group started the first randomized controlled trial of exclusively preoperative chemotherapy for gastric cancer (cardia tumors were excluded)[161]. The regimen used was FAMTX (fluorouracil, doxorubicin, and methotrexate), which was, at that time, the gold standard of treatment for adenocarcinoma of the stomach. This trial had many accrual problems and was prematurely stopped after an interim analysis showed that FAMTX was unlikely to achieve the goal of a 15% increase in curative resectability after preoperative chemotherapy. Several biases have been outlined for this study, particularly the inaccuracy of the staging procedure with optional use of CT and laparoscopy, and inadequate extension of lymphadenectomy. The investigators reported a high rate of tumor progression during treatment (36%) along with a reduction in curative resections (56% *vs* 62%) and a decreased median survival (18 mo *vs* 30 mo), compared with untreated patients. Even if all of the statistical differences in this study were insignificant, both the short-term and long-term results were discouraging[161,167].

Since the late 1990s, ambitious European phase Ⅲ

Table 1 Trials of preoperative chemotherapy in gastric cancer

[1]The "R0" resection rate was calculated only among resection procedures. Pts: Number of patients recruited R0, curative (R0) resections; CR: Complete response; GEJ: Gastroesophageal junction; EFP: Etoposide, fluorouracil, and cisplatin; FPL: Fluorouracil, cisplatin, and leucovorin; IP: Intraperitoneal; FUDR: 5-fluoro-2'-deoxyuridine; RCT: Randomized controlled trial; EAP: Etoposide, doxorubicin, and cisplatin; FP: Fluorouracil and cisplatin; FAMTX: Fluorouracil, doxorubicin, and methotrexate; F: Fluorouracil; NS: Not stated; EEP: Etoposide, epirubicin and cisplatin; ECF: Epirubicin, cisplatin, and fluorouracil.

trials have been designed to provide a definitive demonstration of the efficacy of preoperative treatments. The adoption of strict selection criteria made the selection of patients so difficult that some studies were stopped prematurely (EORTC 40954 and SWS-SAKK-43/99 trials)[165,168]. Only the MAGIC trial (started in the United Kingdom in 1994) and the FFCD 9703 trial (started in France in 1996) have been completed[117,164]. These two studies have yielded substantial evidence supporting the efficacy of perioperative chemotherapy for an increased survival rate (36% *vs* 23%, estimated at 5 years for MAGIC, 38% *vs* 24% estimated at 5 years for FFCD 9703, Table 1), along with a significantly higher curative resection rate in the treated group *vs* the surgery-alone group (79% *vs* 70%, $P = 0.03$ for MAGIC, 84% *vs* 73% in arm 2, $P = 0.04$ for FFCD 9703) without an increase in perioperative morbidity or mortality.

The possible increase in the actual R0-resection rate has been an important goal of preoperative chemotherapy. In a phase Ⅱ study of a perioperative chemotherapy protocol, the achievement of R0 resection in response to preoperative chemotherapy was shown to be the most significant prognostic indicator by univariate and multivariate analysis. Furthermore, R0 resection was the only independent variable in determining the probability of long-term survival in locally advanced gastric carcinoma. The overall survival for all curatively resected patients is higher when compared to historical series treated with surgery alone for locally advanced gastric cancer[163,169].

Based on the results of the SWOG 9008/INT-0116 trial[115], the integration of chemotherapy with radiation applied in the preoperative phase has gained much interest. Some benefits of preoperative radiotherapy for gastric cancer have been reported by a pivotal randomized single-center Chinese study by Zhang *et al*[170]. This study recruited 317 patients with adenocarcinoma of the cardia that were randomly assigned to radiotherapy followed by surgery, or surgery alone. This study indicated a significant 5-year survival benefit for patients treated with neoadjuvant radiotherapy as compared with surgery alone (30.1% *vs* 19.8%, respectively), with an improved rate of complete curative resection after radiotherapy (80% *vs* 62%). Recently, published phase Ⅱ studies have verified the efficacy of chemoradiotherapy in terms of complete pathological response (up to 30% in some series) and increased long-term survival without an increase in morbidity or mortality[171-174].

All of the above results suggest that R0 resection is not an exclusive surgical target in locally advanced gastric cancer, but that it can be facilitated or achieved by preoperative therapy (induction of R0 resection).

Many answers are expected from ongoing trials exploring ways of improving preoperative treatment strategies for resectable gastric cancer: the MAGIC B trial (United Kingdom National Cancer Research Institute ST03 trial) of perioperative epirubicin, cisplatin, and capecitabine, with or without the endothelial growth factor antibody, bevacizumab[175]; the CRITICS trial (Chemo-Radiotherapy after Induction chemoTherapy In Cancer of the Stomach), a phase Ⅲ study that is randomizing between preoperative chemotherapy (three courses of epirubicin/cisplatin/capecitabine) and gastric surgery with

limited lymph node dissection followed by postoperative chemotherapy (another three courses of epirubicin/cisplatin/capecitabine) or chemoradiotherapy[176]; and the JCOG trial 0501 (Japan Clinical Oncology Group Study 0501 trial) and KYUH-UHA-GC04-03 Kyoto trial, which are testing preoperative oral fluoropyrimidine S-1 together with cisplatin *vs* postoperative oral fluoropyrimidine S-1[177].

CONCLUSION

In gastric cancer, radical resection (R0 resection) offers the best chance for a cure because it is defined as the complete surgical removal of any residual cancer cells in the tumor bed. However, distant and loco-regional failure rates in most radically resected patients with positive lymph nodes or involvement of the serosa contradict this statement.

All current therapeutic efforts in resectable gastric cancer are directed toward the individualization of therapeutic protocols, which tailors the extent of resection and the administration of pre- and postoperative treatment. A paradigm shift has rapidly advanced in the past 10 years: three pivotal studies in three different areas of the world (United States, Europe and Japan) have demonstrated that multimodal treatments improve the prognosis for patients with resectable gastric cancer. The common target of all of these strategies is to improve prognosis towards the achievement of a true curative resection (R0 resection) with minimal morbidity and mortality.

In gastric cancer, surgical research has always proceeded slowly, and standardization is still far from being settled. Geographical differences in epidemiology and treatment approaches and a lack of surgical gold standards have diverted attention from the pursuit of a multimodal approach. In other solid neoplasms worldwide, the multimodal approach has already been validated. In the near future, we expect the same to occur for gastric cancer, provided that the published evidence that is needed to reach this goal is further improved and developed. The result of treatment for locally advanced gastric cancer is the sum of the effect of local tumor control by surgery, with or without radiotherapy and/or systemic chemotherapy. The role of each treatment modality varies according to the stage of the disease, individual patient risk, surgical volume, available chemotherapy regimens and quality of radiotherapy. Evidence of the effect of different combinations of treatments should be established for each clinical circumstance, and surgeons should play a key role in this.

Abstract

AIM: To investigate the effect of extracted soybean saponins on the growth of human colon cancer cells.

METHODS: WiDr human colon cancer cells were treated with 150, 300, 600 or 1200 ppm of soy saponin to determine the effect on cell growth, cell morphology, alkaline phosphatase (AP) and protein kinase C (PKC) activities, and P53 protein, c-Fos and c-Jun gene expression.

RESULTS: Soy saponin decreased the number of viable cells in a dose-dependent manner and suppressed 12-O-tetradecanol-phorbol-13-acetate-stimulated PKC activity ($P < 0.05$). Cells treated with saponins developed cytoplasmic vesicles and the cell membrane became rougher and more irregular in a dose-dependent manner, and eventually disassembled. At 600 and 1200 ppm, the activity of AP was increased ($P < 0.05$). However, the apoptosis markers such as c-Jun and c-Fos were not significantly affected by saponin.

CONCLUSION: Soy saponin may be effective in preventing colon cancer by affecting cell morphology, cell proliferation enzymes, and cell growth.

Key words: Soy saponin; Colon cancer; Apoptosis; Cell proliferation; Cell differentiation

INTRODUCTION

Colon cancer is one of the major causes of cancer mortality worldwide, which results from interactions of different factors such as aging, family history and dietary style. It has been suggested that consumption of higher levels of soy foods can lead to a lower incidence of acquiring colon cancer[1,2]. The most discussed compounds related to colon cancer in soy are isoflavone and saponins[3]. Saponins have been found to have biological benefits and have been utilized pharmaceutically[4]. Soy saponins are amphiphilic compounds and categorized as triterpenoic saponins. They are able to interact with the cancer cell membranes that are rich in phospholipids and cholesterol and with the hydroxyl groups on the aglycone moiety[5]. Research has found that steroid saponins extracted from fenugreek reduce the number of aberrant crypt foci in azoxytethane-induced rat colon cancer, and induce apoptosis of HT-29 human colon cancer cells[6]. However, whether soy saponins affect the growth of cancer cells by causing apoptosis or necrosis is still not clear.

In this study, we investigated the *in vitro* physical and biological effects of soy saponins on WiDr colon cancer cells, the same cell line as HT-29[7] (American Type Culture Collection, Rockville, MD, USA; Catalogue 1988), by

examining the number of living cells, cell morphology, alkaline phosphatase (AP) and protein kinase C (PKC) activities, and the expression of c-Jun, c-Fos, and P53 protein, and cell apoptosis.

MATERIALS AND METHODS

Soy saponin preparation and analysis

Saponin extraction was performed according to the method of Berhow *et al*[8]. The purity of crude saponin extracted was examined by high performance liquid chromatography (HPLC) (TSP, Germany) using commercial soy saponin as a standard (Wako, Japan). The HPLC conditions were as follows: C18 column (Vercopak, ODS-3, 4.6 mm × 250 mm); UV absorbance: 190-350 nm; analyzing temperature 30℃; flow rate: 1 mL/min; gradient solvent system: solvent A, 0.05% trifluoroacetic acid in water, solvent B, acetonitrile; 63% A to 52% A in 38 min.

Cell culture and viability

Cells were cultivated in minimal essential medium that contained 10% fetal bovine serum, sodium bicarbonate (1.5 g/L), and 1.0 mmol/L sodium pyruvate at 37℃ and 5% CO_2. Cells were subcultured into a new medium (100 mm diameter dish) when they reached a high density, at a series of dilutions from 1:3 to 1:6. When they reached 2×10^3 cells/well, cells were cultivated in each well of a 96-well plate. After stable attachment in the medium (day 0), cells were treated with five different concentrations (0, 150, 300, 600, 1200, 2400 ppm) of soy saponins (16 wells/concentration). CellTiter 96® Aqueous One Solution Cell Proliferation Assay (Promega, USA) was used to measure the viability of cells every 24 h for 3 d.

Cell morphology observation

After the cells were treated with different concentrations of soy saponins for 24 h, they were examined by electron microscopy. Scanning electron microscopy (SEM; S-2400; Hitachi, Japan) was performed to observe the differences in cell morphology. Transmission electron microscopy (TEM; H600; Hitachi) was used to investigate intracellular morphology.

Cell proliferation/differentiation measurement

Cells were cultivated in a 10-cm Petri dish. After the cells were stable, fresh medium with 0, 150, 300, 600, and 1200 ppm of soy saponins was added. Cells were cultivated for another 72 h before being subjected to tests for proliferation and differentiation. Sodium butyrate (2.5 mmol/L) was used as a positive control for detecting AP activity. The level of differentiation was measured using Alkaline Phophatase Liquicolor (Human, Germany). The activity of PKC was measured using Peptag® Assay (Promega, USA). c-Jun, c-Fos, and wild-type P53 protein expression in WiDr cells was analyzed using SDS-PAGE and western blotting. A 12% resolving gel and a 5% stacking gel were applied. β-actin (43 kDa) was used as the internal control. The antibodies used were rabbit anti-c-Jun polyclonal antibody (Stressgen, Canada), rabbit anti-c-Fos polyclonal antibody, mouse anti-P53 monoclonal antibody, and mouse anti-β-actin monoclonal antibody (Sigma, USA).

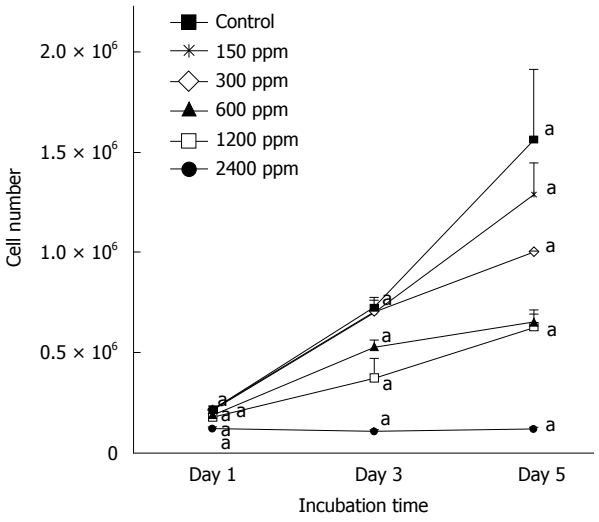

Figure 1 Effect of extracted crude soybean saponins on the growth of WiDr cells. Different concentrations of saponin at each incubation time were compared using one way analysis of variances with Fisher's test. Values are mean ± SD. Points with letter "a" represent significant differences at the $P < 0.05$ level.

Statistical analysis

Data were expressed as mean ± SD. One-way analysis of variances and Fisher's least significant difference were performed using SAS 8.13. Differences were significant at $P < 0.05$.

RESULTS

Soy saponins and cell count

Figure 1 illustrates the dose-dependent inhibitory effect of soy saponins on the number of WiDr cells. At the end of day 1, the cell count was significantly lower in the group treated with 2400 ppm saponins compared to that in the control group ($P < 0.05$). The percentage inhibition was 40.7%. At the end of day 3, compared to the control group, the number of cells in the groups treated with 600, 1200 and 2400 ppm was significantly lower ($P < 0.05$), with percentage inhibition of 27.4%, 56.6% and 84.8%, respectively. At the end of day 5, the groups treated with 300, 600, 1200 and 2400 ppm of soy saponins had a lower cell count than the control group ($P < 0.05$), with percentage inhibition of 36.0%, 57.9%, 59.7% and 92.2%, respectively. Under light microscopic observation at the end of day 5, it was shown that cell density in the medium decreased in parallel with the increase of soy saponins in the medium (Figure 2). Figure 3 shows that under treatment with soy saponins (150-2400 ppm), the percentage cell survival was decreased in a reversed dose-dependent manner ($P < 0.05$) at each time point.

SEM of WiDr cells

Figure 4A-D shows the SEM observation of WiDr cells treated with 0, 300, 600, 1200 and 2400 ppm of soy saponins. When the dose of soy saponins increased, the

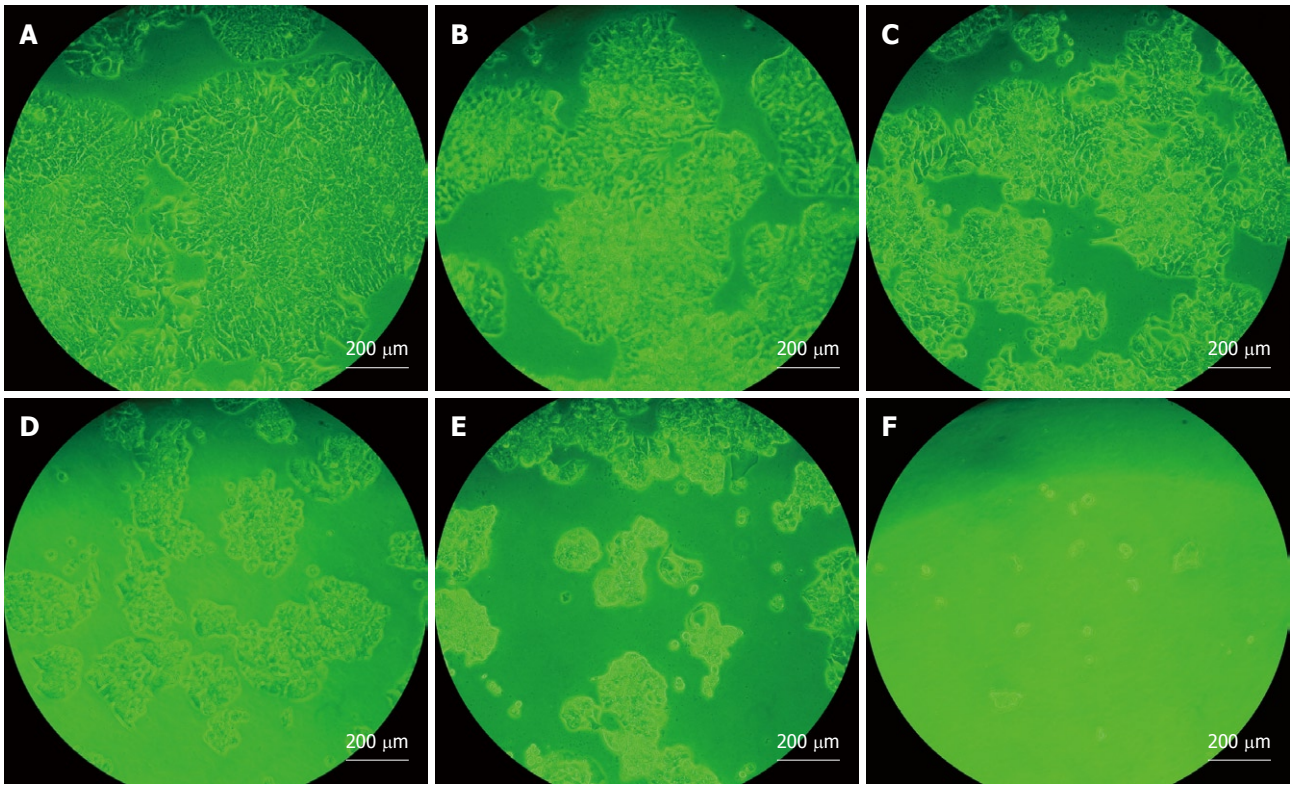

Figure 2 Cell number and morphological effects of extracted crude soybean saponins on WiDr cells. A: Untreated control culture for 5 d; B: Culture exposed to 150 ppm extracted crude soybean saponins for 5 d; C: 300 ppm; D: 600 ppm; E: 1200 ppm; F: 2400 ppm.

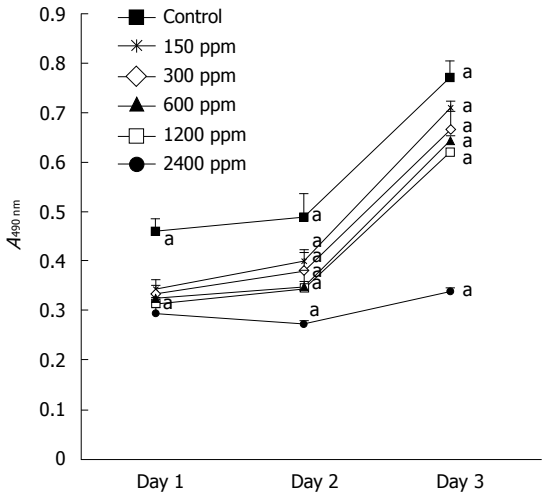

Figure 3 Effect of extracted crude soybean saponins on viability of WiDr cells. Different concentrations of saponin at each incubation time were compared using one way analysis of variances with Fisher's test. Values are mean ± SD. Points with letter "a" represent significant differences at the $P < 0.05$ level.

surface of WiDr cells became rougher, and the cell shape changed from round to irregular. As the dose reached 1200 ppm (Figure 4C), breaks were seen on the surface of WiDr cells. At 2400 ppm soy saponin, complete deformation of WiDr cells was observed (Figure 4D).

Activity of AP

Figure 5 shows that soy saponins induced AP activity in WiDr cells in a dose-dependent manner ($P < 0.05$). The WiDr cell line is one of the colon cancer cell lines without AP activity. The control sample with sodium butyrate showed increased AP activity, while the one without sodium butyrate did not. The activated AP indicated that WiDr cancer cells might slow down the proliferation process but shift toward the differentiation process.

Activity of PKC

The effect of soy saponin on PKC activity is shown in Figure 6. 12-O-tetradecanoyl phorbol-13-acetate (TPA) was added to the medium to induce PKC activity. The medium without TPA showed no PKC activity. As the dose of saponins in the medium increased, the inhibitory effect on PKC increased.

Expression of P53, c-Jun, and c-Fos

There was no significant difference in the expression of P53 and c-Fos proteins between the groups with/without soy saponin treatment (data not shown). On the other hand, Figure 7 shows a trend towards an inhibitory effect of saponins on the expression of c-Jun after 3 d of incubation.

DISCUSSION

In this study, we investigated the effects of soy saponin on cell growth, proliferation/differentiation-related enzyme activities, and the expression of apoptosis-related proteins of WiDr human colon cancer cells. We found that soy saponins effectively inhibited the growth rate and survival

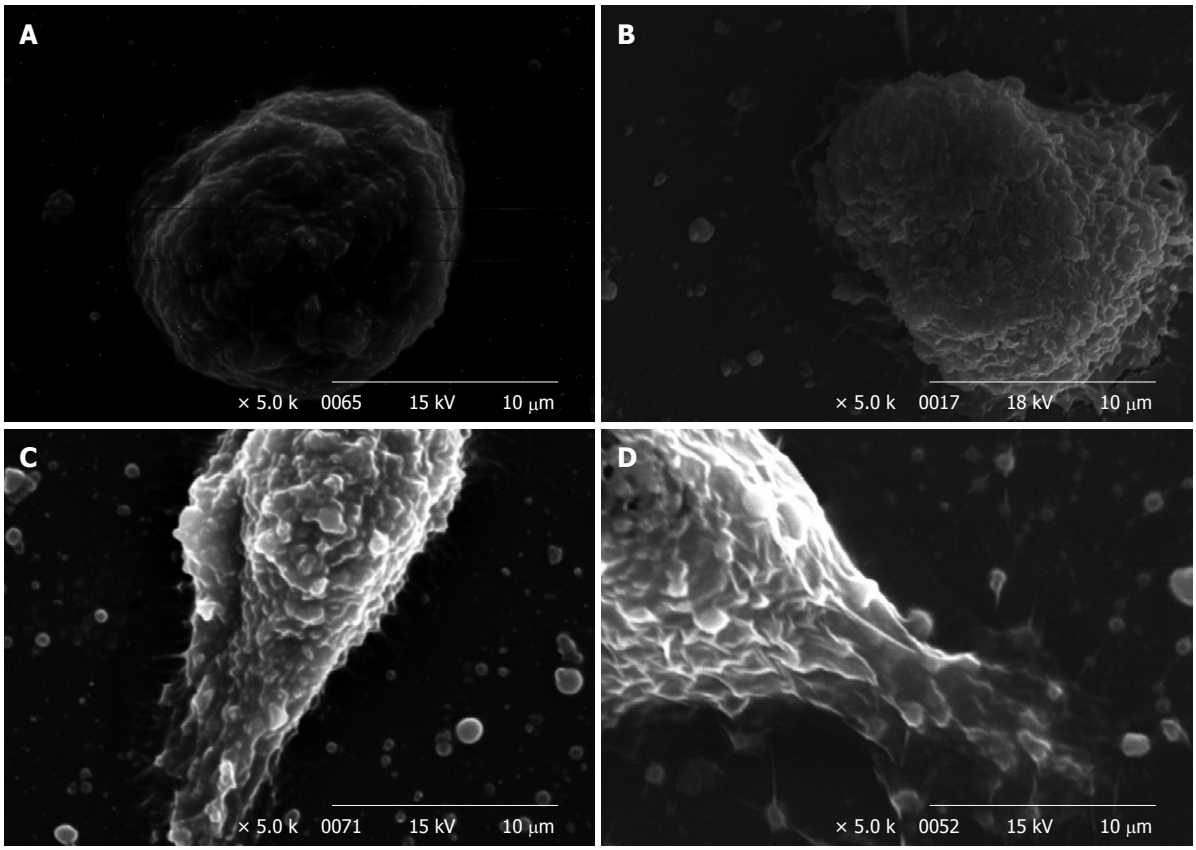

Figure 4 Scanning electron microscopy electron micrographs of WiDr cells. Cells were treated with 0 (A), 300 (B), 1200 (C) and 2400 ppm (D) soy saponin, for 1 d.

of human colon cancer cells in a dose-dependent manner. Soy saponins are amphiphilic compounds that can be used as bio-surfactants. They are structurally similar to oleanolic acid and ursolic, which have been shown to be glucocorticoid receptors with anti-carcinogenic activity[9,10].

PKC is one of the markers for cell proliferation. PKC activity increases as the cells undergo the proliferation process. As shown in our study, the addition of soy saponin effectively inhibited the activity of PKC in a dose-dependent manner. On the other hand, P53 protein is responsible for regulating some reactions such as the cell cycle, DNA repair, and apoptosis[11,12]. The relationship between P53 protein and the HT-29 cell death is still not clear[13]. Shen *et al*[14] have found that 2'-OH flavanone inhibits the growth of HT-29 cells *via* increasing the expres-

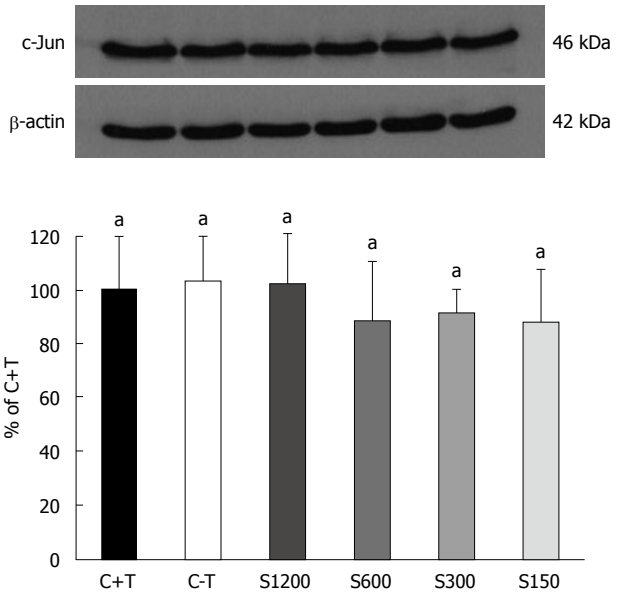

Figure 7 Effect of crude soybean saponins extracted on c-Jun (46 kDa) expression of WiDr cells. C+T: Control culture + 100 ng/mL tetradecanoyl phorbol-13-acetate (TPA); C-T: Untreated control culture for 3 d; S150: Culture exposed to 150 ppm extracted crude soybean saponins + 100 ng/mL TPA for 3 d; S300: 300 ppm; S600: 600 ppm; S1200: 1200 ppm. Values are mean ± SD. Different concentrations of saponin at each incubation time were compared using one way analysis of variances with Fisher's test. Bars with letter "a" represent significant differences at the $P < 0.05$ level.

sion of P21, but it has no effect on P53 protein. In our study, we did not find any inhibitory effect of soy saponin on the P53 protein of WiDr cells.

Under normal conditions, cells proliferate to a certain level and then differentiate to different kinds of cells. If the cells are stimulated by some exogenous factors, for example, carcinogens, cells may not differentiate, proliferate abnormally, and form tumors. In our study, compared to the control group, the cell number was decreased and AP activity was increased by addition of soy saponins, which is an indication of cell differentiation. It has been shown that materials such as vitamin D3, with membranolic actions, can regulate the transportation of Ca^{2+} ions through the membrane and induce cell differentiation[15]. Our SEM results showed that cell morphology was changed by saponins, with a similar membranolic effect. Soy saponins may also promote cell differentiation if the cell membrane has not been destroyed by too high a concentration.

Programmed cell death can be categorized into two types, type I apoptosis and type Ⅱ autophagic death[16-18]. The major differences in these two types are that, in apoptosis, cells die individually, and phagocytes are necessary for cell degradation. On the other hand, in autophagic death, cells die in groups through a lysosomal mechanism, in which vacuoles are observable in cells[17]. In our SEM study, cell membranes became rough and wrinkled when treated with high concentrations of saponins. In addition, under TEM observation (Figure 8), vacuoles appeared in the cells that had been treated with higher concentrations of saponins, which may be an indication of type Ⅱ autophagic death. It has been found that the level of microtubule-associated protein light chain 3 is increased after

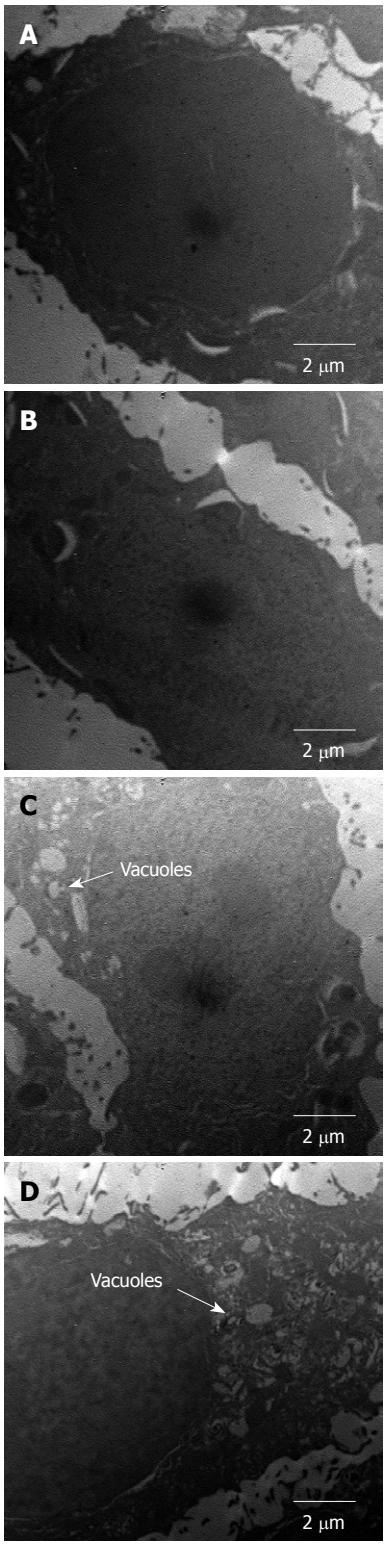

Figure 8 Transmission electron microscopy electron micrograph of WiDr cells treated with 150 (A), 300 (B), 600 (C), and 1200 (D) ppm of extracted crude soybean saponins for 1 d. At 600 and 1200 ppm of saponin, vacuoles were observable.

saponin treatment[19], which is an indication of type Ⅱ autophagic death. For these reasons, the inhibitory effect of soy saponins on WiDr cells may not be apoptosis, but rather autophagic death at higher concentrations.

In conclusion, we found that soy saponins changed the membrane structure and affected the growth of WiDr

cells in two different ways; by increasing the AP activity while reducing PKC activity to induce cell differentiation at lower concentrations, or by inducing type Ⅱ autophagic death at higher concentrations. This may need further investigation.

COMMENTS

Background

Colon cancer is one of the major causes of cancer mortality worldwide. Soy saponins are categorized as amphiphilic compounds, and may be able to react with the phospholipids and cholesterol on the membrane of cancer cells, and with the hydroxyl groups on the aglycone moiety.

Research frontiers

Steroid saponins extracted from fenugreek reduced the number of colon aberrant crypt foci in azoxymethane-induced rat colon cancer and induced apoptosis of HT-29 human colon cancer cells. However, how soy saponins affect the growth of cancer cells is still not clear. In this study, the authors investigated the *in vitro* physical and biological effects of soy saponins on WiDr colon cancer cells.

Innovations and breakthroughs

Recent studied have suggested that saponins affect the growth of colon cancer cells. This is believed to be the first thorough study that has focused on the relationship between biomarkers of apoptosis, such as expression of c-Jun, c-Fos, and P53 protein, and cell morphology, proliferation, and differentiation.

Applications

By understanding how soy saponins affect colon cells, this study may represent a future strategy for prevention or treatment of colon cancer.

Peer review

The authors investigated the inhibitory effects of soy saponins on colon cancer cells. Soy saponins inhibited the growth of colon cancer cells by reducing protein kinase C activity, while the features of type Ⅱ programmed cell death (autophagic death) was observed. It is a well written paper with promising results that may be the basis of forthcoming research in cancer biology and therapy.

Abstract

AIM: To investigate the mechanism by which galangin, a polyphenolic compound derived from medicinal herbs, induces apoptosis of hepatocellular carcinoma (HCC) cells.

METHODS: The 3-(4,5-Dimethyl-thiazol-2-yl)-2,5-diphenyl-tetrazolium bromide assay was used to measure cell viability. Apoptosis was evaluated by *in situ* uptake of propidium iodide and Hoechst 33258 and was then detected by fluorescence microscopy. Protein expressions were detected by Western blotting. To confirm the apoptotic pathway mediated by galangin, cells were transfected by *bcl-2* gene to overexpress Bcl-2 or siRNA to down-regulate Bcl-2 expression.

RESULTS: Galangin (46.25-370.0 μmol/L) exerted an anti-proliferative effect, induced apoptosis, and decreased mitochondrial membrane potential in a dose and time-dependent manner. Treatment with galangin induced apoptosis by translocating the pro-apoptotic protein Bax to the mitochondria, which released apoptosis-inducing factor and cytochrome c into the cytosol. Overexpression of Bcl-2 attenuated galangin-induced HepG2 cell apoptosis, while decreasing Bcl-2 expression enhanced galangin-induced cell apoptosis.

CONCLUSION: Our data suggests that galangin mediates apoptosis through a mitochondrial pathway, and may be a potential chemotherapeutic drug for the treatment of HCC.

Key words: Hepatocellular carcinoma; Galangin; Mitochondria; Bcl-2; Apoptosis

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide, particularly in China. Surgical therapy, chemotherapy, and radiation have been used for the treatment of HCC. However, HCC remains one of the

more difficult cancers to treat. Although chemotherapy is a common therapeutic strategy after surgery, its use has been toxic to normal tissues and limits their use. Therefore, it is important to screen for new anti-cancer drugs.

Recent studies show that a number of dietary compounds possess anti-cancer properties[1], including curcumin, genistein, quercitin, resveratrol, piceatannol and pterostilbene. These dietary compounds may enhance the efficacy of chemotherapeutic agents by modifying the activity of specific targets that control cell proliferation and apoptosis such as Bcl-2, Bcl-xL, X-linked inhibitor of apoptosis protein[2], Akt[3], c-myc, neuronal apoptosis inhibitory protein, c-IAP-2, nuclear factor-κB[4], survivin, p21WAF1 and p53[5].

Galangin (4H-1-Benzopyran-4-one, 3,5,7-trihydroxy-2-phenyl-), a flavonoid, is a polyphenolic compound derived primarily from medicinal herbs, including Alpinia officinarum Hance, Alnus pendula Matsum, Plantago major L, and Scutellaria galericulata L. (S. scrodifolia Fisch.). Eaton *et al*[6] demonstrated that galangin could inhibit the methoxyresorufin *O*-demethylase activity of CYP1A2, CYP1A1 and P-form phenolsulfotransferase. These observations suggest galangin may be a potential chemopreventive agent in sulfation-induced carcinogenesis.

Furthermore, Moon has reported that galangin had cancer preventive properties and induced apoptosis in several cancer cell lines[7]. Another study showed that galangin could induce a G0-G1 cell cycle arrest, modulate the expression of cycline/cdk, and decrease Bcl-2 levels, which leads to apoptosis of imatinib-resistant Bcr-Abl expressing chronic myelogenous leukemia cell lines[8].

Based on these previous reports, it was suggested that galangin could inhibit cell proliferation and induce apoptosis. Therefore, galangin may be a potential anti-tumor agent. However, the mechanism by which galangin exert its anti-tumor activity is unknown. In this study, we demonstrate the effects of galangin on HCC cells and elucidate the mechanism by which galangin induces apoptosis.

MATERIALS AND METHODS

Cell culture

Three human liver cancer cell lines (HepG2, Hep3B and PLC/PRF/5) were obtained from American type culture collection (Rockville, MD, USA) and kept in Institute of Biochemistry and Molecular Biology, Guangdong Medical College. All cell lines were cultured in Dulbecco's modified Eagle medium (Gibco BRL, Grand Island, NY, USA) containing penicillin (100 μg/mL) and streptomycin (100 μg/mL) and supplemented with 10% fetal bovine serum (Sijiqing Laboratories, Hangzhou, China) at 37℃ in a humidified atmosphere with 5% CO_2.

Agents and chemicals

Galangin was purchased from Sigma-Aldrich (St. Louis, MO, USA) and dissolved in dimethyl sulfoxide (DMSO), with the final concentration of DMSO in the culture medium below 0.1% (v/v). 3-(4,5-Dimethyl-thiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT), Hoechst 33258, propidium iodide, rhodamine 123 [2-(6-amino-3-imino-3*H*-xanthen-9-yl) benzoic acid methyl ester] were purchased from Sigma (St. Louis, MO, USA). Rabbit or goat polyclonal antibodies against Bax, caspase-3, caspase-9, cytochrome c, apoptosis-inducing factor (AIF), PAPR, Vox Ⅳ, GAPDH and Bcl-2 were from Santa Cruz Biotechnology (Santa Cruz Biotechnology, CA, USA).

MTT viability assay

HCC cells (5.0×10^3) were seeded and treated with different concentrations of galangin or different times in 96-well plates. The number of viable cells in each well was determined by adding 10 μL 5 mg/mL MTT solution. The cells were dissolved with 100 μL of solution that contained 20% SDS and 50% dimethyl formamide after cells had been incubated for 4 h at 37℃. The optical densities were quantified at a test wavelength of 570 nm and a reference wavelength of 630 nm using a Varioskan Flash Reader spectrophotometer (THERMO, MA, USA)[9].

Cell apoptosis analysis by fluorescence staining

The HCC cells were cultured in 6-well plates (3.0×10^5 cells/well) and treated with different concentrations of galangin at 37℃ in a humidified atmosphere with 5% CO_2 for 24 h. Cell apoptosis was evaluated by *in situ* uptake of propidium iodide and Hoechst 33258 as described by McKeague *et al*[10]. Briefly, galangin-treated cells were washed with phosphate buffered saline (PBS), and incubated in PBS containing 40 μg/mL propidium iodide and 2.5 μg/mL Hoechst 33258 for 10 min. Five hundred microliters of methanol: acetic acid (3: 1) fixative were then added directly to each well. Cells were viewed under fluorescence microscopy (Nikon Eclipse ET2000-E, Japan). The apoptotic index was calculated from the number of apoptotic nuclei *vs* total number of nuclei at each visual field.

Measurement of mitochondrial membrane potential[11]

HCC cells were treated with different concentrations of galangin for different times. Cells were then treated with rhodamine 123 with a final dye concentration of 10 μg/mL at 37℃ for 15 min, 5% CO_2 atmosphere prior to examination. Mitochondrial membrane potential was determined by flow cytometry. The change of fluorescent intensity of rhodamine 123 indicated the change in mitochondrial membrane potential.

Overexpression and knockdown of Bcl-2

The HCC cells were transfected with different plasmids [pcDNA3.1(+)-*Bcl-2*, pcDNA3.1(+)Vectors] using Lipofectamine 2000 (Invitrogen, CA, USA) according to the manufacturer's protocol. Bcl-2 siRNA sequence was synthesized according to Fu's report[12], sense sequence: 5'-CGGAGGCUGGGAUGCCUUUdTdT-3', antisense sequence: 3'-dTdTGCCUCCGACCCUACGGAAA-5'. Before transfection, cells were seeded in 6 well plates or 60 mm tissue culture dishes containing DMEM medium without antibiotics for 24 h. Cells were transfected using lipofectamine 2000 with 2 μg plasmid or 100 pmol siRNA in each well. Bcl-2 protein level was measured by immu-

noblot analysis 24 h post-transfection. Cells were treated with galangin for another 24 h, and viability was determined by MTT and fluorescence staining methods.

Preparation of proteins in the mitochondrial and cytosolic fractions

Twenty four hours after treating with different concentrations of galangin, cells were washed twice in ice-cold PBS and resuspended in five volumes of ice-cold extract buffer (20 mmol/L Hepes-KOH, 1.5 mmol/L $MgCl_2$, 1 mmol/L EDTA, 1 mmol/L EGTA, 1 mmol/L DTT, and 0.1 mmol/L PMSF, pH 7.5). The resuspended cells were homogenized and centrifuged at 750 *g* for 10 min at 4℃. The supernatants were centrifuged at 13000 *g* for 15 min at 4℃ to obtain the mitochondrial pellets. The remaining supernatants were centrifuged to obtain the cytosolic fractions. The protein concentrations of the resulting supernatants and mitochondrial fractions were measured.

Western blotting

The cells were loaded with cell decomposition buffer (pH 8.0) that contained 50 mmol/L Tris-HCl, 150 mmol/L NaCl, 5 mmol/L EDTA, 1% NP40, 0.05% phenylmethanesulfonyl fluoride (PMSF), 2 μg/mL aprotinin (Sigma, USA), and 2 μg/mL leupeptin (Sigma, USA). The proteins were determined as described previously by Western blotting[9] using the antibody (Santa Cruz Biotechology, Santa Cruz, CA, USA), and Western blotting luminal reagent (Amersham Biosciences, Uppsala, Sweden).

Statistical analysis

The values given are presented as mean ± SD. Statistical analysis was performed using one-way analysis of variance with LSD test. In all cases, $P < 0.05$ was considered as significant.

RESULTS

Galangin inhibits proliferation of HCC cells

We used the MTT assay to determine the effects of galangin on the proliferation of HCC cells. Using galangin at concentrations of 46.25, 92.5, 185 and 370 μmol/L, we observed an anti-proliferative effect on HCC cells that was dose-dependent (Figure 1A). Additionally, galangin could also inhibit HCC cell proliferation in a time-dependent manner (Figure 1B). The IC_{50} of galangin to HCC cells (HepG2, Hep3B, and PLC/PRF/5) 24 h post-treatment were 134.0, 87.3 and 79.8 μmol/L, respectively.

Galangin induces apoptosis of HCC cells

To determine whether galangin-treated HCC cells undergo apoptosis, we stained cells using Hoechst 33258/PI. As shown in Figure 2A, we observed a significant increase in the number of cells that exhibited nuclear condensation when treated with galangin for 24 h. This observation was similarly found in all three HCC cell lines tested. Our data also showed that the apoptotic index of the three HCC cells increased in a dose-dependent manner treated by galangin (Figure 2B).

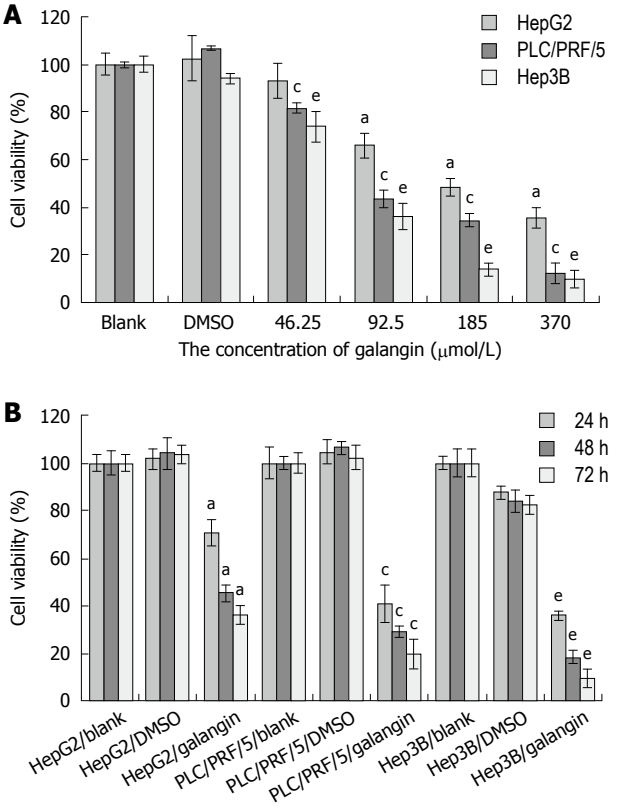

Figure 1 Effects of galangin on cell viability of three hepatocellular carcinoma cell lines. A: Three hepatocellular carcinoma (HCC) cell lines were treated with 46.25, 92.5, 185, and 370 μmol/L galangin for 24 h. The IC_{50} of galangin to HepG2, Hep3B, and PLC/PRF/5 cells were 134.0, 87.3 and 79.8 μmol/L, respectively; B: Three HCC cell lines were treated with 92.5 μmol/L galangin for 24, 48 and 72 h. mean ± SD. $n = 4$. $^aP < 0.05$ *vs* HepG2 cell/dimethyl sulfoxide (DMSO)-treatment group; $^cP < 0.05$ *vs* PLC/PRF/5 cell/DMSO-treatment group; $^eP < 0.05$ *vs* Hep3B/DMSO cell/DMSO-treatment group.

Galangin reduces the mitochondrial membrane potential of HCC cells

We observed a reduction in the mitochondrial membrane potential of all three HCC cell lines after treating with galangin (Figure 3). The mitochondrial membrane potential of the HCC cells decreased following treatment with galangin and this occurred in a dose- and time-dependent manner.

Galangin affects protein levels involved in the apoptosis pathway of HCC cells

In Figure 4, we evaluated the effects of galangin on protein expression involved in apoptosis of the HCC cell lines. Translocation of Bax to the mitochondria can alter the outer mitochondrial membrane permeability. Some pro-apoptotic proteins, including cytochrome c and AIF, are released into the cytosol from the mitochondria. Our data shows that Bax levels in the mitochondrial fraction of galangin-treated HCC cells increased in a dose-dependent manner, suggesting that the translocation of Bax into the mitochondria was involved in cell death induced by galangin (Figure 4A). Furthermore, we observed that the levels of cytochrome c and AIF in the cytosol of galangin-treated HCC cells increased in a dose-dependent manner. This suggests that the mitochondrial release of

cytochrome c and AIF into the cytosol may play a role in induction of cell apoptosis by galangin (Figure 4B). We also analyzed the effects of galangin on caspase-3 and caspase-9 activation, and poly(ADP-ribose) polymerase (PARP) cleavage by Western blotting. We showed caspase-9 activation in a dose-dependent manner, and observed a concomitant increase of caspase-3 activation and PARP cleavage (Figure 4C).

Bcl-2 protein level affects galangin-induced HepG2 cell apoptosis

To determine the role of Bcl-2 in galangin-treated HepG2 cells, we overexpressed and downregulated Bcl-2 by transfecting cells with pcDNA3.1-Bcl-2 and siRNA targeting Bcl-2, respectively. In Figure 5A, we show that we were able to overexpress and knockdown Bcl-2 sufficiently. As shown in Figure 5B and C, HepG2 cells overexpressing Bcl-2 were more resistant to galangin-induced apoptosis than control cells ($P < 0.05$). However, Bcl-2-knockdown HepG2 cells were more sensitive to galangin leading to decreased cell survival ($P < 0.05$) (Figure 5D). Taken together, these observations suggest that galangin induces apoptosis of HepG2 cell apoptosis *via* the mitochondrial pathway.

DISCUSSION

Studies have showed that most flavonoids exhibit anti-proliferative effects against tumor derived cell lines including leukemia[13], melanoma[14], colon[15], breast carcinoma[16], lung, and prostate[17]. Some reports have demonstrated that galangin is a naturally occurring non-toxic flavonoid with chemopreventive and anti-proliferative effects[6-8,18,19].

In this study, we demonstrated that galangin inhibited the proliferation of HCC cells and induced apoptosis at concentrations as low as 46.25 μmol/L and in excess of 185 μmol/L, respectively. Galangin-induced apoptosis was characterized by analyzing the effects on caspase-3 activation, PARP cleavage, and DNA condensation in HCC cells.

The mitochondrial pathway is commonly involved in the death stimuli. There are primarily two major events involved in apoptosis *via* the mitochondrial pathway. The first event is a change in mitochondrial membrane permeability, which leads to decreased mitochondrial membrane potential. Our data demonstrated reduced mitochondrial membrane potential as indicated by rhodamine 123 staining following treatment with galangin at different concentrations. The second event in the mitochondria-induced apoptotic pathway is the release of cytochrome c and AIF from the intermembrane space of the mitochondria into the cytosol. Here, we also showed that galangin increased

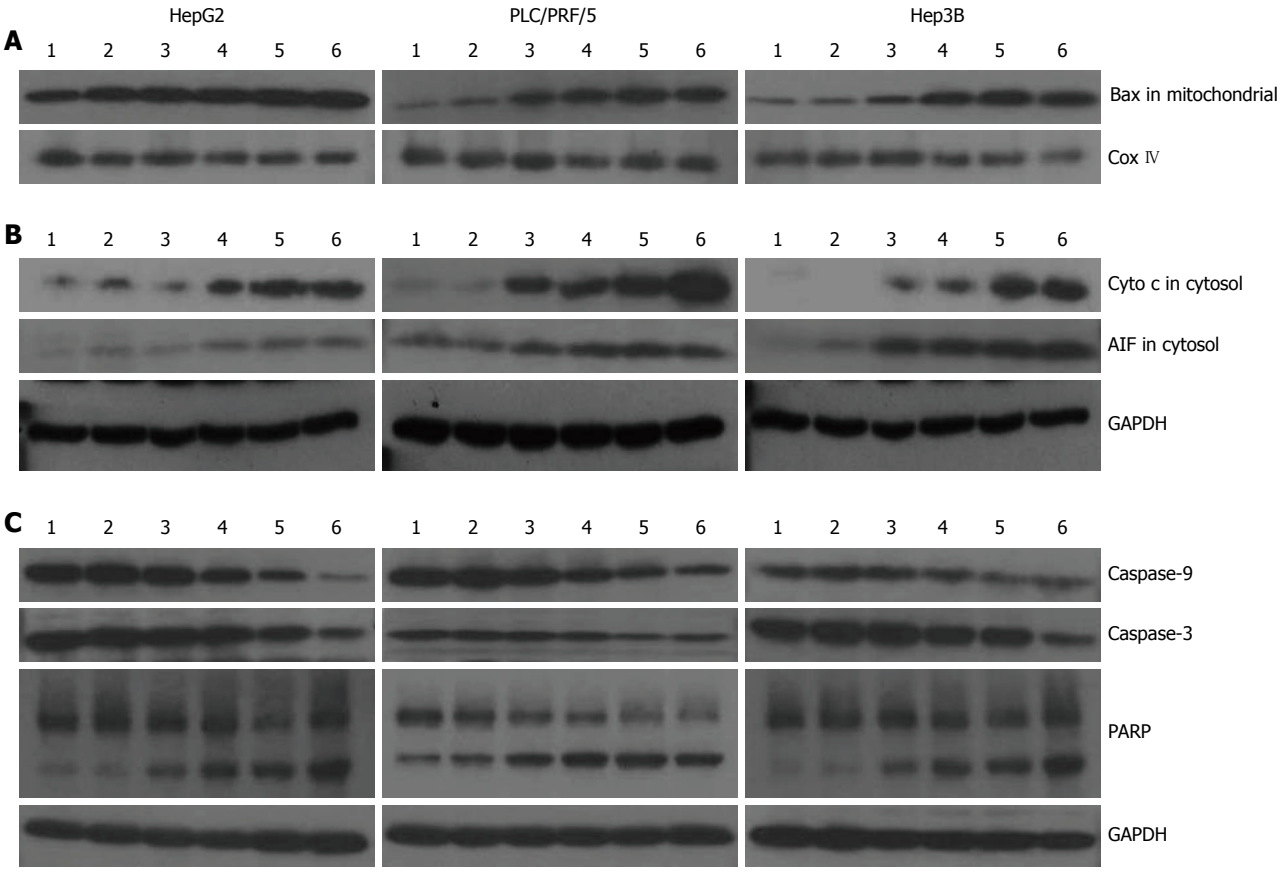

Figure 4 Effects of galangin-treated hepatocellular carcinoma cells on protein expression involved in the mitochondria pathway. A: The changes of Bax in the mitochondria; B: The changes of cytochrome c and apoptosis-inducing factor (AIF) in the cytosol; C: Caspase-3 and caspase-9 activation, and Poly(ADP-ribose) polymerase (PARP) cleavage induced by galangin. 1: Blank control group; 2: Dimethyl sulfoxide-treatment groups; 3: Cells were treated with 46.25 μmol/L galangin for 24 h; 4: Cells were treated with 92.5 μmol/L galangin for 24 h; 5: Cells were treated with 185 μmol/L galangin for 24 h; 6: Cells were treated with 370 μmol/L galangin for 24 h.

the release of cytochrome c and AIF in the cytosol. Thus, our data indicates that galangin-induced apoptosis of HCC cells occurs through the mitochondrial pathway.

The Bcl-2 family of proteins is involved in the mitochondrial apoptotic pathway by inducing the release of cytochrome c from the mitochondrial intermembrane space. Cytochrome c cooperates with Apaf-1 (Apoptotic protease activating factor 1) to induce caspase activation, leading to cell apoptosis[20]. The Bcl-2 family proteins are categorized into three groups based on the four Bcl-2 homology domains (BH1-4 domains). Bcl-2, Bcl-w, Bcl-xL and Mcl-1, which contain BH domains 1-4 and are localized to the outer mitochondrial membrane, are anti-apoptotic Bcl-2 proteins[21]. These proteins can directly bind and inhibit the proapoptotic Bcl-2 family in the mitochondria pathway of apoptosis. The proapoptotic proteins of Bcl-2 family members are functionally divided into two classes. One class is the effector molecule, which includes Bak and Bax, and permeabilizes the outer mitochondrial membrane to release cytochrome c into the cytosol. The other class is the BH3-only proteins including Bad, Bid, Bik, Bim, Bmf, bNip3, Hrk, Noxa and Puma, which promote cell apoptosis through protein-protein interactions with other Bcl-2 family members[21].

Our data indicates that galangin causes Bax translocation to the mitochondria in HCC cells. In non-apoptotic cells, Bax is located in the cytosol or loosely bound to the outer membrane of the mitochondria in monomeric forms. However, Bax translocates to the mitochondrial membrane and homodimerizes in the presence of a death signal. As a result, the outer mitochondrial membrane is permeable to release cytochrome c and AIF into the cytosol. The release of cytochrome c, which is an important protein in the electron transfer chain, can lead to reduced mitochondria membrane potential and adenosine triphosphate (ATP) synthesis. The results of our experiments showed that galangin induces cytochrome c release and decreases mitochondrial membrane potential.

In the cytosol, cytochrome c can bind to Apaf-1, which is a cytosolic protein. Apaf-1 undergoes a conformational change upon binding to dATP or ATP, leading to the formation of the apoptosome complex. The apoptosome recruits procaspase-9, resulting in caspase 9-caspase 3 activation. This caspase cascade is responsible for the hydrolysis of key cytoplasmic proteins and for the cleavage of genomic DNA nucleosomes into 180 bp fragments *via* caspase-activated DNase, such as PARP. Caspase-3 is an executioner of apoptosis that subsequently cleaves many important intracelluar substrates, leading to chromatin condensation, nucleosomal DNA fragmentation, nuclear membrane breakdown, externalization of phosphatidylserine, and formation of apoptotic bodies[22]. Our data also shows galangin-treated HCC cells did indeed cause caspase-9 and caspase-3 activation, and PARP cleavage.

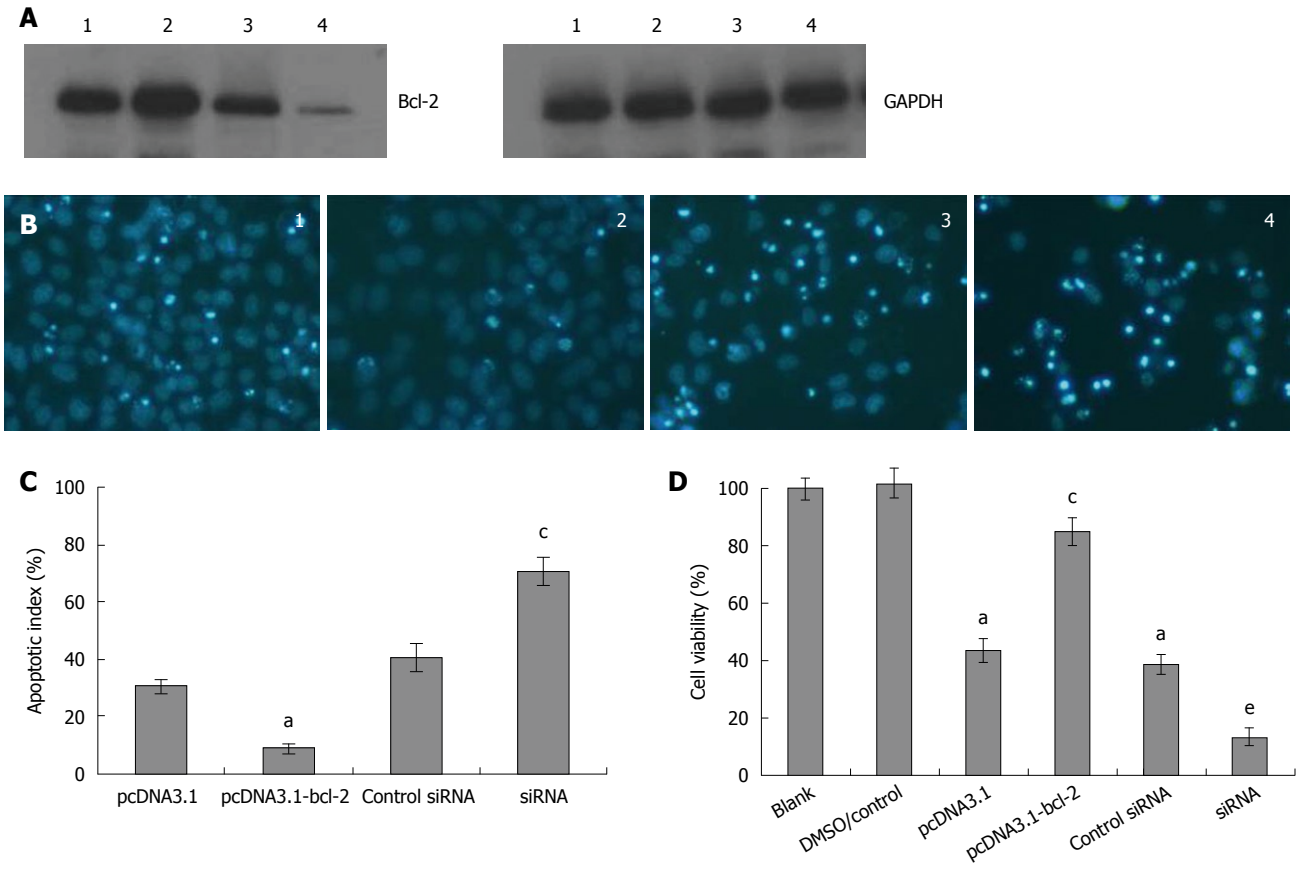

Figure 5 Effects of Bcl-2 on galangin-induced HepG2 cell apoptosis. A: Bcl-2 protein level was measured in HepG2 cells by Western blotting after cells were transfected; B: Morphology of apoptotic cells. Cells were treated with 185 μmol/L galangin for 24 h and stained with Hoechst 33258/PI to measure apoptosis. Pictures were taken under a 20 × objective. 1: Control vector group; 2: pcDNA3.1-bcl-2-transfected group; 3: Control siRNA group; 4: Bcl-2 siRNA-transfected group; C: Bcl-2 level affect apoptotic index of HepG2 cell induced by galangin. mean ± SD. $n = 4$. $^aP < 0.05$ *vs* pcDNA3.1 group; $^cP < 0.05$ *vs* control siRNA group; D: The effect of Bcl-2 level on cell viability induced by galangin. mean ± SD. $n = 4$. $^aP < 0.05$ *vs* HepG2 cell/dimethyl sulfoxide-treatment group; $^cP < 0.05$ *vs* pcDNA3.1-transfected group; $^eP < 0.05$ *vs* control siRNA group.

In our study, overexpression of Bcl-2 could suppress the apoptotic effects of galangin on HCC cells. Bcl-2 is an important anti-apoptotic protein that suppresses different drug-induced activation of the mitochondria-apoptotic pathway, such as etoposide[23], berberine[24], safatoposide[25], epigallocatechin-3-gallate[26], curcumin[27] and anti-inflammatory drugs[28]. The Bcl-2 protein can block the oligomerization of Bax and Bak and inhibit the apoptotic program[29,30]. Moreover, our data also showed that Bcl-2 decrease could enhance HCC cell sensitivity to galangin. These results show that Bcl-2 can modulate the effects of galangin on HCC cells and indicate that galangin induces apoptosis *via* the mitochondrial pathway.

We demonstrated that AIF is released from mitochondria into the cytosol in HCC cells upon galangin treatment. AIF migrates into the nucleus and induces high-molecular-mass DNA fragmentation and marginal chromatin condensation independent of caspases[31,32]. Therefore, HCC cells undergoing apoptosis may be due to a combination of caspase activation and AIF release.

In summary, we demonstrate that galangin induces HCC cell apoptosis *via* the mitochondrial pathway. Our data demonstrated that (1) galangin induces HCC cell apoptosis by triggering Bax translocation to the mitochondria; (2) galangin-treated HCC cells causes the release of AIF and cytochrome c into the cytosol from the mitochondria; and (3) overexpression of Bcl-2 attenuated galangin-induced HepG2 cells apoptosis, while down-regulated Bcl-2 expression enhanced galangin to induce cell apoptosis.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide, particularly in China. However, HCC remains one of the more difficult cancers to treat. It is important to screen for new anti-cancer drugs. Dietary compounds possess anti-cancer properties.

Research frontiers

A number of dietary compounds possess anti-cancer properties. These dietary compounds may modify the activity of specific targets that control cell proliferation and apoptosis. Galangin could inhibit the methoxyresorufin *O*-demethylase activity of CYP1A2, CYP1A1 and P-form phenolsulfotransferase. Galangin induced apoptosis in several cancer cell lines and arrested the cell cycle, modulated the expression of cycline/cdk, and decreased Bcl-2. It was suggested that galangin may be a potential anti-tumor agent. However, the mechanism by which galangin exerts its anti-tumor activity is unknown.

Innovations and breakthroughs

In this study, the authors demonstrate the effects of galangin on HCC cells and elucidate the mechanism by which galangin induces apoptosis. This is the first study to report that galangin mediates apoptosis through a mitochondrial pathway. Galangin may be a potential chemotherapeutic drug for the treatment of hepatocellular carcinoma cells.

Applications

Understanding the mechanism by which galangin induces apoptosis may lead

to its use as an anti-cancer treatment of HCC. This study may represent a future potential chemotherapeutic drug in the treatment of HCC with galangin.

Terminology

The mitochondrial pathway is an important apoptotic pathway involved in the mitochondrial membrane permeability change and the release of cytochrome c and apoptosis-inducing factor (AIF) from the intermembrane space of the mitochondria into the cytosol. Bcl-2 is an important anti-apoptotic protein that suppresses different drug-induced activation of the mitochondria-apoptotic pathway.

Peer review

In this study, Zhang *et al* demonstrated that galangin, a polyphenolic compound from herbs, induced apoptosis in hepatocellular carcinoma cells through the mitochondrial pathway. Galangin treatment led to inhibition of cell growth, nuclear fragmentation, mitochondrial membrane potential collapse, caspase activation, Bax mitochondrial translocation, and release of cytochrome c and AIF. Modulation of Bcl-2 by overexpression or knockdown altered galangin-induced apoptosis. The results are convincing and the study is informative. The manuscript could be improved by making several changes.

Abstract

AIM: To investigate whether the apoptotic activities of 8-bromo-7-methoxychrysin (BrMC) involve reactive oxygen species (ROS) generation and c-Jun N-terminal kinase (JNK) activation in human hepatocellular carcinoma cells (HCC).

METHODS: HepG2, Bel-7402 and L-02 cell lines were cultured *in vitro* and the apoptotic effects of BrMC were evaluated by flow cytometry (FCM) after propidium iodide (PI) staining, caspase-3 activity using enzyme-linked immunosorbent assay (ELISA), and DNA agarose gel electrophoresis. ROS production was evaluated by FCM after dichlorodihydrofluorescein diacetate (DCHF-DA) probe labeling. The phosphorylation level of JNK and c-Jun protein was analyzed by Western blotting.

RESULTS: FCM after PI staining showed a dose-dependent increase in the percentage of the sub-G1 cell population ($P < 0.05$), reaching 39.0% ± 2.8% of HepG2 cells after 48 h of treatment with BrMC at 10 μmol/L. The potency of BrMC to HepG2 and Bel-7402 (32.1% ± 2.6%) cells was found to be more effective than the lead compound, chrysin (16.2% ± 1.6% for HepG2 cells and 11.0% ± 1.3% for Bel-7402 cell) at 40 μmol/L and similar to 5-flurouracil (33.0% ± 2.1% for HepG2 cells and 29.3% ± 2.3% for Bel-7402 cells) at 10 μmol/L. BrMC had little effect on human embryo liver L-02 cells, with the percentage of sub-G1 cell population 5.4% ± 1.8%. Treatment of HepG2 cells with BrMC for 48 h also increased the levels of active caspase-3, in a concentration-dependent manner. z-DEVD-fmk, a caspase-3-specific inhibitor, prevented the activation of caspase-3. Treatment with BrMC at 10 μmol/L for 48 h resulted in the formation of a DNA ladder. Treatment of cells with BrMC (10 μmol/L) increased mean fluorescence intensity of DCHF-DA in HepG2 cells from 7.2 ± 1.12 at 0 h to 79.8 ± 3.9 at 3 h and 89.7 ± 4.7 at 6 h. BrMC did not affect ROS generation in L-02 cells. BrMC treatment failed to induce cell death and caspase-3 activation in HepG2 cells pretreated with N-acetylcysteine (10 mmol/L). In addition, in HepG2 cells treated with BrMC (2.5, 5.0, 10.0 μmol/L) for 12 h, JNK activation was observed. Peak JNK activation occurred at 12 h post-treatment and this activation persisted for up to 24 h. The expression of phosphorylated JNK and c-Jun protein after 12 h with BrMC-treated cells was inhibited by N-acetylcysteine and SP600125 pre-treatment, but GW9662 had no effect. SP600125 substantially reduced BrMC-induced cell death and caspase-3 activation of HepG2 cells. N-acetylcysteine and GW9662 also attenuated induction of cell death and caspase-3 activation in HepG2 cells treated with BrMC.

CONCLUSION: BrMC induces apoptosis of HCC cells by ROS generation and sustained JNK activation.

INTRODUCTION

Epidemiological and intervention studies in both humans and animals have shown that regular consumption of fruits, vegetables, and tea is associated with decreased risk of cancer[1]. Fruits, vegetables, and tea provide essential nutrients and many diet-derived phenolics, in particular flavonoids, which have been demonstrated to exert potential anticarcinogenic activities[2]. Chrysin (5,7-dihydroxyflavone, ChR), a natural and biologically active flavone extracted from many plants, honey, and bee propolis, has been shown to inhibit cell proliferation and induce apoptotic cell death in a variety of cancer cells. Investigations into the molecular mechanisms underlying the inhibition of cell proliferation and induction of apoptosis by ChR have shown that ChR inhibited the growth by downregulating expression of proliferating cell nuclear antigen in HeLa cells[3], induced apoptosis through caspase activation and Akt inactivation in leukemia cells[4-7], and induced cell cycle arrest in human colon carcinoma cells, human esophageal adenocarcinoma OE33 cells and human lung adenocarcinoma cells[8-10]. Nevertheless, poor oral bioavailability has been a major limitation for the successful use of dietary flavonoids as cancer chemotherapeutic agents[11]. It has been reported that ChR halogenated derivatives had stronger bioactivities than the lead compound[12]. The higher hepatic metabolic stability and intestinal absorption of the methylated polyphenols make them more favorable than the unmethylated polyphenols for development as potential cancer chemopreventive agents[13]. Our previous study showed that the effect of 8-bromo-7-methoxychrysin (BrMC) on the inhibition of proliferation and induction of apoptosis in a colon cancer cell line, HT-29, and a gastric cancer cell line, SGC-7901, was stronger than that of ChR[14-17]. However, the molecular mechanisms of induced apoptosis in human hepatocellular carcinoma cells (HCC) by BrMC were not clear.

Although flavonoids are generally considered as antioxidants, they can also generate reactive oxygen species (ROS) depending on their structure and molecular environment[18]. A number of flavonoids exert direct and indirect pro-oxidant effects by inhibiting the mitochondrial respiratory chain complexes I by inducing glutathione (GSH) depletion[19-23]. In addition, Kachadourian *et al*[19-24] have reported that chrysin is a potent inducer of ROS generation and GSH depletion in A549, HL-60, and PC-3 cells. We here demonstrate that BrMC induces apoptosis of human HCC at least partly by promoting generation of ROS, and ROS-dependent sustained activation of c-Jun N-terminal kinase (JNK).

MATERIALS AND METHODS

Cell culture and reagents

Human HCC HepG2 [AFP(+), no tumorigenicity in immunosuppressed mice], Bel-7402 [AFP(+),with high frequency of tumorigenicity], and human embryo liver L-02 cells were maintained in RPMI 1640 supplemented with 10% fetal bovine serum, 2 mmol/L glutamine, 100 mg/L penicillin, and 100 mg/L streptomycin, and incubated in a humidified atmosphere of 5% CO_2 at 37℃. BrMC was synthesized as described previously[14]. ChR was purchased from the Sigma Chemical Co. (St Louis, MO, USA). BrMC and ChR were dissolved in dimethyl sulfoxide (DMSO) to a final concentration of 0.1% in media. N-acetylcysteine (NAC), and GW9662 were obtained from Sigma. Caspase-3 substrate N-acetyl-Asp-Glu-Val-Asp-p-nitroanilide (Ac-DEVD-pNA), and the caspase-3 specific inhibitor Z-Asp-Glu-Val-Asp-CH2F (Z-DEVD-fmk), were obtained from Calbiochem (La Jolla, CA, USA). Dichlorodihydrofuorescein diacetate (DCHF-DA) was from Molecular Probes Inc. (Eugene, OR, USA). Rabbit anti-human total JNK was from Cell Signaling Technology (Beverly, MA, USA); mouse anti-human phospho-JNK, phospho-c-Jun, total c-Jun and β-actin were from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Horseradish peroxidase-conjugated anti-rabbit and anti-mouse secondary antibodies were from Cell Signaling Technology. The commercial anti-hepatoma agent 5-flurouracil (5-FU) was obtained from Sigma Chemical Co. and was used as an apoptotic inducer positive control whereas 0.1% DMSO was used as a negative control.

Flow cytometry with propidium iodide staining

As previously described[25], cells were treated with serum-free medium for 24 h, followed by treatment with media containing different concentrations of test agents for 48 h. Cells were collected and prepared as a single cell suspension by mechanical blowing with phosphate-buffered saline (PBS), washed with cold PBS twice, fixed with 700 mL/L alcohol at 4℃ for 24 h, stained with propidium iodide (PI), and cell apoptosis was detected using flow cytometry (FCM; American BD Company, FACS 420).

DNA agarose gel electrophoresis

As previously described[26], cells were treated with serum-free medium for 24 h, followed by treatment with media containing different concentrations of test agents for 48 h. Cells were washed twice with PBS and DNA was extracted with Apoptotic DNA Ladder Detection Kit (Bodataike Company, Beijing) according to the manufacturer's in-

structions. The extracted DNA was kept at 4℃ overnight. Then 8.5 μL of DNA sample was mixed with 1.5 μL of 6 × buffer solution, electrophoresed on 20 g/L agarose gel containing ethidium bromide at 40 V, and observed through the DBT-08 gel image analysis system.

Caspase-3 activity assay

To evaluate caspase-3 activity, cell lysates were prepared after treatment with test agents. Assays were performed in 96-well microtiter plates by incubating 20 μg cell lysates in 100 μL reaction buffer (1% NP-40, 20 mmol/L Tris-HCl (pH 7.5), 137 mmol/L NaCl, 10% glycerol) containing the 5 μmol/L caspase-3 substrate (DEVD-pNA). Lysates were incubated at 37℃ for 2 h. Thereafter, the absorbance at 405 nm was measured with an enzyme-labeling instrument (ELX-800 type). In the caspase inhibitors assay, cells were pretreated with a caspase-3 specific inhibitor (10 μmol/L, Z-DEVD-fmk) for 1 h prior to addition of test agents.

Determination of ROS

Intracellular ROS accumulation was measured by FCM using the fluorescent probe DCHF-DA. Briefly, cells were incubated with 10 μmol/L of DCHF-DA for 30 min at 37℃ in the dark after treatment with various concentrations of test agents. After incubation, the cells were washed with PBS and analyzed within 30 min by FCM equipped with an air-cooled argon laser tuned to 488 nm. The specific fluorescence signals corresponding to DCHF-DA were collected with a 525 nm band pass filter. As a rule, 10000 cells were counted in each determination.

Western blotting analysis

As previously described[27], cells were collected, washed 3 times with PBS, lysed in cell lysate containing 0.1 mol/L NaCl, 0.01 mol/L Tris-Cl (pH 7.6), 0.001 mol/L EDTA (pH 8.0), 1 μg/mL aprotinin, 100 μg/mL PMSF, and then centrifuged at 13000 × *g* for 10 min at 4℃. Extracted protein sample (25 μg total protein/lane) was added in the same volume of sample buffer solution and subjected to denaturation at 100℃ for 10 min, then electrophoresed on 100 g/L or 60 g/L sodium dodecyl sulfate polyacrylamide gel electrophoresis at 100 mA for 3 h, and finally transferred onto polyvinylidene fluoride membrane (PVDF) (Millipore). The PVDF membrane was treated with Tris-Buffered Saline Tween-20 (TBST) containing 50 g/L skimmed milk at room temperature for 2 h, followed by incubation with the first antibodies phospho-JNK, total JNK, phospho-c-Jun, total c-Jun and β-actin (1:1000 dilution), respectively, at 37℃ for 2 h. After being washed with TBST for 30 min, the corresponding secondary antibody was added and incubated at room temperature for 1 h. Bound antibody was visualized using chemiluminescent substrate (ECL; Amersham, Arlington Heights, IL, USA). Total JNK, total c-Jun and β-actin (1:1000 dilution) were used as an internal control. Images were scanned, followed by densitometry analysis with UN-SCAN-IT software (Silk Scientific).

Statistical analysis

The database was set up with the SPSS 15.0 software package (SPSS Inc., Chicago, IL, USA) for analysis. Data were represented as mean ± SD. The means of multiple groups were compared with one-way analysis of variance, after the equal check of variance, and two-two comparisons of the means were performed using the least significant difference method. Statistical comparison was also performed with two-tailed *t*-test when appropriate. $P < 0.05$ was considered statistically significant.

RESULTS

Effects of BrMC on apoptosis in human HCC

To determine whether BrMC selectively induces apoptosis of human HCC, the human HCC lines HepG2 and Bel-7402 and human embryo liver L-02 cells were treated with increasing concentrations of BrMC for 48 h. Apoptotic cell death was examined by: (1) cell population with sub-G1 contents of DNA using FCM after PI staining; (2) caspase-3 activity determined by enzyme-linked immunosorbent assay; and (3) DNA fragmentation observed by DNA agarose gel electrophoresis. Figure 1A shows that there is a dose-dependent increase in the percentage of sub-G1 cell population ($P < 0.05$), reaching 39.0% ± 2.8% of HepG2 cells after 48 h of treatment with BrMC at 10 μmol/L. The potency of BrMC in HepG2 and Bel-7402 (32.1% ± 2.6%) cells was found to be more effective than the lead compound, chrysin (ChR, 16.2% ± 1.6% for HepG2 cells and 11.0% ± 1.3% for Bel-7402 cells) at 40 μmol/L and similar to 5-FU (33.0% ± 2.1% in HepG2 cells and 29.3% ± 2.3% in Bel-7402 cells) at 10 μmol/L. BrMC had little effect in human embryo liver L-02 cells, with the percentage of the sub-G1 cell population 5.4% ± 1.8%. Compared with HepG2 cells, Bel-7402 cells were less sensitive to BrMC. Parallel to the cell lethal effect and the enhanced caspase-3 activity, treatment of HepG2 cells with BrMC for 48 h increased the levels of active caspase-3, in a concentration-dependent manner (Figure 1B). Requirement of caspase activity for BrMC-induced apoptosis was examined using a caspase-3-specific inhibitor, z-DEVD-fmk. The data showed that z-DEVD-fmk was able to prevent activation of caspase-3 (Figure 1B). Similarly, treatment with BrMC at 10 μmol/L for 48 h resulted in the formation of a DNA ladder (Figure 2). These results indicate that BrMC selectively induced apoptotic cell death of HCC in a caspase-dependent fashion.

Effects of BrMC on ROS generation in HepG2 cells

Because oxidative damage plays an important role in anticancer effects of ChR[19], we subsequently examined the level of intracellular ROS in HepG2 and L-02 cells after treatment with BrMC using an oxidation-sensitive fluorescent probe DCHF-DA, which is oxidized to 2',7'-dichlorofluorescein (DCF) in the presence of ROS. Figure 3A shows that treatment of cells with BrMC (10 μmol/L) increased mean fluorescence intensity of DCF in HepG2 cell from 7.2 ± 1.12 at 0 h to 79.8 ± 3.9 at 3 h and 89.7 ±

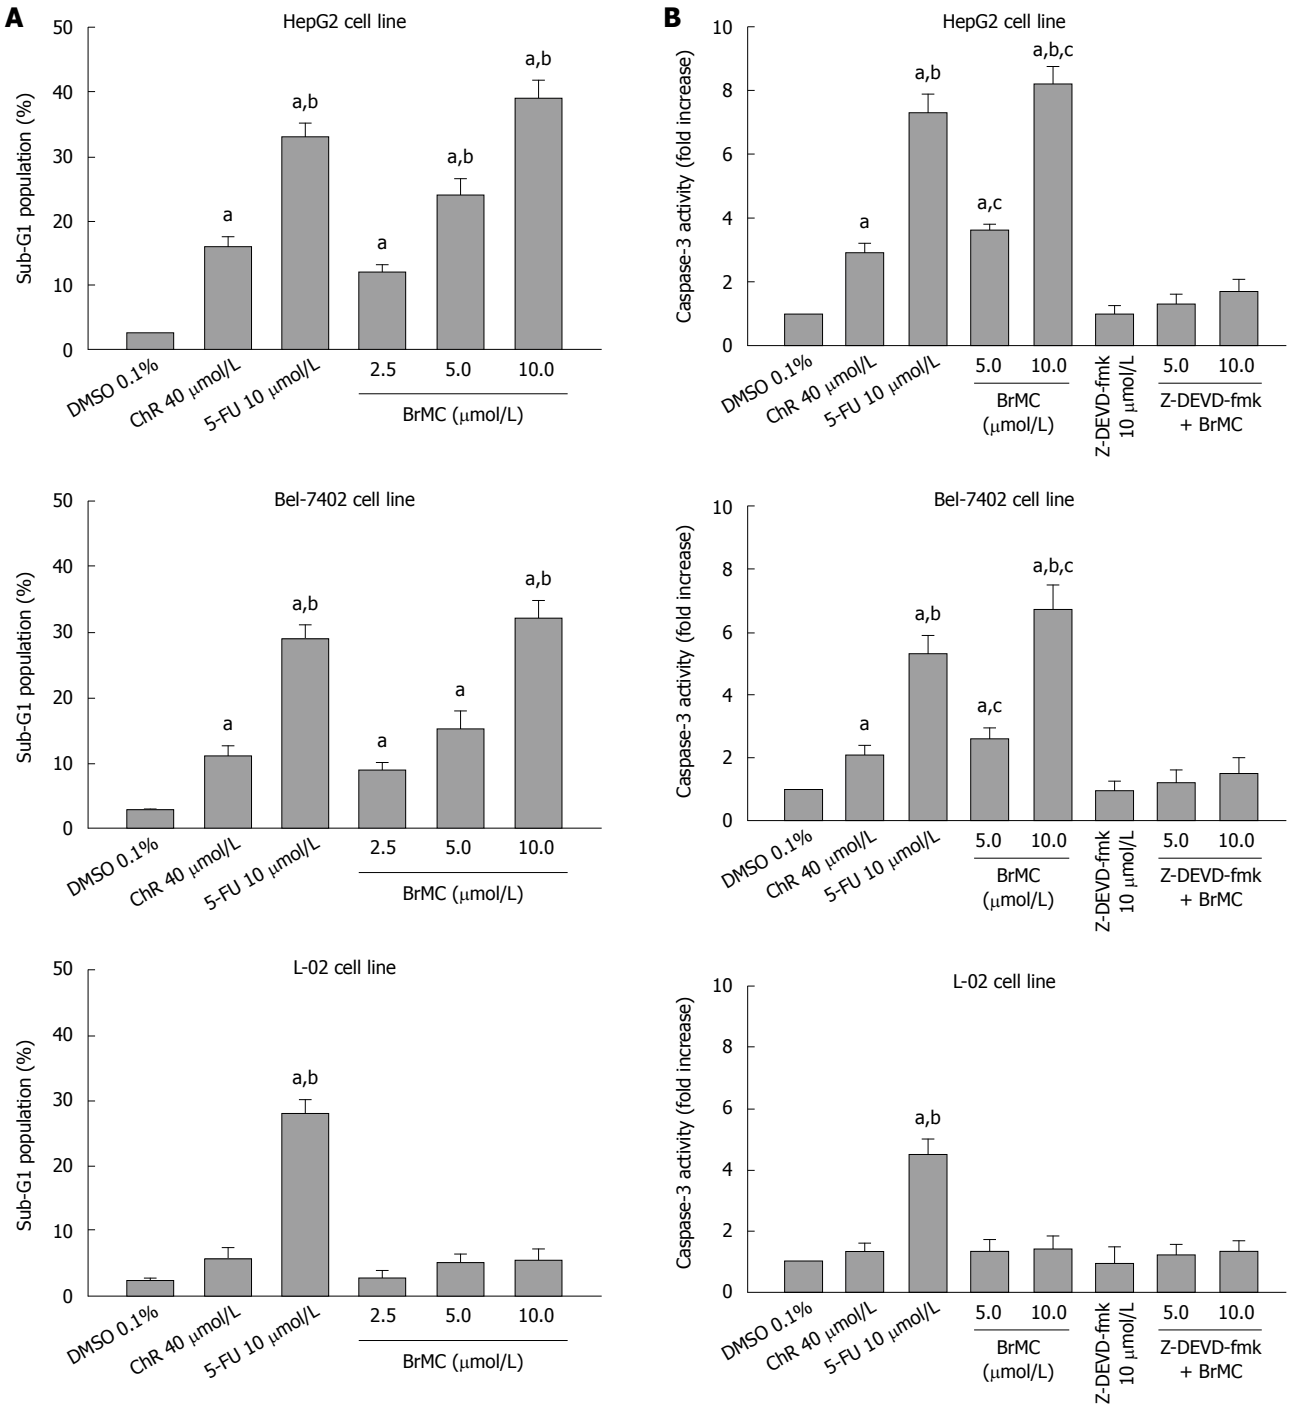

Figure 1 Effects of 8-bromo-7-methoxychrysin on the percentage sub-G1 cell population (A), caspase-3 activity (B) in human hepatocellular carcinoma HepG2, Bel-7402 and human embryo liver L-02 cells. $^{a}P < 0.05$ *vs* treatment with dimethyl sulfoxide (DMSO); $^{b}P < 0.05$ *vs* treatment with chrysin (ChR); $^{c}P < 0.05$ *vs* treatment with Z-Asp-Glu-Val-Asp-CH2F (Z-DEVD-fmk) plus BrMC. 5-FU: 5-flurouracil.

4.7 for 6 h. However, BrMC did not affect ROS generation in L-02 cells. BrMC treatment failed to induce ROS generation in HepG2 cells pretreated with 10 mmol/L NAC. We next investigated whether generation of ROS induced by BrMC was accompanied by apoptotic cell death after BrMC treatment. To determine a link between elevation of the intracellular ROS level and apoptotic cell death in BrMC-treated cells, HepG2 cells were pre-incubated with the thiol-containing antioxidant NAC before treatment with BrMC. BrMC treatment failed to induce

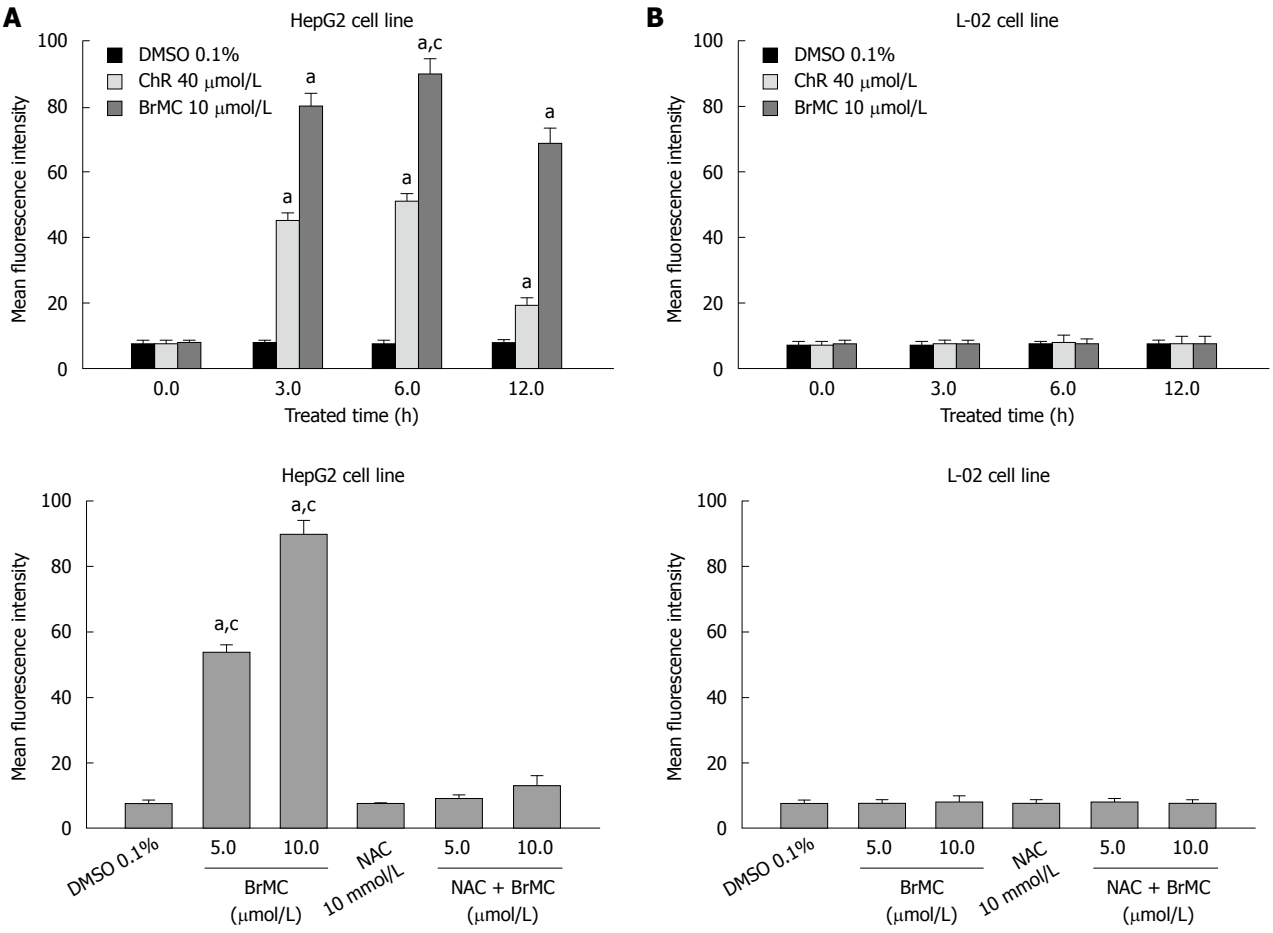

Figure 3 Effects of 8-bromo-7-methoxychrysin on reactive oxygen species generation in human hepatocellular carcinoma HepG2 (A) and human embryo liver L-02 cells (B). [a]*P* < 0.05 *vs* baseline or treatment with dimethyl sulfoxide (DMSO); [c]*P* < 0.05 *vs* treatment with N-acetylcysteine (NAC) plus 8-bromo-7-methoxychrysin (BrMC).

cell death and caspase-3 activation in cells pretreated with 10 mmol/L NAC (Figure 4). These observations suggest that a selective increase in the intracellular ROS level after BrMC treatment in HCC is required in the cell death pathway, accompanied by activation of caspase-3.

Effects of BrMC on JNK activation in HepG2 cells

It is well known that many therapeutic agents trigger apoptosis *via* activation of stress-related signaling pathways including JNK-mediated ones[28]. JNK plays distinct roles in cell death. Transient activation of JNK is believed to be antiapoptotic whereas persistent activation is pro-apoptotic[29,30]. Here we examined the effect of BrMC-induced JNK activation. JNK activation was measured by Western blotting analysis of phosphorylated JNK and its downstream target c-Jun. In HepG2 cells treated with BrMC (2.5, 5.0, 10.0 μmol/L) for 12 h, JNK activation was observed (Figure 5A). Time course experiments revealed peak JNK activation at 12 h post-treatment and this activation persisted for up to 24 h (Figure 5B).

Effects of BrMC-stimulated JNK activation on induction of apoptosis and caspase-3 activation in HepG2 cells

It has been reported that ChR derivatives induce apoptosis of human HCC and human gastric cancer cells by activating peroxisome proliferator-activated receptor-γ (PPARγ)[17,26]. One of the important components in ROS signaling is JNK activation[31]. These results prompted us to investigate whether NAC, an antioxidant, and GW9662, a blocker of PPARγ, and JNK inhibitor SP600125 affected the phosphorylated JNK protein level in HepG2 cells treated with BrMC. Figure 6A shows that the expression of phosphorylated JNK protein after 12 h with BrMC-treated cells was inhibited by NAC and SP600125 pretreatment, but GW9662 had no effect. To examine the effects of BrMC-stimulated JNK activation on induction of apoptosis and caspase-3 activation in HepG2 cells, we used the JNK inhibitor SP600125 to investigate the role of JNK in BrMC-induced cell death and caspase-3 activation. SP600125 substantially reduced BrMC-induced cell death and caspase-3 activation of HepG2 cells (Figure 6B-D). In addition, NAC and GW9662 also inhibited induction of cell death and caspase-3 activation in HepG2 cells treated with BrMC (Figure 6B-D). These results suggest that ROS production and JNK activation are required for BrMC-induced cell death and caspase-3 activation in HepG2 cells.

DISCUSSION

Our previous study showed that the effect of BrMC on

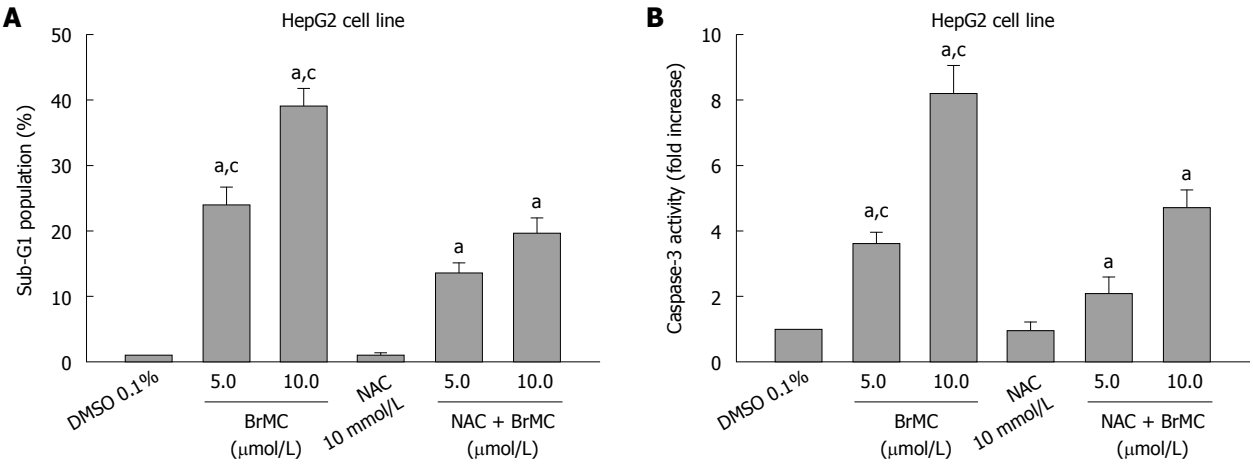

Figure 4 Effects of N-acetylcysteine on 8-bromo-7-methoxychrysin-induced apoptosis rate (A) and caspase-3 activity (B) in HepG2 cells. $^{a}P < 0.05$ *vs* treatment with medium (0 h) or dimethyl sulfoxide (DMSO); $^{c}P < 0.05$ *vs* treatment with N-acetylcysteine (NAC) plus 8-bromo-7-methoxychrysin (BrMC).

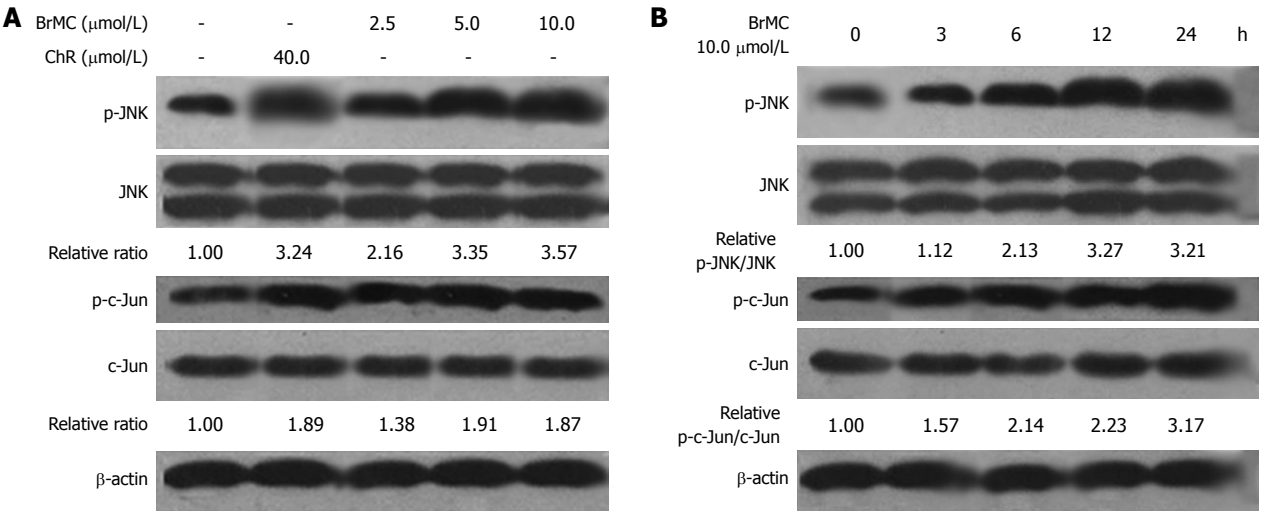

Figure 5 Effects of 8-bromo-7-methoxychrysin on the level of phosphorylated Jun N-terminal kinase and phosphorylated c-Jun in HepG2 cells (Western blotting, mean ± SD, *n* = 3). 8-bromo-7-methoxychrysin (BrMC) elevated the level of phosphorylated Jun N-terminal kinase (JNK) and phosphorylated c-Jun in a concentration-dependent manner (A) and in a time-dependent manner (B). The ratio of p-JNK/JNK or p-c-Jun/c-Jun was normalized to 0 h or the untreated group.

the inhibition of proliferation and induction of apoptosis in a colon cancer cell line HT-29 and gastric cancer cell line SGC-7901 was stronger than that of ChR[14,16]. In addition, it has been reported that ChR is a potent inducer of ROS generation and GSH depletion in A549, HL-60, and PC-3 cells[19,20]. In this study, we firstly showed that BrMC selectively induced apoptotic cell death of human HCC in a caspase-dependent fashion, with little effect on human embryo liver L-02 cells (Figures 1 and 2). The potency of BrMC in HepG2 and Bel-7402 cells was found to be greater than ChR and similar to 5-FU. Secondly, we indicated that BrMC selectively induced apoptosis of HepG2 cells and was accompanied by ROS generation. However, BrMC did not affect ROS generation of L-02 cells (Figures 3 and 4). Furthermore, we demonstrated that BrMC induced sustained activation of JNK in HepG2 cells in a ROS-dependent manner (Figures 5 and 6).

ROS have been associated with carcinogenesis but also, paradoxically, with mitochondrial-mediated cell death in cancer cells. The overproduction of ROS as a central event in mitochondrial-mediated apoptosis is now well documented[32-35]. The antioxidant properties of flavonoids have been associated with their cardioprotective and neuroprotective properties, yet such an association is much less certain concerning their cancer preventive properties. In the case of flavonoids, however, their chemopreventive properties may rather rely on eliminating precancerous cells because of their prooxidant properties *in vivo*. This is likely the case of apigenin and ChR, where their cytotoxicity may result from a combination of interference with the mitochondrial respiratory chain and multidrug resistance protein-mediated GSH depletion[36,37]. It is worth noting that the bee product propolis, which is known to exert antimicrobial, antiviral, and cancer preventive properties, contains ChR, a poor antioxidant, as one of its major components[38]. Intracellular ROS mediate multiple cellular responses, including protein kinase activation[39], cell cycle progression[40], myeloid cell differentiation[41,42], and apoptotic and necrotic cell death[43]. It has been reported in several studies that depletion of intracellular GSH plays

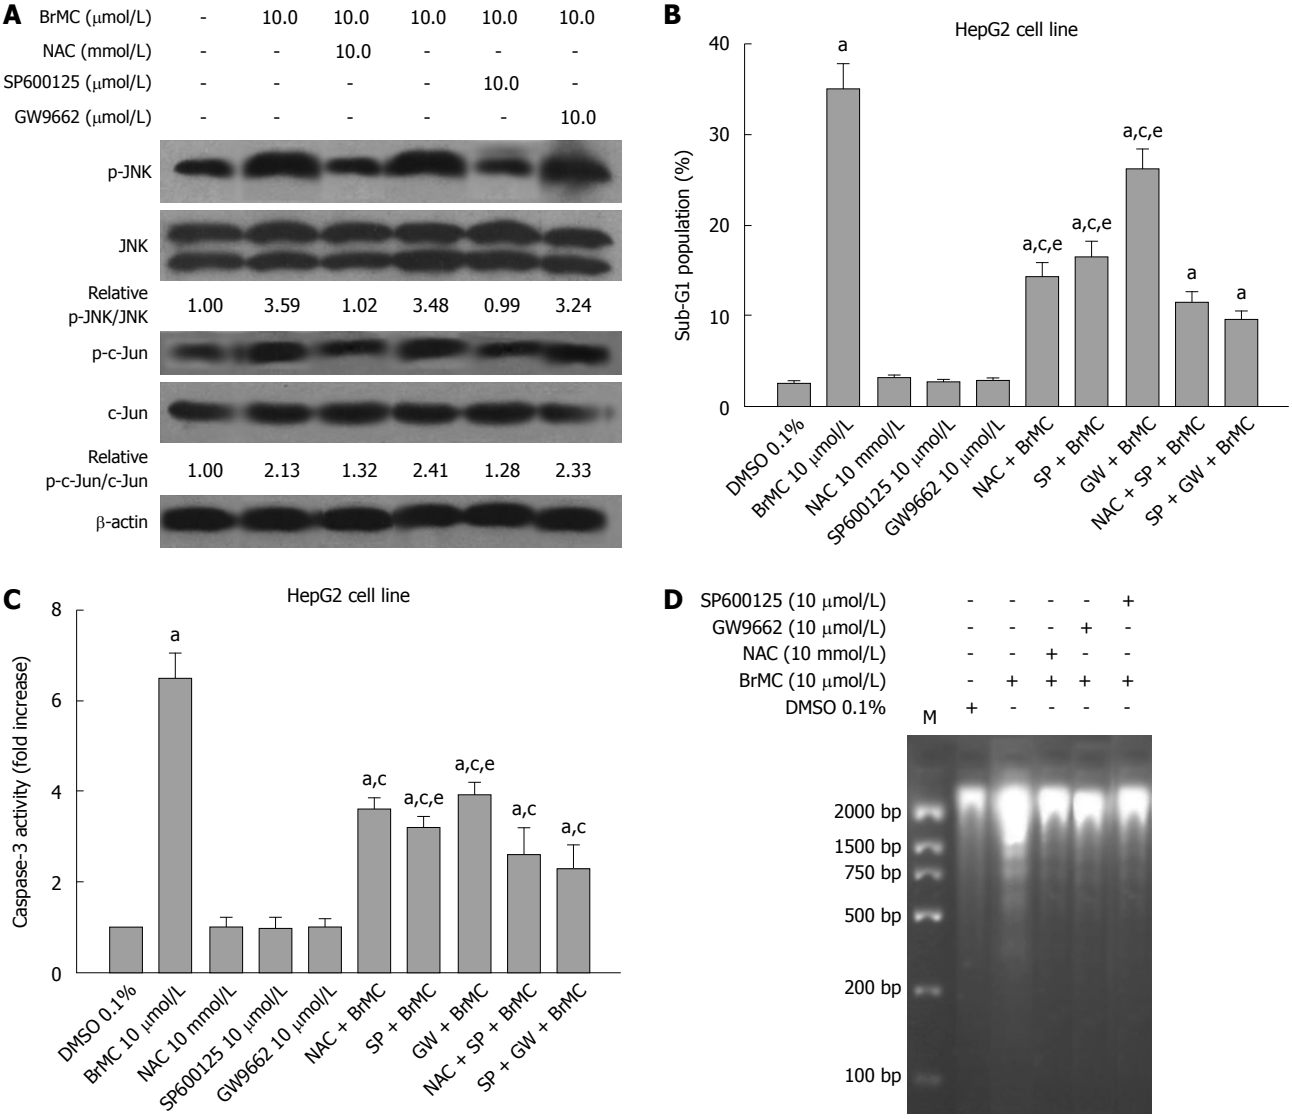

Figure 6 Effect of N-acetylcysteine, an antioxidant, and GW9662, a blocker of peroxisome proliferator-activated receptor-γ, and Jun N-terminal kinase inhibitor SP600125 on 8-bromo-7-methoxychrysin-induced activation of Jun N-terminal kinase (A), apoptosis (B), activation of caspase-3 (C), and DNA fragmentation (D) in HepG2 cells. The ratio of p-Jun N-terminal kinase (JNK)/JNK or p-c-Jun/c-Jun was normalized to 0 h or the untreated group. $^{a}P < 0.05$ *vs* treatment with dimethyl sulfoxide (DMSO); $^{c}P < 0.05$ *vs* treatment with 8-bromo-7-methoxychrysin (BrMC) alone; $^{e}P < 0.05$ *vs* treatment with N-acetylcysteine (NAC) in combination with SP600125 and BrMC or GW9662 in combination with SP600125 and BrMC.

a critical role in initiating apoptosis by ChR[10,19]. This is likely caused by the reversible interaction between ChR and GSH. In present study, we found that the ChR derivative, BrMC promoted accumulation of ROS products in a concentration-dependent manner in HepG2 cells but not in L-02 cells (Figure 3). NAC is an antioxidant agent and mainly known as a ROS scavenger. It reduces ROS generation and protects the cells from oxidative stress. BrMC-induced apoptosis of HepG2 cells was accompanied by ROS generation. It has been reported that arsenic trioxide-induced ROS generation was inhibited by NAC treatment[44]. We used NAC as an antioxidant to investigate the ROS generation induced by BrMC. NAC treatment not only reduced ROS generation but also attenuated induction of apoptosis in HepG2 cells (Figures 3 and 4). All together, these results indicate that induction of ROS generation contributes to BrMC-induced apoptosis in HepG2 cell line.

In this study, we investigated the signaling pathways affected by BrMC in HepG2 cells. We show that BrMC persistently activates JNK and induces apoptosis of HepG2 cells (Figures 5 and 6). BrMC-activated signaling pathways appear to activate executioner caspases because caspase 3 activity was enhanced in cells exposed to BrMC (Figure 1). JNK is implicated in mediating endoplasmic reticulum stress-induced apoptosis[45]. It has been shown that triterpenoids activate JNK leading to apoptosis[46,47]. In the present study, we detected both JNK activation and apoptotic cell death in cells exposed to BrMC. In addition, the presence of the JNK inhibitor SP600125 attenuated BrMC-induced apoptosis of HepG2 cells, indicating that BrMC-induced apoptosis is also JNK dependent (Figures 5 and 6). Collectively, we conclude that JNK activation mediates BrMC-induced apoptosis in the HepG2 cell line. We noted that SP600125 inhibited BrMC-induced c-Jun phosphorylation completely, but only partially prevented induction of apop-

tosis by BrMC in HepG2 cells (Figure 5). Thus, we cannot role out the possibility that other mechanisms also participate in BrMC-induced apoptosis in the HepG2 cell line.

It has been documented in several studies that depletion of intracellular GSH plays a critical role in initiating apoptosis by chrysin[10,19]. Zou *et al*[46]recently showed that triterpenoids deplete intracellular GSH, resulting in JNK-dependent apoptosis in human lung cancer A549 cells. In this study, we found that the presence of NAC blocked the effects of BrMC not only in generating ROS but also in activating JNK and triggering apoptotic cell death (Figure 6).

In summary, the present study has shown that BrMC promotes accumulation of intracellular ROS, resulting in sustained activation of JNK, leading to apoptosis in human HCC but not in human embryo liver L-02 cells. While further investigation is required to provide evidence for the efficacy of this HCC therapy in a nude mouse model and whether it reaches an effective dose *in vivo*, these results highlight a new mechanism responsible for BrMC-induced apoptosis, and raise the possibility that BrMC may be promising as a candidate for human HCC therapy.

COMMENTS

Background

Chrysin (5,7-dihydroxyflavone), a natural and biologically active flavone extracted from many plants, honey, and propolis, has been shown to inhibit cell proliferation and induce apoptotic cell death in a variety of cancer cells. Nevertheless, poor oral bioavailability has been a major limitation for the successful use of dietary flavonoids as cancer chemopreventative agents. The authors have synthesized 8-bromo-7-methoxyhysin (BrMC), a novel chrysin analogue. BrMC has been demonstrated to inhibit proliferation and induction of apoptosis in a colon cancer cell line HT-29 and gastric cancer cell line SGC-7901 and its effect was stronger than that of chrysin.

Research frontiers

Epidemiological and intervention studies in both humans and animals have shown that regular consumption of fruits, vegetables, and tea is associated with decreased risk of cancer. Fruits, vegetables, and tea provide essential nutrients and many diet-derived phenolics, in particular flavonoids, which have been demonstrated to exert potential anticarcinogenic activities. Flavonoids are plant polyphenolic compounds, which comprise several classes including flavonols, flavanones, flavanols, and flavans. Chrysin is a natural flavonoid contained in many plant extracts, honey, and propolis. Several studies in recent years have shown that chrysin and its derivatives have multiple biological activities, such as anti-inflammatory, anti-cancer, and anti-oxidative effects. However, the cellular and molecular mechanisms underlying chrysin and derivatives induced apoptosis of cancer cells are not clearly understood.

Innovations and breakthroughs

The authors firstly showed that BrMC, a novel chrysin analogue induced apoptotic cell death of human hepatocellular carcinoma cells (HCC) in a caspase-dependent fashion. BrMC-induced apoptosis of HepG2 cells was accompanied by ROS generation. Induction of reactive oxygen species (ROS) generation contributes to BrMC-induced apoptosis in a HepG2 cell line. In addition, they demonstrated that BrMC induced sustained activation of Jun N-terminal kinase (JNK) in HepG2 cells in a ROS-dependent manner.

Applications

The present study has shown that BrMC promotes accumulation of intracellular ROS, resulting in sustained activation of JNK, leading to apoptosis in human HCC. These results suggest that BrMC is a promising candidate for human HCC therapy.

Peer review

This is an original article by Jian-Guo Cao's group that investigated the effect of BrMC on HCC. They have found that BrMC induces apoptosis in HepG2 and Bel-7402 cells by generation of ROS, JNK activation, and activation of caspase-3. Overall the experiments were conducted appropriately, and the content is interesting.

Abstract

AIM: To compare the effects of four *Bifidobacteria* strains (*Bifidobacteria L66-5*, *L75-4*, *M13-4* and *FS31-12*, originated from normal human intestines) on weight gain, lipid metabolism, glucose metabolism in an obese murine model induced by high-fat diet.

METHODS: Forty-eight Sprague-Dawley rats were randomly divided into six groups. Control group received standard chow, model group received high-fat diet, and intervention groups received high-fat diet added with different *Bifidobacteria* strains isolated from healthy volunteers' fresh feces. All rats were executed at the 6th weekend. Body weight (BW), obese indexes, oral glucose tolerance test, serum and liver lipid and serum insulin (INS) were tested. Liver lipid deposition was classified pathologically.

RESULTS: Compared with the model group, *B. M13-4* improved BW gains (264.27 ± 26.91 *vs* 212.55 ± 18.54, $P = 0.001$) while *B. L66-5* induced a decrease in BW (188.47 ± 11.96 *vs* 212.55 ± 18.54, $P = 0.043$). The rest two strains had no significant change in BW. All the four strains can reduce serum and liver triglyceride and significantly alleviate the lipid deposition in liver. All strains showed a trend of lowing serum and liver total cholesterol while *B. L66-5* and *B. FS31-12* did so more significantly. In addition, all the four strains showed no significant differences in serum INS and glucose level.

CONCLUSION: The response of energy metabolism to administration of *Bifidobacteria* is strain dependent. Different strains of *Bifidobacteria* might drive different directions of fat distribution.

Key words: *Bifidobacterium*; Obesity; Serum lipid; Body weight

INTRODUCTION

Obesity is becoming a global epidemic, and a major contributor to increased incidence of serious chronic diseases such as type 2 diabetes, cardiovascular diseases, hepatic and skeletal muscle insulin resistance, and certain forms of cancer[1]. Several strategies have been used to

treat obesity, including diet control, exercise, behavior therapy, medications and surgery. However, the diet control and exercise are too hard to be strictly carried on. Also, undesirable side effects of drugs have restricted their therapeutic use. Fortunately, some recent interesting researches on obesity are helping to validate a new approach to control this medical disorder.

Recent researches have demonstrated that obesity may lead to the composition shift of gut microbiota in both mice and humans. Fewer *Bacteroidetes* and more *Firmicutes* are colonized in the gut of obese people and animals, shown by some 16S-rRNA-gene-sequence-based comparative surveys of gut bacteria[2,3]. Weight loss makes the ratio of *Bacteroidetes* to *Firmicutes* up-regulated in humans[3]. Dietary inclusion of *Lactobacillus*, which belongs to *Bacteroidetes* and/or *Bifidobacterium*, can improve obesity both in murine model and humans[4-6]. The intentional manipulation of community structure of gut microbiota may be a novel strategy to treat obesity.

Bifidobacterium is one of the most numerous "probiotic" in mammalian gut among commensal bacteria, which belongs to *Actinomycetes* and also a kind of lactic acid bacteria. It can help *Bacteroides* degrade polysaccharides[7] and inhibit exogenous cholesterol absorption from the small intestine[8]. Although most researches focus on the hypocholesteremia effect of *Lactobacillus*[4,9-11], a study showed that a strain of *Bifidobacterium longum* exhibited a more significant effect in lowering serum total cholesterol than a mixed culture of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp.*bulgaricus* (SL) both in rats and humans[6]. In contrast, probiotics VSL#3 (a combination of *Streptococcus thermophilus* and several species of *Lactobacillus* and *Bifidobacteria*) was found to increase liver fat with no significant changes in comprehensive metabolic panel or in body weight (BW) in a clinical research[12]. These results suggested that different strains may have their specificities in colonization or function. Furthermore, *Bifidobacterium longum* can induce an expansion of *Bacteroides. Thetaiotaomicron*'s substrates range under co-colonized condition, while another *Bifidobacterium* species, *B. animalis* showed no significant impact[7]. *Bifidobacteria* preparations are safe, widely-used, and well-tolerant. Thus, some specific strains of *Bifidobacteria* related to lipid metabolism and BW may be a potential therapeutic candidate for management of obesity.

In order to screen out more efficient strains in obese management among different strains of *Bifidobacteria* originated from normal human intestines, we established an obese model in rats induced by high-fat diet, and compare their effects on weight gain, lipid metabolism and glucose metabolism. Several strains of *Bifidobacteria* showed dependant effects in obese control in this study, thus would act as potential therapeutic candidates.

MATERIALS AND METHODS

Preparation of bacterial cultures

Four *Bifidobacteria* strains were isolated from healthy volunteers' fresh feces in our facility, and identified according to biochemical characteristics (API 20A biochemical strip, BioMerieux sa). The four strains were named *B. L66-5*, *B. L75-4*, *B. M13-4* and *B. FS31-12*, respectively, and maintained at -80℃ in our laboratory. The strains were all grown in MRS medium under anaerobic condition. When measured at 600 nm (A_{600}), the exponential and stationary growth reached an optical density of 1-2 and 1-4.5, respectively. The correspondence between absorbance and bacterial counts was established (1 mL of culture at A_{600} = 1 contains about 10^8 colony-forming units, CFU). The number of CFU administered was routinely verified by plating. Strains were harvested by centrifugation at 2000 × *g* for 20 min, washed twice with neutral saline, and resuspended at 1 × 10^8 CFU/mL concentration in neutral saline, and 0.4 mL bacterial solution was administered to each rat by intragastric gavage.

Animals and diet

Forty-eight 3-wk-old male Sprague-Dawley (SD) rats were purchased from Slaccas Lab Animal Ltd, Shanghai, China, weighing 50-70 g. The animals were housed in individual stainless steel cages under standard conditions (20-22℃, 50%-55% humidity, 12/12 h dark/light cycle). The rats were fed with a solid standard chow [DongChuang Lab Animal Ltd., Hunan, China, including 17.53% (wt/wt) protein, 6.08% (wt/wt) fat, and 59.98% (wt/wt) carbohydrate, calories (1250 kj/100 g)] for 1 wk. After this adaptation period, 48 rats were randomly assigned to six dietary treatment groups, 8 rats in each group. Each rat was fed diet 13 g/d from the 1st wk, which was then increased by 2 g/d per week. Control group was fed on a standard chow, and the other groups were fed on a high-fat diet (HFD)(DongChuang Lab Animal Ltd, HuNan, China, 16.52% (wt/wt) protein, 25.17% (wt/wt) fat, and 56.66% (wt/wt) carbohydrate, calories (1810 kj/100 g). Each interventional group was administered with *B. L66-5*, *B. L75-4*, *B. M13-4* and *B. FS31-12*, respectively. Model and control groups were given equivalently 0.9% saline. All rats had free access to water and were supplied with bacteria liquid or 0.9% saline by intragastric gavage at a fixed time every day. The assigned diets were given to the rats for 6 wk. BW was measured weekly and caloric intake was accounted finally. All the rats were sacrificed by ether for further studies. The care and use of animals followed our institutional and national guidelines and all experimental procedures involving animals were approved by the ethics committee of the Central South University.

Oral glucose tolerance test

At the 6th weekend after dietary treatment, the rats were deprived of diet for 12 h, then given glucose solution (5 g/kg) by intragastric gavage. Blood samples were drawn from tails to do the oral glucose tolerance test (OGTT) test. Serum glucose was measured at 0, 30, 60, 90 and 120 min by fast blood glucose meter (OneTouch-Ⅱ, Johnson, America).

Assay for weight gain and fat index

After the OGTT test, the rats were fasted for 12 h and euthanized with ether. Liver, retroperitoneal (RET) and

epididymal (EPI) white adipose tissues were immediately removed and weighed.

Measurement: (1) Lee's index: (bodyweight)$^{1/3}$ × 10^3/ stem length (length from nasal tip to anus); (2) boby fat index: viscera fat/body weight ratio (viscera fat includes RET and EPI white adipose tissues); and (3) liver index: liver/body weight ratio.

Assay for serum triglycerides, total cholesterol and insulin

Blood samples were collected immediately in sterile tubes by heart puncture. Serum was collected by centrifugation at 2000 × *g* for 15 min at 4℃. The serum samples were analyzed for triglycerides (TG), total cholesterol (TCH) and insulin according to protocols of triglycerides fluid monoreagent (GPO-PAP) and cholesterol oxidase peroxidase-amidopyrine (CHOD-PAP) analysis (CHOD-PAP) and radioimmunoassay (Dongou Bio-Tech Ltd, Wenzhou and 3v Bio-Tech Ltd, Weifang, China).

Assay for liver lipid

Liver tissues (100 mg) were pulverized in liquid nitrogen to prepare 10% tissue homogenate. These homogenates were extracted under 4℃ with chloroform: methanol (2:1) for 48 h, then centrifuged at 12 000 × *g*/min for 15 min at 4℃. The concentrations of TG and TCH in supernatant were determined according to the protocols.

Liver histopathology

Liver tissues were routinely fixed in paraffin-embedded sections, and stained with hematoxylin and eosin (HE). To detect lipid droplets, sections were stained with Sudan Ⅳ and counterstained with hematoxylin. Each histologic section was observed for 5 fields of high power field. The classification and degree of fatty deposition are as follows: mild fatty degeneration (+): fatty hepatocytes occupying 30%-50% of the hepatic parenchyma, moderate fatty degeneration (++): 50%-75%, and severe fatty degeneration (+++): > 75%.

Statistical analysis

All data were presented as the mean ± SD. Univariate analysis of variance test was applied to determine the statistical significance of the difference among the groups, using the General Linear Models procedure of SPSS15.0 (SPSS Inc., Chicago, IL, USA). Some rank/frequency data were analyzed by nonparametric test, with the significance level set at $P < 0.05$.

RESULTS

Caloric intake, BW increment and obesity indexes in high-fat diet treated rats administered with different strains of Bifidobacteria

No rat died throughout the study. Caloric intake in control group (standard chow) was significantly lower than that of model group (HFD) (9055.68 ± 1246.62 kj *vs* 14562.32 ± 541.55 kj, $P < 0.05$). However, among model group and the four *Bifidobacteria* groups which were fed on high-fat diets, caloric intake showed no significant difference ($P > 0.05$). These indicate that the different groups of HFD rats had a similar caloric consumption (Figure 1A). The weight of all groups was increased every week, especially the model group and group *B. M13-4*. At the end of the 3rd wk, the BW increment in group *B. L66-5* was significantly less than in model group (90.26 ± 27.06 g *vs* 115.75 ± 15.13 g, $P < 0.05$), and further increased (156.05 ± 33.19 g *vs* 186.98 ± 16.25 g, $P < 0.05$) at the end of 5th wk. At the 6th week-end, weight increment in group *B. L66-5* was much less than the model group (175.19 ± 31.24 g *vs* 212.55 ± 18.54 g, $P < 0.05$). However, the BW increment was significantly higher in group *B. M13-4* than in the model group (264.27 ± 26.91 g *vs* 212.55 ± 18.54 g, $P < 0.05$). No significant change of BW was found in group *B. L75-4* and group *B. FS31-12* compared with the model group (Figure 1B).

Both the Lee's and liver indexes were decreased in all interventional groups. The liver index was obviously lower in control, *B. L75-4*, *B. M13-4* and *B. FS31-12* groups than in model group (4.04% ± 0.36%, 4.27% ± 0.50%, 4.27% ± 0.47%, 4.04% ± 0.36% *vs* 4.98% ± 0.72%, $P < 0.05$). The body lipid index showed no significant differences among the groups ($P > 0.05$) (Figure 1C). The Lee's index was significantly lower in groups *B. L66-5* and *B. FS31-12* than in model group (312.65 ± 20.18, 311.22 ± 17.52 *vs* 327.98 ± 8.90, $P < 0.05$, Figure 1D).

Effects of Bifidobacteria strains on glucose and lipid metabolism in high-fat diet treated rats

Effect of four *Bifidobacteria* strains on serum glucose: In control group, the peak of serum glucose appeared at 30 min and returned to normal at 120 min when glucose was significantly lower than in model group (5.32 ± 0.98 *vs* 7.17 ± 1.08, $P < 0.05$). In high-fat diet fed groups, the peak was postponed to 60-120 min and lasted longer than that in control group. In these groups, the serum glucose did not return to normal until 120 min. The serum glucose at 5 time points showed no significant differences among model group and interventional groups ($P > 0.05$) (Figure 2A).

Changes of serum insulin, TG and TCH and liver TG and TCH: The serum insulin (INS) showed no significant differences among the groups ($P > 0.05$) (Figure 2B). The TG levels in serum decreased significantly in all intervention groups compared with the model group (1.59 ± 0.73, 1.54 ± 0.30, 1.23 ± 0.65, 1.47 ± 0.70 *vs* 2.23 ± 0.76, $P < 0.05$), so did the TG levels in supernatant of liver homogenate in those groups (0.13 ± 0.02, 0.31 ± 0.16, 0.34 ± 0.08, 0.29 ± 0.10 *vs* 0.56 ± 0.04, $P < 0.05$) (Figure 2C). In groups *B. L66-5* and *B. FS31-12*, the TCH level in serum and liver were obviously lower than in model group (1.11 ± 0.18, 1.37 ± 0.26 *vs* 1.72 ± 0.38, $P < 0.05$ and 1.27 ± 0.08, 0.62 ± 0.6 *vs* 1.47 ± 0.05, $P < 0.05$, Figure 2D), while the other strains also showed a downward trend ($P > 0.05$).

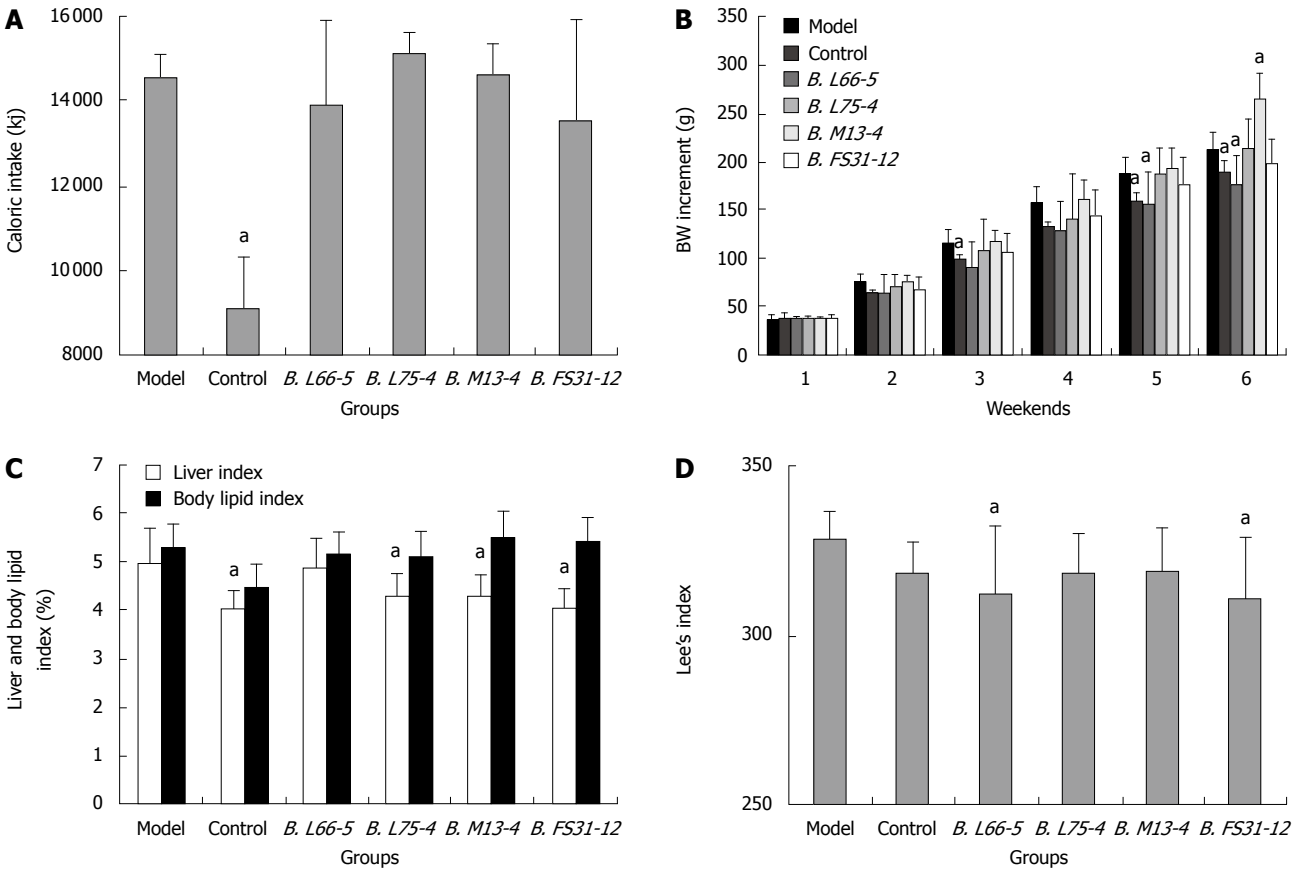

Figure 1 Caloric intake, body weight increment and obesity indexes in high-fat diet treated rats with different strains of *Bifidobacteria*. A: Sum of caloric intake in all groups at the 6th weekend; B: Body weight (BW) increment in all groups for 6 wk; C: Liver index and body lipid index in all groups; D: Lee's index in all groups. Results are shown as mean ± SD (n = 8). $^{a}P < 0.05$ *vs* model group.

Hepatic lipid deposition in high-fat diet induced rats treated with different strains of Bifidobacteria

Moderate degree of microvesicular steatosis was observed in model group. No fatty vacuolization was found in groups *B. L66-5* and *B. FS31-12*. Hepatocyte steatosis was obviously alleviated in groups *B. L75-4* and *B. M13-4* compared with model group (χ^2 = 30.754, P = 0.000) (Table 1 and Figure 3). Sudan Ⅳ staining showed that a plenty of scarlet lipid droplets deposited in the livers of model group, which confirmed the results shown in HE staining. Expectedly, lipid droplets were obviously decreased in all intervention groups compared with the model group, especially in groups *B. L66-5* and *B. FS31-12* (Figure 4).

DISCUSSION

To demonstrate the relationship between the administration of different strains of *Bifidobacteria* and the status of glucose and lipid metabolism, we established a murine obese model based on a 6-wk administration of high-fat diet (HFD), characterized by a significant increase of BW gain, fat mass, TG and TCH in serum and liver, and obesity indexes. Our results demonstrated that administration of the four *Bifidobacteria* (*Bifidobacteria L66-5*, *L75-4*, *M13-4* and *FS3-1-1-2*) played a role in reducing serum and liver TG and TCH, as well as liver lipid deposition. Furthermore, to our surprise, among the four strains of *Bifidobacteria*, two contrary results were yielded in BW changes: *B. M13-4* showed a significant increase in BW while *B. L66-5* showed a decrease in BW based on a similar caloric consumption. *Bifidobacteria L75-4* and *FS3-1-1-2* strains had no significant effect in BW change. However, all the four strains showed no significant influence on serum INS and glucose level. Based on our results, different *Bifidobacteria* strains lead to different responses of energy and fat metabolism in rat models.

Recent researches illustrated that gut microbiome should be considered as a set of genetic factors that, together with host genotype and life style (energy intake and expenditure), contribute to the pathophysiology of obesity. Turnbaugh *et al*[13] observed microbiota samples of obese mice, after transferring the microbiota to germ-free lean mice, significant fat gain was obtained and calorie extraction improved. BW increase has also been observed after administration of *Bifidobacterium*. In a preterm infant study in 1997, the authors added *Bifidobacterium breve* (about 0.5 × 10^9 live bacteria) to very low-birth weight infant formula, and their BW gain became significantly greater than in control group after administration for 4 wk[14]. In other cultures, *Lactobacillus rhamnosus GG* (1 × 10^7 cfu/g) also led to a weight growth in term infants after being supplemented to formulas for 4 mo[15]. However, *Bifidobacterium longum*[16], *Bifidobacterium lactis*[17,18], and *Bifidobacteria* combined with several species of *lactobacilli*

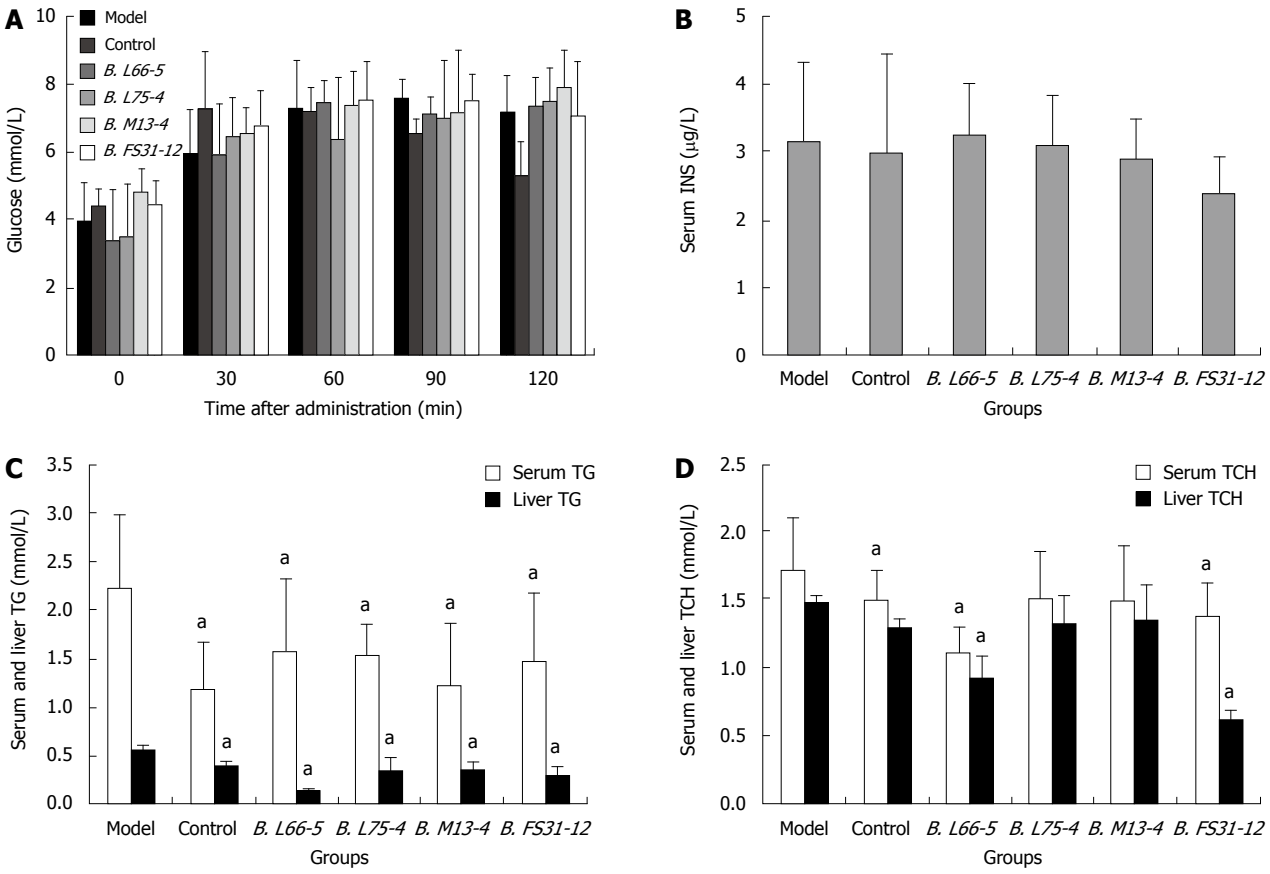

Figure 2 Effects of *Bifidobacteria* strains on glucose and lipid metabolism in high-fat diet treated rats. A: Effect of four *Bifidobacteria* strains on serum glucose; B: Serum insulin (INS) concentration in all groups; C: Serum and liver triglycerides (TG) in all groups; D: Serum and liver total cholesterol (TCH) in all groups. Results are shown as mean ± SD (n = 8), $^aP < 0.05$ *vs* model group.

Table 1 Degrees of liver lipid deposition in all groups

Groups	*n*	Degree of fatty deposition[1]			
		-	+	++	+++
Model	8	0	7	1	0
Control	8	8	0	0	0
B. L66-5	8	8	0	0	0
B. L75-4	8	6	2	0	0
B. M13-4	8	5	3	0	0
B. FS31-12	8	8	0	0	0

[1]The standard of classification and score for the degree of lipid deposition in liver was referred to the liver histopathology mentioned in MATERIALS AND METHODS.

plus *fructooligosaccharides*[19] have not shown any effects. Their similar concentrations and intervention periods indicated different effects *in vivo*. In this study, *B. M13-4* strain can decrease serum and liver TG, TCH and liver index, while no apparent changes were found in body lipid index and Lee's index with an obvious BW gain. It suggests that *B. M13-4* alleviated lipid deposition in liver although more fat was accumulated in the body. The mechanisms may be complex: (1) Intestinal microbiota can help the host to digest polysaccharides and absorb monosaccharides and short-chain fatty acids, which finally converse to lipids[20]; (2) Gut microbiota can modulate some signal pathways associated with energy balance in the gut epithelium: Gpr41, a short-chain fatty-acid binding G protein-coupled receptor, and peptide tyrosine tyrosine[21]; (3) *Bifidobacteria* can also help the host to eradicate *Campylobacter*[22] or *Eandida* and *Enterococcus*[23] to stabilize their intestinal flora; and (4) The amount of visceral fat is positively correlated with the insulin sensitivity[24,25]; the possible effect in improving insulin sensitivity to alleviating visceral adiposity of probiotics is limited in our study and worth further studies. Host colonized by *B. M13-4* absorbed more fat and transmitted them into body fat. This may contribute to the patients with fat/energy malabsorption. We should also reappraise the probiotics use in healthy and obese people for their potential effects such as fat/energy over-absorptions and weight over-growth.

To our surprise, rats colonized by *B. L66-5* showed a weight loss. The opposite outcomes in *B. M13-4* and *B. L66-5*, and strains showing no effect in BW, including *B. L75-4* and *B. FS3-1-1-2*, and other strains, including *Lactobacillus acidophilus ATCC 43121*[4], *Lactobacillus gasseri SBT2055*[5] and *Bifidobacterium longum*[6], *VSL#3*[12], *Lactobacillus reuteri*[26], may result from different interactions between strains and intestinal microbia, inappropriate dosage, variability in end-points, and subjects. Anyhow, *B. L66-5*

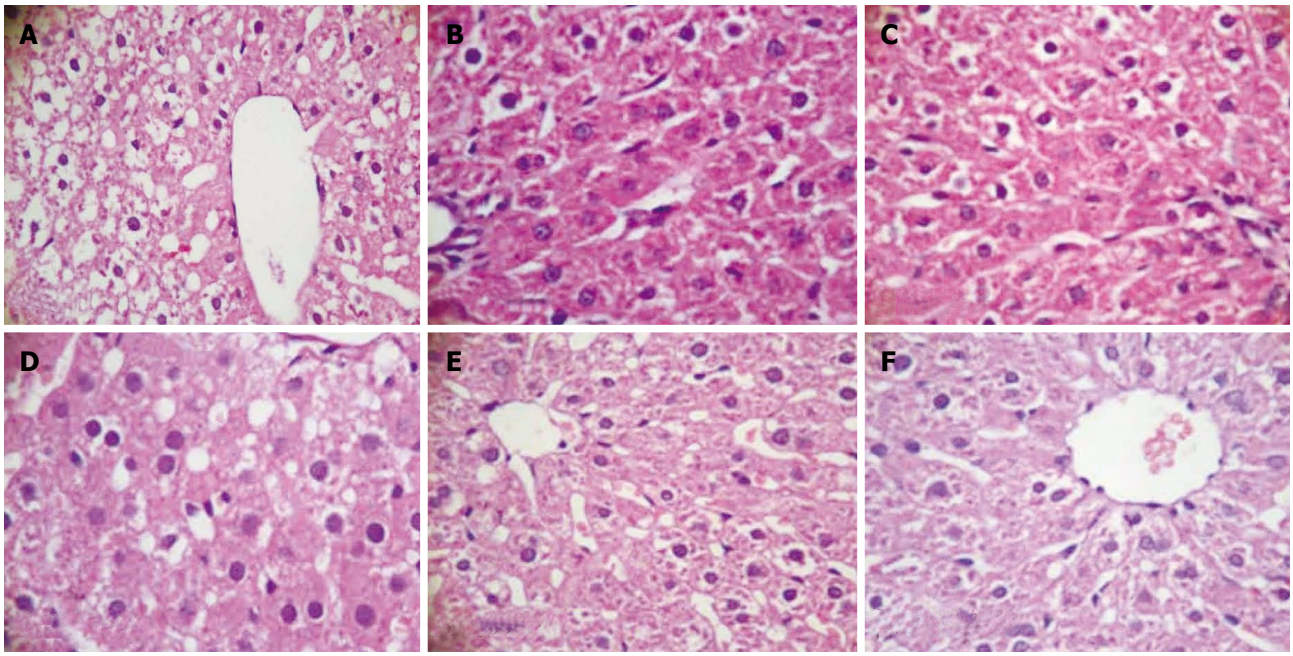

Figure 3 Hepatic tissue sections of each group in HE staining (HE, light microscope, × 400). A: Model; B: Control; C: *B. L66-5*; D: *B. L75-4*; E: *B. M13-4*; F: *B. FS31-12*.

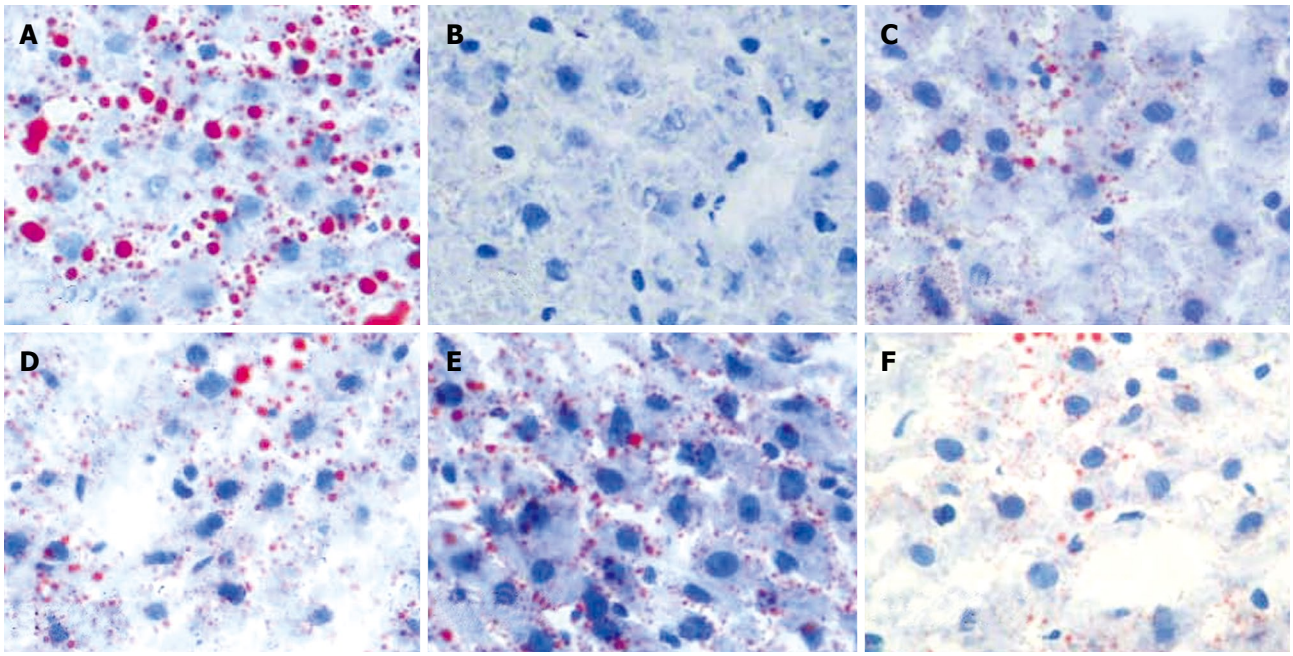

Figure 4 Hepatic tissue sections of each group in Sudan Ⅳ-staining (Sudan Ⅳ, light microscope, × 400), and lipid droplets are scarlet. A: Model; B: Control; C: *B. L66-5*; D: *B. L75-4*; E: *B. M13-4*; F: *B. FS31-12*.

was specific in regulating fat harvest and utilization, and may be a new therapeutic candidate for weight control.

All the four strains showed their effects in reducing serum TG and TCH, especially the strain *B. L66-5*. Administration of *B. L66-5* decreased the serum and liver TG and TCH and BW, and alleviated liver lipid deposition. Recent studies showed that probiotics had hypocholesteremia effects in both rat and human, including *Bifidobacterium longum*[6], *Lactobacillus acidophilus ATCC* 43121[4], *Lactobacillus plantarum MA2*[9], *Lactobacillus gasseri*[27], *Lactobacillus reuteri*[26,28], *Bacillus polyfermenticus SCD*[29], *etc*. Some specific probiotics strains could reduce serum TCH and TG, and increase the ratio of high-density lipoprotein/low-density lipoprotein (HDL/LDL). The mechanisms involved may be as follows: (1) assimilation of cholesterol by bacterial cells; (2) deconjugation of bile acids by bacterial acid hydrolyses (reduces cholesterol reabsorption, increases cholesterol excretion of deconjugated bile salts, and increases cholesterol uptake by low-density lipoprotein receptor pathway in the liver

as a compensatory response); (3) cholesterol binding to bacterial cell walls; and (4) inhibition of hepatic cholesterol synthesis and/or redistribution of cholesterol from plasma to the liver through the action of short-chain fatty acids, the end products of carbohydrate fermentation in the gut[30]. Furthermore, our results showed an individual amelioration effect in hepatic steatosis. The degree of fatty deposition in liver was obviously alleviated in all intervention groups as shown by liver histopathology. Probiotics VSL#3 also showed an effect in improving high-fat-diet induced hepatic steatosis in rats through lowering liver inflammatory signaling, increasing the expression of peroxisome proliferators-activated receptor α and hepatic natural killer T cell numbers[31,32]. However, the signaling capabilities of the four *Bifidobacteria* need further studies.

The four strains showed no significant differences in serum INS and glucose level. Similar negative results were also documented by Esposito *et al*[32] and Sato *et al*[5]. In our study, we fed the rats with high-fat diet for 6 wk, and none had a significant change of INS level, while in other HFD induced SD rats, insulin resistance did not occur until 8 mo or 36 wk[33,34]. So the next experimental period may prolong to 8 mo or longer.

In conclusion, we established a murine obese model based on a 6-wk administration of high-fat diet, which partially resembles the disorder of energy metabolism in human. The response of glucose and lipid metabolism to several strains of *Bifidobacteria* was evaluated. It was indicated that administration of the four strains of *Bifidobacteria* resulted in decreased serum/liver TG, serum/liver TCH, and hepatic steatosis, with no significant response to glucose and INS level. To our surprise, the data we presented demonstrated that administration of strain *B. L66-5* led to BW loss, decreased serum TG/TCH and decreased hepatic adiposity, while administration of strain *B. M13-4* resulted in significant increase of BW gain with alleviated hepatic adipose and serum/liver TG in rats. Thus, it is concluded that the response of energy metabolism to administration of *Bifidobacteria* is strain dependent. Different strains of *Bifidobacteria* might drive different directions of fat distribution. *B. M13-4* action may generate a new conception: certain probiotics may promote BW gain by more effective fat absorption, and a cautious assessment is needed before probiotics therapy is given, especially in obese people. *B. L66-5* might act as a new therapeutic probiotic candidate in controlling BW gain. Further studies should focus on evaluating how the administration of these *Bifidobacteria* modifies gut microbiota of obese rats.

COMMENTS

Background

Obesity is becoming a global epidemic. Recent researches have demonstrated that obesity may lead to the composition shift of gut microbiota in both mice and humans. The intentional manipulation of community structure of gut microbiota may be a novel strategy to treat obesity.

Research frontiers

Bifidobacterium is one of the most numerous "probiotic" in mammalian gut among commensal bacteria, and exhibited a significant effect in lowering serum total cholesterol. Specific strains of *Bifidobacteria* for energy metabolism may be helpful in management of obesity.

Innovations and breakthroughs

This study evaluates the effects of the administration of four strains of *Bifibofacteria* in obese rats. It demonstrated an interesting action of these strains on harvest energy from nutrients and regulation of lipid storage.

Applications

The manuscript gives new and interesting information about the key role of gut microbiota in the harvest energy from nutrients and regulation of lipid storage and metabolism.

Terminology

Probiotic bacteria are defined as living microorganisms that have beneficial effects in human health.

Peer review

This study evaluates the effects of the administration of four strains of *Bifibofacteria* on obese rats. It demonstrated an interesting action of these strains on harvest energy from nutrients and regulation of lipid storage. It is an interesting work that gives new information about the role of gut microbiota in host metabolism.

Abstract

AIM: To study the demographic and endoscopic characteristics of patients with sessile serrated adenoma (SSA) in a single center.

METHODS: Patients with SSA were identified by review of the pathology database of Mayo Clinic Arizona from 2005 to 2007. A retrospective chart review was performed to extract data on demographics, polyp characteristics, presence of synchronous adenomatous polyps or cancer, polypectomy methods, and related complications.

RESULTS: One hundred and seventy-one (2.9%) of all patients undergoing colonoscopy had a total of 226 SSAs. The mean (SE) size of the SSAs was 8.1 (0.4) mm; 42% of SSAs were ≤ 5 mm, and 69% were ≤ 9 mm. Fifty-one per cent of SSAs were located in the cecum or ascending colon. Approximately half of the patients had synchronous polyps of other histological types, including hyperplastic and adenomatous polyps. Synchronous adenocarcinoma was present in seven (4%) cases. Ninety-seven percent of polyps were removed by colonoscopy.

CONCLUSION: Among patients with colon polyps, 2.9% were found to have SSAs. Most of the SSAs were located in the right side and were safely managed by colonoscopy.

INTRODUCTION

Colorectal carcinoma (CRC) follows the adenoma-carcinoma sequence[1] in the majority of patients. CRC development secondary to DNA microsatellite instability (MSI-high) with a deficiency of DNA mismatch repair occurs only in a minority of patients[2,3]. MSI-high carcinoma usually progresses along the "serrated pathway"[4-6]. Historically, hyperplastic polyps (HPs) have usually been regarded as non-neoplastic lesions with no malignant

potential. However, some lesions previously diagnosed as HP but with malignant potential, which are now known as "sessile serrated adenomas" (SSAs), are increasingly being recognized[7,8]. SSAs may develop MSI as they progress toward carcinoma, and are potential precursors of sporadic microsatellite unstable CRC. Clinical and demographic characteristics including age, sex, racial distribution, endoscopic characteristics (location, gross appearance), recurrence rate, and the rate of progression of these polyps to carcinoma are not well known. There are no published consensus practice guidelines, and the optimal surveillance colonoscopy interval of these polyps is unknown, due to the paucity of clinical information regarding these patients.

The aim of our study was to identify demographic and endoscopic characteristics of patients with SSA in a single center and report the clinical experience with SSA in a large group practice.

MATERIALS AND METHODS

Patients with SSA were identified by review of an institutional pathology database from the years 2005-2007. Patient charts were reviewed for data on demographics and colonoscopy details. Colonoscopy reports were reviewed to obtain the number, size, and location of polyps, as well as the morphological appearance and the polypectomy methods. In addition, data were collected on synchronous adenomatous polyps or cancer, and the number of colonoscopies needed to eradicate the polyps, the need for surgical therapy, and colonoscopy-related complications. All colonoscopies were done with standard white light examination technique with standard definition colonoscopes. SSA was defined in practice and in this report as polypoid lesions that lacked typical or conventional dysplasia, but that showed architectural features of disordered growth[9,10]. These features are: basal crypt dilatation, horizontal orientation of deep crypts, prominent serration extending deep into the crypts, irregular crypt branching, and inverted crypts. Other criteria consistent with abnormal proliferation were also useful in the diagnosis of SSA; these were nuclear atypia and/or oval nuclei in mid/upper crypts, prominent nucleoli in middle/superficial crypts, dystrophic goblet cells, irregular distribution of goblet cells, mitoses in mid/upper crypts, and excessive crypt or luminal mucin (Figure 1). We classified the polyps as SSA even if the diagnostic changes were only identified focally.

Descriptive analysis was performed using statistical software (SPSS version 17; SPSS Inc., Chicago, IL, USA) to study the demographic and clinical characteristics of these patients.

RESULTS

Among patients undergoing colonoscopy from 2005 to 2007 (21 238 colonoscopies), a total of 5991 patients were found to have polyps. Of these, 171 (2.9%) patients had a total of 226 SSAs. The majority of patients with SSAs in our study were Caucasian (164, 96%) with a mean (SE) age of 65.9 (0.8) years and a mean body mass index of 29.6 (0.4). Ninety-one patients (53%) were male. The SSA characteristics are summarized in Table 1. The mean size of the SSAs was 8.1 (0.4) mm (range 2-40 mm); 42% were ⩽ 5 mm and 69% were ⩽ 9 mm in size. The majority of SSAs were located in the right side of the colon (Figure 2). All SSAs were described as sessile or flat in appearance (Figure 3). The mean number of SSAs per patient was three (range 1-24); 58 (34%) patients had one SSA, 43 (25%) had two and 70 (41%) had three or more. Approximately half (87, 51%) of the patients had synchronous polyps of other histological appearance. The most common type of associated pathology in these synchronous polyps was tubular adenoma in 62 (49%) polyps, tubulovillous adenoma (TVA) in 13 (10%) and hyperplastic pathology in 50 (40%). One polyp was a small carcinoid. Synchronous adenocarcinoma was present in seven (4%) cases and all of these cancers were present in the cecum or ascending colon.

Thirty-one percent of SSAs were removed by cold biopsy/cold snare, 4% by hot biopsy, 63% by snare cautery, and 2.7% required surgical excision due to size or associated malignancy. Polyp removal techniques depended on the judgment and preference of the endoscopist. All polyps ⩾ 2 cm in size were removed by saline-assisted polypectomy. There were no complications associated with the endoscopic resection of the SSAs. Although up to nine pathologists interpreted the histopathology of these polyps, the majority (75%) were diagnosed as SSA by two

highly experienced gastrointestinal pathologists. In the clinical practice of pathologists interpreting specimens, in 12.6% cases, the diagnosis of SSA was confirmed in consultation by a second pathologist within the department.

DISCUSSION

Colorectal serrated polyps are a group of morphologically related lesions that include aberrant crypt foci, conventional HPs, advanced serrated adenomas (ASAs)[11] and SSAs. These lesions share some histological features, however, they differ significantly at the molecular level, and are biologically distinct[12]. In 1990, Longacre and Fenoglio-Preiser[13] first used the term serrated adenoma. While many patients probably had serrated lesions described as hyperplastic in the past, some have mixed hyperplastic and adenomatous features. Unfortunately, often there is significant disagreement among pathologists in the diagnosis of these polyps. In a study of 185 serrated polyps, five gastrointestinal pathologists had only moderate overall agreement ($\kappa = 0.58$), with near perfect agreement on traditional serrated adenoma, also called ASA, but varying most in the SSA and hyperplastic categories[14]. In our study, the majority of these polyps (75%) were diagnosed as SSA by two experienced gastrointestinal pathologists, however, up to nine pathologists interpreted the histopathology of polyps. In 12.6% of our cases, a second pathologist's opinion was obtained by intradepartmental consultation for diagnosing SSA, which suggests difficulty in day to day clinical interpretation using standard published criteria. Simple standardized diagnostic criteria and terminology could improve interobserver agreement among pathologists, and represent a limitation in the interpretation of this study, and an opportunity for improvement in overall clinical practice.

In the present study, approximately 3% of all polyps were SSAs, which is similar to previous studies[15,16]. However, a prospective study using magnifying chromoendoscopy has reported a 9% prevalence of SSAs[17]. All examinations in our study were performed with standard white light colonoscopes, and the diagnosis of SSAs was made in real time clinical practice between 2005 and 2007. Polyps in the database were not re-examined, which could have changed the actual prevalence. Endoscopically, SSAs commonly appear flat or sessile, have a soft, smooth surface, and are often covered with mucus, which gives an initial yellow appearance[9]. Small, flat, right-sided lesions potentially can be missed by white light colonoscopy. Newer techniques such as high definition colonoscopy, narrow band imaging or chromoendoscopy could help to distinguish these polyps from normal mucosa.

The majority of patients with SSA in our study had multiple SSAs (mean = 3, range = 1-24). Approximately half of these patients also had synchronous polyps of other histological type, such as tubular adenoma, TVA and HPs. Synchronous right-sided adenocarcinoma was seen in 4% of cases.

As noted in other studies[15,18,19], the majority (67%) of SSAs in our study were located proximal to the splenic flexure. Forty-two percent of all SSA were $\leqslant$ 5 mm, and 69% were $\leqslant$ 9 mm in size. In a study of 13 992 colonoscopies from the Clinical Outcomes Research Initiative (CORI) repository[20], when pathology results were available, 1.7% of polyps that measured 5 mm ($n = 3744$) had advanced neoplasia [one cancer, one high-grade dysplasia (HGD), 44 TVA]. In polyps 6-9 mm in size ($n = 1198$), 6.6% had advanced neoplasia (two cancers, nine HGD, and 53 TVA), which suggests that not all small polyps are innocent. The natural history of SSAs is not well understood. Although carcinoma associated with advanced serrated adenoma has been reported to be a distinct type of neoplasm, which accounts for 5.8%-7.5% of all colorectal carcinomas and up to 17.5% of proximal colon cancers[21,22], the overall impact of SSAs on cancer risk is not known because of a lack of data on their true prevalence. There have been reports of rapid progression of SSA to invasive cancer as early as within 8 mo [23]. The current surveillance interval recommendation[24,25] for small SSAs is mainly based on indirect evidence, and is similar to that for small adenoma (5 years). Surveillance of large SSAs or more than three SSAs is similar to large or advanced adenoma (3 years).

The retrospective design and lack of long-term longitudinal follow-up data are major limitations of our study. Demographically, our patient population was predominantly Caucasian and above ideal body weight. These factors could limit the applicability of our results to other populations. Future large prospective studies are needed to understand the natural history of SSAs and to establish

clinical practice guidelines for optimal cost-effective management and surveillance of patients with SSA.

COMMENTS

Background

Colorectal carcinoma (CRC) usually follows a sequence of development from adenomatous polyp to carcinoma. In a minority of patients, CRC development occurs due to alterations of small areas of DNA known as microsatellite instability (MSI). These patients have a defect in their DNA repair mechanism. Carcinomas that develop by this mechanism often have a special serrated appearance. One type of polyp with a serrated appearance, hyperplastic polyps (HPs), have usually been regarded as non-neoplastic lesions with no malignant potential. However, some lesions previously diagnosed as HPs, but with malignant potential, are now known as sessile serrated adenomas (SSAs), and are increasingly being recognized. SSAs can develop MSI as they progress toward carcinoma, and are potential precursors of sporadic microsatellite unstable CRC.

Research frontiers

SSA are uncommon colon polyps. The clinical and demographic characteristics of patients with these polyps, including age, sex, racial distribution, endoscopic characteristics (location, gross appearance), recurrence rate, and rate of progression of these polyps to carcinoma are not well known, and were evaluated in this study.

Innovations and breakthroughs

Between 2005 and 2007, 171 (2.9%) patients undergoing colonoscopy had a total of 226 SSAs. The average size of the SSAs was 8.1 mm. Forty-two percent of SSAs were ⩽ 5 mm and 69% were ⩽ 9 mm. Fifty-one per cent of SSAs were located in the cecum or ascending colon. Approximately half of the patients had coexisting colon polyps of other histological types, including hyperplastic and adenomatous polyps. Coexisting adenocarcinoma was present in seven (4%) cases. Ninety-seven percent of polyps were removed by colonoscopy.

Applications

Most of the SSAs were located in the right side of the colon and were safely managed by colonoscopy. Concurrent lesions including adenomas and right-sided colon cancers were not uncommon. The natural history of SSAs is being learned, and greater concern about small polyps might exist in the future, as some can be aggressive or associated with other lesions.

Peer review

This is an extensive study of a very important topic. The disadvantage of the study is its retrospective nature; especially concerning the endoscopic findings and follow-up.

Abstract

AIM: To evaluate fecal calprotectin concentrations (FCCs) in subjects with chronic gastritis and the correlation between FCCs and gastritis activity score.

METHODS: FCCs were measured in 61 patients with histological diagnosis of gastritis and in 74 healthy volunteers. Histological grading of gastritis was performed according to the updated Sydney gastritis classification. Patients were subdivided into 2 groups according to the presence/absence of an active gastritis. Patients with chronic active gastritis were divided into 3 subgroups on the basis of the activity score (mild, moderate, marked). FFCs in relation to *Helicobacter pylori* (*H. pylori*) infection and proton pump inhibitor (PPI) use were also evaluated.

RESULTS: FCCs in patients with chronic active gastritis were not significantly different to FCCs either in subjects with non active gastritis or in healthy controls. Among patients with chronic active gastritis (even marked), FCCs did not significantly differ according to activity score. No significant differences in FCCs were found when considering *H. pylori*, as well as when considering PPI chronic use.

CONCLUSION: FCCs were not significantly increased in subjects with chronic gastritis, even in those patients with a marked neutrophil infiltration.

Key words: Chronic gastritis; Fecal calprotectin; Intestinal inflammation; Neutrophils

INTRODUCTION

Calprotectin is a calcium and zinc binding protein, mainly contained in neutrophils where it accounts for more than 60% of cytosolic proteins. It has well-known antimicrobial activity, both bacterial and fungicidal[1]. Elevated concentrations of calprotectin can be measured in plasma, synovial fluid, urine, liquor, saliva and feces when an

inflammation process with recruitment of neutrophils is ongoing[2,3]. In particular, the presence of calprotectin in feces quantitatively relates to neutrophil migration towards the gastrointestinal tract[4]. Its levels are closely correlated with the fecal excretion of ^{111}In-labelled leukocytes[5]. Therefore, it is considered a useful marker of intestinal inflammation[6]. Several recent studies reported a significant increase in fecal calprotectin concentrations (FCCs) in intestinal conditions characterized by a conspicuous neutrophil infiltrate, such as inflammatory bowel diseases (IBDs) and non-steroidal antiinflammatory drug (NSAID) enteropathy[7-9]. It may accurately distinguish IBD from non-IBD conditions (such as irritable bowel syndrome)[10,11]. It has also been proposed as a reliable marker able to predict clinical relapse in IBD patients[12,13]. Diagnostic accuracy of FCCs in colorectal neoplasia has not been univocally established yet[14].

Chronic gastritis represents a common and heterogeneous inflammatory process. It can be morphologically characterized by a variable inflammatory infiltrate in the lamina propria, within the epithelium and within the foveolar lumen[15]. According to the updated Sydney System, the presence of a neutrophil infiltrate characterizes the "activity" of gastritis[15].

The aim of our study was to evaluate FCCs in subjects with chronic gastritis and the possible correlation between FCCs and the activity score, according to the updated Sydney System gastritis classification.

MATERIALS AND METHODS

Patients

Between May 2008 and December 2008, subjects who were referred to the Endoscopy Center of "Gemelli Hospital" for upper gastrointestinal endoscopy, were invited to enter the study. In those subjects who agreed to participate in the study, the extraction of at least 5 biopsy samples (2 from the antrum, 2 from the corpus and one from the incisura angularis) had been undertaken to correctly characterize an eventual gastritis process, in accordance with Sydney's recommendations[15]. However, when esophageal lesions, gastric ulcers, gastric polyps or duodenal lesions were found during the endoscopy, the necessary biopsy specimens were taken, and these subjects were not included in the study. In addition, subjects with IBDs or family history of IBDs, colorectal cancer, chronic use of NSAIDs, history of gastric resection, coexisting and severe cardiopulmonary, hepatic, renal, neurologic, psychiatric, endocrine and rheumatologic diseases, malignancy, pregnancy, alcohol abuse, other intestinal disorders characterized by increased mucosal permeability and inflammatory changes, were not considered for the study.

All the eligible subjects were asked to provide a stool sample for measurement of calprotectin levels, within 2 d of endoscopic examination, before starting specific therapy. Stools were also examined to exclude infectious intestinal diseases. All subjects were asked if they were taking proton pump inhibitor (PPI) therapy for at least since 1 mo before the endoscopy.

According to the updated Sydney System, depending on the presence/absence of a neutrophil infiltrate, patients with chronic gastritis were divided into 2 groups: group A which consisted of patients with active gastritis and group B which consisted of patients with non active gastritis. Furthermore, adult healthy volunteers participated as a further control group, providing their own stool sample.

Procedures were in accordance with the ethical standards of the Helsinki Declaration of 1975, as revised in 1983. Each subject gave written informed consent for the study. The study was approved by the Institutional Board of Department of Internal Medicine, Catholic University of Rome.

Histological evaluation

The biopsy samples were fixed in 4% buffered formalin, processed in the usual manner, and paraffin embedded. The sections were stained with hematoxylin and eosin for histological evaluation; Giemsa stain was also used to evaluate the presence of *Helicobacter pylori* (*H. pylori*). The sections were evaluated by 2 separate expert gastrointestinal pathologists working blind. The degree of activity of inflammation was assessed using a semiquantitative 3-tiered scale (mild, moderate, marked) according to the updated Sydney System[15]. The infiltration of neutrophil granulocytes was defined as "mild" when isolated cells of this type were identified in the lamina propria only with difficulty, after a thorough search; it was defined as "moderate" if neutrophils were either easily detectable in the lamina propria or were found within the epithelium, provided they were not crowded; finally, the infiltration was defined as "marked" when a dense neutrophil infiltrate, usually involving both lamina propria and epithelium, was strikingly evident at low power magnification. When activity differed among antrum, corpus and incisura angularis, the activity grade in the most severely affected compartment was considered; when activity grade changed among different biopsies of the same gastric compartment, the predominant grade was considered, according to the updated Sydney classification[16]. *H. pylori* status was evaluated as present/absent in all the examined biopsy samples. *H. pylori* density score was graded as mild, moderate and marked, according to the updated Sydney classification[16].

Fecal calprotectin measurement

Each subject was instructed to collect and return a single stool sample within 48 h of defecation. Upon receipt, the stools were frozen and stored at -20℃ for subsequent biomarker determination.

The stool samples were prepared and analyzed according to the manufacturer's instructions (Calprest; Eurospital SpA, Trieste, Italy). A portion of each sample (40-120 mg) was measured and an extraction buffer containing citrate and urea was added in a weight per volume ratio of 1:50. The samples were mixed for 30 s by a vortex method and homogenized for 25 min. One

Healthy controls	74	32/42	45.93 ± 12.42	31.20 ± 19.18

FCCs: Fecal calprotectin concentrations.

milliliter of the homogenate was transferred to a tube and centrifuged for 20 min. Finally, the supernatant was collected and frozen at -20℃. In most cases, time from sampling to preparation and freezing was estimated to be 1-3 d, except for a few samples that took 4-6 d before handling. The supernatants were thawed and analyzed later with Calprest, a quantitative calprotectin ELISA, for determination of calprotectin in stools. The within-assay coefficient of variation was 1.5%. Calprotectin was expressed as μg/g of feces.

Statistical analysis

Statistical comparison of age and sex among patients with chronic active gastritis, non active gastritis and healthy controls was performed by the *t*-test for unpaired data and χ^2 test. FCCs among subjects with active gastritis, non active gastritis and healthy controls groups were compared by the *t*-test for unpaired data.

In subjects with chronic active gastritis, FCC differences among the subgroups identified by density of neutrophil infiltration (activity score) were analyzed by means of one-way analysis of variance (ANOVA). The *post hoc* effect was assessed by Bonferroni *t*-test. Comparison between FCCs and *H. pylori* status, FCCs and PPI use, was performed by means of the *t*-test for unpaired data. FCC differences among the subgroups identified by density of *H. pylori* infection were analyzed by ANOVA. The *post hoc* effect was assessed by the Bonferroni *t*-test. The statistical analysis of categorical parameters was performed by the χ^2 test. All values were assessed as mean ± SD. A *P*-value of 0.05 or less was regarded as significant.

RESULTS

During the study period, 929 subjects had an upper intestinal endoscopy; 696 were ruled out on the basis of the above-mentioned exclusion criteria. Of the 247 eligible patients, 61 Caucasians (28 male, 33 female, mean age 49.64 ± 13.80 years) gave their consent to participate in the study. Seventy four adult healthy volunteers (32 male, 42 female, mean age 45.93 ± 12.42 years) entered the study as controls. The demographic data of the different study groups are summarized in Table 1. There were no significant differences between the groups regarding age and sex.

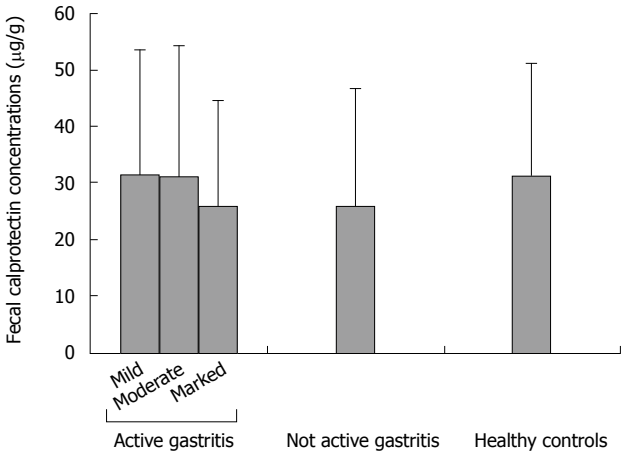

Figure 1 Mean fecal calprotectin concentrations ± SD in the different study groups.

According to the updated Sydney System classification, 35 patients showed chronic active gastritis (group A); in particular, 15 showed mild activity, 10 moderate activity and 10 marked activity. When separately analyzed by antrum gastritis activity (AGA) and corpus gastritis activity (CGA), 21 patients showed predominant antral activity (4 mild AGA without CGA; 7 moderate AGA, 6 with mild CGA and 1 without CGA; 10 marked AGA, 7 with mild CGA and 3 with moderate CGA), 2 showed predominant corpus activity (both with mild CGA without AGA), and the other 12 patients showed a concordant activity between antrum and corpus (9 mild and 3 moderate in both AGA and CGA).

Of the 26 patients with non active chronic gastritis (group B), 15 showed a predominant chronic mononuclear infiltrate, 4 intestinal metaplasia and 7 glandular atrophy.

Mean FCCs were not significantly different between group A and group B, and they both did not differ significantly from FCCs in healthy volunteers (*P* = NS for all comparisons).

When considering only patients with chronic active gastritis, mean FCCs were not significantly different among the 3 subgroups identified by the different degree of neutrophil infiltrate (Table 1 and Figure 1). Also, when separately considering antrum and corpus gastritis, mean FCCs did not correlate with the degree of activity in either subgroup.

When considering the presence of *H. pylori* infection in the whole study group, 24 patients were *H. pylori* positive (7 with mild infection, 8 moderate and 9 marked), while 37 patients were *H. pylori* negative; mean FCCs neither significantly differed between the 2 subgroups (27.35 ± 22.64 *vs* 28.84 ± 24.21, *P* = NS), nor correlated with degree of *H. pylori* infection (*P* = NS for all comparisons). On the other hand, both the presence and density of *H. pylori* significantly correlated with neutrophilic infiltration. In particular, in subjects with chronic active gastritis, 5/15 (33%) with a mild active gastritis, 8/10 (80%) with a moderate active gastritis, and 10/10 (100%) with a severe active gastritis, were *H. pylori* positive, whereas in the group

with non active gastritis, only 1/26 (3.8%) was *H. pylori* positive ($P < 0.001$). In addition, when considering *H. pylori* density, of the 7 patients with a mild *H. pylori* density score, 4 showed mild active gastritis and 3 moderate active gastritis; of the 8 patients with moderate *H. pylori* density, 3 showed moderate active gastritis and 4 showed marked active gastritis, while one had non active gastritis; of the 9 patients with marked *H. pylori* density, one showed mild active gastritis, 2 moderate active gastritis and 6 marked active gastritis ($P < 0.05$).

Finally, when considering PPI use, 22 patients were on PPI therapy and 39 patients were not; mean FCCs were not significantly different between the 2 groups (32.88 ± 25.90 *vs* 25.64 ± 25.83, P = NS).

DISCUSSION

Our study showed no significant differences in FCCs between patients with chronic active gastritis and non active chronic gastritis controls, regardless of the degree of neutrophil infiltration. In addition, FCCs in both groups did not significantly differ with regard to that in healthy controls.

Fecal calprotectin has recently emerged as a reliable marker of intestinal inflammation[14]. Different studies regarding fecal calprotectin have been carried out in bowel diseases, mainly IBDs[8-11]. Up to now, no specific studies have been designed to evaluate FCCs in upper gastrointestinal tract diseases. The few available data on this topic can only be gathered from studies evaluating FCCs in different conditions throughout the gastrointestinal tract. In this regard, only Summerton *et al*[17], in 2002, performed a study evaluating FCCs in different gastrointestinal inflammatory and cancer conditions. In particular, 26 patients showed upper gastrointestinal inflammation because of gastritis and duodenitis. FCCs were in the normal range in all these subjects. Nevertheless, a correlation between FCCs and histological severity of inflammation was not performed in this study.

Chronic gastritis is a very common clinical condition. The updated Sydney System provided the term "activity" as an expression of the presence of neutrophils on a background of chronic inflammation[15].

As expected, we found that patients with non active chronic gastritis did not show increased FCCs, since a neutrophil infiltrate is lacking in these conditions. Nevertheless, we also found that FCCs were not significantly increased in active chronic gastritis, even in subjects with a marked activity score (and so a high grade of neutrophil infiltration). This result could be explained by the consideration that the inflammatory process, and in particular the neutrophil recruitment occurring in gastritis, is far less severe than in other intestinal conditions, mainly IBDs. Furthermore, our findings can be also explained by the smaller extent of inflamed tissue found in gastritis with respect to that in IBDs. In this regard, Sipponenn *et al*[18] reported that subjects with ileal Crohn's disease showed lower fecal markers (calprotectin and lactoferrin) compared to subjects with colonic involvement. They supposed that this finding might be explained by the limited extent of ileal disease, even in the presence of endoscopic and histological inflammation. In addition, in 39 children with IBDs, it has been shown that FCCs were closely related not only to disease severity, but also to disease extent[19].

In our study, we did not consider all those subjects with endoscopic findings involving the esophagus, duodenum or with gastric polyps and ulcers, because our aim was to evaluate FCCs only in chronic gastritis, relating these levels to the neutrophil infiltrate classified according to a validated histological score. Further studies, specifically aimed at this purpose, should clarify if FCCs might be increased in other upper gastrointestinal diseases different from chronic gastritis.

It has been reported that a neutrophil infiltrate is almost always present in *H. pylori* gastritis and usually disappears within a few days of antibiotic therapy[20]. In agreement with data in the literature, we found that the gastritis activity score was closely correlated with the degree of *H. pylori* infection. In particular, only one patient with an absent neutrophil infiltrate was *H. pylori* positive, while all 10 patients with marked active gastritis showed *H. pylori* infection. However, no significant differences were found when FCCs was compared between *H. pylori*-positive and *H. pylori*-negative subjects, regardless of *H. pylori* density score.

Concerning the relationship between PPI therapy and FCCs, Poullis *et al*[21], in a letter, reported that patients using PPIs had significantly higher FFCs compared to those not on PPIs. Nevertheless, data on their population were lacking; they did not undergo endoscopy, and other causes of increased FCCs, such as IBDs and NSAID use were not excluded. On the other hand, it has been reported that PPIs may also inhibit proton pumps present on membranes of phagolysosomes of neutrophils, interfering with neutrophil release of reactive oxygen species, commonly mediated by lysosomal acidification[22,23]. We found that FCCs were not significantly different between subjects taking PPIs and subjects who did not, thus suggesting that gastric pH is unlikely to be responsible for the low levels of FCC we found. On the other hand, it is not possible to exclude that gastric acidity could interfere with FCCs. Until now, no data have been available on this topic and further studies should be encouraged.

In conclusion, we showed that in subjects with chronic active gastritis, even marked, FCCs were not significantly increased when compared with FCCs either in subjects with non active gastritis or in healthy controls. Thus we recommend that in subjects with high FCCs, causes of gut inflammation other than chronic gastritis should be checked.

COMMENTS

Background

Fecal calprotectin is a valid marker of intestinal inflammation, being quantitatively related to neutrophil migration towards the gastrointestinal tract. Fecal calprotectin concentrations (FCCs) are significantly increased in intestinal diseases characterized by a conspicuous neutrophil infiltration, mainly inflam-

matory bowel diseases. Chronic gastritis morphologically shows a variable neutrophil infiltrate, which characterizes the gastritis activity, according to the updated Sydney System classification.

Research frontiers

No systematic study has ever been performed to evaluate FCCs in subjects with chronic gastritis and the possible correlation between FCCs and gastritis activity score.

Innovations and breakthroughs

The authors found no significant difference between FCCs in patients with chronic active gastritis and FCCs either in subjects with non active gastritis or in healthy controls. Among patients with chronic active gastritis (even marked), FCCs did not correlate with the activity score.

Applications

The authors recommend that in subject with high FCCs, causes of gut inflammation other than chronic gastritis should be checked.

Terminology

Calprotectin: A calcium and zinc binding protein, mainly contained in neutrophils where it accounts for more than 60% of cytosolic proteins. It has well-known antimicrobial activity, both bacterial and fungicidal. Elevated concentrations of calprotectin can be measured in plasma, synovial fluid, urine, liquor, saliva and feces when an inflammation process with recruitment of neutrophils is ongoing. The presence of calprotectin in feces quantitatively relates to neutrophil migration towards the gastrointestinal tract. Active gastritis: according to the updated Sydney System, the presence of a neutrophil infiltrate characterizes the "activity" of gastritis.

Peer review

The study is set up correctly. The material studied is big enough to allow conclusions to be drawn. The paper is written sufficiently well, the Introduction gives a good overview of the study background and the authors clearly raised the hypothesis of the study. The description of the method and material studied is accurate. The aim of the study is fulfilled. The Results are presented clearly and have been discussed sufficiently well.

Abstract

AIM: To study the activation of pancreatic and pulmonary mast cells and the effect of mast cell inhibition on the activation of peritoneal and alveolar macrophages during acute pancreatitis.

METHODS: Pancreatitis was induced by intraductal infusion of 5% sodium taurodeoxycholate in rats. The mast cell inhibitor cromolyn was administered intraperitoneally (i.p.) 30 min before pancreatitis induction. The pancreatic and pulmonary tissue damage was evaluated histologically and mast cells and their state of activation were evaluated. Peritoneal and alveolar macrophages were obtained and the expression of tumor necrosis factor α was determined. Myeloperoxidase activity was measured to evaluate the effect of mast cell inhibition on the progression of the inflammatory process. Finally, the effect of plasma on cultured mast cells or macrophages was evaluated *in vitro*.

RESULTS: The mast cell stabilizer significantly reduced inflammation in the pancreas and lung and the activation of alveolar macrophages but had no effect on peritoneal macrophages. Mast cell degranulation was observed in the pancreas during pancreatitis but no changes were observed in the lung. Plasma from rats with pancreatitis could activate alveolar macrophages but did not induce degranulation of mast cells *in vitro*.

CONCLUSION: Pancreatic mast cells play an important role in triggering the local and systemic inflammatory response in the early stages of acute pancreatitis. In contrast, lung mast cells are not directly involved in the inflammatory response related to pancreatic damage.

Key words: Cytokines; Inflammation; Macrophages; Mast cells; Pancreatitis

INTRODUCTION

Acute pancreatitis represents a substantial clinical problem with increasing incidence and it is associated with high morbidity and mortality[1]. The most important predictor of mortality is the development of persistent or multiple organ failure and the commonest affected organ is the lung[2,3]. In these cases, acute lung injury is frequently related to early deaths in the first week of the disease[4]. The mechanisms involved in triggering distant organ inflammation are unclear, however, in addition to the release of activated hydrolytic enzymes, different pathways have been reported, including cytokines[5], oxygen-derived free radicals[6] or activated complement[7].

Among these mechanisms, mast cells have been reported to contribute to several aspects of pancreatitis-associated lung injury. These cells release a number of mediators, including histamine, tumor necrosis factor (TNF)α or monocyte chemotactic protein-1 (MCP-1) which could have a strong effect on pulmonary endothelial cells, thus potentiating the progression of inflammation[8,9]. The expression of different adhesion molecules increases early after pancreatitis induction, and in some of these molecules this increase could be prevented by administering mast cell degranulation inhibitors such as sodium cromolyn[10,11]. These observations suggest that masts cells are responding to mediators released during pancreatitis and, when activated, play a role in the induction of endothelial lung dysfunction and in the progression of the local and systemic inflammatory process.

Mast cells are usually located close to endothelial cells and this explains their effect on endothelial dysfunction when activated during pancreatitis. However, tissue-related variability on the number, phenotype and distribution of mast cell populations have been reported, resulting in different activation during inflammatory processes[12]. In the case of acute pancreatitis, the use of mast cell stabilizers prevented changes in systemic inflammation and in endothelial permeability in different organs[10], however, the involvement of the particular mast cell populations remains unclear.

In this work we have evaluated the effect of mast cell inhibition on the activation of peritoneal and alveolar macrophages in an experimental model of acute pancreatitis.

MATERIALS AND METHODS

Animal model of acute pancreatitis

Male Wistar rats (250-300 g b/w) (n = 6 each group) were anaesthetized with 10% urethane (1 mL/100 g, i.p.). The biliopancreatic duct was cannulated through the duodenum and the hepatic duct was closed by a small bulldog clamp. Severe acute pancreatitis was induced by retrograde infusion into the biliopancreatic duct of 5% sodium taurocholate (Sigma Chemical, St. Louis, MO, USA) in a volume of 0.1 mL/100 g b/w using a *Harvard* '22' infusion pump (Harvard Instruments, Edenbridge, UK)[13]. Control animals received an intraductal infusion of saline solution (0.9% NaCl). In a group of animals, cromolyn (Sigma, St Louis, MO, USA) (5 mg/kg b/w) was administered i.p. 30 min before pancreatitis induction. Three hours after induction, tissue samples of pancreas and lung were obtained, immediately frozen and maintained at -80℃ until processed. This time point was selected because we previously reported that, in this model, a significant systemic inflammation is initiated three hours after the induction of pancreatitis[14]. Plasma samples were pelleted and the supernatant was stored at -40℃ until use. Pancreas and lung samples were also obtained and stored for histological analysis.

Histological analysis

Tissue samples were fixed in 10% neutral buffered formalin, embedded in paraplast, sectioned in 5 μm slices and stained with toluidine blue (0.1%). The dye was allowed to dry on the slide for a few seconds; the slides were then rinsed in xylene for 5-10 min. and rinsed twice with acetone. Finally, the slides were cleared in xylene and mounted in diphenylphthalein xylene. Sections were evaluated by light microscopic examination.

Cell culture

Peritoneal macrophages were harvested by 5 peritoneal washes with 10 mL of phosphate buffered saline (PBS) containing 3 units/mL heparin. The obtained cell suspension was centrifuged (300 × g, 7 min). Cells were suspended in the RPMI1640 culture medium containing 10% fetal calf serum, 2 mmol/L glutamine, penicillin (100 U/mL) and streptomycin (100 μg/mL). Aliquots of about 3×10^6 cells were plated in 6 well plates and cultured at 37℃ under a gas phase of air/CO_2 (95:5). After an attachment period of 4 h, the non-adhered cells were removed by shaking. The resulting adherent population consisted of > 92% peritoneal macrophages.

Alveolar macrophages were obtained by bronchoalveolar wash. After exsanguinations, lung and trachea were excised *en bloc* and washed 5 times with 10 mL cold (4℃) saline solution. The supernatant was centrifuged at 300 × g for 7 min and the cells were resuspended in RPMI1640 culture medium containing 10% fetal calf serum, 2 mmol/L glutamine, penicillin (100 U/mL) and streptomycin (100 μg/mL). Aliquots of about 3×10^6 cells were plated in 6 well plates and cultured at 37℃ un-

der a gas phase of air/CO_2 (95:5). After an attachment period of 4 h, the non-adhered cells were removed by shaking. The resulting adherent population consisted of > 95% alveolar macrophages.

The rat mast cell line RBL-2H3 was maintained as a monolayer culture in RPMI-1640 medium supplemented with 10% fetal calf serum, penicillin (100 U/mL) and streptomycin (100 μg/mL) in an incubator with 5% CO_2 at 37℃.

In vitro effect of plasma

The effects of circulating mediators on mast cells or macrophages were evaluated by incubating alveolar macrophages or the mast cell line RBL-2H3 with plasma obtained from controls, animals with pancreatitis or with cromolyn treated pancreatitis. Cells were cultured in 12 well plates in the presence of 20% plasma in the culture media. One hour after culture at 37℃, the levels of histamine were measured in RBL-2H3 supernatants. For macrophages, RNA was obtained and the expression of TNFα was evaluated by quantitative real-time polymerase chain reaction (RT-PCR).

RNA isolation and RT-PCR

Total RNA from cells was extracted using the TRizol® reagent (Invitrogen, Carlsbad, CA, USA). The RNA was quantified by measurement of the absorbance at 260 and 280 nm using a NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies, USA).

cDNA was synthesized using the iScript cDNA synthesis kit (Bio-Rad Laboratories, Hercules, CA, USA), and reverse transcription was then performed on 1 μg RNA sample by adding iScript reagents. The reaction was incubated at 25℃ for 5 min, 42℃ for 30 min, and 85℃ for 5 min, and then stored at -80℃.

Subsequent PCR amplification was performed in a DNA Engine, Peltier Thermal Cycler (Bio-Rad Laboratories, CA, USA) using IQTM SYBR Green Super mix and the correspondent rat primers: TNFα forward: 5'-AACTCCCAGAAAAGCAAGCA-3' reverse: 5'-CGAGCAGGAATGAGAAGAGG-3'; GAPDH forward: 5'-CTGTGTCTTTCCGCTGTTTTC-3', reverse: 5'-TGTGCTGTGCTTATGGTCTCA-3'.

Initial denaturation was followed by 40 cycles of DNA amplification with fluorescence detection at the end of the elongation step (SYBR Green format). Reactions were performed in duplicate and threshold cycle values were normalized to GAPDH gene expression. The specificity of the products was determined by melting curve analysis. The ratio of the relative expression of target genes to GAPDH was calculated by using the ΔC(t) formula.

Lipase

Plasma lipase was determined using commercial turbidimetric assay kits from Randox (Antrim, UK), according to the supplier's specifications.

Histamine analysis

Histamine levels in plasma and in cell culture supernatants were evaluated using a commercial ELISA assay from Labor Diagnostika Nort (Nordhorn, Germany) according to the supplier's specifications.

TNFα

TNFα concentration in the cell culture medium was measured using a commercial kit for rat TNFα from BLK International (Badalona, Spain), according to the supplier's specifications.

Myeloperoxidase

Neutrophilic infiltration was assessed by measuring myeloperoxidase (MPO) activity. MPO was determined photometrically with 3,3',5,5'-tetramethylbenzidine as substrate. Tissue samples were homogenized with 0.5% hexadecyltrimethylammonium bromide in 50 mmol/L phosphate buffer at pH 6.0. Homogenates were disrupted for 30 s using a Labsonic sonicator (Braun Biotech, Inc., Allentown, PA, USA) at 20% power and submitted to three cycles of snap freezing in dry ice and thawing before a final 30 s sonication. Samples were incubated at 60℃ for 2 h and then spun down at 4000 × *g* for 12 min. The supernatants were collected for MPO assay. Enzyme activity was assessed photometrically using 630 nm wavelength. The assay mixture consisted of 20 μL supernatant, 10 μL tetramethylbenzidine (final concentration 1.6 mmol/L) dissolved in DMSO, and 70 μL H_2O_2 (final concentration 3.0 mmol/L) diluted in 80 mmol/L phosphate buffer, pH 5.4. The results are expressed as units (U) MPO activity per g protein.

Protein measurement: Total protein concentration in homogenates was determined using a commercial kit from BioRad (Munich, Germany).

Statistical analysis

Data are expressed as mean ± SE. Means of different groups were compared using a one-way analysis of variance. Tukey's multiple comparison test was performed to evaluate significant differences between groups. Differences were assumed to be significant when $P < 0.05$.

RESULTS

Mast cell activation during pancreatitis

Histological analysis revealed the presence of mast cells in the interlobular areas of control pancreas (Figure 1A) and a general pancreatic mast cell degranulation after induction of pancreatitis (Figure 1B). This degranulation was prevented by cromolyn treatment (Figure 1C). In lungs, mast cells could also be observed (Figure 1D), however, no apparent degranulation was detected in histological samples of the lung 3 h after induction of pancreatitis (Figure 1E). Cromolyn treatment had no effect on lung mast cells (Figure 1F).

Effects of mast cell inhibition

Pancreatitis resulted in increased levels of circulating lipase and histamine in plasma as well as enhanced MPO activity in both pancreas and lung (Figure 2). The inhibition of mast cell degranulation with cromolyn did not

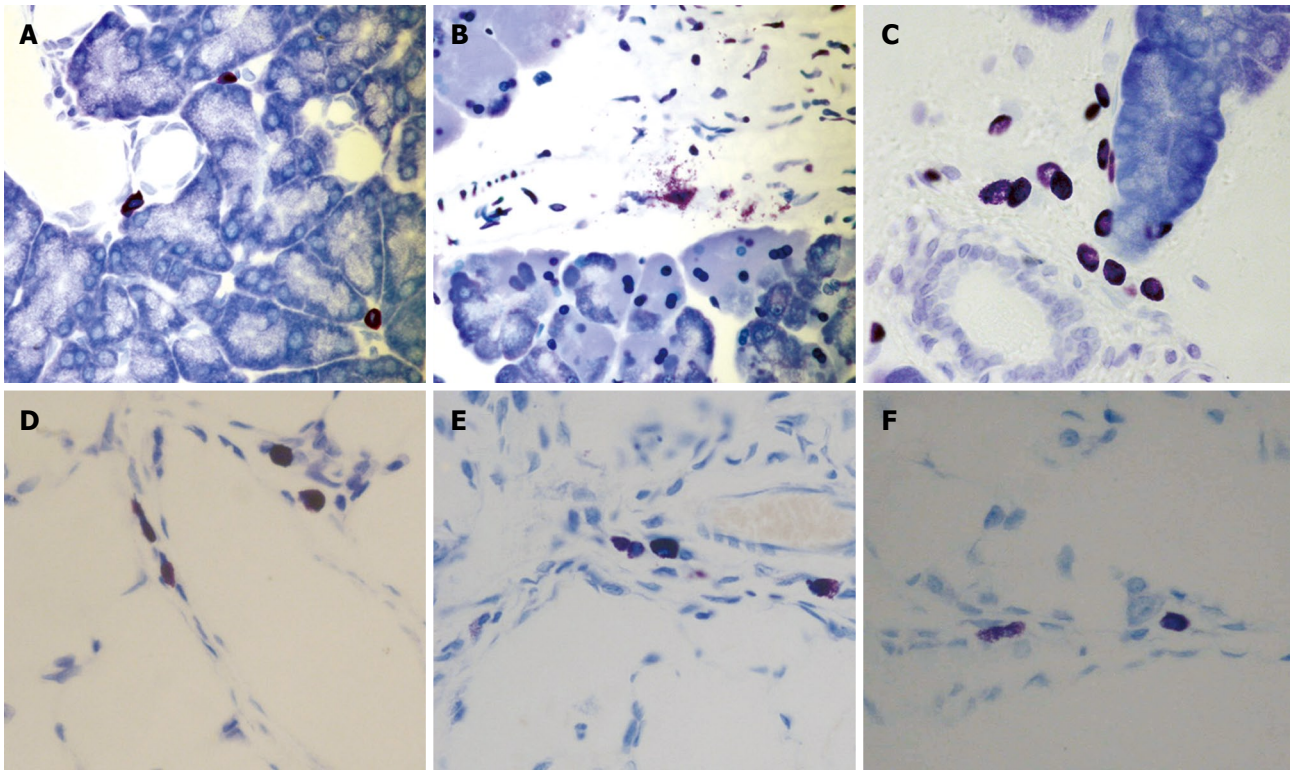

Figure 1 Presence of mast cells in pancreas (A-C) and lung (D-F), in control (A and D). Three hours after induction of pancreatitis (B and E) and under cromolyn treatment (C and F). Degranulating mast cells were observed in the pancreas after pancreatitis induction (B). Cromolyn treatment prevented mast cell degranulation (C). In contrast, no evident degranulation was observed in lung after induction of pancreatitis. Toluidine blue, × 40.

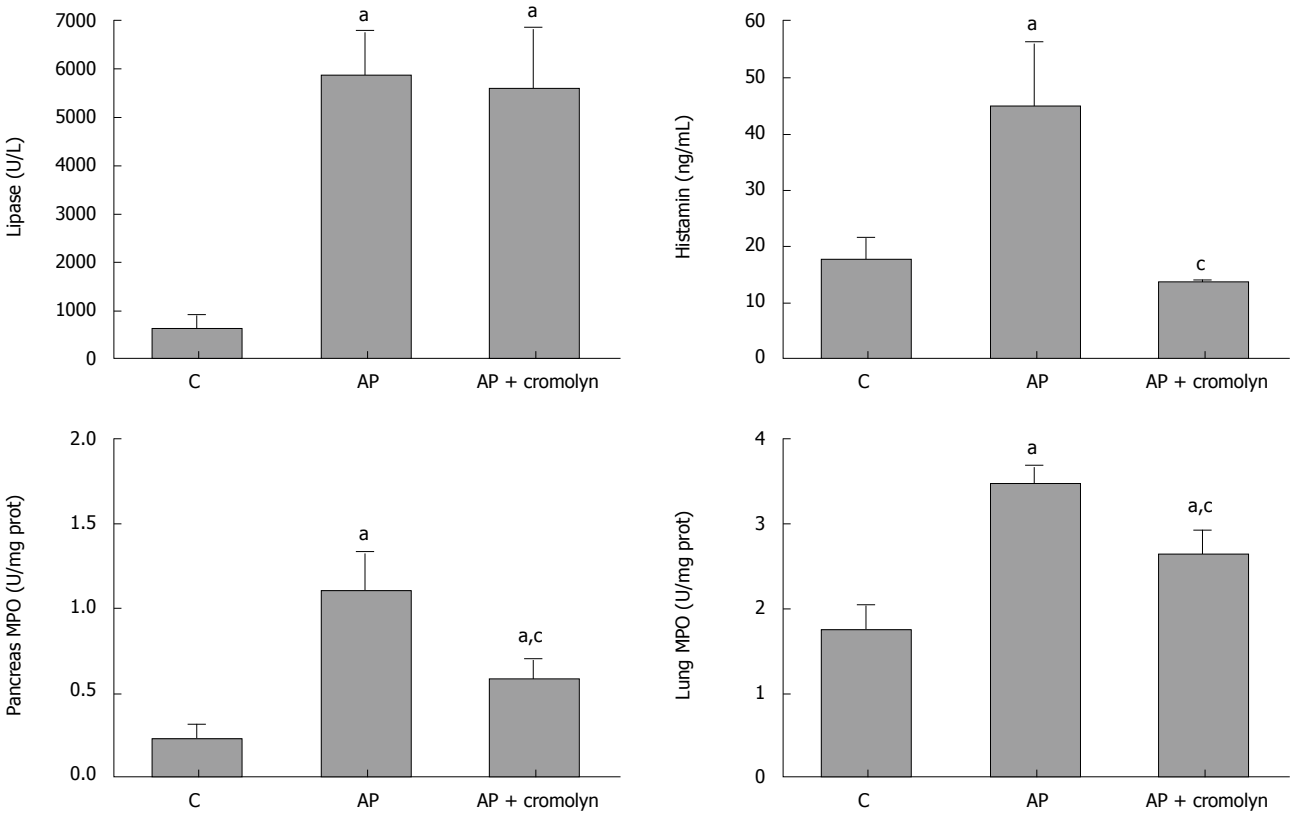

Figure 2 Effect of mast cell inhibitor, cromolyn. Three hours after pancreatitis induction, increased levels of lipase and histamine were detected in plasma. Cromolyn treatment had no effect on lipase, which is related to acinar cell damage, but prevented the increase in histamine. In tissue, leukocyte infiltration was evaluated by measuring myeloperoxidase (MPO) activity. Pancreatitis resulted in increased MPO activity in both pancreas and lung. Cromolyn treatment partially prevented these increases. $^{a}P < 0.05$ *vs* C; $^{c}P < 0.05$ *vs* AP. C: Control; AP: Acute pancreatitis.

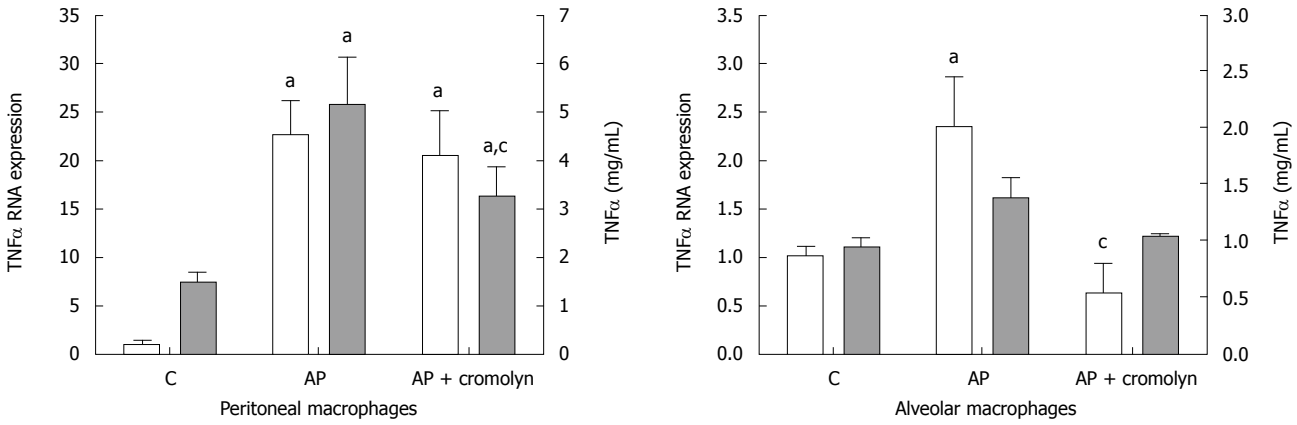

Figure 3 Both peritoneal and alveolar macrophages were activated after induction of pancreatitis, but the expression of tumor necrosis factor α mRNA in peritoneal macrophages was one order of magnitude higher than that observed in alveolar macrophages. Tumor necrosis factor (TNF)α release was induced in peritoneal cells, while in alveolar cells the observed increase was not statistically significant. Cromolyn treatment completely prevented the activation of alveolar macrophages. In contrast, peritoneal macrophages remained activated under cromolyn treatment. $^{a}P < 0.05$ *vs* C; $^{c}P < 0.05$ *vs* AP. C: Control; AP: Acute pancreatitis.

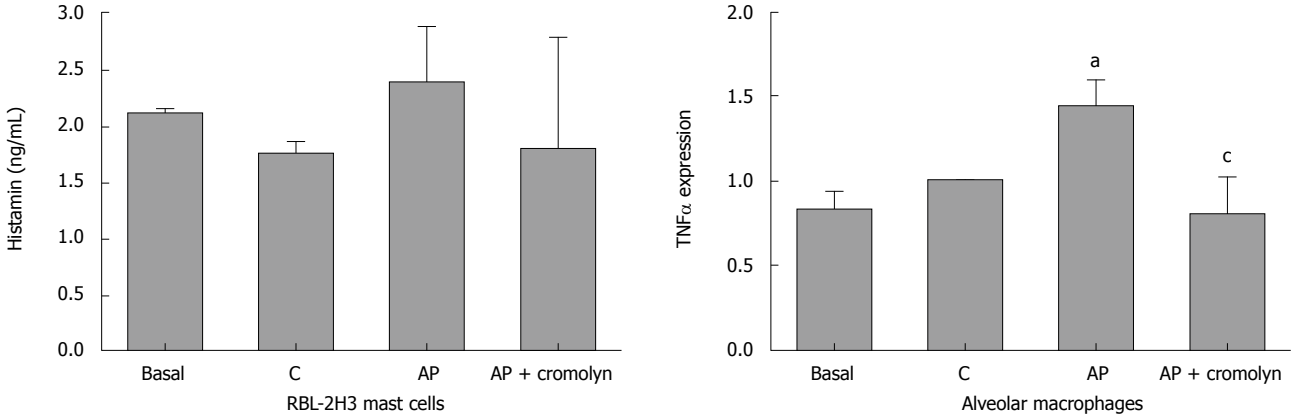

Figure 4 The effect of plasma on cultured mast cell line RBL-2H3 and alveolar macrophages. Mast cells were not activated by plasma from animals with pancreatitis. In contrast, the expression of tumor necrosis factor (TNF)α in alveolar macrophages was induced by plasma from animals with pancreatitis. This induction was not observed when animals were treated with cromolyn. $^{a}P < 0.05$ *vs* C; $^{c}P < 0.05$ *vs* AP. C: Control; AP: Acute pancreatitis.

modify the lipase levels, but resulted in a reduction in pancreatic MPO activity, indicating that this treatment had no effect on acinar cell damage but reduced pancreatic inflammation. Inhibition of the inflammatory process in lung was also observed. Nevertheless, these inhibitions did not achieve the control values and MPO activity remained significantly increased with respect to the control group in both pancreas and lung.

Changes in peritoneal and alveolar macrophages

Pancreatitis resulted in the induction of TNFα expression in both peritoneal and alveolar macrophages (Figure 3). However, at this time point the activation observed in peritoneal macrophages was one order of magnitude greater than that observed in alveolar macrophages. This was reflected in the release of TNFα which only showed a significant increase in peritoneal macrophages after pancreatitis induction, while the increase observed in alveolar macrophages was not statistically significant (Figure 3). Inhibition of mast cell degranulation had no effect on peritoneal macrophage activation, but completely prevented the increase observed in TNFα expression in alveolar macrophages.

Effect of plasma on cultured mast cells and macrophages

Incubation of the RBL-2H3 cell line with plasma obtained from animals with pancreatitis did not result in increased histamine release (Figure 4). In contrast, this plasma was able to induce the activation of alveolar macrophages, reflected in an increase in the expression of TNFα. This induction was not observed when plasma was obtained from animals treated with cromolyn (Figure 4).

DISCUSSION

The development of systemic inflammation during the progression of severe acute pancreatitis involves multiple pathways and cell systems. Among them, mast cells appear to play a pivotal role between the hydrolytic enzymes released by damaged pancreatic acinar cells and the stress-induced response mediated by free radicals and inflammatory mediators.

In this sense, mast cells seem to play a role amplifying the acute inflammatory response in different organs early after the onset of pancreatitis. Several mediators known to be released by mast cells, including platelet activating factor (PAF), histamine or prostaglandin D_2 (PGD_2), have been shown to be increased a few minutes after the induction of pancreatitis in experimental models[15,16]. In addition, the administration of mast cell inhibitors results in a reduction of the local and systemic inflammatory response and, in particular, prevents changes in endothelial cells and vascular permeability[10].

However, it is important to evaluate the particular role of the different mast cell populations in this process, in order to design therapeutic strategies centered on these cells. Due to the rapid activation of pancreatic mast cells in the onset of pancreatitis, the obvious therapeutic target may be pulmonary mast cells that are suspected of being activated in the later stages of the disease.

In the present study, we evaluated the degranulation of mast cells in pancreas and lung and found a different response during pancreatitis. Histological evaluation showed a clear and extensive degranulation of mast cells located in pancreatic tissue (Figure 1B). As expected, this degranulation was prevented by cromolyn administration (Figure 1C). In contrast, no clear evidence of mast cell degranulation was observed in lung tissue (Figure 1E).

This was a surprising result, taking into account that cromolyn administration resulted in a clear reduction in lung inflammation revealed by MPO activity and by a lower activation of alveolar macrophages (Figure 3). In addition, these results are in line with other authors who reported on the critical role of mast cells in the inflammatory response in lung during pancreatitis.

An explanation for this apparent contradictory result is an indirect effect of pancreatic mast-cell derived mediators on distant organs. Activation of mast cells results in the immediate release of mediators that play a role in the activation of circulating leukocytes as demonstrated by Zhao *et al*[11]. On the other hand, the progression of inflammation in pancreatic tissue is modified by cromolyn treatment (Figures 1 and 2). Consequently, it is suspected that the profile of pro-inflammatory mediators released to the bloodstream by pancreatic tissue and their ability to induce lung endothelial dysfunction could be modified by pancreatic mast cell inhibition.

To evaluate this possibility we treated alveolar macrophages as well as the mast cell line RBL-2H3 *in vitro* with plasma obtain from the different experimental groups. Our results indicate that plasma from the pancreatitis-induced group did not stimulate the production of significant amounts of histamine in culture (Figure 4). This result suggests that while pancreatic damage could enhance the activation and degranulation of mast cells in the pancreas a few minutes after pancreatitis induction[8], mediators present in plasma are not sufficient to activate these cells in distant organs.

However, plasma from pancreatitis animals was able to induce the activation of macrophages *in vitro*, reflected in the increased expression of TNFα. This effect was clearly reduced when animals were treated with cromolyn (Figure 4). Together, these results indicate that pancreatic mast cells play an important role in triggering the local and systemic inflammatory response in the early stages of acute pancreatitis. In contrast, lung mast cells are not directly involved in the inflammatory response related to pancreatic damage. The early activation reported in pancreatic mast cells may make the use of these cells as a pharmacological target difficult due to the short therapeutic window.

COMMENTS

Background

Mast cells have been reported to contribute to several aspects of pancreatitis associated lung injury. However, the involvement of particular mast cell populations remains unclear.

Research frontiers

Using an experimental model of acute pancreatitis in rats, the authors evaluated the activation of mast cells from pancreas and lung as well as the effect of mast cell inhibitors on progression of the inflammatory reaction.

Innovations and breakthroughs

Pancreatic mast cells play an important role in triggering the local and systemic inflammatory response in the early stages of acute pancreatitis. In contrast, lung mast cells are not directly involved in the systemic inflammatory response related to pancreatic damage.

Applications

The identification of active mast cells in the early stages of pancreatitis may improve our understanding of their role in this disease and the possible therapeutic strategies focussed on these cells.

Terminology

Cromolyn is a mast cell stabilizer that prevents the release of inflammatory mediators, such as histamine, from these cells.

Peer review

In this work, the authors have evaluated the effect of mast cell inhibition on the activation of peritoneal and alveolar macrophages in an experimental model of acute pancreatitis. The manuscript portrays a good effort by its authors.

Abstract

AIM: To demonstrate that the double balloon enteroscopy (DBE) can be safely performed in general anesthesia with intubation.

METHODS: We performed a retrospective examination between August 2005 and November 2008 among patients receiving intubation narcosis due to DBE examination. The patients were grouped based on sex, age and physical status. Anesthesia records included duration of anesthesia, quantity of medication used and anesthesia-related complications. We determined the frequency of complications in the different groups and their relation with the quantity of medication used and the duration of anesthesia.

RESULTS: We compiled data for 108 cases of general anesthesia with intubation. We did not observe any permanent anesthesia-related complications; the most frequent side effects of anesthesia were hypotension (30.55%), desaturation (21.29%), and apnea (17.59%). These complications were significantly more frequent among patients with multiple additional diseases [hypotension (23.1% *vs* 76.9%, $P = 0.005$), desaturation (12.3% *vs* 69.2%, $P < 0.001$) and apnea (7.7% *vs* 53.8%, $P = 0.001$)], however, their incidence was not proportional to the quantity of medication used or the duration of anesthesia.

CONCLUSION: General anesthesia with intubation is definitely a viable option among DBE methods. It is highly recommended in patients with multiple additional diseases.

Key words: Double balloon enteroscopy; General anesthesia; Intubation; Sedation; Patient autonomy

INTRODUCTION

Although gastroenterological endoscopic examinations are performed with some form of sedation or anesthesia at increasing rates worldwide, gastroscopy and colonoscopy are still often performed without any sedation, even today[1]. A reason for the widespread use of anesthesia is that patients receiving sedation are more satisfied, because they recall less pain and discomfort related to the intervention. Also, gastroenterology specialists

can examine patients that are otherwise not suitable for examination because of psychological reasons or strong abdominal pain.

However, the dissemination of gastroenterology sedation has limitations[2]. This is partly because the intervention costs significantly more because of personnel and infrastructure requirements, and also because anesthesia itself may also have moderate or severe side effects[3]. According to the literature, over 50% of the complications are heart- or lung-related (aspiration, airway obstruction, low ventilation frequency, vaso-vagal episode, oversedation). So far, there is no consensus on whether sedation should be performed by gastroenterology specialists, anesthetist physicians or assistants, or the patient (patient-controlled anesthesia); or whether the medication should be administered as a bolus, as a continuous infusion, or automatically provided based on pre-calculated plasma level (target controlled infusion)[4].

The emergence of double balloon enteroscopy (DBE) among endoscopic examinations also means a shift of paradigm for internal medicine specialists, because its safe and efficient completion requires an advanced level of anesthesia. As the method has only been widely used for a couple of years, little data are available on the respective anesthetic procedures. According to the literature, three methods of sedation are used with significant geographical preferences, including conscious sedation, deep sedation (propofol anesthesia) and general anesthesia.

The goal of our research was to assess the suitability and advantages of general anesthesia with intubation for DBE.

MATERIALS AND METHODS

Patients

We retrospectively analyzed the data from 108 patients that had not been pre-selected, in whom DBE was carried out under general anesthesia with intubation. The interventions were carried out in the 1st Department of Internal Medicine of Semmelweis University, Budapest, Hungary between August 2005 and November 2008. Patients were classified into groups based on sex, age, physical status (ASA Physical Status Classification System) and DBE indication[5]. Anesthesia records included the duration of the intervention, anesthesia protocol, quantity of medication used, and complications.

Following recovery from anesthesia, the patients were asked to recall memories of the intervention and describe any possible complaint.

Method of anesthesia

Electrocardiography and transdermal oxygen saturation were constantly monitored during the intervention, and non-invasive blood pressure measurements were also performed every 5 min. Based on the literature, the definitions were as follows: hypotension, systolic blood pressure < 90 mmHg; desaturation, transdermal oxygen saturation < 90%; and apnea, > 30 s pause in respiration.

During intervention, proper anesthesia was provided by the combined administration of benzodiazepine, opioids and propofol in all cases; the mentioned medications were selected based on availability because these are all readily available in every endoscopy laboratory. We supposed that complete anesthesia was reached with their combined usage, and we also wished to adapt continuously the degree of anesthesia to the requirements of the intervention.

First, peripheral venous access was provided, and then infusion was administered (500-1000 mL). All patients received 0.5 mg atropine prior to the intervention, followed by gradual intravenous midazolam injection (3-10 mg) to reach a consciousness level equivalent to conscious sedation. All patients received 1-1.5 μg/kg fentanyl, and induction of narcosis was achieved by 1 mg/kg propofol as a bolus. For the maintenance of narcosis, further doses of propofol were used. We used two anesthesia protocols. According to these, propofol was either provided as continuous infusion or given in discrete fractions. In the case of continuous use, the infusion rate was set at 200 mg/h; for fractioned use, 25 mg fractions were given as a bolus following induction and intubation, until the end of intervention. If the degree of anesthesia was insufficient (patient motion, changes in vegetative reactions), we increased the speed of propofol infusion, or another fraction was administered. Fentanyl was repeatedly provided every 30 min at 0.5-1 μg/kg.

Statistical analysis

Arithmetic mean and SD values were used for continuous parameters, whereas frequency percentages were calculated for discrete parameters. Statsoft version 8.0 software (www.statsoft.com) was used for statistical analysis. The quantity of medication was compared using non-parametric variance analysis (Kruskal-Wallis analysis of variance), and the frequency of the observed complications was compared with Fisher's exact test among the various groups. $P < 0.05$ was considered statistically significant.

RESULTS

The indications for intervention in the 108 patients enrolled in the study are presented in Table 1. In patients with obscure gastrointestinal bleeding (OGIB), abnormal small-bowel findings were seen in 41 patients (65.1%). Most of them were classified as probable (angiodysplasia, erosion), and others as definitive (e.g. small ulcers) causes of bleeding. Other definitive causes were malignant disease, found in five patients, including polypoid gastrointestinal stromal tumor (GIST) in three patients, non-Hodgkin lymphoma (NHL) in one, and melanoma in one. In suspected inflammatory bowel disease (IBD), enteroscopy confirmed the diagnosis in five out of 12 cases. In patients with suspected neoplasia/stenosis, malignant disease was proven in three cases. In patients with known polyposis syndromes [familial adenomatous polyposis (FAP) or Peutz-Jeghers syndrome], small-bowel polyps were removed in eight patients. The average insertion length was 209 cm (50-460 cm, SD: 113 cm). Using the oral route (n = 95), a larger proportion of the

Age (yr)	45.88 (15.93)	60.42 (13.36)	70.69 (19.47)	52.53 (18.44)
Duration (min)	91.85 (24.79)	79.17 (19.17)	65.77 (10.77)	85.18 (23.72)
Propofol (mg)	464.31 (91.84)	410.33 (66.82)	346.92 (61.29)	435.18 (91.16)
Midazolam (mg)	7.17 (1.29)	5.50 (1.04)	4.08 (0.76)	6.31 (1.60)
Fentanyl (mg)	0.1307 (0.0350)	0.1217 (0.0284)	0.0731 (0.0259)	0.1213 (0.0369)

small intestine was accessible for examination (226 cm, SD: 107 cm) compared with procedures that started with anal endoscope insertion and colonoscopy (n = 13, 98 cm, SD: 58 cm, $P < 0.01$).

Fifty-five patients were male (50.92%) and 53 were female (49.08%), with the average age being 52.53 years (SD: 18.44 years). The patients were classified into three groups based on the ASA Physical status classification system (ASA P1-P3). P1 included 65 patients (average age: 45.87 years, SD: 15.93 years), P2 included 30 patients (average age: 60.42 years, SD: 13.36 years), and P3 included 13 patients (average age: 70.69 years, SD: 19.47 years). The three groups were compared based on the duration of the intervention, the quantity of medication used, and the observed complications. Demographic and clinical data of the three groups are shown in Table 2.

The average length of the intervention was 85.18 min (SD: 23.72 min); with 91.85 min in P1 (SD: 24.79 min), 79.17 min (SD: 19.17 min) in P2, and 65.77 min (SD: 10.77 min) in P3. Although the time of intervention gradually decreased with deteriorating physical status, a significant difference was only found between P1 and P3 ($P < 0.001$).

The average amount of propofol used during the intervention was 435.18 mg (SD: 91.16 mg) per patient, with 464.31 mg (SD: 91.84 mg) in P1, 410.33 mg (SD: 66.82 mg) in P2, and 346.92 mg (SD: 61.29 mg) in P3. The dose of propofol decreased in patients with deteriorating physical status and significant differences were found between groups P1 and P2 ($P = 0.027$) and P1 and P3 ($P < 0.001$).

Table 3 Number and ratio of frequent complications *n* (%)

	P1	P2	P3	Sum
n	65	30	13	108
Hypotension	15 (23.1)	8 (12.3)	10 (76.9)	33 (30.6)
Desaturation	8 (12.3)	6 (20.0)	9 (69.2)	23 (21.3)
Apnea	5 (7.7)	7 (23.3)	7 (53.8)	19 (17.6)

The average quantity of midazolam used per patient was 6.31 mg (SD: 1.60 mg); with 7.14 mg (SD: 1.29 mg) in P1, 5.5 mg (SD: 1.04 mg) in P2, and 4.08 mg (SD: 0.76 mg) in P3. Significant differences were found between the groups P1 and P2 ($P < 0.001$) and P1 and P3 ($P < 0.001$), as well as P2 and P3 ($P = 0.045$). The average amount of fentanyl used per patient was 0.1213 mg (SD: 0.0369 mg); with 0.1307 mg (SD: 0.0350 mg) in P1, 0.1217 mg (SD: 0.0284 mg) in P2, and 0.0731 mg (SD: 0.0259 mg) in P3. Significant differences were found between groups P1 and P3 ($P < 0.001$) and P2 and P3 ($P = 0.001$).

Among anesthesia-related complications recorded during the intervention, hypotension, desaturation and apnea occurred frequently. Table 3 presents the number of complications and their comparison between the groups. We analyzed statistically the correlation between the occurrence of the above complications (hypotension, desaturation and apnea) and patients' physical status, the duration of the intervention, and the quantity of medication (propofol, midazolam, fentanyl).

Only the physical-status-based classification and the occurrence of the recorded complications showed a significant positive correlation. ASA P stage significantly influenced the frequency of hypotension ($P = 0.005$), de-saturation ($P < 0.001$) and apnea ($P < 0.001$). These complications were more frequently observed among patients classified into group P3 than would have been expected based on random incidence.

A significant positive correlation was not found between the quantity of medication and complications. There was a significant negative correlation between propofol dosage and the development of hypotension ($P = 0.002$). We found a significant negative correlation between midazolam dosage and the three most frequent complications (hypotension, $P = 0.001$; de-saturation, $P = 0.004$; apnea, $P = 0.001$). There was a significant negative correlation between fentanyl dosage and desaturation ($P = 0.003$), but not with the other complications. There was a significant negative correlation between the duration of the intervention and the frequency of desaturation ($P = 0.018$) and apnea ($P = 0.040$).

Among the 108 DBE anesthesia cases, three imminent anesthesia-related problems had to be resolved. In one case, peripheral venous access could not be provided due to the physical status of the patient, but instead, central venous access was established without any complication. In another case, intubation could not be completed and hence enteroscopy had to be delayed. One week later, both the intubation and intervention were completed with

the application of a depolarizing muscle relaxant. For a third patient, who had obesity and chronic obstructive pulmonary disease, continuous respiration assistance and oxygen supply had to be provided, and extubation could only be performed in the seated position due to breathing difficulty.

Anesthesia was not related to any permanent or severe complication (aspiration, malignant dysrhythmia, resuscitation, malignant hyperthermia) in any case. More than 98% of the patients had amnesia concerning events during anesthesia. Frequent complaints included discomfort at the site of peripheral venous access, sore throat or dysphagia, and abdominal distension.

DISCUSSION

Thanks to international recommendations based on the accumulating amount of data published about sedation techniques related to endoscopic interventions performed in the gastrointestinal tract, these interventions have become extremely safe[6-8]. Severe complications are generally rare and deadly fatal complications mostly affect patients in a severely impaired or terminal physical state[9]. Data concerning recently introduced enteroscopic examinations and the related sedation techniques are scarce, and randomized, multicenter comparative studies with large numbers of patients have been lacking.

The goal of our study was to examine the utility of general anesthesia with intubation as a method of choice for DBE. The enrolled patients were divided into three groups according to the ASA Physical Status Classification System.

We first examined whether the 108 enteroscopy cases corresponded with published data in terms of intervention indications and duration. Among the indications, OGIB (58.33%), IBD (11.11%) and tumor (7.41%) were the most frequent in our practice, as in the literature (OGIB: 59%-62.8%; IBD: 2.9%-6.4%; tumor: 8.3%-10.2%)[10-12]. The average duration of the intervention in our study (85.18 min) was also found to be similar to that in the literature (53-113 min)[13,14]. The detailed outcome of the endoscopic procedures has been published in a separate paper[15].

However, we need to highlight some differences in sedation complications. Anesthesia-related complications occurred at much higher frequencies in our practice than during conscious sedation described in the literature, but these have either quickly resolved without any or with minor medical intervention. Hypotension was found to be the most frequent complication in our study (30.55%), which occurred at much lower frequencies during conscious sedation (1.8%-23.08%)[10,13,16]. If hypotension was observed, we increased intravenous fluid therapy, although the positive effects of the procedure are not obvious[17], and we also decreased the administration of propofol and fentanyl. Hypertensive drugs were not used in any case, and hypotension resolved within minutes with the above procedures.

The frequency of desaturation was 21.29% in our study, which is similar to the frequencies reported in the literature (0%-30.78%)[13,18]. In cases of hypoxia, transient or continuous oxygen inhalation was necessary, depending on the patient's requirements, and if oxygen levels normalized, we discontinued oxygen administration. Apnea was observed in 17.59% of the cases in which respiratory assistance was initiated, which was discontinued as soon as spontaneous respiration was restored. However, some patients required continuous respiratory assistance during the intervention. The severe complication of aspiration did not occur during intubation, and probably this is the most prominent difference between intubation and conscious sedation (0% *vs* 1.2%-2.77%).

We found a significant positive correlation between the number of complications and poor physical status. Poor physical status and senior age both predict occurrence of hypotension, desaturation and apnea. With the increase in ASA physical status level, the duration of the intervention and the quantity of medication decreased.

We consider it important to highlight that side effects observed during anesthesia are not related to medication use, because there was no significant positive correlation found between the frequency of complications and dose of propofol, midazolam or fentanyl. For some complications, the opposite was true, as patients with poor health status (P3), who experienced the most complications, received much less anesthetic.

The amount of medication used for narcosis in our study was higher than that required for examinations performed under conscious sedation[13]. The reason for this is that a greater amount of medication is required for deeper sedation (general anesthesia). Also, patients receiving orotracheal intubation require more medication to tolerate the procedure.

The ratio of complete amnesia observed among patients examined in intubation narcosis was much higher (98%) than among those receiving venous sedation (24%-56%)[14].

Therefore, who is advised to undergo general anesthesia as an alternative sedation method performed by an anesthetist? Every patient who belongs to a sedation-related risk group. Such risk factors include emergency interventions; senescence; cardiac, lung, renal or liver diseases possibly resulting in organ failure; pregnancy; drug or alcohol abuse; disorientation; post-prandial or non-cooperative patients, and alleged airway obstruction[4]. In our study, patients classified as P3 or higher also belonged to the high-risk group, therefore, ASA physical status helps us to choose the right method of anesthesia.

General anesthesia with intubation was a viable option when performing DBE in all three patient groups. With the deterioration of physical status (increasing ASA P status), the advantage of intubation narcosis increases compared to other sedation methods. In the case of poor physical status, the number of complications significantly increases, however, these are readily treatable due to pre-existing intubation. The occurrence of hypoxia, apnea or aspiration can result in an emergency situation in patients sedated without intubation, which can lead to deterioration of the patient's physical status and halt the course of

the examination, thus significantly increasing the number of complications and healthcare costs. General anesthesia can also be used safely in ASA groups P1-2 because severe or permanent anesthesia-related complications have not been observed in any case. Alternative anesthetic methods that suit the patient's needs will be justified in the future if, in the institutions performing enteroscopy, venous sedation (conscious or deep) and general anesthesia are provided. Self autonomy of patients with good health status, who are suitable for ambulatory intervention (ASA P1-2), should be emphasized, and after providing sufficient information, choices of alternative anesthesia methods should be offered.

Our study had some limitations, because the study was retrospective and patients were not randomized. Patient numbers were not equal between the groups, with especially few patients in group P3. Another limitation was that we performed only general anesthesia with intubation; the other sedation methods that were used for comparison were based on published data only. We compared the average frequency of side effects observed in our patients with those reported in the literature.

COMMENTS

Background

Three methods of sedation are used for double balloon enteroscopy (DBE), with significant geographical preferences, including conscious sedation, deep sedation (propofol anesthesia) and general anesthesia. The goal of this research was to assess the suitability and advantages of general anesthesia with intubation for DBE.

Research frontiers

The best anesthetic method for DBE is not clear at present, because all sedation methods have many different advantages and disadvantages.

Innovations and breakthroughs

This research shows that the ASA physical status classification system helps us to choose the right anesthetic method. With the deterioration of physical status (increasing ASA P status), the advantage of intubation narcosis increases compared to other sedation methods. The authors found a significant positive correlation between the number of complications and poor physical status. They consider that the side effects observed during anesthesia are not related to medication use.

Applications

Based on the results of this clinical study, general anesthesia with intubation was a viable option for DBE in all three patient groups. Alternative anesthetic methods that suit the patient's needs will be justified in the future in institutions that perform enteroscopy.

Peer review

The study demonstrates that the double balloon enteroscopy examination can also be safely performed in general anaesthesia with intubation.

Abstract

AIM: To evaluate the long-term results of liver resection for the treatment of primary intrahepatic lithiasis. Prognostic factors, especially the impact of bilioenteric anastomosis on recurrence of symptoms were assessed.

METHODS: Forty one patients with intrahepatic stones and parenchyma fibrosis/atrophy and/or biliary stenosis were submitted to liver resection. Resection was associated with a Roux-en-Y hepaticojejunostomy in all patients with bilateral stones and in those with unilateral disease and dilation of the extrahepatic biliary duct (> 2 cm). Late results and risk factors for recurrence of symptoms or stones were evaluated.

RESULTS: There was no operative mortality. After a mean follow-up of 50.3 mo, good late results were observed in 82.9% of patients; all patients submitted to liver resection alone and 58.8% of those submitted to liver resection and hepaticojejunostomy were free of symptoms (P = 0.0006). Patients with unilateral and bilateral disease showed good late results in 94.1% and 28.6%, respectively (P < 0.001).

CONCLUSION: Recurrence of symptoms in patients with hepaticojejunostomy showed that this may not be the ideal solution. Further studies are needed to establish the best treatment for patients with bilateral stones or unilateral disease and a dilated extrahepatic duct.

INTRODUCTION

Primary intrahepatic lithiasis or hepatolithiasis, is a prevalent disease in Southeastern Asia but is rare in the Western world; it is a challenging condition due to its varied forms of presentation and complex treatment. In some Western countries, it has been increasingly diagnosed and a relative incidence of 2.1% from all cases of biliary stone disease has been reported[1,2]. The goals of treatment are to promote stone clearance, control bile infection, decompress the biliary tree, and prevent progressive hepatic dysfunc-

tion. Since each patient has a distinctive stone distribution within the biliary tree, treatment has to be individualized accordingly. Liver resection has been reported to promote excellent long-term results, since stones and biliary strictures can be simultaneously removed reducing the risk of recurrence. In patients with unilateral stones, liver resection is considered a potentially curative treatment[3-8]. For bilateral stones, the ideal treatment has not yet been established; bilioenteric anastomosis or a percutaneous approach associated or not with liver resection have been employed with good long-term results in up to two thirds of cases.

Although resection can lead to a cure in patients with bilateral disease, the recurrence of symptoms is not rare. Moreover, it has been shown that patients submitted to liver resection associated with a bilioenteric anastomosis, had higher rates of recurrent cholangitis when compared to those submitted to resection only[4,8].

The purpose of this study is to report our experience with patients submitted to liver resection for the treatment of non-oriental hepatolithiasis, and to evaluate the influence of different prognostic factors, especially bilioenteric anastomosis, on late results.

MATERIALS AND METHODS

Ninety eight patients with symptomatic primary intrahepatic lithiasis were treated at our institution between 1990 and 2006.

According to our treatment protocol, liver resection was indicated in patients with irreversible hepatic lesions such as unilateral or segmental liver fibrosis/atrophy or the presence of intrahepatic biliary stenosis. A complementary Roux-en-Y hepaticojejunostomy was performed in patients with unilateral liver disease who presented with common bile duct stones with a duct diameter larger than 2 cm, and in all patients with bilateral stones[2].

Forty one patients (41.8%) underwent liver resection; data regarding gender, age, history of cholangitis and previous biliary surgery, intrahepatic stone location, liver function tests, intraoperative findings, type of surgery performed and postoperative outcome are presented in Table 1.

There were 16 men (39.9%) and 25 women (60.1%), with a mean age of 41.3 years (range 18 to 67 years). A history of right upper quadrant pain was present in all cases, jaundice in 31 patients (75.6%), cholangitis in 25 (61%) and nineteen (46.3%) had previously undergone biliary tract surgery: cholecystectomy in 13, hepaticojejunostomy in 3 and cholecystectomy plus common bile duct exploration in 3. None of the patients showed any sign of liver failure at physical examination.

Preoperative diagnosis was based on ultrasonography, helicoidal three-phase tomography, endoscopic or percutaneous cholangiography that in the last 5 years were replaced by magnetic resonance cholangiography. A complementary operative cholangiography was performed in all cases.

Indications for liver resection were: parenchymal atrophy in 27 patients, intrahepatic biliary stenosis in 8 and unilobular severe liver fibrosis in 6. Two patients were submitted to liver resection in a septic condition, due to cholangitis.

Table 1 Analysis of the effect of each variable on late results

Variable (*n*)	Late complications (poor results) *n* (%)	Statistical analysis
Gender		
Female (25)	6 (24.0)	$P = 0.1406$
Male (16)	1 (6.3)	
Previous biliary surgery		
No (22)	3 (13.6)	$P = 0.5291$
Yes (19)	4 (21.1)	
History of cholangitis		
Yes (25)	7 (28.0)	$P = 0.0608$
No (16)	0 (0)	
Preoperative serum bilirubin		
Normal (32)	6 (18.8)	$P = 0.5905$
Raised (9)	1 (11.1)	
Preoperative white blood cells		
Normal (37)	6 (16.2)	$P = 0.6574$
Raised (4)	1 (25.0)

Major liver resection (more than 3 segments)		
Yes (14)	1 (7.1)	$P = 0.2237$
No (27)	6 (22.2)	

HJ: Hepaticojejunostomy.

Mean follow-up was 50.3 mo, ranging from 18 to 198 mo. Long-term results were considered good when no recurrence of symptoms or complications of the disease such as cholangitis or liver abscess during the follow-up period were observed.

Independent variables and their impact on late prognosis were compared using Student's t and Pearson's χ^2 tests. Statistical significance was set at $P < 0.05$.

RESULTS

Forty one patients were submitted to liver resection, 34 (82.9%) had unilateral disease and the left lobe was more frequently affected (28 cases). Bilirubin, alkaline phosphatase and gamma glutamyl transpeptidase serum levels were raised in 21.9%, 61% and 53.7% of patients, respectively.

Five patients underwent right hepatectomy (12.2%), nine left hepatectomy (22%), twenty six bisegmentectomy 2-3 (63.4%) and one patient underwent a segment 5 resection. A Roux-en-Y hepaticojejunostomy was associated with liver resection in 14 patients as follows: seven with bilateral and seven (21.8%) with unilateral disease and common bile duct dilation larger than 2 cm in diameter. Another three patients with unilateral stones who had previously been submitted to hepaticojejunostomy were submitted to liver resection and the anastomosis was maintained. All patients had a drain placed at the site of resection.

There was no operative mortality. Two patients submitted to liver resection (right hepatectomy and bisetorectomy 2-3) in a septic condition had an uneventful outcome. Four patients (9.8%) had a postoperative biliary fistula and were conservatively managed with an uneventful outcome; one patient (2.4%) developed a right subphrenic abscess which was percutaneously drained with good outcome.

Thirty two patients with unilateral and two with bilateral disease (82.9%) had good long-term results. Seven patients (17.1%), 2 with unilateral and 5 with bilateral stones, had late complications of the disease: cholangitis associated with recurrent stones in three (bilateral disease); cholangitis in two (unilateral disease); liver abscess associated with recurrent stones in one and liver abscess in one (all with bilateral stones).

One of these patients had caudate lobe recurrent stones and an abscess 93 mo after resection of segments 2 and 3, and died 28 d after drainage of the abscess due to sepsis; one had a liver abscess percutaneously drained with good outcome; three patients with cholangitis and stone recurrence, received antibiotic therapy and percutaneous stone removal and have remained well; two patients with cholangitis were treated with systemic antibiotics with good outcome. The long-term mortality rate was 2.4%.

The overall rate of good long-term results was 82.9% and was 94.1% and 28.6%, respectively for unilateral and bilateral disease. Comparing the data of good results between patients with unilateral and bilateral disease, statistical analysis showed a significant difference ($P < 0.001$) (Table 1).

All patients submitted to liver resection only, showed good long-term results (100%), while seven of seventeen patients (41.2%) who underwent liver resection associated with hepaticojejunostomy had late postoperative complications. A comparison between liver resection alone and resection associated with hepaticojejunostomy showed a statistically significant difference ($P = 0.0006$) (Table 1).

Twenty seven out of 34 patients with unilateral disease were submitted to liver resection alone and all had a good outcome. Of the remaining seven patients with unilateral disease who were submitted to liver resection associated with a bilioenteric anastomosis, two had recurrence of symptoms (2/7, 28.5%). A comparison between liver resection alone and resection associated with hepaticojejunostomy for patients with unilateral disease, showed a statistically significant difference ($P = 0.0498$).

DISCUSSION

Primary intrahepatic lithiasis is a rare disease in Western countries but, the high number of cases diagnosed in our institution, led to a treatment protocol based on presentation of the disease[2,9], where 41 out of 98 patients with symptomatic hepatolithiasis underwent liver resection.

The aim of treatment was the removal of intrahepatic and extrahepatic stones as well as duct strictures and to promote adequate drainage of the remaining segments of the biliary tree. Liver resection is the only treatment that can achieve these goals, thus reducing the risk of recurrence[4,5,7,8,10-14]. In this series, liver resection was indicated in patients with irreversible lesions such as biliary strictures or severe parenchymal fibrosis or atrophy, criteria initially proposed by Choi and Wong[6] and employed by many others[4,7,15,16].

Hepatic resection for the treatment of hepatolithiasis can lead to low rates of cholangitis or stone recurrence and good long-term results ranging from 80% to 98%[3-5,7,10-13,16]. In this series, good late results were observed in 100% of the patients submitted to liver resection only, showing that in some situations cure of the disease is possible.

With regard to the long-term results, seven patients (17.1%), 2 with unilateral and 5 with bilateral stones, all submitted to liver resection and bilioenteric anastomosis, had complications: five had cholangitis and two had liver abscesses. One of these patients died and the other 6 were treated successfully.

Patients with unilateral disease had significantly better results compared to those with bilateral stones, 94.1% and 28.6% had good late results, respectively. These data are comparable to other reports from the Far East and to our own previous experience, where good results were achieved in 80% to 100% of patients with unilateral stones and in 50% to 80% of those with bilateral disease[3-7,9-11]. These results can be explained by the fact that in patients with unilateral disease, all the compromised liver parenchyma is removed, potentially leading to cure of the disease, while the same is not always possible in those with bilateral disease. Indeed, if one looks at our data, good late results were achieved in all patients with unilateral stones who did not present with extrahepatic biliary disease. However, if stones were present in the remnant parenchyma or there was a dilation of the extrahepatic biliary tree and a biliary drainage procedure and hepaticojejunostomy was required, the rate of good results fell significantly to 58.8%. This was probably due to two factors: (1) Associated extrahepatic biliary disease (persistence of a possible cause for stone formation and/or inadequate biliary or stone drainage); and (2) Bilateral disease (persistence of affected liver tissue).

Most authors emphasize that at long-term follow-up, patients submitted to liver resection associated with a bilioenteric anastomosis, have a worse prognosis when compared to those submitted to resection only[4,8]. In recent years, reports have shown higher rates of postoperative cholangitis in patients submitted to hepaticojejunostomy[17-19].

Although patients submitted to hepaticojejunostomy had a higher incidence of poor late results, it is difficult to state whether cholangitis in these cases was due to recurrent stones in the remnant liver or to the presence of a bilioenteric anastomosis. Indeed, Roux-en-Y hepaticojejunostomy is the procedure of choice because the long jejunal loop is employed to avoid bacterial reflux into the liver. In an attempt to solve this question, we compared only patients with unilateral disease, with and without hepaticojejunostomy and, despite a small number of patients; there was a significant difference between the groups

showing a direct effect of the bilioenteric anastomosis on patient outcome.

Although the majority of groups perform a Roux-en-Y hepaticojejunostomy in patients with bilateral stones, the real benefits of this procedure have not yet been proven. Indeed, Li *et al*[19] showed that stones located in the lateral and posterior segments of the liver, do not drain easily through the biliary anastomosis. Moreover, Chen *et al*[20] showed excellent results employing percutaneous treatment without any surgical treatment in patients with bilateral stones. According to this data and reinforced by the poor results in our patients with hepaticojejunostomy, a biliary anastomosis may not be the ideal solution for these patients. Further studies are needed to establish the best treatment for bilateral hepatolithiasis and for those with unilateral disease and a dilated extrahepatic duct.

This study with the largest non-oriental series of primary intrahepatic lithiasis showed that liver resection can lead to the cure of unilateral hepatolithiasis. However, in patients with bilateral disease and in those with extrahepatic biliary duct dilation, where a hepaticojejunostomy was performed, more than 30% of patients had symptom recurrence and a rigorous follow-up is necessary. For the late group of patients, other treatment modalities such as resection associated with percutaneous treatment instead of hepaticojejunostomy should be considered.

COMMENTS

Background

Surgical treatment of primary intrahepatic lithiasis in a Western country was evaluated. The paper reports the largest non-oriental series of liver resection for hepatolithiasis. Prognostic factors were evaluated and bilateral disease treated with a bilioenteric anastomosis had a negative impact on outcome.

Research frontiers

It may be necessary for surgeons who deal with this challenging disease to reevaluate the benefit of hepaticojejunostomy.

Innovations and breakthroughs

Evaluation of prognostic factors in patients submitted to surgical treatment of primary intrahepatic lithiasis.

Applications

The benefit of other treatment modalities such as resection associated with percutaneous treatment instead of hepaticojejunostomy in patients with extrahepatic biliary duct dilation and for those with bilateral intrahepatic stones.

Peer review

This is an interesting manuscript on a challenging group of patients.

Abstract

AIM: To investigate the prevalence of, and risk factors for, diabetes mellitus (DM) in Algerian patients with chronic hepatitis C virus (HCV) infection and in a control group.

METHODS: A cross-sectional study was undertaken. A total of 416 consecutive patients with viral chronic hepatitis attending the Internal Medicine Department of the University Hospital Center Touhami Benflis in Batna [290 HCV-infected and 126 hepatitis B virus (HBV)-infected patients] were prospectively recruited.

RESULTS: The prevalence of DM was higher in HCV-infected patients in comparison with HBV-infected patients (39.1% *vs* 5%, $P < 0.0001$). Among patients without cirrhosis, diabetes was more prevalent in HCV-infected patients than in HBV-infected patients (33.5% *vs* 4.3%, $P < 0.0001$). Among patients with cirrhosis, diabetes was more prevalent in HCV-infected patients, but the difference was not significant (67.4% *vs* 20%, $P = 0.058$). The logistic regression analysis showed that HCV infection [odds ratio (OR) 4.73, 95% CI: 1.7-13.2], metabolic syndrome (OR 12.35, 95% CI: 6.18-24.67), family history of diabetes (OR 3.2, 95% CI: 1.67-6.13) and increased hepatic enzymes (OR 2.22, 95% CI: 1.1-4.5) were independently related to DM in these patients.

CONCLUSION: The high prevalence of diabetes in HCV-infected patients, and its occurrence at early stages of hepatic disease, suggest that screening for glucose abnormalities should be indicated in these patients.

Key words: Prevalence; Hepatitis C virus; Hepatitis B virus; Diabetes mellitus; Algeria

INTRODUCTION

Hepatitis C virus (HCV) infection is a common worldwide medical problem; it is one of the major causes of chronic liver disease. According to recent World Health Organization estimates the worldwide prevalence of HCV infection is 2.2%, affecting approximately 130 million people globally[1]. Patients with chronic HCV infection may develop various extrahepatic manifestations, including cryoglobulinemia, the presence of serum antibodies, glomerulonephritis, sialoadenitis and porphyria cutaneous tarda[2]. Several studies from different parts of the world have reported that HCV infection may also contribute to the development of diabetes mellitus (DM), and higher prevalence of type 2 DM has been observed in patients with HCV infection than in those with other forms of chronic hepatitis[3-5]. However, the prevalence of type 2 DM in patients with HCV infection has not been reported in Algeria, as far as we know.

Thus, in order to examine the prevalence of DM in patients with chronic HCV infection in Batna (Algeria), we conducted a cross-sectional study assessing the prevalence of this metabolic disorder in patients with HCV infection in comparison with the prevalence in those with hepatitis B virus (HBV) infection. In addition, risk factors associated with DM development such as age, body mass index (BMI), diabetic familial history and metabolic syndrome were also evaluated to clarify the possible role of chronic HCV infection in association with development of diabetes.

In this study, the prevalence of diabetes in patients with chronic HCV has not been compared to that in the general population, because patients with chronic liver disease, regardless of etiology, have a higher prevalence of diabetes mellitus[6]. We have chosen patients with chronic hepatitis B as a control group, because HBV infection is the second leading cause of chronic hepatitis after HCV in Algeria[7].

MATERIALS AND METHODS

Patients

From September 2004 to September 2007, we conducted a cross-sectional study by enrolling patients with chronic viral hepatitis admitted to the University Hospital Center Touhami Benflis in Batna, Algeria. The diagnosis of HCV infection was made if patients were positive for anti-HCV antibody and HCV RNA. The presence of anti-HCV antibody was assessed using the third generation microparticle enzyme immunoassay test. The presence of HCV RNA was confirmed by Cobas Ampliprep/Roche Taq Man (Pasteur Institute, Algiers and Sadelaoud Laboratory, Batna, Algeria). HBV infection was diagnosed if patients had evidence of hepatitis B surface antigen. Patients with concomitant HCV and HBV infection were excluded. There was no serologic evidence of co-infection with other hepatotropic viruses or with human immunodeficiency virus. Patients having other causes of liver disease, in particular those known to be involved in the pathogenesis of diabetes, such as hemochromatosis or alcoholic liver disease, were excluded. None of the study patients had received corticosteroids during the previous 6 mo before the study. Patients with a history of, or evidence of, pancreatitis, pancreatic tumor, hepatic tumor or cirrhosis with Child-Pugh category C were excluded from the study. None of the study patients had previously received anti-viral treatment. No woman was pregnant in this study. Patients who were infected with HCV or HBV after being diagnosed with diabetes were also excluded from the analysis.

According to the American Diabetes Association criteria[8], patients were assigned a diagnosis of DM if they were using oral hypoglycemic medication or insulin, or if they showed fasting glucose greater than 126 mg/dL on two occasions, or glucose greater than 200 mg/dL, 2 h after an oral glucose tolerance test, performed in patients with impaired fasting glucose (fasting glucose concentration $\geqslant$ 110 mg/dL and $<$ 126 mg/dL).

A diagnosis of cirrhosis was established either by histology or by presumptive diagnosis made when patients had ascites, hematologic evidence of hypersplenism, esophageal varices or relevant ultrasonographic findings. Liver biopsy was performed in patients with increased alanine aminotransferase (ALT) and who gave their informed consent beforehand. Liver biopsy specimens were analyzed by a single experienced pathologist, who was informed of clinical and biologic data. Fibrosis was assessed using the METAVIR score[9]. Fibrosis stage (F) was scored as F0 (absent), F1 (portal fibrosis), F2 (portal fibrosis with few septa), F3 (septal fibrosis), and F4 (cirrhosis).

The BMI and family history of DM were recorded for each patient during enrollment. The BMI was expressed as the body weight divided by the square of the body length (kg/m^2). Overweight was defined as a BMI 25-29.9 kg/m^2 and obesity as a BMI $\geqslant$ 30 kg/m^2. The family history of diabetes was obtained from the patients themselves and was recorded as positive if their first-degree relatives had DM. The metabolic syndrome was diagnosed according to the National Cholesterol Education Program's Adult Treatment Panel Ⅲ definition[10].

Statistical analysis

All data values were expressed as mean ± standard deviation. Results were compared between HCV and HBV patients using the χ^2 test for categorical variables and Student *t*-test for continuous variables. Stepwise multivariate logistic regression was performed to evaluate the predictive variables associated with the presence of diabetes in the study patients. All statistical analyses were performed using Epi info 2000 (Statistics Program for Public Health. CDC, Atlanta, USA), and a P value < 0.05 was considered significant.

RESULTS

In total, 416 patients (290 HCV-infected patients and 126 HBV-infected patients) were enrolled in this study. Considerable differences could be noted when the demographic characteristics of the two groups were compared (Table 1).

Table 1 Characteristics of all patients in the chronic viral hepatitis cohort *n* (%)

Clinical features	Virological diagnosis		*P*
	HBV (*n* = 126)	HCV (*n* = 290)	
Age (yr)			
< 40	57 (45.2)	13 (4.5)	< 0.001
40-59	60 (47.6)	193 (66.6)	< 0.001
⩾ 60	9 (7.1)	84 (29)	< 0.001
Male sex	79 (62.7)	78 (26.9)	< 0.001
Family history of diabetes	38 (30.2)	103 (35.5)	0.28
BMI (kg/m^2), mean ± SD	25.22 ± 4.48	26.27 ± 4.51	0.05
BMI ⩾ 25 kg/m^2	68 (54)	161 (55.5)	0.42
Metabolic syndrome	20 (15.9)	122 (42.1)	< 0.0001
Increased ALT	15 (11.9)	177 (61)	< 0.0001
Cirrhosis	5 (4)	51 (17.6)	0.00018

HBV: Hepatitis B virus; HCV: Hepatitis C virus; BMI: Body mass index; ALT: Alanine aminotransferase.

Table 2 Analysis of variables associated with diabetes in chronic viral hepatitis *n* (%)

Variables	Virological diagnosis		*P*
	HBV (*n* = 121)	HCV (*n* = 261)	
Diabetic	6 (5)	102 (39.1)	< 0.0001
Age (yr)			
< 40	0/56 (0)	1/12 (8.3)	
40-59	4/58 (6.9)	61/174 (35.1)	< 0.0001
⩾ 60	2/7 (28.6)	40/75 (52.6)	0.56
Family history of diabetes	1/37 (2.7)	52/92 (56.5)	< 0.0001
BMI ⩾ 25 kg/m^2	5/66 (7.6)	70/147 (47.6)	< 0.0001
Metabolic syndrome	4/18 (22.2)	75/108 (69.4)	< 0.001
Increased ALT	2/14 (14.3)	79/155 (51)	0.01
Cirrhosis	1/5 (20)	29/43 (67.4)	0.058
No cirrhosis	5/116 (4.3)	73/218 (33.5)	< 0.0001

HBV: Hepatitis B virus; HCV: Hepatitis C virus; BMI: Body mass index; ALT: Alanine aminotransferase.

Patients with hepatitis C were older than those with hepatitis B (55 ± 9 years *vs* 40 ± 13 years, $P < 0.0001$). Percentage of men was lower in the HCV-infected patients than in those with HBV (26.9% *vs* 62.7%, $P < 0.0001$). In addition, there were significantly more patients with metabolic syndrome among the hepatitis C patients, and more cirrhosis in the hepatitis C group.

DM was observed more often in HCV-infected patients than in HBV-infected patients (39.1% *vs* 5%, $P < 0.0001$). However, this difference is statistically significant only in patients aged between 40 and 60 years.

We compared variables associated with diabetes in patients with patent diabetes (6 HBV-infected patients and 102 infected HCV patients) and in those who were non-diabetics (115 HBV-infected patients and 159 HCV-infected patients). Patients with impaired fasting glucose (5 HBV-infected patients and 29 HCV-infected patients) were excluded from this comparison.

A family history of diabetes appeared to be matched in the present study; of the subjects infected with HCV and HBV, 35.5% and 30.2%, respectively, had a familial history of DM. Patients with a family history of diabetes were more likely to have DM compared with those without (41.08% *vs* 21.73%, $P < 0.0001$). For patients with a family history of DM, the prevalence of diabetes was significantly higher in subjects with HCV infection compared with those with HBV infection (56.5% *vs* 2.7%, $P < 0.000001$) (Table 2).

Metabolic syndrome was more frequent in HCV-infected patients (42.1% *vs* 15.9%, $P < 0.0001$). Patients with metabolic syndrome were more likely to have DM compared with those without (62.69% *vs* 11.32%, $P < 0.000001$). For patients with metabolic syndrome, DM was significantly more frequent in HCV-infected patients than in those with HBV infection (69.4% *vs* 22.2%, $P < 0.001$). In obese or overweight subjects (BMI ⩾ 25 kg/m^2), DM was more frequent in HCV-infected patients (47.6% *vs* 7.6%, $P < 0.0001$).

Liver disease appeared more severe in the HCV group. Cirrhosis was more frequent in HCV-infected patients

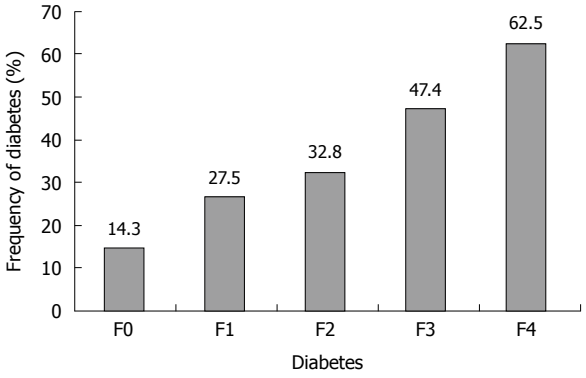

Figure 1 Frequency of diabetes by stage of fibrosis in hepatitis C virus-infected patients.

than in those with HBV infection (17.6% *vs* 4%, $P < 0.001$). In patients without cirrhosis, DM was more frequent in patients with HCV infection than in those with HBV infection (33.5% *vs* 4.3%, $P < 0.00001$). However, in patients with cirrhosis, diabetes was more prevalent in HCV-infected patients, but the difference was not significant (67.4% *vs* 20%, $P = 0.058$).

In HCV-infected patients in whom liver biopsy was performed, DM prevalence increased progressively and significantly with the fibrosis stage (Figure 1). DM was more frequent in patients with increased ALT plasma concentration (> 40 IU/L) compared with those with normal ALT plasma concentration (47.92% *vs* 12.67%, $P < 0.00001$). In patients with increased ALT plasma concentration, DM was significantly more frequent in HCV-infected patients than in those with HBV infection (51% *vs* 14.3%, $P = 0.01$).

The multiple regression analysis revealed that the major independent variables associated with type 2 diabetes were metabolic syndrome [odds ratio (OR) 12.35, $P = 0.0001$, 95% CI: 6.18-24.67], HCV infection (OR 4.73, $P = 0.0029$, 95% CI: 1.69-13.20), family history of diabetes (OR 3.2, $P = 0.0004$, 95% CI: 1.67-6.13) and increased ALT (OR 2.22, $P = 0.027$, 95% CI: 1.09-4.52) (Table 3).

Table 3 Factors associated with the development of diabetes in patients chronically infected with hepatitis virus

Variables	Odds ratio	95% CI	*P* value
Metabolic syndrome	12.35	6.18-24.67	0.00001
Hepatitis C	4.73	1.69-13.20	0.0029
Family history of diabetes	3.2	1.67-6.13	0.0004
Increased ALT	2.22	1.09-4.52	0.027

ALT: Alanine aminotransferase.

DISCUSSION

Our epidemiological and virological data suggest that HCV infection is more closely related to diabetes than HBV infection. Diabetes was observed in 39.1% of patients with HCV infection, as compared with 5% of HBV-infected subjects in our population. However, our study has some limitations, related to the small size of the control group. Indeed, chronic hepatitis B is much less common than chronic hepatitis C in our area[7]. Our findings are in concordance with similar epidemiological studies from different part of the world.

Allison *et al*[11] published, in 1994, the first article about a link between viral hepatitis C and diabetes. In their retrospective study of 100 cirrhotic patients listed for transplantation, these authors reported that the prevalence of type 2 DM was higher in patients with HCV-associated cirrhosis than in cirrhotics with other underlying liver diseases. In a cross-sectional survey including 9841 persons, Mehta *et al*[12] found that HCV-positive persons who were older than 40 years had an increased risk for type 2 diabetes mellitus, more than 3-fold when compared to persons without HCV infection. However, no difference was seen between HBV-infected subjects and the general population[12].

In a retrospective analysis of 1117 patients with chronic viral hepatitis, diabetes was present in significantly more patients with HCV compared to those with HBV infection (21% *vs* 12%)[13]. In a separate case-control trial included in the same report, the prevalence of HCV infection was significantly higher among patients with diabetes than among controls (4.2% *vs* 1.6%).

Diabetes mellitus has been more often seen in cirrhotic patients[14]. However, in a cohort of 45 non-cirrhotic patients with chronic hepatitis C the prevalence of type 2 DM was 33%, higher than in the matched control group and in a group of patients with chronic hepatitis B[15]. Furthermore, in a large retrospective study DM was present in 23.6% of patients with hepatitis C, and in 9.4% of those with hepatitis B[16].

Recently, in a Spanish study which included 525 chronic hepatitis C patients treated with peginterferon plus ribavirin, patients were followed up after treatment. The incidence of altered baseline glucose and the appearance of type 2 DM was greater in non-responders than in sustained responders, even after multivariate analysis including such confounding variables as previous type 2 DM in relatives, age older than 40 years and male sex. Thus, hepatitis C virus clearance induced a decrease in insulin resistance index during short time follow-up and decreased the incidence of type 2 DM in long-term follow-up[17].

Shintani *et al*[18], in an experimental model, observed that the HCV core antigen transgenic mouse had higher basal insulin levels than non-transgenic mice, and readily developed diabetes when fed a high-fat diet, in addition to exhibiting marked insulin resistance as demonstrated by the insulin tolerance test.

In the present study, logistic regression analysis confirmed that family history of diabetes, metabolic syndrome and increased transaminases were the major independent variables associated with DM. This finding is consistent with reports in the literature[19-21].

The mechanisms by which hepatitis C induces increased insulin resistance and the risk for development of diabetes has not been completely understood. Liver fibrosis progression has long been considered responsible for the appearance of insulin resistance and type 2 DM in patients with chronic liver diseases[22]. However, in our study, diabetes occurs in the early stages of liver disease. The mechanism through which HCV is associated with insulin resistance involves direct viral effects, proinflammatory cytokines and suppressors of cytokine signaling[23-25].

In conclusion, this study shows a higher prevalence of DM in patients with HCV infection than in those with HBV infection, and that DM occurs at an early stage of hepatic disease. However, other factors such as metabolic syndrome, family history of diabetes and increased transaminases seem also to be important risk factors for the development of diabetes in Algeria.

ACKNOWLEDGMENTS

The advice from Professor Francesco Negro (Geneva, Switzerland), Professor Dominique Valla (Clichy, France) and Christian Pagnoux, MD (Paris, France), was greatly appreciated while performing this study. The authors also thank Professor Daoud Roula (Constantine, Algeria), Rabah Ait Hamouda (Batna, Algeria) and Saadi Berkane (Algiers, Algeria), for their critical review of the manuscript. In addition, they are indebted to Professor AbdelAziz Agti and Mss Asma Bounecer (Batna, Algeria) for English grammar review. Finally, the authors thank Roche for paying the publishing fee.

COMMENTS

Background

A higher prevalence of diabetes mellitus (DM) has been observed in patients with hepatitis C virus (HCV) infection than in those with other forms of chronic hepatitis and several mechanisms have been implicated in the pathogenesis of DM. However, there is no information from Algeria regarding this issue, and few reports from Africa.

Research frontiers

Recent data link HCV infection with diabetes. However, diabetes is a multifactorial disease; other factors such as age, weight, family history of diabetes and cirrhosis contribute to the development of diabetes.

Innovations and breakthroughs

This is a cross-sectional study assessing the prevalence of diabetes in patients with HCV infection in comparison with the prevalence in those with hepatitis B virus (HBV) infection. It is the first study of its kind performed in Algeria. In addition, risk factors associated with DM development were also evaluated.

Applications

Diabetes plays a role in the initiation and progression of liver injury. The high prevalence of diabetes in HCV-infected patients, and its occurrence at early stages of hepatic disease, suggest that screening for glucose abnormalities should be indicated in these patients.

Peer review

The authors used 290 HCV-infected and 126 HBV-infected patients. It would be better if they had used equal numbers for both the groups or slightly fewer.

Abstract

AIM: To investigate the associations between *CDH1* gene polymorphisms and gastric cancer (GC) risk predisposition.

METHODS: We analyzed four *CDH1* polymorphisms (*+54 T>C*, *-160 C>A*, *-616 G>C*, *-3159 T>C*) in an Omani population, by extraction of genomic DNA from the peripheral blood of 192 patients with GC and 170 control participants and performed *CDH1* genotyping using DNA sequencing.

RESULTS: *CDH1 -160 -AA* genotype was associated with an increased risk of GC (OR = 3.6, 95% CI: 1.1-11.8) (P = 0.03). There was no significant association between the other polymorphisms and GC risk. The haplotype analysis of *+54 T>C*, *-160 C>A*, *-616 G>C*, *-3159 T>C* genotypes revealed that the OR of *CCGC* and *CAGC* haplotypes was 1.5 (95% CI: 0.7-3.5) and 1.5 (95% CI: 0.2-3.0), but did not reach statistical significance.

CONCLUSION: The current study suggests that the *-160 AA* genotype was associated with an increased risk of GC in Oman.

Key words: Gastric cancer; Polymorphism; *CDH1*

Association of *E-cadherin* (*CDH1*) gene polymorphisms and gastric cancer risk. *World J Gastroenterol* 2010; 16(27): 3432-3436 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i27/3432.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i27.3432

INTRODUCTION

Gastric cancer (GC) is the fourth most common cancer and second most common cause of cancer mortality worldwide; therefore, it remains a global health burden[1,2]. GC has been associated with *Helicobacter* infection and environmental factors such as smoking, salted fish, and low intake of fruit and vegetables[3,4]. However, while these factors might affect large proportions of some populations, only subsets of these populations develop GC, and

therefore, increased genetic susceptibility has been postulated. Possible genetic risk factors have included single nucleotide polymorphisms (SNPs) in several pathways involved in chronic inflammation of gastric mucosa and subsequent carcinogenesis. The involved SNPs affect agents such as pro-inflammatory cytokines, xenobiotic metabolizing enzymes, and growth factors[5-11]. The study of these molecular pathways has helped to identify individuals at higher risk, particularly when examined with *Helicobacter pylori* (*H. pylori*) infection and other environmental exposure[7,8].

Adhesion molecules, especially the calcium-dependent intercellular adhesion molecule E-cadherin and its *CDH1* gene (located on chromosome 16), play a central role in carcinogenesis and metastasis[10,12]. The *CDH1* gene encodes a transmembrane glycoprotein that mediates intercellular adhesion and cellular polarity. The E-cadherin protein is a tumor invasion suppressor, and loss of its function results in transition to an invasive phenotype in human epithelial cancers[10,12].

Several SNPs in the *CDH1* gene are associated with GC. The most widely studied polymorphism is *CDH1 -160C>A*, where the *A* allele decreases transcriptional activity of the *CDH1* gene and E-cadherin expression, and increases susceptibility to GC in some populations[9,13-19]. Moreover, several other SNPs, including *+54 T>C*, *-3159 T>C*, *-160 C>A*, *-2076 C>T* and *-616 G>C*, were studied in Japanese and Italian populations, which resulted in the identification of haplotypes associated with increased risk of GC[12,20].

The above studies have highlighted the ethnic variation in frequency and risk predisposition of these SNPs[15,16]. Therefore, we studied in an Omani population, four *CDH1* gene polymorphisms (*+54 T>C*, *-160 C>A*, *-616 G>C* and *-3159 T>C*) that were previously examined in Japanese and Italian populations[12,20]. We evaluated the potential association of these SNPs and their haplotypes with GC susceptibility in a case-control design.

MATERIALS AND METHODS

Study participants

The study population consisted of a series of unrelated patients with GC who were diagnosed at two main hospitals in the Sultanate of Oman (Sultan Qaboos University Hospital and Royal Hospital). The healthy control group comprised persons of the same ethnic and geographical origin as the patients. The Medical Research and Ethics Committee of the College of Medicine of Sultan Qaboos University approved the study design. The study participants provided informed consent prior to participation, in compliance with the Declaration of Helsinki.

Genotyping method

From each participant, 10 mL blood was collected in an EDTA tube and stored frozen until the extraction of the DNA. DNA was extracted from whole blood using a commercial DNA blood kit (Gentra Puregene DNA Purification kit; Qiagen, Gaithersburg, MD, USA) and stored until processing for genotyping.

Analysis of the *CDH1* SNPs, *+54 T>C*, *-160 C>A*, *-616 G>C* and *-3159 T>C*, was performed using multiplex polymerase chain reaction (PCR) with an ABI premix. Genomic DNA from whole blood was used as a PCR template in a total reaction volume of 10 μL that contained 10 pmol designed primers: *+54 T>C (rs3743674)*: [5'-CCCCTGGTCTCATCATTTC-3' (forward) and 5'-AATTCCTCCAAGAATCCCCAG-3' (reverse)]; *160 C>A (rs16260)*: [5'-TGATCCCAGGTCTTAGTGAG-3' (forward) and 5'-GCTCCTCAGGACCCGAAC-3' (reverse)]; *-616 G>C (rs7203904)*: [5'-TTGACTGAGGCCACAGAGTG-3' (forward) and 5'-CTGCCTAAATCTGCTGAGCC-3' (reverse)]; *-3159 T>C* (*rs2010724*): [5'-GAGCTTCCCAGAGCCTTTCT-3' (forward) and 5'-ATTGGACTTGCCAAGGGTG-3' (reverse)]. PCR was performed as follows: one cycle at 94℃ for 10 min, 35 cycles at 94℃ for 30 s, 59℃ for 30 s, and 72℃ for 30 s, followed by 72℃ for 5 min. The final extension was at 72℃ for 10 min. PCR products were analyzed on a 2.5% agarose gel stained with ethidium bromide and photographed under UV light. The PCR product was subsequently sequenced in an ABI PRISM 3100 sequencer using BigDye Terminator v3.1 Cycle Sequencing method (Applied Biosystems,USA) as recommended by the manufacturer. Candidate SNP regions were detected and typed with the aid of DNA Star Software (DNASTAR, Madison, WI, USA).

Statistical analysis

The genotypic distributions of different polymorphic loci in the control samples were compared with those expected from the Hardy-Weinberg equilibrium using the χ^2 test. The differences in frequency distributions of the genotypes between the patient and control groups were also tested using the χ^2 test. Age- and sex-adjusted ORs and 95% CIs were calculated using logistic regression analysis. Haplotype frequencies, haplotype-survival analyses, and standardized disequilibrium coefficients (D) were calculated using Thesias software available at http://genecanvas.ecgene.net/. $P < 0.05$ was considered statistically significant. Analysis of data was performed using SPSS version 10.0 software (SPSS, Chicago, IL, USA).

RESULTS

One hundred and ninety-two GC patients and 170 unrelated controls were included. The age range for the participants included in the study was 19-80 years, and the mean ages for the patients and controls were 55.1 ± 12.5 and 32.8 ± 6.6 years, respectively. The percentages of male and female participants were 58.3% and 41.7% for GC patients respectively, and 56.5% and 43.5% for controls. *H. pylori* infection status was available in 116 GC patients and 90 control participants, with a positivity rate of 58% and 60% (Table 1). Most GC patients in this cohort presented at an advanced stage, with slight predominance of non-intestinal type according to Lauren's classification, as shown in Table 2.

CDH1 genotypic frequencies and GC risk

The frequencies of the *+54 T>C*, *-160 C>A*, *-616 G>C* and *-3159 T>C* genotypes are shown in Table 3. The SNP analysis was successful in the majority of GC patients and control subjects, however, 15-23 samples failed for GC patients and 4-13 samples for control subjects, as shown in Table 3. The allelic distributions for control subjects did not deviate significantly from those expected from the Hardy-Weinberg equilibrium. There was a significant association between the *CDH1-160 AA* genotype, with an increased risk of GC, with OR 3.6 (95% CI: 1.1-11.8, $P = 0.03$) (Table 3). There was no significant association between the other *CDH1* polymorphisms and GC risk (Table 3).

Table 3 *CDH1* genotype frequencies and their associated risk of gastric cancer predisposition

CDH1 genotype	Patients *n* (%)[1]	Control *n* (%)[1]	OR[2] (95% CI)	*P* value

[1]The number of patients and control indicates successful single nucleotide polymorphism analysis for each polymorphism; [2]Age and sex-adjusted.

Haplotype analysis

The common haplotypes were identified, as shown in Table 4. There were significant differences in the distribution of these haplotypes between patients and controls (Table 4). The haplotype analysis of *+54 T>C*, *-160 C>A*, *-616 G>C* and *-3159 T>C* genotypes revealed that the OR of *CCGC* and *CAGC* haplotypes was 1.5 (95% CI: 0.7-3.5) and 1.5 (95% CI: 0.2-3.0), respectively, but did not reach statistical significance.

Table 4 Frequencies of *CDH1* haplotypes and associated risk of gastric cancer predisposition

Haplotype	Frequency (%)		OR[1] (95% CI)	*P* value
	Patient	Control		
TCGT	20.1	22.1	1	
TACG	10.4	11.0	0.99 (0.5-1.9)	1.0

DISCUSSION

Six polymorphisms of the *CDH1* gene have been studied previously in Caucasian, East Asian, and Mexican populations and included: *-616 G>C*, *-160 C>A*, *-3159 T>C*, *+54 T>C*, *2076C>T* and *347G>GA*[12-17,20]. A recent meta-analysis has highlighted the role of ethnic differences by showing that the associations between these polymorphisms and GC among Asian and Caucasian populations are in opposite directions[15,18]. Therefore, we investigated the association between GC and the *CDH1 +54 T>C*, *-160 C>A*, *-616 G>C* and *-3159 T>C* polymorphisms in an Omani population, an ethnic group in which the association between GC and these polymorphisms has not been studied previously.

The most widely studied *CDH1* polymorphism in various cancers is *CDH1 -160 C>A*[13-19]. In the present study, we found that this polymorphism affected the risk of developing GC. The carriage of the *CDH1 -160 AA* genotype increased the risk of GC (OR: 3.6, 95% CI: 1.1-11.8) (P = 0.03). Two meta-analyses have suggested that the association of *CDH1 -160 AA* with GC risk is ethnicity-dependent, whereby the OR estimates for *CDH1 -160 AA* carriers are less than 1.0 for Asians but significantly greater than 1.0 for Caucasians[15,18]. Thus, our results are consistent with the findings in Caucasian populations. The explanation for this observation remains unclear, however, the A variant decreases transcription efficiency by 68% compared with the C allele *in vitro*[9]. The altered expression of adhesion molecule E-cadherin results in tumor development and carcinogenesis. Possible explanations for the discrepancy between ethnic groups include the frequency of the polymorphism in the population studied or linkage disequilibrium with other, perhaps undiscovered, functional SNPs in the *CDH1* gene. The present study shows that there is no association between the *CDH1 +54 T>C* and *-616 G>C* SNPs and GC development. Although a study by Zhang *et al*[13] has found an association between *+54 T>C* and esophageal and gastric cancer, other studies were negative[15].

It has been suggested that haplotype analysis might be more useful than single SNP analysis in identifying cancer risk[12,20]. In particular, the combined analysis of *CDH1 -160 C>A*, *-2076C>T* and *+54 T>C* has suggested that a haplotype ATT increases susceptibility to GC, whereas the CTT haplotype has a protective effect[12,20]. Yamada *et al* have studied the *+54 T>C*, *-160 C>A*, *-616 G>C*, *-2076 T>C* and *3159 T>C* polymorphisms and have found that the TCGTT haplotype is the most common haplotype and has a protective effect, whereas the TAGTC haplotype increases susceptibility to GC[12,20]. The haplotype analysis of *+54 T>C*, *-160 C>A*, *-616 G>C* and *-3159 T>C* genotypes revealed that the OR of *CCGC* and *CAGC* haplotypes was 1.5 (95% CI: 0.7-3.5) and 1.5 (95% CI: 0.2-3.0), respectively, but did not reach statistical significance. The reason for the difference can be attributed to differences in polymorphisms studied, genetic background and local environmental factors, and highlights the need for comparative studies between different ethnic groups.

In conclusion, the current study confirms the ethnic variations in the association between *CDH1 -160 C>A* polymorphisms and GC susceptibility. We demonstrated that the *-160 AA* genotype was associated with an increased risk of GC. This finding could allow the identification of higher-risk groups who might benefit from intensive prevention strategies (aimed at infections or environmental factors). A better understanding of the functional aspects of these polymorphisms in tumor tissue could lead to a better understanding of tumor biology and behavior, and elucidate the discrepancies observed between and within studies.

COMMENTS

Background

E-cadherin plays a central role in carcinogenesis and metastasis. *E-cadherin* (*CDH1*) gene polymorphisms at various loci and their significance for predisposition to gastric cancer (GC) risk have been studied previously with different results that have suggested ethnic variation. The authors investigated the associations between *CDH1* gene polymorphisms and GC risk predisposition.

Research frontiers

A better understanding of *CDH1* gene polymorphisms in GC could lead to a better understanding of tumor biology and behavior.

Innovations and breakthroughs

The current study confirms the ethnic variations in the association between *CDH1 -160 C>A* polymorphisms and GC susceptibility. The authors demonstrated that the *-160 AA* genotype was associated with an increased risk of GC.

Applications

These findings could allow the identification of higher-risk groups who might benefit from intensive prevention strategies (aimed at infections or environment factors).

Terminology

CDH1 gene encodes E-cadherin protein, which is an important adhesion molecule. Single nucleotide polymorphisms are DNA sequence variations that occur when a single nucleotide is altered.

Peer review

This study provides some useful epidemiological information about genetic predisposition and the risk of GC.

Abstract

AIM: To evaluate the efficacy of transcatheter arterial chemoembolization (TACE) using a suspension of a fine-powder formulation of cisplatin (DDPH) for hepatocellular carcinoma (HCC).

METHODS: The study population was comprised of 164 patients who were treated by TACE alone. Of these patients, 76 underwent TACE using a suspension of DDPH in lipiodol (LPD) (DDPH group), and the remaining 88 underwent TACE with an emulsion of doxorubicin (ADM) with LPD (ADM group). We compared the DDPH group with the ADM group in terms of the objective early response rate, progression free survival (PFS) and overall survival (OS).

RESULTS: The objective early response rate in the DDPH group was significantly higher than that in the ADM group (54% *vs* 24%, $P < 0.001$). The PFS rate in the DDPH group was also significantly higher than that in the ADM group ($P < 0.001$). Moreover, the OS in the DDPH group was significantly longer than that in the ADM group ($P = 0.002$). Although the incidence rate of nausea or vomiting in the DDPH group was higher than that in the ADM group, the ADM group showed a higher incidence rate of the adverse events of hepatic arterial damage and leucopenia. No other serious complications were observed in either group.

CONCLUSION: We conclude that TACE using a suspension of DDPH in LPD could be a useful treatment for HCC.

Transcatheter arterial chemoembolization with a fine-powder formulation of cisplatin for hepatocellular carcinoma. *World J Gastroenterol* 2010; 16(27): 3437-3444 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i27/3437.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i27.3437

INTRODUCTION

Hepatocellular carcinoma (HCC) is the cancer with the sixth highest incidence in the world[1]. The number of deaths from HCC is also increasing throughout the world[2-5]. Development of new treatments for HCC has

helped improve the patient prognosis[6,7]. Local ablating therapies such as percutaneous ethanol injection (PEI) or radiofrequency ablation (RFA) have been effective in cases of limited tumor spread and are increasingly used[7,8]. However, the majority of patients are not eligible for these modalities because of large tumor size or diffuse tumor growth. In these patients regional transcatheter arterial chemoembolization (TACE) has been widely used as a palliative treatment[9,10]. Two randomized trials from Europe and Asia recently confirmed a survival benefit after TACE using gelfoam and iodized oil (lipiodol) compared to conservative treatment[11,12]. In recent years, TACE using an emulsion of doxorubicin (ADM) with lipiodol (LPD) (ADM-LPD emulsion) followed by embolization with a gelatin sponge has been employed commonly for HCC treatment[13,14]. However, the tumors have been demonstrated to show a high frequency of recurrence after TACE[10,15,16]. Cisplatin (CDDP), a platinum compound, is an effective anticancer agent used in the treatment of various malignancies[17]. Researchers have recently reported that TACE using a suspension of CDDP powder in LPD may be more effective against unresectable HCC as compared with TACE using ADM-LPD emulsion[18,19]. However, only limited institutions have used this for TACE because it is laborious to refine the CDDP powder. Since 2004, a fine-powder formulation of CDDP (DDPH, IA-call; Nippon Kayaku, Tokyo, Japan) has also been available as a therapeutic agent for intra-arterial infusion in Japan. As a result, TACE using DDPH has become widespread in Japanese institutions. Nevertheless, the efficacy of TACE using DDPH-LPD suspension has not yet been reported.

In this article, we compared the effectiveness with regard to the response rate (RR), progression free survival (PFS) and overall survival (OS) between TACE using a suspension of DDPH in LPD (DDPH-LPD suspension) and ADM-LPD emulsion. Moreover, we analyzed the prognostic factors for clinical outcome of patients treated with TACE.

MATERIALS AND METHODS

Patients

Between January 2006 and July 2009, 164 HCC patients who showed no indication for surgical resection or local ablation therapy such as RFA and PEI therapy were enrolled in the study. HCC was diagnosed by the distinctive findings on ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI) and angiography, and the serum levels of des-γ-carboxy prothrombin (DCP) and α-fetoprotein (AFP). Histologic examination was not always carried out. Liver function was evaluated according to the Child-Pugh classification[20]. Tumor stage was judged by the TNM classification established by the International Union Against Cancer[21]. The extent of portal vein invasion was classified as follows: Vp 0, no invasion of the portal vein; Vp 1, invasion of the third or more distal branch of the left or right portal vein; Vp 2, invasion of the second branch of the portal vein; Vp3, invasion of the first branch of the portal vein; and Vp4, invasion of the trunk of the portal vein. After being presented with the clinical results of previous studies of TACE using DDPH-LPD suspension or TACE using ADM-LPD emulsion, all 164 patients themselves selected the therapeutic option on the basis of informed consent. All of the enrolled patients met the eligibility criteria for inclusion in the analysis described in the next paragraph. The patients were divided into two groups: one group consisting of 76 patients who underwent TACE using DDPH-LPD suspension (DDPH group), and another group consisting of 88 patients who underwent TACE using ADM-LPD emulsion (ADM group). They were all treated by TACE alone.

Informed consent was obtained from all of the patients. The study protocol was approved by the Ethics Committee of Iwate Medical University and the study was conducted in accordance with the Declaration of Helsinki 1975.

Eligibility criteria

The eligibility criteria of the patients for this study were as follows: (1) No indication for surgical resection or local ablation therapy such as RFA and PEI therapy; (2) No evidence of extra-hepatic metastasis; (3) No tumor thrombus in the main trunk of portal vein; (4) No evidence of active heart or renal diseases meeting the contraindications for ADM and CDDP therapy, respectively; (5) Eastern Cooperative Oncology Group (ECOG) performance status (PS)[22] level 0-2; (6) Hypervascular tumors showing enhancement during angiography; (7) Bidimensionally measurable hepatic lesions; (8) No uncontrolled ascites or pleural effusion; and (9) Total serum bilirubin (T-Bil) less than 3 mg/dL.

The presence of underlying liver diseases such as hepatitis or cirrhosis was confirmed by laboratory, radiological examinations and pathological examinations. We classified the chronic hepatitis patients into Child-Pugh class A, because chronic hepatitis is a known precirrhotic condition.

Preparation of the agents for TACE

We used DDPH or ADM (Adriacin; Kyowa Hakko Kogyo, Tokyo, Japan) mixed with LPD (iodized oil; Andre Guerget, Aulnay-sous-Bois, France).

The DDPH-LPD suspension was prepared by mixing 50 mg of DDPH into 3-10 mL of LPD.

The ADM-LPD emulsion was prepared by the following procedure: 10-30 mg of ADM was dissolved in 1-2 mL of a contrast medium (Iomeron; Eisai Co., Ltd., Tokyo, Japan) and then mixed with 3-10 mL LPD.

The dosage of LPD and the anticancer drugs was adjusted depending on the tumor size, number of tumors, degree of liver impairment and renal function, however, the maximum dose of LPD was not allowed to exceed 10 mL.

Treatments

Hepatic arteriography, superior mesenteric arterial porto-

venography, CT during arteriography and CT during arterio-portography were performed to define the size and locations of tumor nodules and to exclude tumor thrombus in the main trunk of the portal vein. Following hepatic angiography, a catheter was selectively inserted into the hepatic artery supplying the target tumor and the DDPH-LPD suspension or the ADM-LPD emulsion was injected. In patients with several tumors in the liver, superselective catheterization was performed for each lesion. If superselective catheterization was not possible, the DDPH-LPD suspension or the ADM-LPD emulsion was injected into the right and left main hepatic artery distal to the origin of the cystic artery. After the injection, arterioembolization was performed used gelatin sponge particles (Gelpart; Nippon Kayaku, Tokyo, Japan) mixed with contrast medium.

All the patients were followed up with US, CT and/or MRI after 1 mo and every 3 mo thereafter. TACE was undertaken again when relapse of the treated lesions and/or new hepatic lesions were detected. These patients received additional TACE using the same agent during the follow-up period. The TACE was repeated until complete regression of the tumor was obtained, or until the patient could no longer be treated.

Post treatment assessment

Early tumor response was assessed by US, CT and/or MRI, conducted 1 mo after the initial treatment. We regarded LPD accumulation in the tumor as representing a necrotic area, based on previous reports of such LPD retention areas corresponding to the necrotic areas on CT[23-26]. By measurement of the two largest perpendicular diameters of the tumor, we classified the tumor response into four categories using the following criteria: complete response (CR), complete disappearance or 100% necrosis of all tumors; partial response (PR), reduction and/or necrosis, with at least 50% decrease of all the measurable lesions; progressive disease (PD), an increase of the tumor size exceeding 25% of all the measurable lesions or appearance of a new lesion; stable disease (SD), disease not qualifying for classification as CR, PR, PD.

Toxicity was evaluated by the National Cancer Institute-Common Terminology Criteria for Adverse Events, version 3.0 (CTCAE v3.0).

Statistical analysis

The differences in the background clinical characteristics of the patients between the DDPH group and ADM group were assessed by Mann-Whitney's *U* test, logistic regression test, or the χ^2 test, as appropriate.

PFS and OS were calculated from the date of start of the therapy to the date on which tumor progression was documented and the date of death of the patient, respectively. Both were assessed by the Kaplan-Meier life-table method, and the differences between the two treatment groups were evaluated by the log rank test. Univariate analysis to identify the predictors of survival in the patients was conducted by the Kaplan-Meier life-table method, and the differences between the two groups were evaluated by the log rank test. Multivariate analysis to identify the predictors of survival was conducted using the Cox proportional hazards model. Statistical significance was defined as a *P* value of less than 0.05. All of the above analyses were performed using the SPSS software (version 11, SPSS, Chicago, IL, USA).

Table 1 Patient characteristics

Characteristics	DDPH group	ADM group	*P* value
No. of patients	76	88	
Age (yr) [median, (range)]	67 (32-87)	69 (21-90)	0.093
Gender (male/female)	57/19	52/36	0.031
Etiology (HBV/HCV/NBNC)	11/50/15	8/64/16	0.508
Child-Pugh classification (A/B/C)	47/26/3	45/36/7	0.303
TNM classification (Ⅰ-Ⅱ/Ⅲ-Ⅳ)	10/66	24/64	0.026
Tumor size (≤ 3.0/> 3.0 cm)	21/55	30/58	0.373
Number of tumors (1-3/≥ 4)	35/41	46/42	0.427
PVTT (Vp0-2 /Vp3)	62/14	80/8	0.080
Total bilirubin (≤ 1.5/> 1.5 mg/dL)	66/10	75/13	0.906
Albumin (≤ 3.5/> 3.5 g/dL)	38/38	45/42	0.822
AFP (≤ 1000/> 1000 ng/mL)	68/8	79/8	0.776
DCP (≤ 1000/> 1000 mAU/mL)	59/14	73/14	0.609

Data are expressed as median with range values, or the number of patients. The stages of HCC by TNM classification are clustered into two groups (Ⅰ-Ⅱ and Ⅲ-Ⅳ). The tumor characteristics and other parameters are classified as follows: tumor size: ≤ 3.0, > 3.0 cm; tumor number: 1-3, > 4; extent of PVTT: Vp 0-2, and Vp 3; serum bilirubin: ≤ 1.5, > 1.5 mg/dL; serum albumin: ≤ 3.5, > 3.5 g/dL; serum AFP levels: ≤ 1000, > 1000 ng/mL. Serum DCP levels: ≤ 1000, > 1000 mAU/mL. HBV: Hepatitis B virus; HCV: Hepatitis C virus; NBNC: Negative for hepatitis B surface antigen and HCV antibody; PVTT: Portal vein tumor thrombosis; AFP: α-fetoprotein; DCP: Des-γ-carboxy prothrombin; DDPH group: Using a suspension of DDPH in lipiodol (LPD); ADM group: With an emulsion of doxorubicin (ADM) with LPD.

RESULTS

Patient profile

The characteristics of the 164 patients of both groups are summarized in Table 1. There were 109 male and 55 female patients, ranging in age from 21 to 90 years old (mean, 68 years old).

Regarding the assessment of differences in the characteristics of the patients, there were significant differences in the gender distribution and in the TNM classification between the two groups, i.e. there was a higher proportion of males ($P = 0.031$) and more subjects with advanced TNM classification ($P = 0.026$) in the DPHH group. There were no significant differences in any of the other characteristics between the two groups.

Treatments and early tumor response

The median follow-up period was 13.1 mo (range: 1-40 mo). We performed 392 TACE procedures (157 sessions in the DDPH group, 235 sessions in the ADM group) in 164 patients. The median number of TACE

Table 2 Early tumor response *n* (%)

	DDPH (*n* = 76)	ADM (*n* = 88)	*P* value
CR	2 (3)	5 (6)	
PR	39 (51)	16 (18)	
SD	23 (30)	5 (6)	
PD	12 (16)	62 (70)	
CR + PR	41 (54)	21 (24)	< 0.001

Data are expressed as number of patients and percentages. DDPH group: Using a suspension of DDPH in lipiodol (LPD); ADM group: With an emulsion of doxorubicin (ADM) with LPD; CR: Complete response; PR: Partial response; SD: Stable disease; PD: Progressive disease.

Table 3 Univariate analysis for identifying the predictors of survival

Variable	Hazard ratio	95% CI	*P* value
Treatment regimen (ADM *vs* DDPH)	0.580	0.325-1.035	0.065
Age (≤ 65 yr *vs* > 65 yr)	1.286	0.741-2.231	0.372
Gender (female *vs* male)	1.651	0.944-2.888	0.079
Etiology (NBNC *vs* HBV/HCV)	0.734	0.432-1.246	0.252
Child Pugh classification (A *vs* B/C)	1.142	0.689-1.891	0.607
TNM classification (Ⅰ-Ⅱ *vs* Ⅲ-Ⅳ)	2.765	1.252-6.106	0.012
Tumor size (≤ 3.0 cm *vs* > 3.0 cm)	2.094	1.161-3.776	0.014
Number of tumors (1-3 *vs* ≥ 4)	2.612	1.535-4.444	0.001
PVTT (Vp0-2 *vs* Vp3)	4.714	2.520-8.819	< 0.001
Total bilirubin (≤ 1.5 mg/dL *vs* > 1.5 mg/dL)	1.730	0.874-3.422	0.116
Albumin (≤ 3.5 g/dL *vs* > 3.5 g/dL)	0.996	0.603-1.647	0.989
AFP (≤ 1000 ng/mL *vs* > 1000 ng/mL)	1.323	0.528-3.315	0.551
DCP (≤ 1000 mAU/mL *vs* > 1000 mAU/mL)	2.396	1.288-4.459	0.005

DDPH group: Using a suspension of DDPH in lipiodol (LPD); ADM group: With an emulsion of doxorubicin (ADM) with LPD; HBV: Hepatitis B virus; HCV: Hepatitis C virus; NBNC: Negative for hepatitis B surface antigen and HCV antibody; PVTT: Portal vein tumor thrombosis; AFP: α-fetoprotein; DCP: Des-γ-carboxy prothrombin.

procedures was 2 sessions (range: 1-5 sessions) in the DDPH group and 3 sessions (range: 1-6 sessions) in the ADM group. The median interval to the re-treatment with TACE was 9.4 mo in the DDPH group and 3.8 mo in the ADM group. One hundred and ten sessions (70.1%) in the DDPH group and 170 sessions (72.3%) in the ADM group were treated by superselectivity of TACE. There was no significant difference in the incidence of superselectivity of TACE between the two groups.

In the DDPH group, 2 (3%), 39 (51%), 23 (30%) and 12 (16%) patients showed CR, PR, SD and PD, respectively. In the ADM group, 5 (6%), 16 (18%), 5 (6%) and 62 (70%) patients showed CR, PR, SD and PD, respectively. Therefore, the objective early response rate of the DDPH group (54%) was significantly higher than that in the ADM group (24%). The difference in the rate between the two groups was statistically significant ($P < 0.001$) (Table 2).

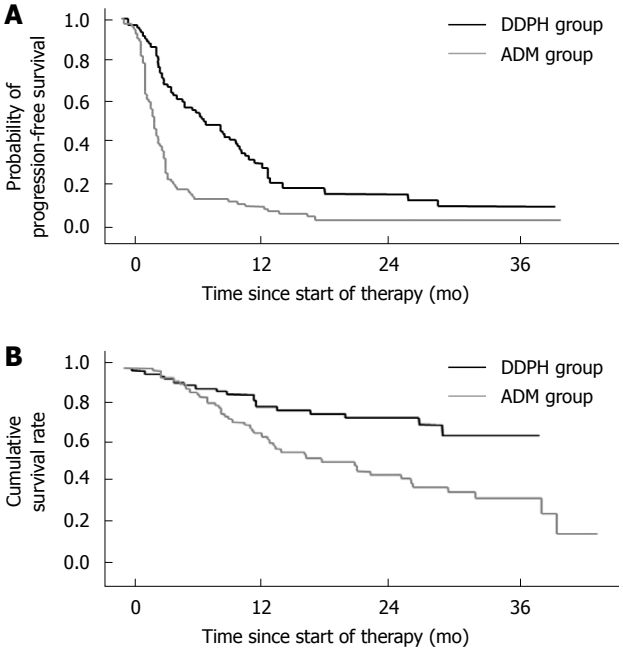

Figure 1 Comparison of the progression-free survival rates (A) and overall survival (B) between the DDPH and ADM groups. A: The progression-free survival rate was significantly higher in the DDPH group than in the ADM group (log-rank test: $P < 0.001$); B: The overall survival was significantly longer in the DDPH group than in the ADM group (log-rank test: $P = 0.002$). DDPH group: Using a suspension of DDPH in lipiodol (LPD); ADM group: With an emulsion of doxorubicin (ADM) with LPD.

PFS

The median PFS was 8.6 mo in the DDPH group and 3.0 mo in the ADM group. The PFS rates at 6, 12, 24 and 36 mo were 58%, 32%, 18% and 11%, respectively, in the DDPH group. In contrast, the corresponding values were 18%, 10%, 5% and 5%, respectively, in the ADM group. The PFS rates in the DDPH group were significantly higher than those in the ADM group ($P < 0.001$) (Figure 1A).

Survival

The median survival time (MST) in the DDPH and ADM groups was "not reached" and 20.8 mo, respectively. The OS values at 6, 12, 24, and 36 mo were 92%, 81%, 76% and 67%, respectively, in the DDPH group. The corresponding values in the ADM group were 87%, 68%, 46% and 37%, respectively. The OS in the DDPH group was significantly longer than that in the ADM group ($P = 0.002$) (Figure 1B).

Univariate analysis to identify the predictors of survival indicated five possible factors affecting the survival: TNM classification; tumor size; number of tumors; portal vein tumor thrombosis (PVTT) and serum DCP level. The treatment regimen was close to being statistically significant ($P = 0.065$) for survival (Table 3). Multivariate analysis performed using factors that were considered

Table 4 Multivariate analysis for identifying predictors of survival

Variable	Hazard ratio	95% CI	*P* value
Treatment regimen (ADM *vs* DDPH)	0.329	0.149-0.726	0.006
Gender (female *vs* male)	2.291	1.174-4.470	0.015
Number of tumors (1-3 *vs* ≥ 4)	6.541	3.201-13.363	< 0.001
PVTT (Vp0-2 *vs* Vp3)	6.704	2.581-17.418	< 0.001
Albumin (≤ 3.5 g/dL *vs* > 3.5 g/dL)	0.311	0.157-0.612	0.001

DDPH group: Using a suspension of DDPH in lipiodol (LPD); ADM group: With an emulsion of doxorubicin (ADM) with LPD; PVTT: Portal vein tumor thrombosis.

significant ($P < 0.1$) on univariate analysis identified the treatment regimen, gender, number of tumors, PVTT, and serum albumin as independent factors affecting the survival (Table 4).

Adverse effects

Table 5 shows a summary of the adverse effects in the two groups. The incidence rate of nausea/vomiting in the DDPH group was significantly higher than that in the ADM group ($P < 0.001$). In addition, the incidence rates of hepatic arterial damage (HAD) after TACE and leucopenia in the ADM group were significantly higher than those in the DDPH group ($P < 0.001$ and $P = 0.002$, respectively). We observed HAD in 17 patients. Although one patient in the DDPH group was observed to have slight wall irregularity of the hepatic artery (HA), HAD associated with TACE did not interfere with catheterization at the next TACE session. On the other hand, in the ADM group, we observed slight wall irregularity of HA in six patients, overt stenosis of HA in four patients and occlusion of HA in six patients. In six patients who were observed as having occlusion of HA, it became impossible to treat with repeated TACE.

No other serious complications or treatment-related deaths were observed in either group.

Table 5 Adverse events *n* (%)

Adverse effect	Treatment group (%)		*P* value
	DDPH group (*n* = 76)	ADM group (*n* = 88)	
Nausea/vomiting	64 (84)	48 (55)	< 0.001
Fever	61 (80)	73 (83)	0.571
Abdominal pain	53 (69)	63 (72)	0.958
Elevation of transaminase levels	55 (72)	62 (71)	0.993
Liver abscess	1 (1)	2 (2)	0.765
Hepatic arterial damage	1 (1)	16 (18)	< 0.001
Renal or liver failure	0 (0)	2 (2)	0.229
Leucopenia	3 (4)	12 (14)	0.002
Thrombocytopenia	4 (5)	6 (7)	0.650
Fatigue	21(28)	27 (31)	0.839

DDPH group: Using a suspension of DDPH in lipiodol (LPD); ADM group: With an emulsion of doxorubicin (ADM) with LPD; Data are expressed as number of patients, with the percentages indicated in parentheses.

DISCUSSION

TACE has been widely used for the treatment of unresectable HCC[9,10]. The most commonly used agent used in TACE for HCC treatment is ADM-LPD emulsion, followed by embolization with a gelatin sponge[13,14]; however, the tumors frequently recur[10,15,16] or residual tumors are observed at a high incidence. CDDP is an effective anticancer agent used in the treatment of various malignancies[17]. It has been reported to exert its actions by binding to the DNA in cancer cells, inhibiting DNA synthesis and subsequent cellular division. The antitumor activity of CDDP is closely associated with the serum concentration of the drug[27]. Therefore, the antitumor activity can be enhanced by increase of the dose. LPD acts as a selective carrier of anticancer agents and as an embolic material[23]; the anticancer agent is gradually released from the iodized oil. Although the mechanism of topical accumulation of LPD in the tumor is not yet precisely understood, it is used nonetheless to achieve a targeting drug delivery system with long-lasting accumulation in the tumor and gradual drug release. Consequently, augmented antitumor efficacy and milder side-effects have come to be expected with the use of this substance for TACE. In fact, Morimoto *et al*[28] investigated the pharmacological advantages of TACE using DDPH for hypervascular hepatic tumors in animal experiments. They reported that the tumor concentration of the platinum agent in the DDPH-LPD-TACE group was about 14 times higher than that in the DDPH-hepatic arterial infusion (HAI) group. In addition, they reported that the plasma concentrations of the platinum agent at 5 and 10 min from start of the infusion were lower in the DDPH-LPD-TACE group than those in the DDPH-HAI group. Recently, Ono *et al*[18] reported that TACE using a suspension of CDDP powder in LPD was more effective than that using ADM-LPD emulsion against unresectable HCC. Other investigators have also frequently reported favorable results obtained with TACE using a suspension of CDDP powder in LPD in HCC patients[19,29]. However, the CDDP powder for this therapy is difficult to produce because of the characteristics of the drug formulation. Therefore, CDDP powder had to be a custom-made formulation in individual institutions[30]. Consequently, when an institution was able to dispense CDDP powder in its own pharmacy department, TACE using a suspension of CDDP powder in LPD was undertaken.

A fine-powder formulation of CDDP, namely "DDPH", for intra-arterial infusion has been available for HCC treatment since 2004 in Japan. Dispensing of CDDP powder improved with the development of DDPH, and DDPH has now come to replace CDDP powder. Using DDPH-LPD suspension for TACE in HCC patients was expected to yield better therapeutic outcomes; therefore, TACE using DDPH became widespread in Japanese institutions. Nevertheless, the efficacy of TACE using DDPH-

LPD suspension has not yet been reported. Therefore, we compared the outcomes of TACE using DDPH-LPD suspension and ADM-LPD emulsion.

Analysis of the results in our study revealed that the objective response rate in the DDPH group was significantly higher than that in the ADM group. Moreover, the OS of the patients in the DDPH group was significantly longer than that of the patients in the ADM group. This could be explained as being due to the fact that TACE with ADM cannot be repeated as required because of the high frequency of adverse effects of ADM such as leucopenia, severe vascular changes and occlusion of the hepatic artery[18,31,32]. In fact, the incidences of leucopenia and HAD in the ADM group in our study were significantly higher than those in the DDPH group. Considering the fact that TACE is often repeated in most patients, longer patency of the hepatic artery is preferable for properly deploying the lipiodol mixture and embolic agents into the tumor. In addition, we conclude that anthracyclines such as ADM may be relatively less effective against HCC; this is because of the high expression level of P-glycoprotein, which transports antitumor agents such as anthracyclines or vinca alkaloids from cells with a high active efflux mechanism, in HCC tumors[33].

On the other hand, Pelletier *et al*[34] reported that TACE with CDDP sometimes caused severe complications, such as acute hepatic failure. The treatment also did not produce any significant improvement of the survival rate in this study. Severe complications could be expected with the high doses (2 mg/kg) of CDDP used in their study. Therefore, we performed TACE using DDPH-LPD suspension in our study with half of the dose (50 mg = 1 mg/kg) that they had used. Modification of the CDDP dose used for the treatment to DDPH 50 mg in our study resulted in a lower severity of complications.

Takayasu *et al*[35] reported a nationwide prospective cohort study which was performed in 8510 patients with unresectable HCC who underwent TACE using an emulsion of lipiodol and anticancer agents followed by gelatin sponge particles as an initial treatment. In their report, multivariate analysis for the factors affecting survival showed significant differences in degree of liver damage, AFP, maximum tumor size, number of lesions, and PVTT. In contrast to their report, we could not observe AFP value as a prognostic factor in our multivariate analysis. This may be due to fewer in the study population and a shorter observation period in our study compared with their study. In addition, a cut-off value for AFP of 1000 ng/mL in our study was much higher than that (400 ng/mL) in their study because we aimed to analyze the difference in the effect of TACE with the extent that HCC had progressed. Therefore, we could not observe AFP value as a prognostic factor in our multivariate analysis.

This study was not a well-controlled prospective study. Nevertheless, the patients in the two groups had fairly similar characteristics with regard to age, etiology, Child-Pugh classification, tumor size, number of tumors, PVTT, total bilirubin, albumin, AFP, and DCP. In relation to the differences in the characteristics of the patients, the DDPH group had a significantly higher proportion of males and a more advanced stage in TNM classification than the ADM group. Several investigators[36,37] have shown that TNM classification and tumor stage are independent prognostic factors for survival of patients who are treated by TACE. Therefore, we forecast that the prognosis of the CDDP group was worse than that of the ADM group, because the DDPH group had more advanced stage in TNM classification than the ADM group. However, the OS in the DDPH group was significantly longer than that in the ADM group. Moreover, to avoid the confounding effects of any deviations in the patient characteristics causing an impact on the results, we used the multivariate analysis for comparison of the efficacy between the regimens. The analysis identified the treatment regimen employed for the TACE as one of the most important prognostic factors. Compared to a previous report[18] describing TACE using a suspension of CDDP powder in LPD, the objective response rate and OS in the DDPH group in our study were significantly higher.

Considering these facts, we conclude that TACE using DDPH-LPD suspension could be a useful treatment strategy for HCC patients. To confirm these results, randomized controlled trials comparing TACE using DDPH-LPD suspension with TACE using ADM-LPD suspension for patients with HCC are mandatory.

The authors wish to thank Ms. Kouko Motodate for preparing serum samples.

COMMENTS

Background

In recent years, transcatheter arterial chemoembolization (TACE) using an emulsion of doxorubicin (ADM) with lipiodol (LPD) (ADM-LPD emulsion) followed by embolization with a gelatin sponge has been employed commonly for hepatocellular carcinoma (HCC) treatment. However, the tumors have been demonstrated to show a high frequency of recurrence after TACE.

Research frontiers

Cisplatin, a platinum compound, is an effective anticancer agent used in the treatment of various malignancies. Since 2004, a fine-powder formulation of cisplatin (DDPH, IA-call; Nippon Kayaku, Tokyo, Japan) has also been available as a therapeutic agent for intra-arterial infusion in Japan. Researchers have recently reported that TACE using a suspension of cisplatin powder in LPD may be more effective against unresectable HCC as compared with TACE using ADM-LPD emulsion. Therefore, TACE using DDPH has become widespread in Japanese institutions. However, the efficacy of TACE using DDPH-LPD suspension has not yet been reported.

Innovations and breakthroughs

In this article, the authors reported the effectiveness of TACE using DDPH-LPD suspension compared with that using ADM-LPD emulsion.

Applications

Although randomized controlled trials comparing TACE using DDPH-LPD suspension with TACE using ADM-LPD suspension for patients with HCC are needed, this study shows that TACE using DDPH-LPD suspension can be a useful treatment strategy for HCC patients.

Terminology

TACE: Transarterial chemoembolization, a procedure in which the blood supply to a tumor is blocked (embolized) and chemotherapy is administered directly into the tumor.

Peer review

Kasai *et al* evaluated the efficacy of TACE using a suspension of DDPH for HCC. The authors indicated that early response rate, progression free survival and overall survival in the DDPH group was significantly higher than that in the ADM group.

Abstract

AIM: To demonstrate the possible associations between genetic polymorphisms of aldehyde dehydrogenase-2 (*ALDH2*) and esophageal squamous cell dysplasia (ESCD).

METHODS: All participants came from an area of high incidence of esophageal cancer and underwent an endoscopic staining examination; biopsies were taken from a non-staining area of the mucosa and diagnosed by histopathology. Based on the examinations, the subjects were divided into the control group with normal esophageal squamous epithelial cells and the ESCD group. *ALDH2* genotypes of 396 cases were determined including 184 ESCD cases and 212 controls. The odds ratio (OR) and 95% confidence intervals (95% CI) were calculated by binary logistic regression models.

RESULTS: The distribution of *ALDH2* genotypes showed significant differences between the two groups. The adjustment factors were gender and age in the logistic regression models. Compared with *2*2/2*2* genotype, *2*1/2*1* genotype was found to be a risk factor for ESCD, and the OR (95% CI) was 4.50 (2.21-9.19). There were significant correlations between *ALDH2* genotypes and alcohol drinking/smoking/history of esophageal cancer.

CONCLUSION: The *ALDH2* polymorphism is significantly associated with ESCD.

Key words: Aldehyde dehydrogenase 2; Polymorphism; Alcohol; Smoking; Esophageal squamous cell dysplasia; History of esophageal cancer

INTRODUCTION

Esophageal squamous cell carcinoma (ESCC) is one of

the most common malignant tumors, and alcohol consumption is a major risk factor for esophageal cancer[1-3]. Alcohol is first oxidized by alcohol dehydrogenase (ADH) to acetaldehyde[4,5], which is then oxidized to acetate by acetaldehyde dehydrogenase (ALDH). The *ALDH2* gene encoding ALDH2 is composed of 13 exons residing on chromosome 12. Deficiency at ALDH2 is a dominant trait that is caused by a single Glu to Lys amino acid substitution at residue 487, a change that can be attributed to a G-to-A transition (dbSNP: rs671) in exon 12 of the gene. This deficient allele (*ALDH2*487Lys*) is common in many East Asian populations[6,7], and approximately 45% of Chinese and Japanese individuals have inactive ALDH2 phenotype[8].

The *ALDH2* alleles encoding the active and inactive subunits are termed "*ALDH2*1*" and "*ALDH2*2*" respectively, and *ALDH2*2* exhibits functional polymorphism that is associated with a lower rate of alcohol dependence[6]. In persons with *ALDH2*2*, the body fails to metabolize acetaldehyde rapidly, leading to excessive accumulation of acetaldehyde, so *ALDH2*2* enhances the risk of esophageal squamous cell carcinoma in East Asian drinkers[9-11].

The stages of the carcinogenic process of esophageal cancer develop from normal esophageal mucosa to esophagitis, esophageal hyperplasia, dysplasia, and then to cancer in situ and early cancer[12]. It is also noteworthy that Japanese and Chinese pathologists prefer to classify "atypical" squamous epithelium dysplasia as a precancerous lesion. Historically, atypical squamous dysplasia has been classified as mild, moderate, or severe[13,14].

Most reports of case-control studies have only consisted of one case-group of esophageal cancer and one normal control group[15,16], and few reports based on population screening data found an association of *ALDH2* with esophageal squamous cell dysplasia (ESCD). Recently, we carried out such a screening survey for esophageal lesions in a high incidence area of esophageal cancer and performed sampling to determine the association of genetic polymorphism of *ALDH2* with the ESCD in this area.

MATERIALS AND METHODS

Study population

The subjects in this study consisted of 184 patients with ESCD and 212 controls with normal esophageal mucosa. All subjects in the present study were selected from the screened participants of Feicheng County between January 2004 and December 2006.

The screening included a cardiograph, ventral ultrasound, and endoscopic examination, which used mucosal stain with 1.2% iodine solution. The biopsies were taken from a non-stained area of mucosa, which then underwent pathologic evaluation carried out by two pathologists. Participating subjects who suffered from cardiovascular, liver and kidney diseases, cancers, and psychiatric disorders were excluded. A uniform questionnaire was used to interview all the subjects to obtain information such as socio-demographic characteristics, alcohol intake, tobacco use, and family history of esophageal carcinoma. The local ethics committee approved the study protocol, and all participants gave their written informed consent.

DNA extraction

A 3-5 mL elbow venous blood sample was collected at 9-10 am after a 12-h fast from each participant. The heparinized sample was centrifuged for 10 min at 3000 r/min to separate plasma and obtain blood cells. Genomic DNA was extracted using phenol-chloroform method and frozen at -20℃.

PCR amplification

The following two pairs of primers were produced by Takara Biotechnology (Dalian Co., Ltd.): F1, 5'-TCATGCCATGGCAACTCCAGC-3'; R1, 5'-CCCACACTCACAGTTTTCTCTTC-3'; F2, 5'-TACGGGCTGCAGGCATACACTA-3'; R2, 5'-TGATCCCCAGCAGGTCCTGAA-3'. F1 and R1 were used to amplify the *ALDH2*1* allele (296 bp), and F2 and R2 to amplify the *ALDH2*2* allele (203 bp). Two 25 microliters reaction tubes were needed for each specimen to amplify *ALDH2*1* (G) and *ALDH2*2* (A) respectively, each containing 30-100 ng DNA, 0.12 mmol/L dNTPs, 12.5 pmol F1 (or R1) primer, 12.5 pmol F2 (or R2) primer, 0.5 U *Taq* polymerase, and 2.5 μL 10 × PCR buffer (containing 15 mmol/L $MgCl_2$). The reaction tubes were heated to 95℃ for 5 min followed by 30 cycles of 95℃ for 60 s, 60℃ for 60 s, 72℃ for 60 s, and 72℃ for 45 s, and then followed by a final extension of 5 min at 72℃. Ten microliters PCR product was used in agarose gel electrophoresis and the electrophoresis result was photographed.

Electrophoresis results

Two lanes were used for each specimen. If one showed 296 bp band and the other showed no band, the corresponding genotype was *ALDH2*1/2*1* (G/G); if one showed 296 bp band and the other showed 203 bp band, the corresponding genotype was *ALDH2*1/2*2* (G/A); and if one showed 203 bp band and the other showed no band, the corresponding genotype was *ALDH2*2/2*2* (A/A).

Statistical analysis

Results for the enumeration of data (e.g. the number of individuals with various genotypes) and comparison of percentages between groups were evaluated with a χ^2 test. Allele frequencies were calculated using allele counting tests for the Hardy-Weinberg equilibrium by the chi-square, while the odd ratio (OR) and 95% confidence intervals (95% CI) were calculated by multinomial logistic regression model. The statistical analysis were made using SPSS program (version 11.5), and $P < 0.05$ (two-sided) was taken as statistically significant.

[1]Smoking index = cigarettes/d × number of smoking years; [2]Alcohol ⩾ 65 g/d = heavy drinker; [3]*t* test and χ^2 test were used for quantitative data variables and categorical data variables respectively. SBP: Systolic blood pressure; DBP: Diastolic blood pressure.

RESULTS

Basic data

All analysis variables are shown in Table 1. Gender, age, smoking, and *ALDH2* genotypes were significantly different between the two groups. The Hardy-Weinberg test for the control group showed the genotype distribution was in equilibrium. Gender and age as potential confounders were adjusted in the logistic models. Other variables including income (yuan/year per person), height, weight, body mass index, systolic blood pressure (SBP), diastolic blood pressure (DBP), alcohol drinking, and family history of esophageal cancer were not significantly different between the two groups.

Association of ALDH2 genotypes with ESCD

As shown in Table 2, after the potential confounders were adjusted, compared with *ALDH 2*2/2*2* genotype, *2*1/2*1* and *2*1/2*2* genotypes were related to having ESCD, and the ORs (95% CI) were 4.50 (2.21-9.19) and 2.19 (1.08-4.43), respectively. Meanwhile, after adjusting for gender and age, no significant association of smoking, alcohol drinking or family history of esophageal cancer with ESCD were observed in the two groups.

Table 2 Association of factors with squamous cell dysplasia of esophagus

Factors	OR (95% CI)[1]	OR (95% CI)[2]
Smoking index		
0	1.00	1.00
< 500	1.32 (0.80-2.18)	1.19 (0.64-2.24)
⩾ 500	1.81 (1.12-2.90)	1.56 (0.83-2.91)
Drinking index

[1]Crude OR; [2]Adjusted ORs were adjusted for age and gender. OR: Odds ratio; CI: Confidence intervals.

Interaction analysis of the ALDH2 genotypes and environmental factors

The frequency distribution of *ALDH2* genotypes combined with smoking index/alcohol drinking status and history of esophageal cancer are listed in Table 3.

As shown in Table 3, in the no smoking stratum only *ALDH 2*1/2*1* genotype increased the relative risk (OR = 6.97, 95% CI: 1.88-25.87); in the light smoking stratum *2*1/2*2* and *2*1/2*1* increased the relative risk and there was an interaction effect between the genotypes and smoking; and in the heavy smoking stratum either smoking or any genotypes of *ALDH2* were associated with the dysplasia, when compared with *ALDH2*2/2*2* genotype combined with no smoking as baseline.

In the no drinking stratum only *ALDH 2*1/2*1* genotype increased the relative risk (OR = 3.16, 95% CI: 1.19-8.41); and in the light and heavy drinking strata both *2*1/2*2* and *2*1/2*1* increased the relative risk with an interaction effect between the genotypes and drinking, when compared with *ALDH2*2/2*2* genotype combined with no drinking as baseline.

There was a significant interaction between *ALDH2*1/2*1* genotype and family history of esophageal cancer, when compared with *ALDH2*2/2*2* genotype and no family history of esophageal cancer as baseline.

DISCUSSION

Feicheng, a County in Shandong Province of China, was found to be a high incidence area of esophageal cancer. Its mortality rates from esophageal cancer were 63.19, 71.68, 66.87 and 82.33/100 000 in the years 1970-1974,

Table 3 Interaction between *ALDH2* genotypes and environmental factors for esophageal dysplasia *n* (%)

Factors	Genotype	Controls	Cases	OR (95% CI)[1]	OR (95% CI)[2]

1985-1989, 1990-1992, and 1997-1999, respectively[17]. In the present study, the cases and controls came from the same communities of Feicheng County, and they possessed similar environment and customs, so their data are comparable. All diseases were determined by endoscopic and pathological examinations, and the possibility of misclassification was small. Considering the information with little recall bias, we believe the results of this study provide more convincing evidence to elucidate the relationship between *ALDH2* polymorphism and ESCD.

The *ALDH2*2* allele produces an inactive protein subunit, which is unable to metabolize acetaldehyde. Genetic epidemiologic studies have suggested that the *ALDH2*2* allele inhibits the development of alcoholism. The inheritance of alcohol-induced flushing in families also suggested that the trait is dominant, that is, both *ALDH2*1/2*2* and *ALDH2*2/2*2* genotype encode inactive ALDH2[18,19].

The *ALDH2*1/2*1* allele has a dual effect on esophageal cancer. On one hand, it can convert acetaldehyde to acetate and get rid of the carcinogenic role of acetaldehyde. On the other, it decreases the blood level of acetaldehyde and alleviates adverse response to alcohol consumption[20], so individuals who have an *ALDH2*1/2*1* genotype are prone to heavy drinking and an increased risk of esophageal cancer. We found in this study that *ALDH2*1/2*1* genotype was a risk factor for ESCD compared with *ALDH2*2/2*2* genotype. Although individuals with *ALDH2*1/2*1* have a strong alcohol metabolism ability, if the alcohol consumption is beyond the metabolism ability the alcohol becomes a dangerous factor for ESCD.

Most reports have indicated that alcohol increases the risk of ESSC in drinkers with *ALDH2*2/2*2* genotype. This leads us to speculate that alcohol will also increase the risk of ESCD in drinkers with *ALDH2*2/2*2* genotype. However, our result did not confirm this association. The reason may be related to the very low frequency of residents who drink alcohol, in particular who indulge in heavy drinking, in Feicheng County, where the people's living standard is relatively low and the majority of farmers cannot afford to drink wine[21,22].

The main finding in the study was an interaction between the *ALDH2* genotype and smoking/family history of esophageal cancer in cases of ESCD, indicating that a polymorphism of *ALDH2* is involved in the process of some carcinogen metabolism, and that it is helpful to control alcohol and tobacco consumption in high incidence areas of esophageal cancer to reduce ESCD and other esophageal diseases.

COMMENTS

Background

Esophageal squamous cell carcinoma (ESCC) is one of the most common malignant tumors, and alcohol consumption is a major risk factor for esophageal cancer. Acetaldehyde dehydrogenase (ALDH) is related to the risk of ESCC, and esophageal squamous cell dysplasia(ESCD) is one of precancerous lesions, so it is necessary to study the relationship of ALDH and ESCD.

Research frontiers

Most previous reports have indicated that alcohol increases the risk of ESSC in drinkers with *ALDH2*2/2*2* genotype. This leads to speculation that alcohol will also increase the risk of ESCD in drinkers with *ALDH2*2/2*2* genotype. However, this association was not found in this study, but interactions between the *ALDH2* genotype and smoking/family history of esophageal cancer were found in cases of ESCD.

Innovations and breakthroughs

Most reports of case-control studies have only consisted of one case-group of esophageal cancer and one normal control group, and few reports based on population screening data found an association of *ALDH2* with ESCD. In this study, the data of a screening survey for esophageal lesions in a high incidence area of esophageal cancer were used and the association of genetic polymorphisms of *ALDH2* with ESCD in this area was determined.

Applications

It was found that *ALDH2* genotype has interactions with smoking/family history of esophageal cancer for ESCD cases, indicating that a polymorphism of *ALDH2* is involved in the process of some carcinogen metabolism; so it is necessary to control alcohol and tobacco consumption in high incidence areas of esophageal cancer to reduce ESCD and other esophageal diseases.

Terminology

Alcohol is first oxidized by alcohol dehydrogenase to acetaldehyde which is then oxidized to ALDH. The *ALDH2* gene is composed of 13 exons residing on chromosome 12. Deficiency at ALDH2 is a dominant trait that is caused by a single Glu to Lys amino acid substitution at residue 487, a change that can be attributed to a G-to-A transition (dbSNP: rs671) in exon 12 of the gene. The *ALDH2* alleles encoding the active and inactive subunits are termed "*ALDH2*1*" and "*ALDH2*2*" respectively, and *ALDH2*2* exhibits functional polymorphism that is associated with a lower rate of alcohol dependence.

Peer review

This is a well-designed and well-organized study of acetaldehyde dehydrogenase 2 polymorphisms and the risk of esophageal squamous cell dysplasia.
