Abstract

AIM: To study the biological and clinical characteristics of transcription factor forkhead box protein 3 (FOXP3) in hepatocellular carcinoma (HCC).

METHODS: We analyzed the expression and localization of FOXP3 in HCC tissues and cell lines to evaluate its biological features. The relationship between FOXP3 staining and clinical risk factors of HCC was assessed to identify the clinical characteristics of FOXP3 in HCC.

RESULTS: The mRNA and protein expression of FOXP3 were found in some hepatoma cell lines. Immunohistochemical (IHC) analysis of HCC sections revealed that 48% of HCC displayed FOXP3 staining, but we did not find any FOXP3 staining in normal liver tissues and para-tumor tissues. IHC and Confocal analysis showed that the expressions of FOXP3 were mainly present in the nucleus and cytoplasm of tumor cells in tissues or cell lines. In HCC, the distribution of FOXP3 was similar to that of the cirrhosis, but not to the hepatitis B virus. Those findings implicate that FOXP3 staining seems to be associated with the high risk of HCC.

CONCLUSION: The clinical characteristics of FOXP3 in HCC warrants further studies to explore its functions and roles in the cirrhosis and development of HCC.

Key words: Forkhead box protein 3; Hepatocellular carcinoma; Tumor differentiation; Cirrhosis; Hepatitis B virus

INTRODUCTION

Hepatocellular carcinoma (HCC), which consists predom-

inantly of primary liver cancer, is the fifth most common malignancy in men and the eighth one in women worldwide. The number of new cases of HCC is about 564 000 per year[1]. Cirrhosis and virus infection, such as hepatitis B virus (HBV) and hepatitis C virus (HCV), are the major known risk factors for HCC[2,3]. HCC has a poor prognosis and a low survival rate in the majority of patients[4]. The current treatment options of HCC include surgical resection, liver transplantation and local ablative therapy, which are effective only in limited tumors[5]. To improve the treatment of HCC will require a better understanding of the biological development and molecular events in the immune system of HCC.

Forkhead box protein 3 (FOXP3) is a member of the forkhead/winged-helix family of transcriptional regulators and is highly conserved in normal cells. The full-length protein contains 431 amino acids. *Foxp3* is considered to be an important gene of thymically derived and naturally occurring regulatory T cells (Tregs)[6]. Mutations in human *Foxp3* are associated with immune diseases, such as multi-organ autoimmune disorder, immune dysregulation, polyendocrinopathy, enteropathy and X-linked syndrome (IPEX)[7], in which Tregs from affected patients are greatly reduced in number and suppressive activity[8-10]. A high prevalence of Tregs is thought to be an unfavorable prognostic indicator for HCC[11].

Recent publications described the expression of FOXP3 in pancreatic carcinoma cells, melanoma cells and other tumor cells[12-14]. It has been found that FOXP3 expression was related to the regulation of several cytokines, such as IL-10 and TGF-β2, and FOXP3 might mediate the inhibiting efficacy of tumor cells to escape immune destruction. Those reports implicated that FOXP3 performs its functions in the regulation of tumor progression by expressing not only in Tregs, but also in tumor cells. We assumed that FOXP3 may also be functional in tumor cells of HCC.

This study was designed to investigate whether expression of FOXP3 transcripts and mature protein is related to HCC. We also evaluated the distribution of FOXP3 in human HCC tissues and its relationship with the diagnosis, differentiation and clinical risk factors of HCC.

MATERIALS AND METHODS

Source of normal and cancerous liver tissue sections and tissue array

Normal (8) and cancerous liver tissues (21) were obtained from HCC patients who underwent resection of liver. The circulating HBV markers and ultrasound examination were performed regularly. The quantitative cirrhosis score was derived from the ultrasonographic evaluation of the liver surface, liver parenchyma, caliber of intrahepatic blood vessels and spleen size. Cirrhosis scores of $\geqslant 7$ were used to define cirrhosis[15]. Normal controls were histologically normal tissues obtained from patients who underwent partial hepatectomy for metastatic tumor or liver biopsy. Microarray tissues were obtained from Cybrdi, USA. The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki in a prior approval by the Fourth Military Medical University, China.

Cell culture

Complete medium (RPMI-1640) contained RPMI-1640 supplemented with 2 mmol/L Glutamax, 100 U/mL penicillin, 100 μg/mL streptomycin, and 10 mmol/L HEPES (Invitrogen, USA) and 10% FCS (Thermo Trace, Australia). The following cell lines were obtained from the Biotechnology Center of the Fourth Military Medical University, such as SMMC-7721 and Hepa-G2. All tumor cell lines were maintained in complete RPMI-1640 and passaged using trypsin/EDTA (Invitrogen, USA). *Foxp3* transiently transferred 293 cells were established. Melanocytes were freshly prepared when used (derived from normal human skins from the Department of Dermatology of Xijing Hospital of the Fourth Military Medical University).

Semi-quantitative and reverse-transcription polymerase chain reaction

Total RNA was isolated from HCC cells and melanocyte (as control) using Trizol reagent (Invitrogen, USA). A total of 500 ng RNA was reversely transcribed using the Kit from Takara, Japan. The polymerase chain reaction (PCR) was performed for *Foxp3* fragment amplification. The following primers were used (5'-3'): *Foxp3* sense: CACAACATGCGACCCCCTTTCACC; *Foxp3* antisense: AGGTTGTGGCGGATGGCGTTCTTC. β-actin was used as an internal control for normalization (primer sequences available on request). Semi-quantitative PCR of *Foxp3* transcripts was done by comparing the signal intensity of PCR product of *Foxp3* gene with that of β-actin gene from the same RNA sample using agarose gel electrophoresis. The intensity of the product band was quantified by densitometric scanning of the gel (Pharmacia Biotech) using "Total image" 1D GEL ANALYSIS software. DNA marker (Takara, Japan) was run in each gel to confirm the size of PCR product.

Western blotting analysis

To examine the protein expression level of FOXP3 in HCC, whole cell lysate was subjected to SDS-PAGE electrophoresis followed by blotting on a nitrocellulose (NC) membrane. During FOXP3 detection, membranes were probed with goat anti-human FOXP3 polyclonal antibody at 4℃ overnight followed by incubation with a secondary horseradish peroxidase-conjugated antibody. The mouse anti-human β-actin monoclonal antibody was used as an internal control (R&D, USA). Chemiluminescent detection was done with the enhanced chemiluminescence detection kit (Anmei, China).

Flow cytometric analysis

To determine the expression levels of FOXP3, hepatoma cell lines were stained for FOXP3 and analyzed by flow cytometry. Cells were washed in PBS containing 1% bovine serum albumin (BSA) and 0.1% NaN_3 before antibody staining followed by fixation with 1% paraformaldehyde.

Fluorescein isothiocyanate (FITC)-conjugated rat anti-human FOXP3 monoclonal antibody was purchased from eBiosciences, USA. A total of 10^5 events were collected using Becton Dickinson FACScaliber (Becton Dickinson, USA). Analysis was performed using the WinMDI 2.8 program (Purdue University Cytometry Laboratories, USA).

Confocal microscopic analysis

For double-label immunofluorescence, formalin-fixed cell line slides were treated in 3% hydrogen peroxide in methanol for 10 min. Following three rinses in PBS, the slides were treated in blocking solution (Zhongshan, China) for 1 h, and then incubated with fluorescein isothiocyanate (FITC)-conjugated rat anti-human FOXP3 monoclonal antibody (eBioscience, USA) for another 1 h at room temperature. After rinsed in PBS, the slides were treated with a 1:1000 dilution of diamidino-phenyl-indole (DAPI) (stock solution: 1 mg/mL) (Sigma-Aldrich, USA) for 30 min. DAPI staining was used to visualize nuclei. The slides were mounted with the anti-fade mounting medium. Slides were examined under a Leica TCS-SP laser scanning confocal microscope (Leica, German). All images were collected using a pinhole of 1 Airy.

Immunohistochemistry

Paraffin-embedded resected liver cancer specimens were provided by Xijing Hospital tissue bank. Rat anti-human FOXP3 monoclonal antibody was applied to paraffin-embedded sections after microwave antigen retrieval for 10 min in citrate buffer (pH 6.0). Specimens were treated with 0.3% hydrogen peroxide in methanol for 15 min after incubation with the primary antibody to block endogenous peroxidase activity. The secondary antibody of horseradish peroxidase-labeled goat anti-rat antibody (Zhongshan, China) was incubated for 1 h. These slides were examined systematically using an image analyzer system (Olympus BH-2 microscope, Japan).

Semi-quantitative analysis of IHC

Slides were reviewed under light microscopy by two pathologists separately. Semi-quantitative analysis of FOXP3 staining was assessed as 0, 1+, 2+, and 3+ as previously established[16,17]. Grade 0 was defined as the complete absence or weak FOXP3 staining in < 1% of the tumor cells; grade 1+ was focal FOXP3 staining in 1%-10% of tumor cells; grade 2+ was positive FOXP3 staining in 11%-50% of tumor cells; and grade 3+ was positive FOXP3 staining in > 50% of tumor cells. A global assessment of the entire tumor was made without selection for the invasive front or areas of active tumor growth. The frequency and semi-quantitative analysis of positive tumors for all regions were calculated for statistical comparisons.

Statistical analysis

Differences in proportions were compared by a Pearson Chi-square test or Fisher's exact test as appropriate. The statistical correlation between the grades of HCC differentiation and the staining level of FOXP3 was analyzed by the Cochran-Mantel-Haenszel test. The dependability between the distribution of cirrhosis or HBV infection and FOXP3 expression was evaluated by *t* test. Differences with a *P* value less than 0.05 were considered to be statistically significant. All analyses were done using SAS statistical software version 9.1 (Cary, USA).

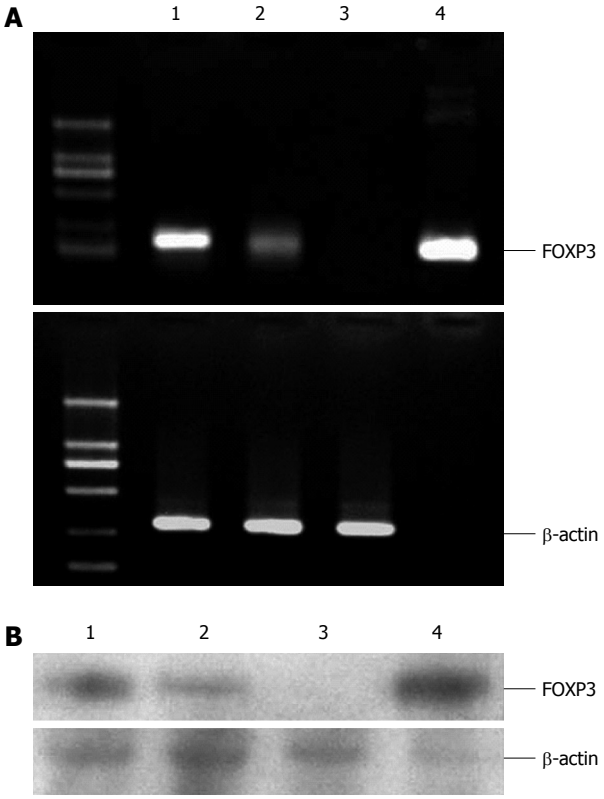

Figure 1 Expression of forkhead box protein 3 in hepatoma cell lines. A: Expression of forkhead box protein 3 (FOXP3) mRNA is different in hepatoma cell lines by reverse-transcription polymerase chain reaction. β-actin was used to verify the integrity of the template cDNA preparations. 1: SMMC-7721, 2: Hepa-G2, 3: Melanocytes, 4: Foxp3-plasmid; B: Expression of FOXP3 protein was different in hepatoma cell lines by Western blotting. Melanocytes served as a negative control. Foxp3 transiently transferred 293 cells were established as a positive control. 1: SMMC-7721, 2: Hepa-G2, 3: Melanocytes, 4: Foxp3/293 cells.

RESULTS

FOXP3 expression in hepatoma cell lines

In RT-PCR analysis, *Foxp3* was found in some hepatoma cell lines. To further validate the changes of *Foxp3*, semi-quantitative RT-PCR analysis from two hepatoma cell lines and melanocytes were conducted. The results revealed a significant overexpression of *Foxp3* in HCC specimens as compared with nonmalignant melanocytes (Figure 1A). The cell lines shown in Figure 1A (SMMC-7721 and Hepa-G2) were uniformly positive for *Foxp3* transcription. But we did not find any *Foxp3* transcription in melanocytes as expected. *Foxp3* full length plasmid was constructed and performed as a positive control.

Furthermore, as shown in Figure 1B, FOXP3 protein expression could be detected in hepatoma cell lines by Western blotting. Because it was the first time to dem-

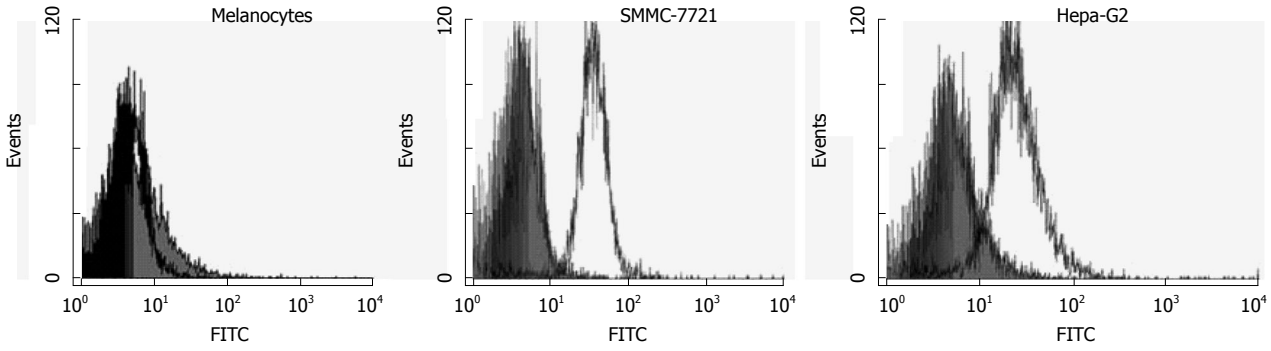

Figure 2 Flow cytometry of forkhead box protein 3 expression in various hepatoma cell lines. Melanocytes served as a negative control. The grey underlaid plot represents staining with the isotype, and the white underlaid plot represents staining with anti-human forkhead box protein 3 antibody. FITC: Fluorescein isothiocyanate.

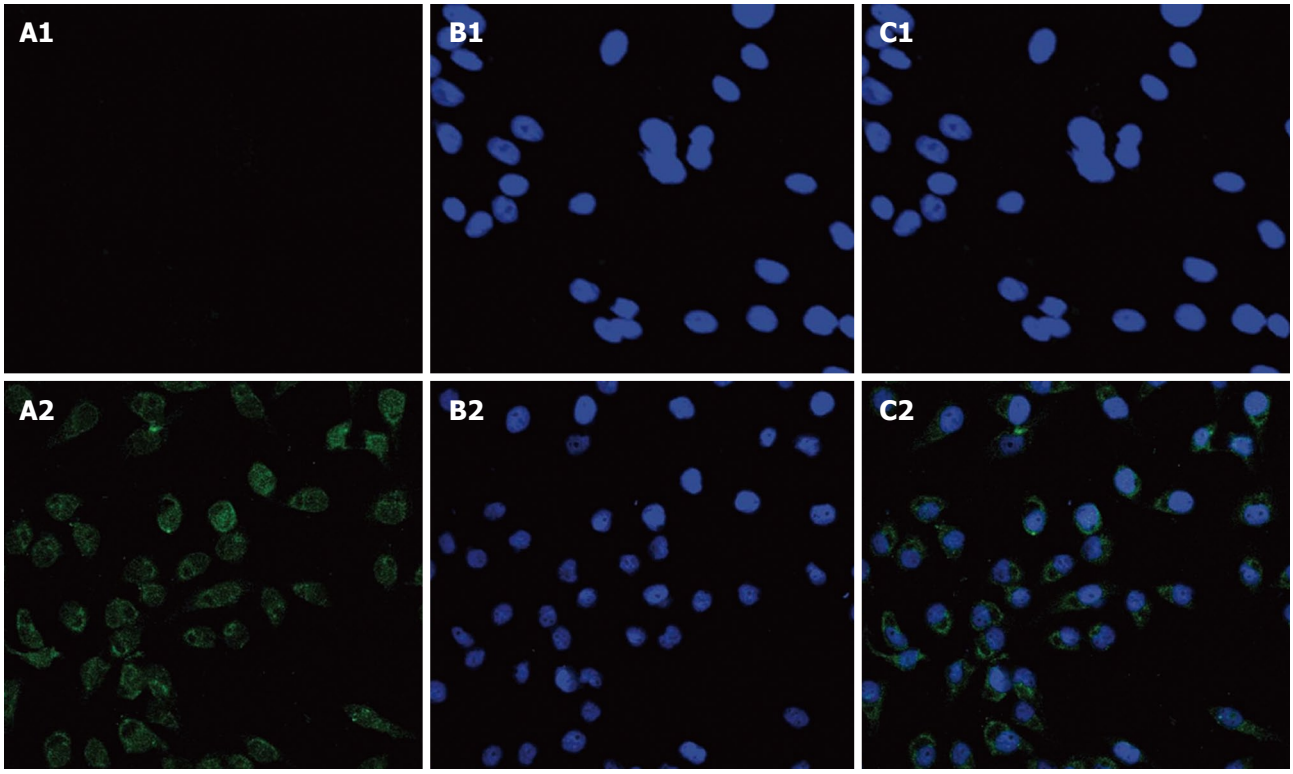

Figure 3 Double-label immunofluorescence analysis of forkhead box protein 3 expression in hepatoma cell line. A: SMMC-7721 cells express forkhead box protein 3 (FOXP3) in both nuclei and perinuclear cytoplasm (imaged with green fluorescent) (A1: Melanocytes FOXP3-FITC, A2: SMMC-7721 FOXP3-FITC); B: Imaged with diamidino-phenyl-indole (DAPI) to identify the nuclei of SMMC-7721 and melanocytes (B1: Melanocytes DAPI, B2: SMMC-7721 DAPI); C: Image superimposed on a differential interference contrast background confirmed colocalization (C1: Melanocytes merge, C2: SMMC-7721 merge).

onstrate FOXP3 expression in liver cells, we confirmed the staining results in Western blotting with two different anti-FOXP3 antibodies (eBioscience and R&D, USA). We found that the intensity of FOXP3 expression varied in different cell lines. In this experiment, *Foxp3* transiently transferred 293 cells were established as a positive control cell line.

Localization of FOXP3 in hepatoma cell lines

FOXP3 FITC-staining resulted in a shift in the fluorescence of the entire population of hepatoma cell lines compared with the isotype control in the results of flow cytometry. In contrast, melanocytes did not express FOXP3, as shown in Figure 2. Confocal microscopy was used to examine the distribution of FOXP3 in hepatoma cell lines and melanocytes. In these experiments, the nuclei were stained with DAPI to facilitate analysis. The results showed that SMMC-7721 cells exhibited intense nucleic and less cytoplasmic FOXP3 expression (Figure 3).

Expression and distribution of FOXP3 in HCC tissues

IHC was used to analyze the protein expression and localization of FOXP3 in HCC tissues. FOXP3 staining was done on a set of 29 tissue sections (Table 1) and a tissue array containing 154 cores (Table 2). Those samples were selected from normal and cancerous HCC tissues.

[1]Fisher's exact test; [2]Pearson χ^2. [a]$P < 0.05$. FOXP3: Forkhead box protein 3.

Pathologists evaluated the expression level of FOXP3 in different HCC tissue samples according to the percentage of FOXP3 staining (Figure 4). Ten of 21 (48%) HCC tissue sections displayed FOXP3 staining. Interestingly, we noticed that FOXP3 was mainly localized in the nucleus of well differentiated HCC tissues and cytoplasm of moderately and poorly differentiated HCC tissues in tissue sections and array. To confirm the validity of the observation, we used two different anti-human FOXP3 antibodies (eBioscience and R&D, USA) to repeat the experiments. Both antibodies gave similar patterns about FOXP3 localization in HCC tissues.

Occurrence of FOXP3 is not associated with differentiation

The expression of FOXP3 at each histopathological grade were examined and recorded in all the patients. It is interesting that many cancerous patients were found to be FOXP3 positive, whereas the intensity of FOXP3 staining was low. The proportion of FOXP3 staining cells had no differences among the histopathological grades in HCC tissue array. In this experiment, 11 of 32 grade Ⅰ (34%), 14 of 73 grade Ⅱ (19%), and 9 of 35 grade Ⅲ (26%) carcinoma cores (Figure 5) were positive in FOXP3 staining ($P = 0.2410$, Pearson χ^2 test; Table 2). This result implicated that FOXP3 staining might be a useful prognostic factor, but not a clue in differentiation of HCC patients. We also found that normal liver tissues were devoid of FOXP3 expression (Figures 4 and 5). In addition, there was no relationship between FOXP3 expression and gender or age, no matter in tissue section or array (Tables 1 and 2).

Relationship between HCC risk factors and FOXP3 expression in tumor tissues

HCC is a heterogeneous tumor. Cirrhosis, HBV and HCV infections represent the major known risk factors for HCC. Those factors could cooperate or act alone to promote the incidence of HCC depending on the different pathways and molecules.

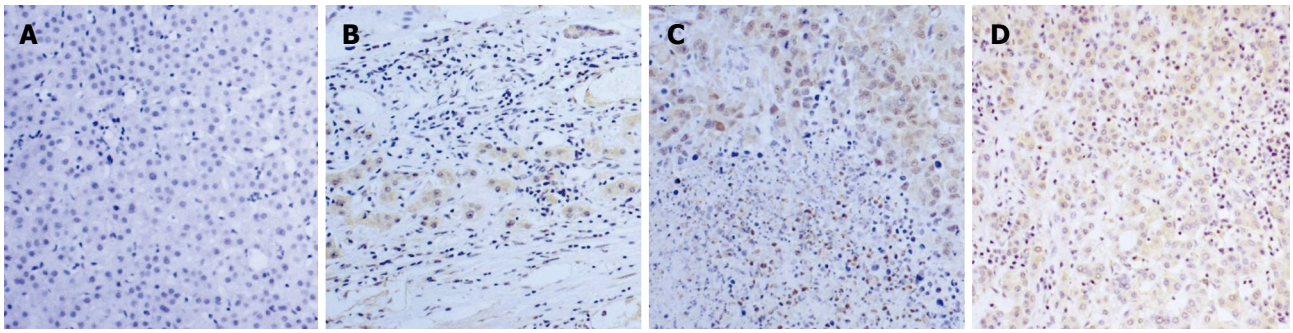

Figure 4 Hepatocellular carcinoma immunohistochemical score (× 100). Forkhead box protein 3 (FOXP3) expression in hepatocellular carcinoma (HCC) by immunohistochemical (IHC). Images represent HCC tissues with IHC scores of 0 (A), 1 (B), 2 (C) and 3 (D). In IHC score 0, many FOXP3-positive lymphocytes are tumor-infiltrating Tregs.

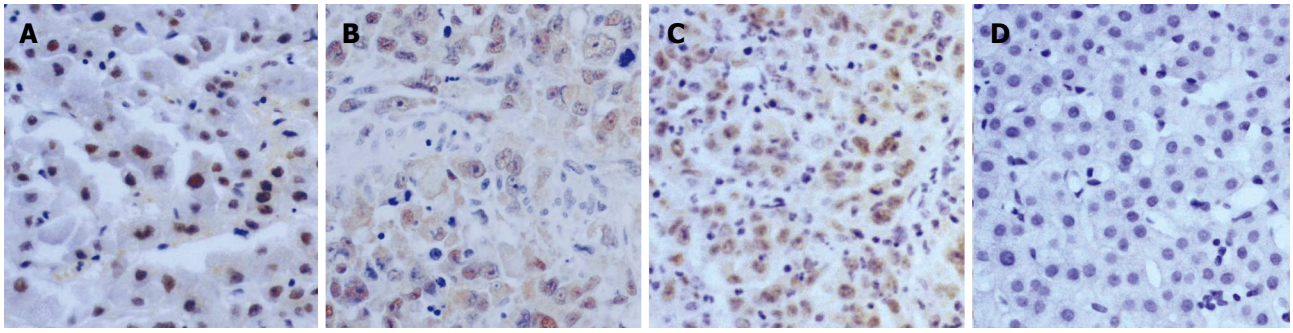

Figure 5 Hepatocellular carcinoma immunohistochemical staining (× 200). Immunohistochemical (IHC) staining of paraffin embedded hepatocellular carcinoma (HCC) tissues revealed different levels of forkhead box protein 3 (FOXP3) expression in HCC cells (PCH101 antibody, eBioscience). A: Well-differentiated HCC (nuclear FOXP3 staining); B: Moderately-differentiated HCC (cytoplasmic FOXP3 staining); C: Poorly-differentiated HCC (cytoplasmic FOXP3 staining); D: Normal liver tissue (nuclear FOXP3 staining in Tregs).

Table 3 Relationship between hepatitis B virus infection (or cirrhosis) distribution and forkhead box protein 3 expression in 21 hepatocellular carcinoma samples

		FOXP3 expression		*P*
		-	+	
HBV infection	-	2	1	0.021[a]
	+	9	9	
Cirrhosis	-	1	3	0.092
	+	10	7	

FOXP3: Forkhead box protein 3; HBV: Hepatitis B virus. [a]$P < 0.05$.

We detected the circulating HBV markers and liver cirrhosis levels to analyze the relationship between the expression of FOXP3 and HBV/cirrhosis to evaluate the potential clinical characteristics of FOXP3.

As shown in Table 3, among the HCC patients, 42.9% HBV infection and 33.3% cirrhosis of the section samples were FOXP3 positive. Statistical results revealed that FOXP3 expression coincided with the occurrence of cirrhosis ($P = 0.092$), while it is highly significant with HBV infection ($P = 0.021$) in HCC patients.

DISCUSSION

Although the factors and molecular events associated with the progression of HCC are complex and not well established, FOXP3 has been shown to play an important role in Tregs in HCC invasion[1,5,11]. In this study, we assessed the expression and subcellular localization of FOXP3 in hepatoma cell lines and HCC tissues to identify the fact that FOXP3 is expressed by tumor cells. We also identified some clinical characteristics of FOXP3 in HCC.

Few studies assessing FOXP3 expression in tumor tissues and cell lines have been reported. Hinz *et al*[12] described for the first time the expression and function of FOXP3 in pancreatic ductal adenocarcinoma cells and tissues. They detected FOXP3 expression in tumor cells of 24/39 patients with pancreatic carcinoma. Although they were unable to find a correlation between FOXP3 expression and tumor stage or survival rate, their findings indicate that pancreatic carcinoma cells share growth suppressive effects with Tregs depending on the function of FOXP3. Their results also suggest that FOXP3 may promote tumor cells to mimic characters of Tregs to represent an immune evasion function in microenvironment. Ebert *et al*[13] and Karanikas *et al*[14] reported that FOXP3 transcription factor was expressed by melanoma cells and lots of tumor cells. These evidences suggest that FOXP3 is related to tumor escape and can be used as a potential tumor antigen.

In agreement with their findings, *Foxp3* transcription and protein expression were found in hepatoma cell lines

(SMMC-7721 and Hepa-G2) in this study. After Confocal analysis, we noticed that nuclear and less cytoplasm FOXP3 expression was more prevalent in hepatoma cell lines. To our knowledge, this study provides the first evidence of nuclear and cytoplasm localization of FOXP3 in hepatoma cell lines. In addition, we found that FOXP3 was mainly expressed in the nucleus in well differentiated HCC tissues and cytoplasm in moderately and poorly differentiated HCC tissues. It implicates that the factors (such as cytokines, immune cells, ligand and receptor of tumor cells) coming from microenvironment and differentiation of tumor might induce a change in the subcellular localization of FOXP3 between cytoplasmic and nuclear expression patterns, which would result from post-translational modifications[18]. Therefore, the heterogeneous subcellular localization of FOXP3 in hepatoma cell lines and HCC tissues may reflect the different post-translationally modified forms of FOXP3. In particular, previous reports revealed the interaction of FOXP3 with nuclear factor of activated T cells (NFAT, a transcription factor) in Tregs[19]. It revealed that FOXP3 plays a key role in the formation of nuclear complexes that are important to regulate the transcription of functional genes[20].

In this study, we also found some clinical characteristics of FOXP3 in HCC. The statistical results revealed that HBV infection had different distribution patterns compared with the expression of FOXP3 in HCC. In our previous study, FOXP3 was not found in the hepatitis and normal liver cells. Therefore, we may draw a conclusion that FOXP3 of tumor cells has little relationship with the inflammation induced by HBV infection alone. But because of the limited number of patients, this still needs further studies to validate. On the other hand, 70% of FOXP3 positive HCC cases were companied with liver cirrhosis. This indicates that the pathogenesis and molecules of cirrhosis may have some effects on the regulation of FOXP3 expression. FOXP3 may be involved in the progression of cirrhosis-induced HCC.

On the contrary, Zou *et al*[21,22] reported that functional somatic mutations and down-regulation of the *Foxp3* gene were commonly found in human breast cancer tissues. The expression of FOXP3 was correlated with HER-2/ErbB2 and SKP-2 overexpression. So the function and mechanism of FOXP3 may be different in various tumor cells, which still remains to be elucidated.

In conclusion, this is the first report of FOXP3 staining in hepatoma cell lines and HCC tissues, creating a new focus that FOXP3 is widely expressed in tumor cells and tissues. As the molecular mechanisms of FOXP3 still remain unclear, the real function of FOXP3 in different tumors need to be further studied so as to understand the critical molecular events associated with tumor progression.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors. It is highly resistant to many conventional treatments and has a poor prognosis. forkhead box protein 3 (FOXP3) is considered to play an important role in naturally occurring regulatory T cells (Tregs). Recent reports have implicated that FOXP3 might have different effects on tumor cells. But the expression and mechanism of FOXP3 in HCC cells remain unclear.

Research frontiers

Few reports showed the expression of FOXP3 in pancreatic carcinoma cells, melanoma cells and other tumor cells. The reports found that FOXP3 expression was related to the regulation of several cytokines, such as IL-10 and TGF-β2. FOXP3 might mediate the immune inhibiting efficacy of tumor cells to escape immune destruction. The authors assumed that FOXP3 may also be functional in HCC.

Innovations and breakthroughs

Interestingly, the authors found that hepatoma cell lines expressed FOXP3 mainly in nuclear and cytoplasm. But FOXP3 was almost expressed in nuclear in well differentiated HCC tissues and cytoplasm in moderately and poorly differentiated HCC tissues. It suggests that the microenvironment and differentiation of tumor might induce a change in the subcellular localization of FOXP3 between cytoplasmic and nuclear expression patterns. Therefore, the heterogeneous subcellular localization of FOXP3 in hepatoma cell lines and tissues may reflect the different post-translationally modified forms of FOXP3. The authors also found that the distribution of FOXP3 was similar to that of the cirrhosis, but not to that of HBV infection in HCC. Although the function of FOXP3 in HCC is not clear, the result suggests that FOXP3 may be involved in the cirrhosis-induced HCC. Altogether, those findings implicate that FOXP3 staining seems to be associated with a high risk in HCC.

Applications

This study is creating a new focus that FOXP3 is widely expressed in HCC cells and tissues. However, the real function of FOXP3 in HCC needs to be further studied so as to understand the critical molecular events in HCC progression.

Peer review

The manuscript by Wang *et al* provides evidences supporting FOXP3 expression both in human hepatoma cells and in HCC tumors. Since this is the first time that expression of FOXP3 has been reported in liver cancer, the information is of interest.

Abstract

AIM: To investigate the association of the cyclooxygenases-2 (COX-2) polymorphisms and susceptibility to gastric cancer (GC) by means of meta-analysis.

METHODS: Publications addressing the association between polymorphisms of COX-2 and susceptibility to GC were selected from the MEDLINE, EMBASE and CBMdisc databases. Data was extracted from the studies by 2 independent reviewers. The meta-analyses were performed by RevMan 5.0.23. From these data, odds ratio (OR) with 95% confidence interval (CI) was calculated.

RESULTS: Ten studies were retrieved reporting a total of 11 COX-2 polymorphisms. Carriers of -765C, -1195A, -1290G, *2430T alleles and *429TT genotype revealed increased risk for GC (OR = 1.71, 95% CI: 1.01-2.90, *P* = 0.05; OR = 1.58, 95% CI: 1.05-2.38, *P* = 0.03; OR = 1.55, 95% CI: 1.01-2.39, *P* = 0.05; OR = 2.62, 95% CI: 1.20-5.73, *P* = 0.02 and OR = 0.74, 95% CI: 0.59-0.95, *P* = 0.02, respectively).

CONCLUSION: The -765C, -1195A, -1290G, *2430T alleles and *429TT genotype of COX-2 polymorphisms were determined a significant association with susceptibility to GC.

INTRODUCTION

Gastric cancer (GC) is the fourth most common cancer and the second leading cause of cancer-related death worldwide[1-3]. In 2008, around 21 500 people were diagnosed with gastric cancer and approximately 135 130 died of the disease in the United States[4]. GC is a complex and multifactorial disease. The marked geographic variation, time trends, and the migratory effect on GC incidence suggest that environmental or lifestyle factors are major contribu-

tors to the etiology of this disease. Examples include: diet, lifestyle, *Helicobacter pylori* (*H. pylori*) infection and genetic material[1].

Recent data has expanded upon the concept that inflammation is a critical component of tumor progression. Many cancers arise from sites of infection, chronic irritation and inflammation[5]. Tumor microenvironment is largely orchestrated by inflammatory cells, which are an indispensable participant in the neoplastic process, fostering proliferation, survival and migration. Inflammation also plays an important role in the development and progression of GC[6]. Epidemiological and animal data revealed that the use of non-steroidal anti-inflammatory drugs (NSAIDs) might reduce the risk of GC[7]. NSAIDs primarily inhibit the activity of the cyclooxygenase enzymes (COXs) and thereby affect the synthesis of prostaglandin signalling molecules, which are involved in a wide range of physiological processes beyond inflammation[8].

COXs catalyze the rate-limiting step in the production of prostaglandins (PG), bioactive compounds involved in processes such as fever and sensitivity to pain, and are the target of NSAIDs[9]. In mammals, the two COXs genes encode a constitutive isoenzyme (COX-1) and an inducible isoenzyme (COX-2); both of which are of significant pharmacological importance[9]. COX-1 is constitutively expressed in the majority of tissues and is associated with housekeeping functions such as vascular homeostasis and platelet aggregation[10]. COX-2, which is highly inducible and almost undetectable under normal physiological conditions, is readily induced in response to mitogens, tumor promoters, cytokines, growth factors, stress-inducing agents promoting inflammatory reactions, and tumor development[11]. COX-2 overexpression was found in a large proportion of GC tissues and was significantly associated with advanced tumor stage, *H. pylori* infection and lymph node metastasis[12]. COX-2 may also play a role in gastric carcinogenesis, which was associated with inhibition of apoptosis, increased metastasis potential and neoangiogenesis[13-16]. The expression of COX-2 is regulated by a complex signal transduction pathway in which many nuclear proteins interact with the COX-2 promoter region and play a decisive role in gene transcription[17]. Therefore, single nucleotide polymorphisms (SNPs) in the COX-2 promoter may have a great impact on gene transcriptional activity by altering the binding capability with certain nuclear proteins, resulting in inter-individual variability in susceptibility to cancer[18].

Systematic review can be a resourceful tool in detecting an association that could otherwise remain masked in the sample size studies, especially in those evaluating rare allele frequency polymorphisms[19]. The aim of this meta-analysis was to investigate the association of the COX-2 polymorphisms with susceptibility to GC by conducting a meta-analysis from all eligible case-control studies published to date.

MATERIALS AND METHODS

Search strategy and identification of studies

Medline, EMBASE and CBMdisc databases search were performed to retrieve papers linking COX-2 polymorphisms and susceptibility to GC available online by April 2010 without language restrictions, using the following query: [COX 2 OR COX-2 OR COX2 OR PEGS2 OR PEGS-2 OR "Cyclooxygenase 2" (MeSH)] AND [polymorphism OR polymorphisms OR "Polymorphism, Genetic" (MeSH) OR "Polymorphism, Single Nucleotide" (MeSH)] AND [gastric cancer OR "Stomach Neoplasms" (MeSH)]. The reference lists of major textbooks, review articles, and of all the included articles identified by the search were then individually searched to find other potentially eligible studies.

Inclusion criteria

To be eligible for inclusion in this meta-analysis, the following criteria were established: (1) the study must include a case-control study that addressed GC patients and normal or benign gastric diseases controls; (2) the study must have evaluated the COX-2 polymorphisms and susceptibility to GC; and (3) the study must have included sufficient data for extraction.

Exclusion criteria

Studies were excluded from consideration if: (1) the study was based on family data or incomplete raw data; (2) the study did not have the outcomes of comparison reported or it was not possible to determine them; or (3) the study contained a smaller sample size (number of cases < 30) and overlapped others.

Data extraction and quality assessment

Using a standardized form, data from published studies were extracted independently by two investigators (Liu JL and Liang Y) to populate the necessary information. From each of the included articles the following information was extracted: first author, year of publication, country, ethnicity, study design, source of cases, sample size, histological type, polymorphisms of genes, histopathological confirmations and evidence of Hardy-Weinberg equilibrium (HWE).

The quality of papers was also independently assessed by two researchers (Liu JL and Xing LL) based on the STROBE quality score systems[20]. 39 items relevant to the quality appraisal were used for assessment, scores ranged from 0 (lowest) to 50 (highest)[21]. Main items for quality assessment included: title and abstract, introduction, methods, study design, setting, participants, variables of interest, bias, HWE, sample size, statistical methods, funding and disclosure statement, internal validity, descriptive data, outcome data, main results, discussion, limitations, generality and interpretation[20,21].

Statistical analysis

Individual or pooled odds ratio (OR) and 95% confidence interval (CI) were calculated for each study using Review Manager version 5.0.23 software (provided by The Cochrane Collaboration, Oxford, England)[22]. Between-study heterogeneity was estimated using the χ^2-based Q statistic[23]. Heterogeneity was considered statistically

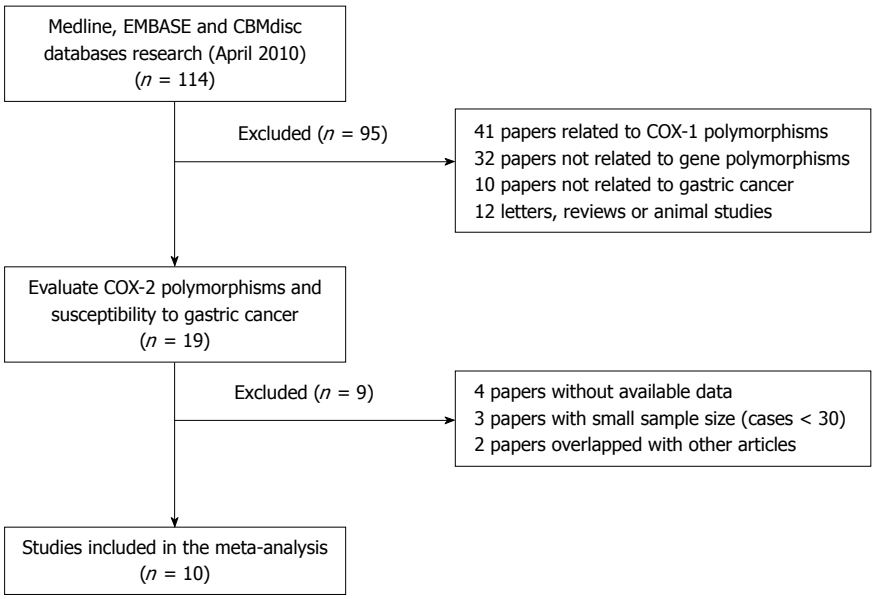

Figure 1 Flow chart showing study selection procedure. COX: Cyclooxygenases.

significant when $P_{\text{heterogeneity}} < 0.01$ or $I^2 > 50\%$. If heterogeneity existed, data was analyzed using a random effects model. In the absence of heterogeneity, a fixed effects model was used. Sources of heterogeneity were appraised by subgroup stratification analysis, based on several study characteristics, such as ethnicity and source of control individuals (population or hospital based). The funnel plot method was used to assess the possible presence of publication bias[24].

Before the effect estimation of the several COX-2 polymorphisms in gastric carcinogenesis, the HWE was assessed for all the polymorphisms in each study. A χ^2 test was performed to examine HWE when genotype data was available. If HWE disequilibrium existed ($P < 0.05$), or it was impossible to evaluate this equilibrium, sensitivity analysis was performed.

RESULTS

Search results

The search strategy retrieved 114 potentially relevant papers (52 in Medline, 35 in Embase, 27 in CBMdisc). There were 10 studies included in this meta-analysis. One-hundred and four studies were subjected to a full text review and excluded according to the selection criteria stated above. The flow chart of study selection is summarized in Figure 1.

Study characteristics and quality

In total, 3074 GC cases from 10 case-control studies were included in the meta-analysis. All studies were considered as case-control studies. Five ethnicities were addressed: two studies focused on Caucasian populations[25,26], five on Asian populations[27-31], one on a Hispanic population[32], one on a Dutch population[18] and one on an Indian population[33]. Eight studies[18,25,26,28-31,33] used hospital-based cases and controls and two studies[27,32] described a population-based design. Cases and controls of four studies[25,27,30,32] were mainly defined through endoscopic multiple biopsies procedures and three studies[18,31,33] through endoscopy, with histological assessment. However, there were three studies[26,28,29] that did not mention the method of confirmation. The characteristics and methodological quality of all studies are summarized in Table 1.

The characteristics of COX-2 polymorphisms in gastric cancer

Eleven COX-2 polymorphisms were addressed in gastric carcinogenesis: -765G>C, -1195G>A, Gly587Arg(G>A), 1290A>G, 8473T>C, IVS5-275T>G, IVS7+111T>C, V102V, *429T>C, *2430C>T, 587codonG>A. The genotype distribution of COX-2 polymorphisms and the variant allele frequency are described in Table 2. A HWE test was performed on all included studies, all of them showed in HWE ($P > 0.05$).

Association between COX-2 polymorphism and gastric cancer

Meta-analysis of eight studies identified a significant association between the -765C allele and susceptibility to GC (OR = 1.71, 95% CI: 1.01-2.90, $P = 0.05$) using the random effects model ($P_{\text{heterogeneity}} < 0.00001$, $I^2 = 89\%$). The -1195G>A COX2 polymorphism analysis revealed that the -1195A allele was also a risk factor for susceptibility to GC (OR = 1.58, 95% CI: 1.05-2.38, $P = 0.03$) using the random effects model ($P_{\text{heterogeneity}} = 0.04$, $I^2 = 70\%$). The -1290A>G analysis showed that the -1290G allele was a risk factor for GC (OR = 1.55, 95% CI: 1.01-2.39, $P = 0.05$). The *429T>C analysis also revealed that a significant association between the *429T allele and susceptibility to GC (OR = 0.74, 95% CI: 0.59-0.95, $P = 0.02$) using the fixed effects model ($P_{\text{heterogeneity}} = 0.42$, I^2

n: No. of patients; OR: odds ratio; 95% CI: 95% confidence interval; COX-2: Cyclooxygenases-2.

= 0%). A significant association with the susceptibility to GC was also determined in the *2430T allele analysis (OR = 2.62, 95% CI: 1.20-5.73, P = 0.02) (Figure 2). However, the Gly587Arg(G>A), 8473T>C, IVS5-275T>G, IVS7+111T>C, V102V and 587codonG>A polymorphisms showed no association with the susceptibility to GC (OR = 0.82, 95% CI: 0.43-1.54, P = 0.53; OR = 1.13, 95% CI: 0.80-1.60, P = 0.48; OR = 0.93, 95% CI: 0.71-1.21, P = 0.58; OR = 0.95, 95% CI: 0.68-1.33, P = 0.77; OR = 1.03, 95% CI: 0.49-2.14, P = 0.95 and OR = 1.35, 95% CI: 0.64-2.87, P = 0.43, respectively).

Subgroup analysis was performed on -765G>C polymorphism by ethnicity, such as Caucasian, Asian, Indian and Dutch. Results showed no significant association between the -765C allele and susceptibility to GC in Caucasians (OR = 1.19, 95% CI: 0.65-2.15, P = 0.58), while an obviously significant association was determined in Asians (OR = 1.87, 95% CI: 1.19-2.94, P = 0.006) and Indians (OR = 8.38, 95% CI: 4.34-16.16, P < 0.00001). However, the results showed that the -765C allele was a protective factor for GC in Dutch (OR = 0.53, 95% CI: 0.33-0.87, P = 0.01) (Figure 3). Sensitivity analysis was performed after excluding studies conducted by Saxena *et al*[33] and Sitarz *et al*[18], because of the anomalous OR and rare ethnicity.

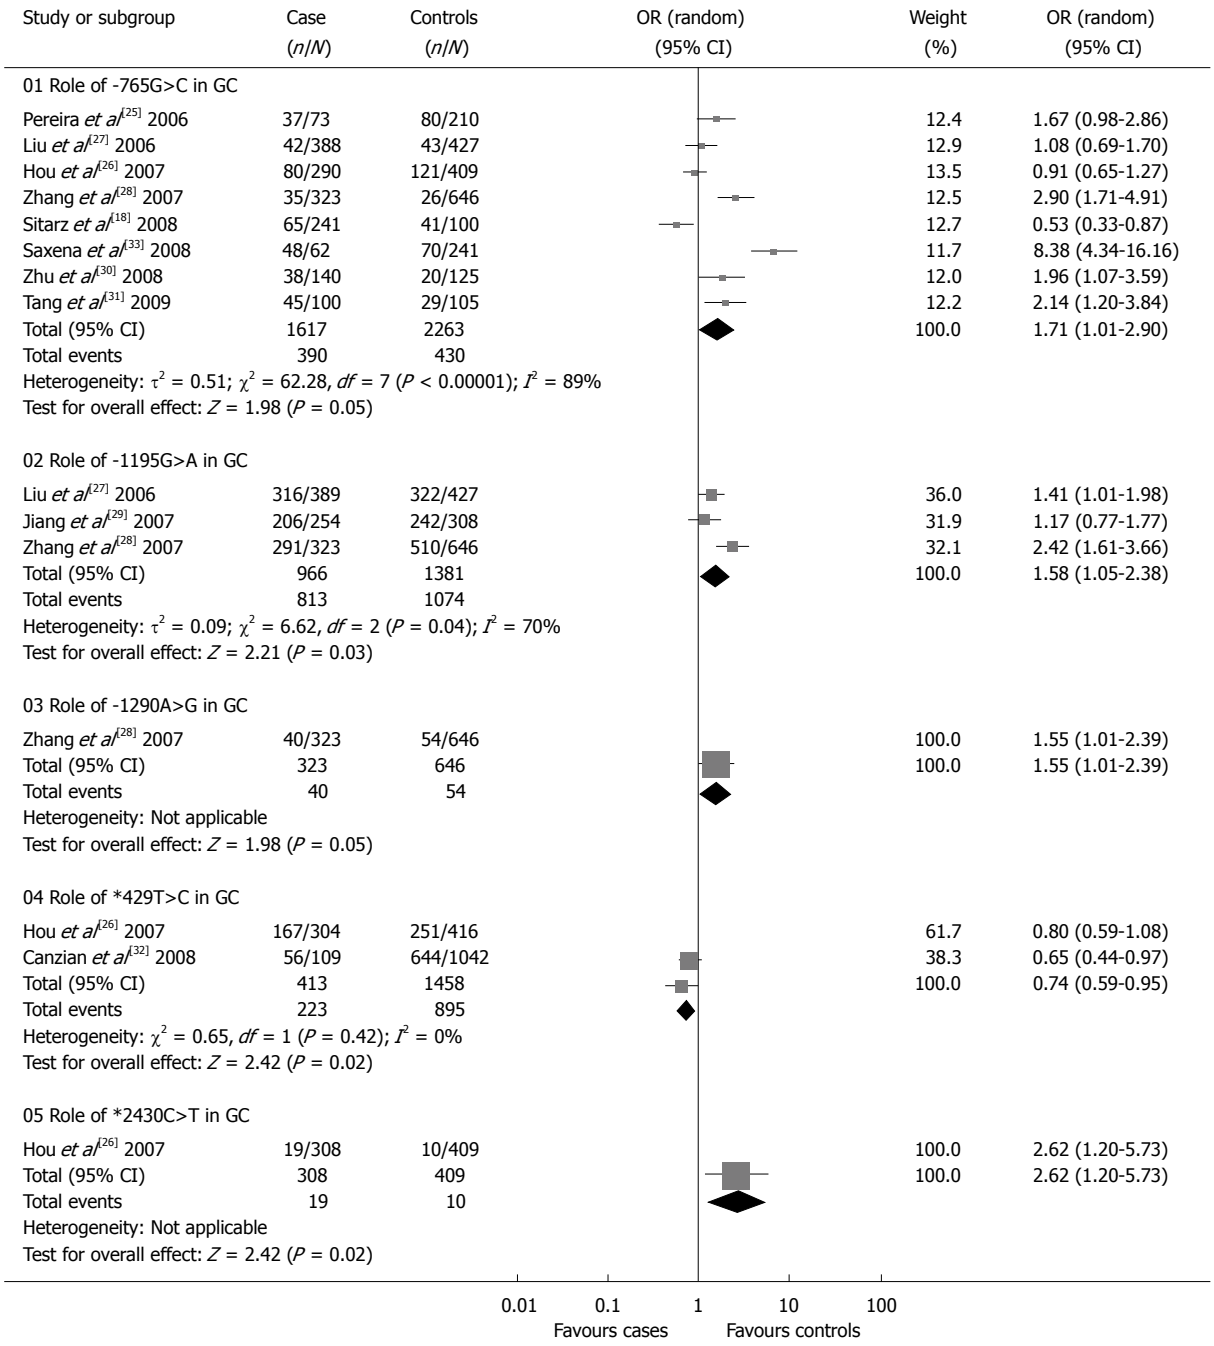

Figure 2 Meta-analysis of the association between cyclooxygenases-2 polymorphisms and susceptibility to gastric cancer.

No significant differences were observed between before and after results (OR = 1.59, 95% CI: 1.08-2.35, $P = 0.02$) (Figure 4).

Publication bias

The publication bias of the meta-analysis on the association between COX-2 and GC was detected by the funnel plot on -765G>C. The graphical funnel plot of 8 studies of -765G>C polymorphism appeared to be asymmetrical (Figure 5). Publication bias might occur if smaller studies showed no significant results remain unpublished, leading to an asymmetrical appearance of the funnel plot with a gap at the bottom of the graph.

DISCUSSION

Evidence suggests that COX-2 plays an important role in the carcinogenesis pathway, such as in the inhibition of apoptosis, tumor growth, angiogenesis, invasion and metastasis[34-36]. The specific function of COX-2 in the formation of prostaglandins makes it a strong candidate for increasing susceptibility to common cancers such as GC, colorectal cancer, lung cancer and other cancers[37]. As is known, genetic polymorphisms altering the level of protein expressed would be anticipated to have a substantial influence on disease activity. Several polymorphisms in COX-2 have been reported previously, although some

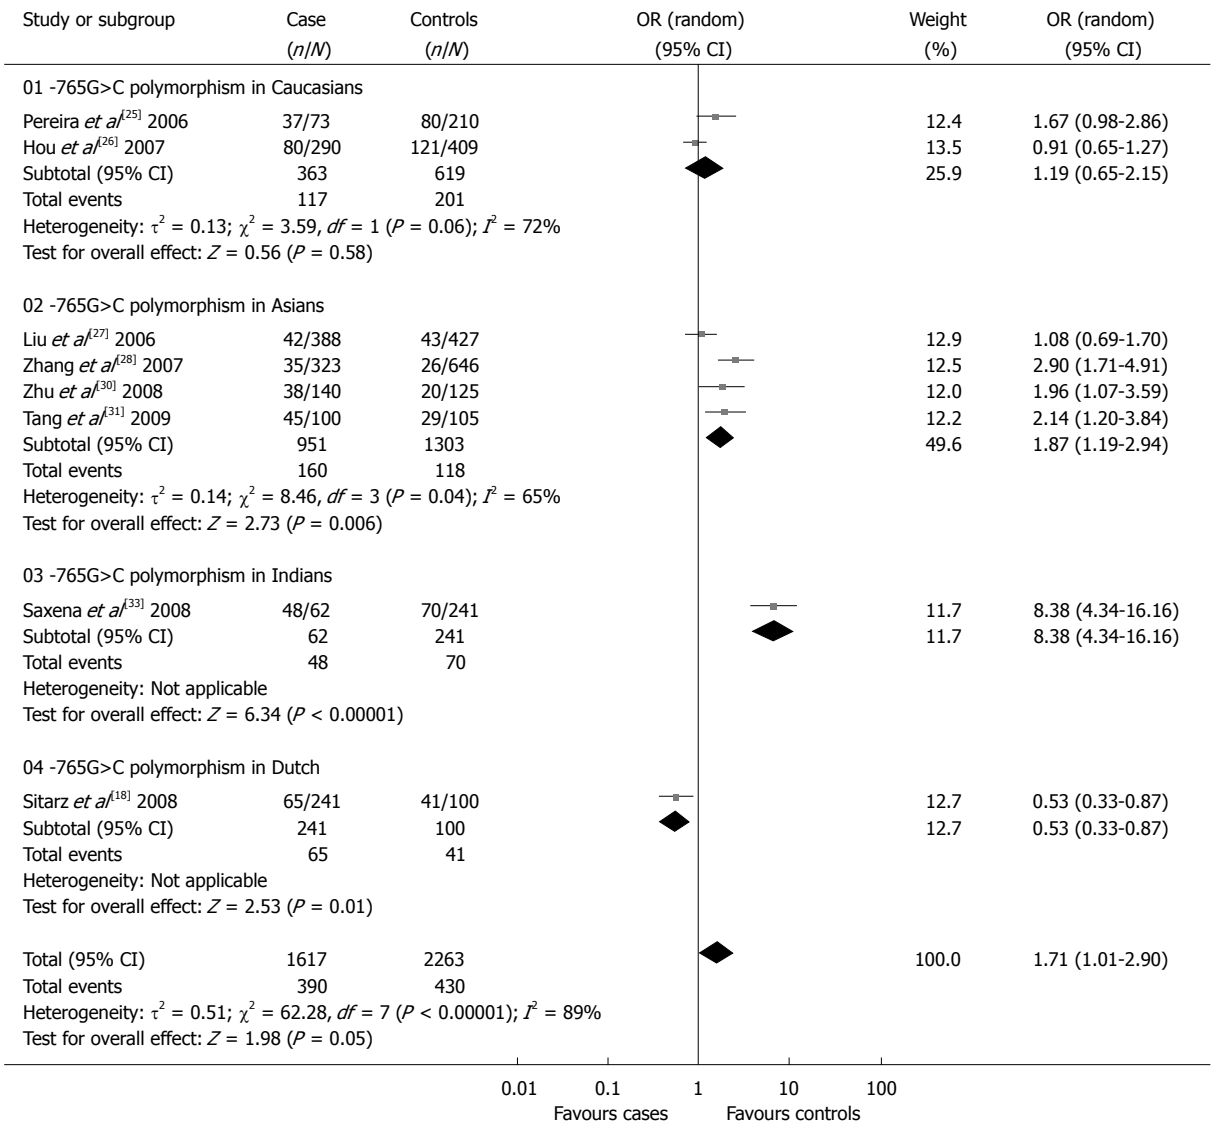

Figure 3 Subgroup analysis of -765G>C polymorphism by ethnicity.

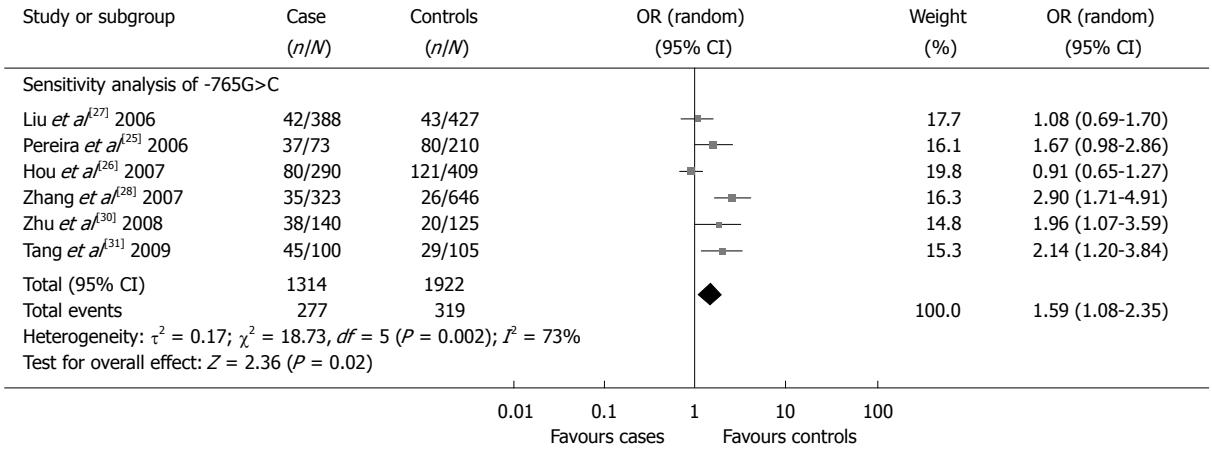

Figure 4 Sensitivity analysis of -765G>C polymorphism.

of these polymorphisms are not functionally significant or associated with susceptibility to cancer[21]. There were also many polymorphisms of COX-2 gene which were determined to have a significant association with the susceptibility to GC[21,38].

Our meta-analysis quantitatively assessed the asso-

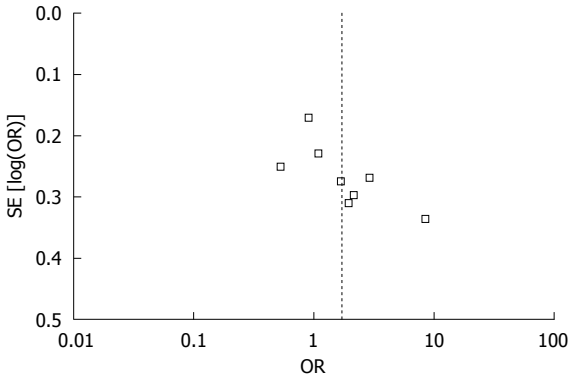

Figure 5 Funnel plots to explore publication bias.

ciation between COX-2 polymorphisms with the susceptibility to GC. Finally, 10 case-control studies were included and assessed. In this meta-analysis, 11 COX-2 polymorphisms were addressed and evaluated in gastric carcinogenesis: -765G>C, -1195G/A, Gly587Arg(G>A), 1290A>G, 8473T>C, IVS5-275T>G, IVS7+111T>C, V102V, *429T>C, *2430C>T, 587codonG>A. -765G>C, the most common polymorphism of the COX-2 gene and investigated in eight studies, revealed an increased risk behavior associated with gastric carcinogenesis in the normal population (OR = 1.71, 95% CI: 1.01-2.90, $P = 0.05$). As strong heterogeneity was reported, an ethnicity-based subgroup analysis was performed. The results showed that no association between the -765C allele and the susceptibility to GC in Caucasians, but an obviously significant association was determined in Asians (OR = 1.87, 95% CI: 1.19-2.94, $P = 0.006$) and Indians (OR = 8.38, 95% CI: 4.34-16.16, $P < 0.00001$). Interestingly, the -765C allele was a protective factor for GC in Dutch (OR = 0.53, 95% CI: 0.33-0.87, $P = 0.01$). Three studies discussed the association of the -1195G>A polymorphism and the susceptibility to GC. The results of the pooled analysis indicated that the -1195A allele was a risk factor for susceptibility to GC (OR = 1.58, 95% CI: 1.05-2.38, $P = 0.03$). In the study carried out by Zhang *et al*[28], the increased susceptibility was higher in individuals that were -1290G allele carriers (OR = 1.55, 95% CI: 1.01-2.39, $P = 0.05$). Unlike most of the COX-2 polymorphisms addressed, the *429C allele seems to play a protective role in GC development. However, the *429T allele was a risk factor for susceptibility to GC (OR = 0.74, 95% CI: 0.59-0.95, $P = 0.02$). Another study worth mentioning is the one by Hou *et al*[26], where we observed an increased risk of GC in Caucasians population with the *2430T allele (OR = 2.62, 95% CI: 1.20-5.73, $P = 0.02$). Unfortunately, no statistically significant results were observed in the Gly587Arg(G>A), 8473T>C, IVS5-275T>G, IVS7+111T>C, V102V and 587codonG>A COX-2 polymorphisms in gastric carcinogenesis. Therefore, in further functional studies, future investigations should focus on the -765G>C, -1195G>A, -1290A>G, *429T>C, and *2430C>T COX-2 polymorphisms and their molecular mechanism involving gastric carcinogenesis.

There were some limitations in our meta-analysis. Firstly, because of incomplete raw data or publication limitations, some relevant studies could not be included in our analysis. Secondly, we were not able to address the sources of heterogeneity that existed among studies for most polymorphisms. However, we could not perform subgroup stratification analysis for the limited number of published studies. Thirdly, the lack of genotype frequency information provided by some published studies did not allow the estimation of the best genetic model of inheritance to follow. Although we actively contacted the authors, they did not provide a comprehensive set of data. In addition, the small sample size available was not ideal for detecting small genetic effects. Finally, our systematic review was based on unadjusted data, as the genotype information stratified for the main confounding variables was not available in the original papers and also the confounding factors addressed across the different studies were variable.

In conclusion, our meta-analysis of 10 case-control studies demonstrated an association between the -765C, -1195A, -1290G, *2430T alleles and *429TT genotype of COX-2 polymorphisms and GC. In addition, all of these findings suggested that ethnicity was the main sources of heterogeneity, and different ethnicities with COX-2 polymorphisms had varying susceptibility to GC. From the analysis, we also concluded that the Gly587Arg(G>A), 8473T>C, IVS5-275T>G, IVS7+111T>C, V102V and 587codonG>A polymorphisms showed no association with susceptibility to GC. As few studies are available in this field and current evidence remains limited, the necessity should be emphasized to conduct large studies with an adequate methodological quality, properly controlling for possible confounds in order to obtain valid results.

ACKNOWLEDGMENTS

We would like to thank Wu Yan (Department of Dermatology, First Affiliated Hospital, China Medical University) for her valuable contribution and kindly revising the manuscript.

COMMENTS

Background

Accumulated evidence indicates that the cyclooxygenases-2 (COX-2) play an important role in gastric carcinogenesis, which was associated with inhibition of apoptosis, increased metastasis potential and neoangiogenesis. To investigate the association of COX-2 polymorphisms with susceptibility to gastric cancer (GC), the authors carried out a meta-analysis of all related case-control studies.

Research frontiers

Much attention has been paid to the potential role of COX-2 in gastric carcinogenesis. Some of them have been trying to confirm the definite relationship between COX-2 polymorphisms and susceptibility to GC, and meanwhile, others attempt to uncover underlying mechanisms.

Innovations and breakthroughs

The current study demonstrated that the -765C, -1195A, -1290G, *2430T alleles and *429TT genotype of COX-2 polymorphisms have significant association regarding the susceptibility to GC.

Applications

Meta-analysis suggests that the -765C, -1195A, -1290G, *2430T alleles and *429TT genotype of COX-2 polymorphisms were statistically significant risk

factors for GC. These genetic profiles may enable clinicians to select individuals for early diagnosis strategies, diverse management schedules such as the follow-up of patients with GC, or even to propose selective COX-2 inhibitors or nonspecific COX inhibitors in patients with precancerous lesions.

Terminology

Meta-analysis is a statistical tool in detecting an association that could otherwise remain masked in the sample size studies, especially in those evaluating rare allele frequency polymorphisms.

Peer review

This is an interesting and good paper, the described analysis has been performed with precision and accuracy.

Abstract

A case of hepatocellular carcinoma (HCC) with pulmonary recurrence after liver transplantation for HCC is presented in this report. The patient showed disease progression on sorafenib therapy demonstrated by computed tomography scans as well as serial serum α-fetoprotein (AFP) elevation. After his immunosuppression therapy was successfully transitioned to sirolimus and a continuation of sorafenib, he achieved partial remission based on RECIST criteria and normalization of AFP. Mammalian target of rapamycin inhibitors including sirolimus alone or in conjunction with sorafenib may be useful in the treatment of post transplant HCC.

Key words: Hepatocellular carcinoma; Liver transplantation; Mammalian target of rapamycin inhibitor; Sirolimus; Sorafenib

INTRODUCTION

Hepatocellular carcinoma (HCC) is a major health problem with a rising incidence in Western countries[1,2]. It is the third leading cause of cancer-related deaths worldwide, the seventh in the United States, and also the most common cause of death in patients with liver cirrhosis. The trend parallels an increase in advanced hepatitis C virus (HCV) related liver disease. The prevalence is much higher in developing countries and is associated with a significant morbidity and mortality. The treatment of HCC remains challenging due to the comorbidities with hepatitis B or C virus infection combined with decompensated liver cirrhosis. Only about 30% of patients with HCC are eligible for potentially curative treatment modalities such as liver resection, liver transplantation, or local ablation[3]. Conventional cytotoxic chemotherapeutic agents have been proven ineffective for patients with HCC[4]. Based on the SHARP trial[5], the Raf/vascular endothelial growth factor receptor (VEGF)/platelet derived growth factor receptor inhibitor, sorafenib, has increased the overall survival rate in patients with advanced HCC. The study was carried out in a highly selected population of HCC patients with liver function classified as Child-Pugh A and a small percentage of patients classified as Child-Pugh B. Orthotopic liver transplantation (OLT) for HCC has been highly successful with a low tumor recurrence rate in selected patient

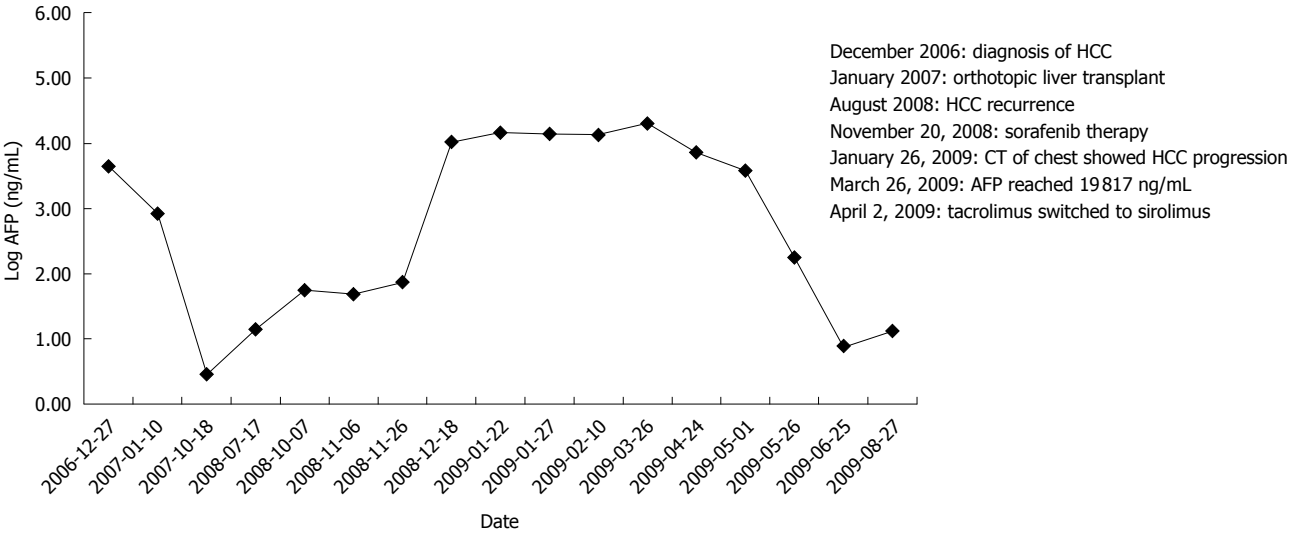

Figure 1 Serum α-fetoprotein level measured as related to the treatment history. Serum α-fetoprotein (AFP) level was trending up after sorafenib therapy but normalized after sirolimus was initiated. Events are outlined in the Figure. CT: Computed tomography; HCC: Hepatocellular carcinoma.

populations[6]. Tumor recurrence post OLT is the major obstacle in preventing successful liver transplantation in patients with HCC. Therefore, it is important to develop strategies for preventing HCC recurrence post OLT. Here, we present a case of HCC recurrence post OLT that was treated with sorafenib in addition to switching from tacrolimus to sirolimus as an immunosuppressant.

CASE REPORT

A 60-year-old male with a history of hepatitis C virus infection and liver cirrhosis was found to have several liver lesions consistent with HCC with an elevated α-fetoprotein (AFP) level on routine surveillance in December 2006. Based on his typical images and serum AFP level, the patient was diagnosed as HCC. He underwent an uneventful OLT at our liver transplant center in January 2007. Pathology showed multi-focal HCC with 4 lesions (3 lesions preoperatively), the largest measuring 5.0 cm × 3.0 cm × 2.9 cm. The tumors were moderately differentiated with vascular invasion and the pathologic staging was pT2N0Mx. The patient was given tacrolimus 4 mg twice a day for immunosuppression with serum tacrolimus levels at a range of 5-15 ng/mL after liver transplantation. HCV hepatitis recurrence was diagnosed by liver biopsy and serology in February 2008 when the patient had laboratory evidence of transaminase elevation. He continued on tacrolimus with no anti-HCV therapy and was followed up by the liver transplant team. In August 2008, he was admitted to the hospital for renal failure and hyperkalemia suspicious for tacrolimus toxicity with an elevated tacrolimus level at 16 ng/mL. His creatine level was 1.7 mg/dL. His tacrolimus dose was reduced to 2 mg twice a day orally and his tacrolimus target levels were at a low normal therapeutic range. During hospitalization, he was found to have new pulmonary nodules on a computed tomography (CT) scan. A biopsy confirmed those lesions to be metastatic HCC with its morphology similar to his original HCC. Due to bilateral pulmonary metastasis, the patient was not a candidate for surgery. He was referred to the medical oncology clinic in October 2008 for treatment. The recommendation was sorafenib therapy for his recurrent metastatic HCC after liver transplantation. Four weeks after he started on oral sorafenib at a dose of 400 mg twice a day from November 20, 2008, he developed the adverse effects of painful hand/foot syndrome. The dose of sorafenib was reduced to 200 mg orally twice a day on December 18, 2008. He tolerated sorafenib at 200 mg orally twice daily very well with less chest wall pain and resolution of hand/foot syndrome. His CT scan on January 26, 2008 showed progression of the disease based on RECIST criteria. Since the patient had improvement in symptoms, he wanted to continue taking sorafenib at 200 mg orally twice daily. Unfortunately, his AFP continued rising and reached a peak level of 19817 ng/mL on March 26, 2009 (Figure 1). The metastatic tumors in his lungs were also increasing in size based on a CT scan performed on January 26, 2009. He was advised to consider systemic chemotherapy due to his excellent performance status and good graft liver function, but there was no other evidence based treatment available for him. He refused systemic chemotherapy after the literature of chemotherapy in HCC was reviewed with him. He was not eligible for an experimental trial since he was on an immunosuppressant and had active hepatitis C virus infection.

Given the positive preclinical data on mammalian target of rapamycin (mTOR) inhibitors in HCC as well as the potential benefit of sirolimus for HCC patients requiring immunosuppression, his immunosuppressant was switched from tacrolimus to sirolimus at 2 mg orally once daily for a week after the visit on March 26, 2009. He continued taking sorafenib at 200 mg orally twice a day against advice from his physician because he believed that it helped him symptomatically. He

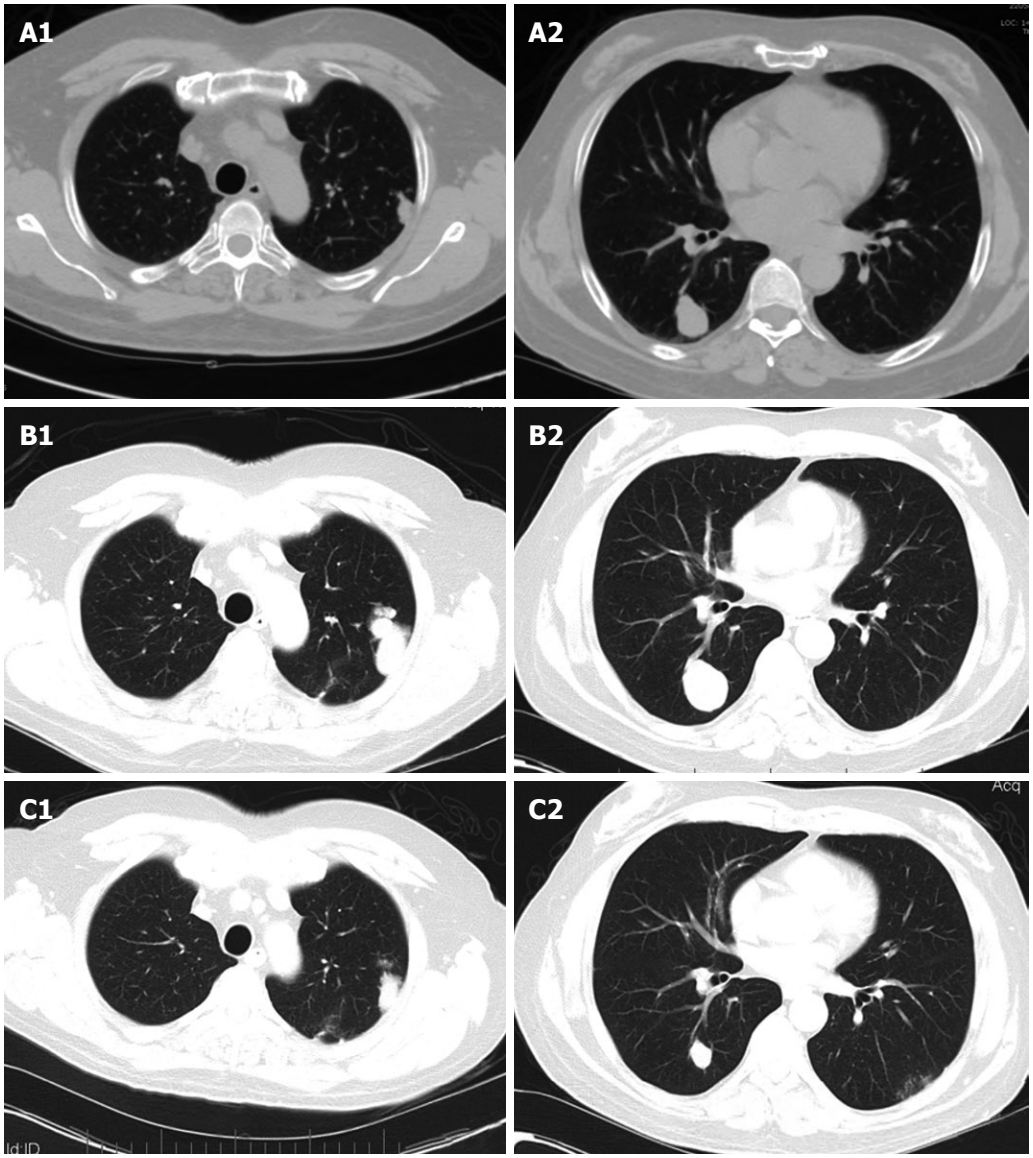

Figure 2 Computed tomographys of chest at different time points of the treatment. The lung lesions were increased in size after sorafenib therapy but significantly reduced in size after sirolimus was introduced in combination with sorafenib. The dates were August 6, 2008 (A), January 26, 2009 (B) and August 26, 2009 (C).

tolerated sirolimus at 2 mg orally daily with no obvious toxicity, and a desirable serum level (4-12 ng/mL) of sirolimus was achieved shortly after sirolimus therapy was initiated. His AFP dropped to normal limits and the CT showed a partial response (Figure 2). The dates for the representative images shown in Figure 2 were August 6, 2008, January 26, 2009 and August 26, 2009. There was no evidence of biochemical or radiographical progression when he was seen in the clinic on February 4, 2010.

DISCUSSION

The treatment algorithm for HCC is based on functional status, liver functional reserve and stage of the tumor[3]. Surgical resection of HCC can be achieved in patients with a tumor that is amenable to surgical resection and has a good liver functional reserve. For smaller tumors, local therapy with radiofrequency ablation is used. OLT in selected patients is the most desirable modality because it cures both liver cirrhosis and HCC. Tumor recurrence is a cause of transplant failure in this population of patients. Adjuvant therapy for HCC post liver transplantation is an active research area but currently there is no evidence that supports the practice.

The treatment of recurrent HCC after liver transplantation is a great challenge in clinical practice. The use of immunosuppressant and liver transplantation are usually exclusion criteria for participation in clinical trials. The use of sorafenib in this setting is an extrapolation of data and by no means evidence-based care.

The most commonly used immunosuppressant after liver transplantation is a calcineurin inhibitor. In contrast, sirolimus, a mTOR inhibitor has also been used successfully for immunosuppression after liver transplantation[7].

In comparison to tacrolimus as an immunosuppressant, the advantages of sirolimus include less nephrotoxicity and potential antineoplastic properties. This makes it suitable for patients with renal insufficiency or HCC. The drug development for mTOR inhibitors has generated several novel anti-cancer mTOR inhibitors which have been approved by the FDA for the treatment of renal cell carcinoma[8,9]. The use of sirolimus has been limited to immunosuppression in organ transplantation patients. There is an ongoing phase 3 clinical trial (SiLVER trial) studying the use of sirolimus as an immunosuppressant in liver transplantation for high risk HCC to reduce tumor recurrence (ClinicalTrials.gov Identifier: NCT00355862). Currently, there is no standard therapy for HCC recurrence post OLT. Sorafenib has been used empirically for relapsing HCC after OLT, but there are no data supporting the use of sorafenib in this setting. Our own experience with sorafenib for recurrent HCC post liver transplantation is disappointed. Preclinical and clinical data indicate that mTOR inhibitors have significant anti-tumor activity for HCC[10-13]. There was a case report of complete remission of lung metastases from HCC post liver transplantation under therapy with sirolimus and mycophenolate mofetil[14], and experience with the use of sirolimus as an immunosuppressant for patients with HCC post OLT.

The use of sirolimus as an immunosuppressant is a reasonable approach for patients with HCC post liver transplantation for HCC or for patients with relapsing HCC post liver transplantation. The PI3K/Akt/mTOR signal pathway is involved in multiple cellular functions including proliferation, differentiation, tumorigenesis, and apoptosis. In about 15%-41% HCC patients, activation of the mTOR pathway is reported[15-17] and implicated in metastasis, invasion and prediction of poor prognosis[10,18]. Blocking of the mTOR pathway confers combined anticancer and immunosuppressive properties. Therefore, mTOR inhibitor treatment for HCC is directed by the molecular biology of HCC. Multiple clinical trials have been carried out using an mTOR inhibitor as an anticancer agent for HCC. Experimental data indicate that tumor inhibition can be accomplished by mTOR inhibitors while protecting allografts against rejection. The role of mTOR inhibitors as an immunosuppressant in HCC patients post OLT can be further determined depending on data from the SiLIVER trial. The case presented in this report clearly suggests that an mTOR inhibitor, sirolimus, may have antitumor activity in this patient with advanced metastatic relapsing HCC post OLT. This conclusion is also supported by published preclinical data[12]. The patient was at a high risk of tumor recurrence based on the presence of multifocal liver lesions and vascular invasion. Molecular evaluation of tumor samples from patients with HCC may give us an insight about post surgical or post transplantation adjuvant therapy using either sorafenib, sirolimus or their combination. The hypothesis that sirolimus synergizes with the anti-tumor activity of sorafenib is supported by pre-clinical data[12], but whether this applies to the patient reported here is unknown. The tumor sample is being analyzed for Erk/MAPK pathway and PI3/Akt/mTOR pathway abnormalities. The fact that the patient did not derive any apparent benefit from more than 4 mo of sorafenib therapy alone after his tumor recurrence indicated that his HCC had inherent resistance to the Raf/VEGF/platelet derived growth factor receptor inhibitor, sorafenib. No reports are available on the delayed antitumor effects of sorafenib. Biomarkers that predict the effectiveness of mTOR inhibitor and/or sorafenib therapy and clinical trials to explore the effectiveness of sirolimus alone and in combination with sorafenib with molecular pathway correlation analysis are justified.

In conclusion, mTOR inhibitor, sirolimus, may have anti-tumor activity in HCC. Use of sirolimus as an immunosuppressant for HCC post OLT is being investigated, and its use in HCC alone or in combination with sorafenib warrants further investigation with biomarker correlation.

Acknowledgments to reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Mark Bloomston, MD, FACS, Assistant Professor of Surgery, Division of Surgical Oncology, N924 Doan Hall, 410W. 10th Avenue, Columbus, OH 43082, United States

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Contents

Weekly Volume 16 Number 44 November 28, 2010

World Journal of Gastroenterology
Volume 16 Number 44 November 28, 2010

Contents

NAME OF JOURNAL
World Journal of Gastroenterology

LAUNCH DATE
October 1, 1995

RESPONSIBLE INSTITUTION
Department of Science and Technology of Shanxi Province

SPONSOR
Taiyuan Research and Treatment Center for Digestive Diseases, 77 Shuangta Xijie, Taiyuan 030001, Shanxi Province, China

EDITING
Editorial Board of *World Journal of Gastroenterology*,
Room 903, Building D, Ocean International Center,
No. 62 Dongsihuan Zhonglu, Chaoyang District,
Beijing 100025, China
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893
E-mail: wjg@wjgnet.com
http://www.wjgnet.com

PUBLISHING
Baishideng Publishing Group Co., Limited,
Room 1701, 17/F, Henan Building,
No.90 Jaffe Road, Wanchai, Hong Kong, China
Fax: +852-3115-8812
Telephone: +852-5804-2046
E-mail: baishideng@wjgnet.com
http://www.wjgnet.com

SUBSCRIPTION
Beijing Baishideng BioMed Scientific Co., Ltd.,
Room 903, Building D, Ocean International Center,
No. 62 Dongsihuan Zhonglu, Chaoyang District,
Beijing 100025, China
Telephone: +86-10-8538-1892

Abstract

Sepsis is a systemic inflammatory response representing the leading cause of death in critically ill patients, mostly due to multiple organ failure. The gastrointestinal tract plays a pivotal role in the pathogenesis of sepsis-induced multiple organ failure through intestinal barrier dysfunction, bacterial translocation and ileus. In this review we address the role of the gastrointestinal tract, the mediators, cell types and transduction pathways involved, based on experimental data obtained from models of inflammation-induced ileus and (preliminary) clinical data. The complex interplay within the gastrointestinal wall between mast cells, residential macrophages and glial cells on the one hand, and neurons and smooth muscle cells on the other hand, involves intracellular signaling pathways, Toll-like receptors and a plethora of neuroactive substances such as nitric oxide, prostaglandins, cytokines, chemokines, growth factors, tryptases and hormones. Multidirectional signaling between the different components in the gastrointestinal wall, the spinal cord and central nervous system impacts inflammation and its consequences. We propose that novel therapeutic strategies should target inflammation on the one hand and gastrointestinal motility, gastrointestinal sensitivity and even pain signaling on the other hand, for instance by impeding afferent neuronal signaling, by activation of the vagal anti-inflammatory pathway or by the use of pharmacological agents such as ghrelin and ghrelin agonists or drugs interfering with the endocannabinoid system.

Key words: Sepsis; Ileus; Nitric oxide; Prostaglandins; Oxidative stress; Residential macrophages; Mast cells; Neurons; Afferent; Neuroimmunomodulation; Inflammation

DEFINITION AND CLINICAL RELEVANCE OF SEPSIS

Sepsis originates from the Greek word sepsios meaning "rotten" or "putrid". Sepsis is defined as a systemic inflammatory response syndrome secondary to infection. It represents a leading cause of death in critically ill patients, mainly due to the development of organ dysfunction and tissue hypoperfusion[1-3]. The incidence of severe sepsis is still increasing and ranges from 11%-15% in intensive care unit (ICU) patients: 11.8 patients per 100 ICU admissions in an Australian and New Zealand population[4]; 14.6% in a French ICU population[5], 11% of all ICU admissions in the US[6] and 12% of ICU patients in Spain[7]. Although

the overall mortality rate among patients with sepsis is declining - related to general improvements in acute and intensive hospital care rather than specific sepsis-related therapy - the number of sepsis-related deaths still increases and ranges between 25%-60%[2,4-6,8]. The development of organ dysfunction is a major determinant of mortality and is influenced by the co-existence of chronic comorbidity[8].

According to the International Guidelines of Severe Sepsis 2008[3], the management of severe sepsis complicated with hypoperfusion and organ failure is based on initial resuscitation (first 6 h) with, as main goals, maintaining the mean arterial pressure above 65 mmHg, a CVP of 8-12 mmHg, a urinary output above 0.5 mL/kg per hour and a central venous oxygen saturation above 70%. Secondly, the source and type of infection needs to be established by obtaining appropriate cultures before antibiotic therapy is initiated. The use of fluid therapy, vasopressors (norepinephrine and dopamine as initial choice) and dobutamine as inotropic therapy is recommended[3]. The use of corticosteroids remains controversial in the management of sepsis and is advised only in refractory sepsis, as is the use of recombinant human activated protein C which should be reserved for patients with organ dysfunction and a high clinical risk of death[2,9].

During sepsis a complex interaction takes place between the infecting microorganism, the host immune response, inflammatory and coagulation responses[9]. Different mechanisms such as the innate immune system, the coagulation pathways, endothelial dysfunction, mitochondrial dysfunction and apoptosis are described and associated with severe sepsis[9]. A cross-talk takes place between different immune cells including macrophages, dendritic cells and CD4+ T cells, leading to either a proinflammatory or anti-inflammatory cytokine reaction[10]. Patients can thus present with either an exaggerated proinflammatory systemic inflammatory response (often described in the early phase) or rather a state of immunosuppression and even anergy in a later phase[10,11]. Generally accepted is the theory that cells of the innate immune system recognize microorganisms and initiate responses through pattern recognition receptors (PRRs), pathogen-associated molecular patterns (PAMPs) and Toll-like receptors (TLRs). The latter will result in activation of intracellular signal transduction pathways such as the activation of nuclear factor (NF)-κB and caspase-1[9,11]. On the other hand, an excess production of reactive oxygen and nitrogen species is described resulting in oxidative and nitrosative stress. Other pathogenic mechanisms leading to sepsis-related organ dysfunction are exacerbated coagulation, impaired anticoagulation and decreased fibrin removal, together with endothelial disturbances, mitochondrial dysfunction and apoptosis[9].

ROLE OF THE GASTROINTESTINAL TRACT IN SEPSIS

Hassoun *et al*[12] described in the early 2000s how the gastrointestinal tract might play a pivotal role in the pathogenesis of post-injury multiple organ failure. Gut hypoperfusion is an important inciting event in the pathogenesis of organ failure, whereas the reperfused gut is an early source of proinflammatory mediators. Ischemia and reperfusion in the gastrointestinal tract will activate a cascade of stress-sensitive protein kinases (MAPK, ERK, p38, JNKs) that converge on transcription factors regulating the expression of proinflammatory genes[12]. Important mechanisms playing a role in gastrointestinal dysfunction as a result of post-injury multiple organ failure are increased intestinal permeability, bacterial translocation and paralytic ileus[13]. Bacterial translocation is defined as the passage of both viable and non-viable microbes and microbial products such as endotoxins across the mucosal barrier[12], whereas ileus is defined as an inhibition of propulsive intestinal motility[14]. These mechanisms play an important role in the maintenance of multiple organ failure and secondary infections[12]. Frequently, the source of bacteria can be traced to the endogenous flora of the gastrointestinal tract[15]. Ileus predisposes to luminal accumulation and bacterial colonisation of the stomach and small intestine and therefore promotes bacterial translocation and pneumonia by aspiration of gastric contents. Ileus therefore plays a pivotal role in the occurrence and maintenance of infections in multiple organ failure[12]. The guidelines on the management of severe sepsis of 2008 concluded that prophylactic use of selective digestive tract decontamination in severe sepsis patients would be targeted towards preventing secondary ventilator-associated pneumonia[3]. There are, however, insufficient data available from severe sepsis patients to support global use of selective digestive tract decontamination.

The gastrointestinal tract therefore has a dual role in sepsis, being a target organ and a pathogenic player. It is now understood that the gut is not only a source of bacteria and endotoxins, but also a source of pro-inflammatory mediators and a cytokine-generating organ. These inflammatory mediators reach the circulation *via* the intestinal lymph[16,17]. Bacteria and endotoxins crossing the mucosal barrier further potentiate the gut inflammatory response, even when the bacteria and their products are trapped within the gastrointestinal wall or intestinal lymph nodes, not reaching the systemic circulation[16]. Studying the impact of experimentally-induced sepsis on gastrointestinal motility and its immunological modulation therefore merits further attention.

ANIMAL MODELS OF SEPSIS

Several animal models of sepsis exist, all with their advantages and disadvantages (Table 1)[18-20]. One of the main criticisms of the animal models is that the demonstrated benefits of therapeutic agents in animals are rarely translated into successful clinical trials, indicating the difficulty of mimicking the complex interaction between current illness, sepsis and supportive therapy in an animal model. The lack of supportive therapeutic interventions in animal models represents therefore an important caveat in the use of animal models. Also, the

Table 1 Overview of septic animal models displaying advantages and disadvantages (adapted from[18-20])

Endotoxin model
Advantages
Endotoxins play a significant role in the pathogenesis of sepsis
Simple model
Using sublethal doses, providing active resuscitation, using continuous infusion and the use of intraperitoneal injection are four measures reproducing more accurately the human situation
Lipopolysaccharides is stable (compared to the use of bacteria), therefore the model is more accurate and reproducible compared to the bacterial infection models
Disadvantages
Exaggerated release of host cytokines
Most of the time only Gram-negative sepsis
Single toxin does not mimic human sepsis
Therapies shown to be effective in animal models, failed in clinical trials
Rats are very resistant compared to humans
Lack of an infectious focus
Bacterial infection model
Advantages
Endotoxins play a significant role in the pathogenesis of sepsis
Reduction of the dose, increasing the infusion time, giving active resuscitation can prolong survival and render the model more comparable to the human situation
Disadvantages
Uncommon clinical occurrence
High doses of bacteria are needed
Significant interlaboratory variability
Survival is short
Serum cytokine responses are transient and exaggerated
Peritonitis model: cecal ligation puncture model
Advantages
Resemblance to clinical situation
Peritoneal contamination with a mixed flora
The cytokine response is comparable to human situation
Severity can be adjusted by increasing the needle puncture size or the number of punctures, delaying mortality over several days
Disadvantages
The model needs a surgical procedure that by itself may induce ileus
Difficult to control the magnitude of septic challenge
Variability within the cecal ligation puncture model

timing of most animal models is not comparable to the human situation as most animal models represent acute syndromes unlike sepsis in humans (hours to days in animal models *vs* days to weeks in humans)[20].

Animal models of sepsis are generally divided into 3 categories: endotoxin models, bacterial infection models and peritonitis models[18-20]. The major advantages and disadvantages of these models are described in Table 1. In the endotoxin model lipopolysaccharides (LPS) of bacteria are injected, while in the bacterial infection models the bacteria themselves are injected. Different peritonitis models are described, such as cecal ligation and puncture (CLP), implantation of a fibrin clot suspended with bacteria in the abdominal cavity or implantation of a colonic stent. These peritonitis models have as a major advantage the presence of a local infection focus and some authors consider the CLP model as the gold standard for sepsis research[20]. However, it is important to understand that this procedure requires a major surgical procedure which might have no effect in sepsis survival studies but strongly interferes with gastrointestinal motility because of the induction of postoperative ileus.

In the endotoxin model, LPS is injected intravenously or intraperitoneally. The choice of the animal (mouse, rat, guinea pig), and the strain and gender of the animal are all confounding parameters in these models, as well as the strain of bacteria or endotoxins used, the dose and the administration route. Studying gastrointestinal motility and its immunological modulation by administering a single intraperitoneal injection of endotoxin at a sublethal concentration represents an adequate model for experimental sepsis[13,21]. It has been shown previously in different animal species that a single dose of LPS alters gastrointestinal motility. By 1963, Turner *et al*[22] had already shown that endotoxins reduce water and food intake and gastric emptying in mice. We investigated the effect of a single intraperitoneal injection of LPS of *Escherichia coli* and showed a significant delay in gastric emptying and small intestinal transit[23-26]. In rats, endotoxins delay gastric emptying, increase small intestinal transit[27-31], and reduce jejunal spontaneous circular muscle activity[32,33]. In dogs, endotoxins delay gastric emptying and abolish intestinal migrating motor complexes[34-37]. In horses, a low dose of endotoxin was reported to disrupt the motility pattern and to decrease the cecal and colonic contractile activity[38,39]. Therefore, endotoxins are definitely able to induce gastrointestinal ileus, which we will now refer to as sepsis- or endotoxin-induced ileus.

On the other hand, ileus is often studied in a surgically-induced postoperative model. It is generally accepted that postoperative ileus is triggered by two different phases: an early neurogenic and a late inflammatory phase[40]. During the initial neuronal phase, inhibitory effects on motility are related to the activation of an inhibitory reflex pathway involving adrenergic, nitrergic and VIP-ergic neurons[41,42]. In the second phase, the activation of an inflammatory cascade plays a crucial role and is triggered by the handling of the intestines activating the cross-talk between the immune system, the autonomic nervous system and the muscle effector apparatus of the gastrointestinal wall[40].

Both the endotoxin-induced model and the postoperative ileus model accentuate the important role of inflammation in the development and maintenance of gastrointestinal ileus. It is therefore our opinion that the endotoxin-induced ileus model and the postoperative ileus model are both relevant in the study of inflammation-induced motility disturbances.

PATHOGENESIS OF INFLAMMATORY-MEDIATED ILEUS

Initial research focussed on the mediators that could be involved in the inflammation-induced impairment of gastrointestinal motility by a direct action on the intestinal smooth muscle cells. Later on, the focus was broadened in an attempt to clarify not only the mediators involved but also the cell types and the transduction pathways. The

main goals were to identify possible target molecules enabling the development of novel drugs for clinical use.

Mediators involved in the pathogenesis of inflammatory-mediated ileus

Nitric oxide (NO) was one of the first molecules postulated to play an important role in the pathogenesis of LPS-induced motility disturbances in rats and mice mainly mediated *via* the inducible isoform of NO synthase (iNOS)[23,27,29,30,32,43]. Several groups showed that blockade of NOS reverses the endotoxin-induced changes in gastrointestinal motility in different animal species by the use of selective or non-selective NOS blockers and iNOS knock-out mice[23,27,29,30,32]. Our group proved that this effect of NO, derived from iNOS, is mediated at least partially by activation of guanylyl cyclase in a murine endotoxic model[23,44]. Furthermore, we also found evidence of a role for NO-mediated oxidative stress mechanisms, indirectly *via* the use of the solvent DMSO which also has radical scavenging properties, and directly by the use of antioxidant molecules[23,24,45]. Treatment of mice with the antioxidant pegylated superoxide dismutase reversed the endotoxin-induced delay in gastric emptying and improved the delay in intestinal transit. This was associated with a decrease of iNOS-positive residential macrophages and a decrease of immunohistochemical staining for nitrotyrosine and 4-hydroxy-2-nonenal, markers for oxidative and nitrosative stress, in the gastric and ileal mucosa of LPS-treated mice[24]. In agreement with these results, we found that the antioxidant melatonin reversed the endotoxin-induced motility disturbances in mice through a reduction of intestinal lipid peroxidation, MAPK activation, NF-κB activation, iNOS transcription and expression, and nitrite production[45].

In addition, NO produced from neuronal NOS may be involved in sepsis-induced ileus. Quintana *et al*[46,47] showed synthesis of NO in postganglionic myenteric neurons during the early phase of endotoxemia (30 min after injection of LPS) in rats, as well as an increase in nNOS mRNA in the dorsal vagal complex of the brainstem 2 h after administration of LPS.

Prostaglandins are also postulated to play an important role in the pathogenesis of inflammatory-mediated ileus[13,21,48]. In rat studies on postoperative ileus, a role for prostaglandins was proven by the presence of COX2 mRNA and protein in residential macrophages, recruited monocytes and in a subpopulation of myenteric neurons[49]. This study also demonstrated an amelioration of the gastrointestinal motor function by treatment with the COX2 inhibitor, DFU[49]. Other animal studies, also from our own group, showed a differential effect of different COX inhibitors on postoperative motility induced by laparotomy alone or laparotomy with bowel manipulation, suggesting a possible involvement of both COX1 and COX2 isoforms and different sites of action in different stages of postoperative ileus[50,51]. A recent clinical trial comparing the effect of diclofenac (standard non-steroidal anti-inflammatory drug) and celecoxib (COX2 selective inhibitor) in patients after abdominal surgery also showed a differential effect of both drugs. Celecoxib significantly reduced the development of paralytic ileus, whereas both drugs did not result in a more rapid restoration of the gastrointestinal function compared to placebo[52]. To our knowledge, no studies of different COX inhibitors on sepsis- or endotoxin-induced ileus are available.

Moreover, prostaglandins are postulated to modulate afferent nerve signaling from the gut to the spinal cord and higher brain centers, indicating that they play a role not only in motility disturbances but also in sensitivity disturbances and pain signaling pathways. These effects are described both in the postoperative ileus model and in the endotoxin-induced ileus model[50,53].

Cell types involved in the pathogenesis of inflammatory-mediated ileus

The initial search for the location of iNOS production in the endotoxin-induced ileus model pointed to an important role for residential macrophages[24,32]. We clearly showed the presence of iNOS in residential muscular macrophages in the stomach and ileum of LPS-treated mice[24]. Besides residential muscular macrophages, the gastrointestinal tract contains a dense population of mucosal macrophages which play a crucial role in tissue homeostasis on the one hand and in the initiation, propagation and resolution of inflammation on the other hand. Mucosal macrophages are conditioned towards an anti-inflammatory role under normal circumstances and switch towards a pro-inflammatory modus during inflammation[54-56]. The relationship and the interaction between muscular and mucosal residential macrophages in the gastrointestinal tract have not been studied so far. In the field of ileus, research is focussed largely on the muscular population. Several groups have hypothesized that LPS initiates an inflammatory cascade consisting of the activation of the normally quiescent network of residential muscularis macrophages, resulting in the production of a plethora of inflammatory cytokines, chemokines and other substances such as nitric oxide and prostaglandins[13,23,24,32,33,43,48]. This inflammatory milieu results in the recruitment of circulating leukocytes and consequently in the further release of leukocyte-derived substances such as nitric oxide and prostaglandins capable of altering gastrointestinal motility[23,48] and activating inhibitory neurogenic reflex pathways[57]. The presence of iNOS is not only demonstrated in residential macrophages but also in the recruited leukocytes, thereby augmenting the inhibitory effects on gastrointestinal motility[21,58]. Monocyte-chemoattractant protein-1 (MCP-1), derived from the residential macrophages, is a key molecule in the recruitment of additional monocytes during endotoxemia, leading to an enhanced secretion of kinetically active substances that may alter gastrointestinal motility[59,60]. In a polymicrobial model of sepsis, such as the CLP model, this complex inflammatory response is induced within the intestinal muscularis with recruitment of leukocytes and mediators that inhibit intestinal muscle activity[48]. The activation of residential muscular macrophages within the gastrointestinal wall also plays a crucial role in the late inflammatory phase

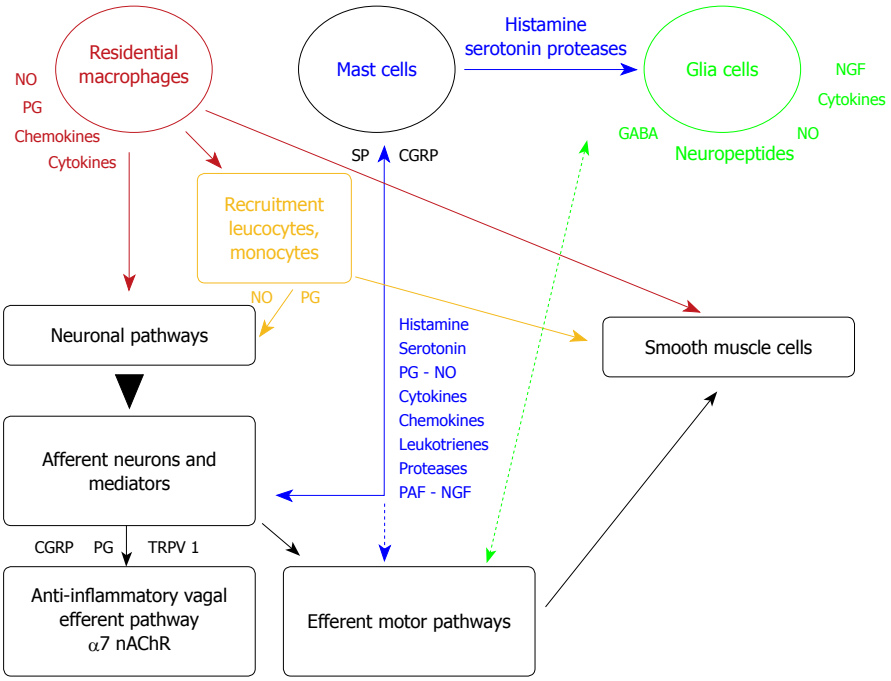

Figure 1 Hypothetical scheme of the complex interplay between, on the one hand residential macrophages (red), mast cells (blue), glial cells (green) and the recruitment of inflammatory cells (yellow), and on the other hand the activation of neuronal reflex pathways (black). Mediators involved in the different cell populations are marked in the same color as the cell type involved. NO: Nitric oxide; PG: Prostaglandins; SP: Substance P; CGRP: Calcitonin gene-related peptide; GABA: γ-aminobutyric acid; NGF: Neuropeptides, growth factors; PAF: Platelet-activating factor; TRPV: Transient receptor potential channel of the vanilloid subtype; nAChR: Nicotinic acetylcholine receptor.

of postoperative ileus, resulting in secretion of molecules such as lymphocyte function-associated antigen-1 and intercellular adhesion molecule-1 (ICAM-1), again attracting more leucocytes within the intestinal muscularis and therefore maintaining the inflammatory cascade[13,21,57]. In the postoperative model, the important role of intestinal residential macrophages was definitely proven by the work of Wehner *et al*[61], showing that depletion and inactivation of the macrophages in rats and mice prevented intestinal inflammation and postoperative ileus.

In addition to residential macrophages and inflammatory leucocytes, mast cells are also put forward as important cells in the induction and maintenance of the inflammatory cascade and its effects on motility. There is evidence for bidirectional communication between mast cells and neurons in the gastrointestinal tract[62-64]. de Jonge *et al*[65] proved elegantly that the degranulation of connective tissue mast cells is a key event in the establishment of the intestinal infiltrate in the abdominal wall in a murine model of postoperative ileus. The importance of mast cells in the pathogenesis of postoperative ileus could be translated to the human situation; The *et al*[66] showed that intestinal handling triggered mast cell activation as well as leucocyte infiltration in patients undergoing an abdominal hysterectomy. In a pilot trial with the mast cell stabiliser ketotifen, the same authors demonstrated that ketotifen improved the surgery-induced delay in gastric emptying of liquids in humans[67]. The number and activity of both residential macrophages and mast cells in LPS-treated mice is upregulated (personal communication)[68]. More studies on the role of mast cells and their mediators need to be performed in models of sepsis-induced ileus.

The question as to whether the main initiator of the inflammatory reaction is the residential macrophage or the mast cell remains unresolved. In a recent paper, Boeckxstaens *et al*[40] suggest a role for peritoneal mast cells adjacent to mesenteric blood vessels. Activated by neuropeptides such as substance P and calcitonin gene-related peptide (CGRP) released from the adjacent afferent neurons, mast cells are able to release proinflammatory mediators into the peritoneal cavity diffusing into the blood vessels and increasing mucosal permeability. In turn, luminal bacteria and/or bacterial products enter the gastrointestinal wall and activate the resident macrophages triggering intracellular signaling pathways, leading to transcription of inflammatory molecules, cytokines, chemokines and adhesion molecules[40]. Others support a role for the residential macrophages as the first responders and conductors which would orchestrate the inflammatory events after surgical manipulation or endotoxin exposure[21]. More importantly, the interplay between these initiating cells and the nervous system should be further investigated as both the mediators released from mast cells and from residential macrophages are able to affect neuronal signaling within and from the gastrointestinal wall (Figure 1)[21,62].

Neuro-immunomodulatory pathways involved in the pathogenesis of inflammatory-mediated ileus

The gastrointestinal tract is richly innervated by an intrinsic enteric nervous system and by an extrinsic autonomic nervous system consisting of parasympathetic vagal and pelvic neurons and sympathetic splanchnic neurons. During inflammation of the gut, there is a complex multidirectional interaction between immune and inflammatory cells, neurons and smooth muscle cells (Figure 1)[21,69]. Wang *et al*[53] proved that inflammatory mediators released from the gut during endotoxemia were able to affect jejunal afferent discharge in the rat. Both LPS itself and mesenteric lymph fluid collected after injection of LPS were able to increase the afferent discharge. Liu *et al*[70] demonstrated an increased discharge in capsaicin-sensitive

mesenteric vagal afferents following systemic LPS. It was also shown that the endotoxin-induced delay in gastric emptying in rats could be suppressed by systemic capsaicin, by local application of capsaicin to the vagal nerve (but not to the celiac ganglion), and by a CGRP receptor antagonist[31]. Our own group also provided evidence for a role of afferent neurons in the motility disturbances induced by endotoxin in mice[25]. Neuronal afferent involvement was demonstrated by the beneficial effect of hexamethonium and capsaicin, and the effect of the afferent neurons was mediated by CGRP and the TRPV1 receptor. In a postoperative murine model, the involvement of both vagal and spinal afferent neurons in the inhibition of gastrointestinal motility was shown, with a differential effect of COX2 inhibition on the two types of afferent neurons[71]. All these results underline the importance of an initial activation of afferent neurons leading to the activation of inhibitory neuronal reflex pathways in gastrointestinal motility disturbances induced by sepsis or surgical manipulation of the intestine.

Activation of the vagovagal pathway is able to modulate inflammation in the gastrointestinal tract on the one hand and motility on the other hand. The cholinergic nervous system is able to attenuate the production of proinflammatory mediators and to inhibit inflammation; this mechanism is known as the cholinergic anti-inflammatory pathway[69,72,73]. The cholinergic anti-inflammatory surveillance system starts with the activation of vagal sensory afferent fibers by proinflammatory cytokines, secreted by innate immune responses stimulated *via* exogenous and endogenous molecular products of infection and injury such as LPS. Information is transmitted to higher brain centres. In the brain, vagal efferent fibers are activated; signaling back to the gastrointestinal tract. Acetylcholine inhibits the cytokine release directly *via* the α7 nicotinic acetylcholine receptor (nAChR) expressed on macrophages. Animal models showed that the anti-inflammatory effect is not exclusively mediated *via* macrophages but that other immune cells such as dendritic cells and mast cells may also be involved[73]. However, anti-inflammatory properties of vagal activation were also shown in murine isolated intestinal and peritoneal macrophages in the light of inflammatory surveillance: whereas acetylcholine stimulated the phagocytic potential of the macrophages, it inhibited the immune reactivity, as evidenced by reduction of NF-κB and proinflammatory cytokines and stimulation of IL10 production *via* nAChR α4/β2[74]. On the other hand, there is also evidence for indirect modulation of inflammatory processes *via* postganglionic neuromodulation of immune cells in primary immune organs such as the spleen[69,72,75]. In a lethal rat endotoxemia model, direct electrical stimulation of the peripheral vagus nerve was shown to inhibit tumor necrosis factor (TNF) synthesis in the liver, attenuate peak serum TNF levels and prevent the development of shock[76]. In a rat cecal ligation and puncture model, stimulation of the caudal vagal trunk prevented the induced hypotension, alleviated the hepatic damage and plasma TNFα production but had no effect on liver NF-κB activation[77]. In a murine sepsis model, transcutaneous vagal nerve stimulation reduced TNFα levels and improved survival[78]. In a murine postoperative ileus, stimulation of the vagal nerve ameliorated surgery-induced inflammation and ileus, whereas AR-R17779, an α7AChR agonist, prevented postoperative ileus and reduced the inflammatory cell recruitment in a similar mouse model[79,80].

Furthermore, sympathetic nerves might be involved in the neuroimmunomodulation of the different functions of the gastrointestinal tract. Hamano *et al*[81] showed that yohimbine, an α2-adrenergic receptor antagonist, improved endotoxin-induced inhibition of gastrointestinal motility in mice. They suggest the mechanism of action is related to the activation of α2-adrenergic receptors on macrophages downregulating the expression of iNOS. However, it could not be excluded that gastric emptying was improved *via* inhibition of the presynaptic α2-adrenergic receptors on cholinergic vagal nerves. Under normal conditions, these receptors decrease the release of acetylcholine and thereby reduce gastrointestinal motility[81]. Nevertheless, Vanneste *et al*[82] could demonstrate that presynaptic α2-adrenergic receptor control of cholinergic nerve activity was unchanged in a rat model of postoperative ileus. Also in the postoperative ileus model, a beneficial effect of spinal cord stimulation at the level of T5-T8 segments was recently shown on gastric emptying, although the mechanism of action remains to be unravelled[83]. An interaction of sympathetic neurotransmitters with the gut immune system, glial cells and gut flora was recently suggested, in correlation with the vagal immunomodulatory mechanisms in conditions of inflammation or ileus[84].

A cell population that might be relevant to consider in this neuroimmunomodulatory framework is the enteric glial cell population. Enteric glial cells are part of the enteric nervous system, along with neurons and interstitial cells of Cajal (ICC); originating from the neuroectoderm. They form a widespread network in the gastrointestinal wall where they outnumber the neuronal cell population at the level of the myenteric plexus, the submucosal plexus and the interconnecting nerve strands. Glial cells are small, star-shaped cells with numerous processes extruding from the epithelium and can be identified by the presence of specific proteins such as glial fibrillary acidic protein (GFAP), vimentin, S100B and glutamine synthetase. Glia contain precursors for neurotransmitters such as GABA and NO, express receptors for certain purinoceptors, express cytokines - interleukin (IL)-1β, IL-6, TNFα - and neuropeptides such as neurokinin A and substance P after activation[85]. Enteric glial cells can directly or indirectly modulate neuromuscular transmission, gastrointestinal motility and secretion. They also control - together with enteric neurons - intestinal barrier functions and gut immune homeostasis. Glial cells should therefore be recognised as important players in the multidirectional interactions between neurons, immune cells and intestinal epithelium (Figure 1)[85,86]. Ablation of glial cells in adult transgenic mice results in a fulminant and lethal jejunoileitis characterized by an increased myeloperoxidase activ-

ity, degeneration of myenteric neurons and intraluminal hemorrhage, pointing towards an important role of enteric glia in the maintenance of bowel integrity[87].

LPS administration in mice increases the expression of S100B in the intestine, which is indicative of an upregulation of glial cells. This effect of LPS is reversed by the cannabinoid cannabidiol, paralleled by a decrease in glial cell hyperactivation and a decrease in mast cells and macrophages (personal communication)[68]. The role of enteric glia and S100B in human gastrointestinal inflammation has been recently investigated in human biopsies, showing increased S100B in the duodenum of patients with celiac disease and in rectal biopsies of patients with ulcerative colitis; both associated with an increase in iNOS protein expression and nitrite production[88,89]. Changes in enteric glial cells and their markers (GFAP and S100β) have also been described in inflammatory bowel disease (IBD)[86].

Intracellular signaling pathways involved in the pathogenesis of inflammatory-mediated ileus

Intracellular signaling pathways play an important role in the initiation of the inflammatory immune response. Luminal bacteria and/or bacterial products enter the gastrointestinal wall and activate the resident macrophages, inducing phosphorylation of MAP kinase (ERK1/2, JNK and p38), thereby activating intracellular transcription factors such as NF-κB, STAT3, Egr-1 and NF-IL6 in both macrophages and leucocytes[21,40,79,90,91]. This leads to the induction of numerous inflammatory molecules (iNOS and COX2), cytokines (TNFα, IL1β, IL6), chemokines (MCP-1, GM-CSF, MIP1α, VEGF) and adhesion molecules (ICAM-1).

Inhibition of protein tyrosine kinases (PTK), resulting in the phosphorylation of tyrosine residues on proteins, occurs at multiple steps in the signaling cascade. Tyrphostin AG 126, a PTK inhibitor, reduces the inflammatory mediator expression induced by surgical manipulation probably through inhibition of the transcription factor NF-κB[92]. Wehner *et al*[93] showed the contribution of early p38-MAPK activation in murine postoperative ileus by the use of the macrophage specific inhibitor, semapimod. A role for Egr-1 was demonstrated in murine postoperative ileus in Egr1 knockout mice and in mice treated with the PPARγ agonist, rosiglitazone[90,91]. In addition, the beneficial effects of CO-releasing molecules in the development of postoperative ileus seem to be mediated by interference with p38 and ERK1/2 activation[94]. These data provide evidence for a key role of activation of transcription factors in postoperative ileus.

These intracellular signaling pathways also play a crucial role in endotoxic ileus. However, during sepsis and endotoxemia, TLRs come into sight and might represent an important pathogenic tool. Cells of the innate immune system recognize microorganisms and/or parts of microorganisms and initiate responses through PAMP binding to PRRs. TLRs are a family of PRRs (similar to, for instance, NOD), while PAMPs are often cell-wall molecules. LPS, a specific PAMP from Gram-negative bacteria, is known as a potent TLR4 ligand[9,95]. Specific TLR pathways (TLR2, TLR4, TLR5) are under investigation in the pathogenesis of gastrointestinal ileus in sepsis models[96-98].

Downstream intracellular signaling pathways after TLR4 activation involve different adaptor molecules (for a schematic overview see[97,99]). The bacterial molecules are presented more efficiently to the innate immune system by the complex of LPS-binding protein, CD14 and MD2, forming an essential part of the LPS-receptor next to TLR4[95,100]. Further on, stimulation of TLR recruits the adaptor molecule, myeloid differentiation primary response gene 88 (MyD88), to the receptor complex, leading to the activation of IL1R-associated protein kinases and TNF-receptor-associated factor 6 to finally activate NF-κB and MAP kinases, resulting in the production of proinflammatory cytokines and chemokines[97,99,101,102]. MyD88 plays a key role in the cytokine production in response to TLR ligands. Nevertheless, several other adaptor proteins are involved, such as TIR-domain-containing adaptor protein/MyD88 adaptor-like (TIRAP/Mal), TIR-domain-containing adaptor inducing IFNs (TRIF), TRIF-related adaptor molecule and sterile α- and armadillo-motif-containing protein[99,101,103].

Buchholz *et al*[96] recently showed the involvement of TLR4 pathways in endotoxin-induced ileus. They hypothesise that endotoxin-induced ileus is induced by TLR4 signaling in nonhematopoietic cells in the early phase (6 h after injection of LPS), whereas at high doses of LPS and at later time points both hematopoietic and nonhematopoietic TLR4 signaling contributes. The molecular response attributed to the hematopoietic cells points towards a role for residential macrophages and potentially also leucocytes in the late phase. The role of mast cells has not been investigated so far, to our knowledge. But which nonhematopoietic non-bone marrow-derived cells could then be involved in TLR4 signaling? Related to gastrointestinal disturbances, possible candidate cells are smooth muscle cells, intrinsic neurons and ICC[96]. No data are yet available, to our knowledge, regarding the expression of TLR4 on ICC. However, functional TLR4 expression is described on smooth muscle cells and myenteric plexus cells in the murine and human intestine, with expression of TLR4 on both neurons and glial cells in mice. TLR4 expression seems absent in enterocytes[104,105]. Outside the gastrointestinal wall, TLR4 receptors are also expressed in dorsal root ganglia primary sensory neurons[105] and in the rat nodose ganglion[106]. The enteric nervous system, therefore, can be directly implicated in intestinal immune defence towards intestinal microbiota.

Very recently, a dominant role for the MyD88-dependent signaling pathway in early endotoxin-induced murine ileus was shown, as MyD88 deficient mice were completely protected from endotoxin-induced ileus and the induction of the inflammatory cascade, whereas TRIF deficiency only partially protected the mice from ileus[98].

A study by Kuno *et al*[107] reported a beneficial effect on LPS-induced changes in colonic motility in the guinea pig after administration of TAK-242, a selective TLR4 signal transduction inhibitor, illustrating again the potential therapeutic options of interference with the TLR4 pathway.

POSSIBLE NOVEL THERAPEUTIC STRATEGIES

The current treatment strategies for sepsis as described in the Sepsis Guidelines 2008 were described in the first part of this paper. They largely rely on general supportive measures such as fluid resuscitation, cardiovascular support and antimicrobial treatment. The use of corticosteroids is controversial and the use of recombinant activated protein C is reserved for patients with severe sepsis and a high risk of death[2,3,10,108,109]. More specific anti-inflammatory therapy such as antilipopolysaccharide treatment and blocking of proinflammatory cytokines such as TNFα and IL1β were ineffective or have failed to improve mortality so far[108]. Selective digestive tract decontamination is not recommended in the sepsis guidelines[3]. Selective digestive tract decontamination reduces infections (mainly pneumonia) and mortality in a general population of critically ill and trauma patients, however no studies are available in patients with severe sepsis or septic shock. The juries were split on the issue of selective gut decontamination with equal numbers in favor and against the recommendation of the use of selective gut decontamination. They agreed that further research was needed in patients with severe sepsis or septic shock and they voted against inclusion in the current guidelines[3].

Therapeutic interventions related to gastrointestinal motility, secretion and epithelial barrier function might be effective as well. As ileus plays a pathogenic role in the maintenance of sepsis and multiple organ failure and in the occurrence of secondary infections, prokinetic therapy might be of value. Theoretically, ileus could be overcome, increasing gastrointestinal motility thereby reducing bacterial stasis, bacterial overgrowth and bacterial translocation and so interrupting the activation of the inflammatory cascade. Motility can, for instance, be enhanced by stimulation of excitatory neuronal pathways or by direct smooth muscle effects. For the treatment of postoperative ileus *per se*, comprehensive reviews are available in the literature[13,40,110,111]. So far, treatment of postoperative ileus is also largely supportive and based on a multimodal approach including fluid restriction, optimal (epidural) analgesia, minimally invasive surgical procedures, early mobilization and early oral feeding.

Before going into more detail regarding potential therapeutic targets, two general considerations about drug development need to be taken into account. First of all, it has been clearly shown over the last few years that the transition of promising drug targets in experimental animal models towards beneficial clinical trials is hard, difficult to predict and few products have been commercialized[112,113]. For instance, with regard to the therapeutic pipeline for irritable bowel syndrome (IBS), another disorder associated with motility and sensitivity disturbances and a possible pathogenic role for inflammation, several drugs could not finalize the research developmental trajectory towards clinical use: the neurokinin receptor antagonists and fedotozine, a peripheral κ-opioid receptor agonist, could not prove clinical efficacy in phase ⅡB and phase Ⅲ trials, although promising results were shown in experimental studies. Other drugs have been withdrawn despite clinical benefit due to safety reasons, impacting the risk-benefit ratio, such as tegaserod and alosetron. The definition of clear end points and biomarkers with clinical relevance emphasizing symptoms and quality of life need to be considered[112,113]. Secondly, interference with the patients' immune system could affect their first line defence against other infections and could affect patient wound healing[114]. In the 1990s, several controlled clinical trials of immunomodulators in severe sepsis were undertaken but failed to show benefit or even increased mortality[11,108].

As evidence for a bidirectional communication between the neuroendocrine and immune systems accumulates in the pathogenesis of inflammatory ileus (for hypothetical scheme, see Figure 1), and also in IBD and IBS, interference with the immune system seems a promising therapeutic strategy[40,64,114-117]. The interplay between the epithelial barrier function, intestinal motility and secretion, and the cellular function of immunocytes can be influenced by neuronal and immune mediators with therapeutic potential. Several potential target cells, mediators or intracellular pathways can be proposed such as mast cells, residential macrophages, glial cells, the cholinergic anti-inflammatory pathway, afferent neurons, intracellular signaling pathways such as egr-1, p38 and TLR4 transduction inhibitors, together with a plethora of neuroactive substances released by damaged or inflamed tissue such as cytokines (IL-1β, IL-6), chemokines, prostaglandins and leukotrienes, neuropeptides, growth factors (NGF), hormones, histamine, tryptase, *etc*[40,114-116]. In the field of inflammation-associated ileus, therapeutic strategies combining anti-inflammatory with prokinetic properties might have more potential for future drug development.

Ghrelin is one of these compounds with therapeutic potential, as it has been shown to possess anti-inflammatory properties together with prokinetic activity[114,118-120]. Ghrelin and the ghrelin receptor are expressed by lymphocytes, monocytes and dendritic cells. Activation of the ghrelin receptor results in an inhibition of proinflammatory cytokine expression and an increase in survival in various inflammatory disease models[114,118]. Furthermore, ghrelin and ghrelin receptor agonists are proven to be prokinetic in animal models of delayed gastric emptying and in patients with gastroparesis of different origins (for review see[119]). Experimental studies with ghrelin and clinical trials with synthetic ghrelin agonists (TZP-101, TZP-102) and a selective growth hormone secretagogue (ipamorelin) are currently ongoing. Ipamorelin, a ghrelin mimetic, proved beneficial in a postoperative ileus model in the rat[121]. In a phase ⅡB trial, the ghrelin agonist TZP-101 accelerated recovery of the gastrointestinal tract after (partial) colectomy compared to placebo[122]. Specifically related to sepsis, it was shown that ghrelin ameliorates the gut barrier dysfunction by reducing serum HMGB1 and by activation of the vagus nerve *via* central ghrelin receptors[123]. We have shown the prokinetic potential of ghrelin and the ghrelin receptor agonist, growth hormone releasing peptide 6, in a septic mouse model[26]. In a simi-

lar model, Dixit *et al*[124] showed potent anti-inflammatory effects of ghrelin on the mRNA expression of IL-1β, IL-6 and TNFα in the liver, spleen, lungs and mesenteric lymph nodes of LPS-treated mice, associated with an attenuation of the LPS-induced anorexia. The combination of prokinetic and anti-inflammatory properties enhances the potential of ghrelin-related drugs in inflammation-induced ileus. These effects are hypothesized to be mediated by the anti-inflammatory cholinergic pathway and by interactions with immune cells[118,119,120,124].

Another intestinal hormone with potential in the treatment of postoperative ileus is glucagon-like peptide 2 (GLP-2). Activation of GLP-2 was recently reported to ameliorate inflammation and intestinal dysmotility associated with surgical manipulation of the bowel in a murine model[125]. The beneficial effects on the proinflammatory milieu were more pronounced in the mucosa compared to the intestinal muscularis and the authors speculate that the protective effect of GLP-2 is associated with mucosal inflammation and barrier dysfunction, not excluding interference with the anti-inflammatory vagal pathway[125].

The endocannabinoid system is involved in the regulation of physiological and pathophysiological responses in the gastrointestinal tract such as food intake, emesis, gastric protection, gastric secretion, visceral sensation, gastrointestinal motility, intestinal inflammation and cell proliferation[126]. CB1 and CB2 receptors are the classical receptors for all kinds of cannabinoid agonists, whereas non-CB receptor-mediated effects of cannabinoids are also described[126]. Generally it is accepted that CB1 activation inhibits gastrointestinal motility in different regions of the gastrointestinal tract, whereas the role of CB2 receptors in the control of physiological motility is less clear. Both CB1 and CB2 receptors have been shown to play a role in motility in pathophysiological inflammatory conditions[126]. In septic ileus in mice and rats, CB1 and CB2 receptor antagonists protected against LPS-induced changes in motility (*in vitro* and *in vivo*), without affecting the increase in TNFα, but reduced the increase in IL6 in the group treated with a low dose of LPS[127]. We demonstrated that septic ileus in mice was associated with an upregulation of intestinal CB1 but not CB2 receptors and an increase in fatty acid amide hydrolase (FAAH), which is the principal catabolic enzyme for fatty acid amides. Cannabidiol, a non-psychotropic cannabinoid without significant binding activity to CB1 or CB2 receptors, however, further decreased the LPS-induced motility disturbances *in vivo*[128]. Very recently, we showed that LPS-induced sepsis in mice resulted in a hyperactivation of glial cells, an increase in intestinal mast cells, macrophages and TNFα. These effects were abrogated by cannabidiol treatment and associated with a decrease in S100B expression, suggesting a crucial role of glial cells (personal communication)[68].

As mast cells and residential muscular macrophages are proposed as key players in the pathogenesis of ileus, targeting these cells might also show therapeutic potential. Depletion and inactivation of macrophages in rodents prevented intestinal inflammation and postoperative ileus[61]. As interfering with immune responses could also affect wound healing as stated above, it is important to investigate the effect of macrophage depletion on the healing process. Very recently, it was shown that pharmacological and genetic inhibition of muscularis macrophages in mice did not affect intestinal anastomotic healing[129]. Whether this approach is translational to the human situation remains questionable. However, interference with the macrophages could occur at several levels. Additionally, interference with the TLR4 receptor, as described above, offers a therapeutic potential.

An interesting way to downregulate macrophages is to interfere with the cholinergic anti-inflammatory pathway; for instance, by the use of α7 nicotinic acetylcholine receptors agonists, direct vagal stimulation or the use of acetylcholine esterase inhibitors[40,69]. Electrical stimulation of the vagal nerve attenuates systemic inflammation in rodent models of endotoxemia, cecal ligation and puncture, and intestinal manipulation[76-79]. Pretreatment with the α7 nAChR, AR-R17779, prevented postoperative ileus and the inflammatory reaction in mice[80]. Nicotine itself has also been tested in clinical trials for IBD, however its use is jeopardized by its toxicity[117,130]. Electrical stimulation of the vagus nerve remains an invasive procedure and pharmacological interference with acetylcholine receptors might have side-effects; both treatment strategies need further optimization. Recently, stimulation of the vagal nerve in a rodent postoperative model by enteral administration of lipid-rich nutrition was shown to be beneficial and to be mediated by a CCK-dependent vagal mechanism[131].

With regard to mast cells, a first randomized and placebo-controlled pilot study in humans undergoing major abdominal surgery for gynecological malignancy showed that ketotifen, a mast cell stabilizer with histamine 1 receptor blocking activity, restored gastric emptying, ameliorated abdominal cramping and tended to improve colonic transit[67]. Mast cells can also be modulated at several levels including development, homing, secretory phenotype, stabilization, interference with membrane receptors or downstream pathways, or blocking the effect of the mediators released[132]. Potential drugs or drug targets are cromolyn, ketotifen, Syk kinase inhibitors; even TLR antagonists and blockers of the mediators released by mast cells such as tryptase, proteases, chymase, prostaglandins, leukotrienes, cytokines and growth factors, chemokines and neuropeptides (CRF and substance P)[63,132].

CONCLUSION

The impact of the gastrointestinal tract on the initiation and maintenance of inflammation and secondary infections involved in the pathogenesis of multiple organ failure is generally accepted. Therapeutic interventions related to gastrointestinal motility can therefore be effective in sepsis treatment, as bacterial translocation and activation of the inflammatory cascade can be put on hold. This hypothesis stresses the important link between gastrointestinal inflammation and motility.

Both endotoxic and postoperative animal models offer the opportunity to study the role of, and interference with, inflammation related to gastrointestinal motility and sensitivity. The complex interplay within the gastrointestinal wall between mast cells, residential macrophages and glial cells on the one hand, and neurons and smooth muscle cells on the other hand, forms the basis for further research towards novel therapeutic strategies. Many molecules have potential to intervene with this complex cellular interplay at the level of intracellular signaling pathways, chemokines, cytokines, neuroactive substances and mediators involved in afferent neuronal signaling and the anti-inflammatory vagal pathway. The combination of anti-inflammatory properties and prokinetic properties within one drug seems the most promising route for translational research.

Abstract

Low bone mineral density is an established, frequent, but often neglected complication in patients with inflammatory bowel disease (IBD). Data regarding the diagnosis, therapy and follow-up of low bone mass in IBD has been partially extrapolated from postmenopausal osteoporosis; however, the pathophysiology of bone loss is altered in young patients with IBD. Fracture, a disabling complication, is the most important clinical outcome of low bone mass. Estimation of fracture risk in IBD is difficult. Numerous risk factors have to be considered, and these factors should be weighed properly to help in the identification of the appropriate patients for screening. In this editorial, the authors aim to highlight the most important clinical aspects of the epidemiology, prevention, diagnosis and treatment of IBD-related bone loss.

Key words: Inflammatory bowel disease; Crohn's disease; Osteoporosis; Osteopenia; Prevention

Peer reviewer: Kevin Cheng-Wen Hsiao, MD, Assistant Professor, Colon and rectal surgery, Tri-Service General Hospital, No. 325, Sec. 2, Cheng-Kung Rd, Nei-Hu district, Taipei 114, Taiwan, China

INTRODUCTION

Low bone mineral density (BMD) is an established complication in patients with inflammatory bowel disease (IBD). Data regarding IBD-related osteoporosis needs further clarification.

Epidemiological data of bone loss are very conflicting, due to different study methodologies, patient groups, geographical distribution, *etc*[1-3].

Fracture is the most important clinical outcome of low bone mass. However, estimation of fracture risk in IBD is difficult. Numerous risk factors need to be considered, and these factors should be weighed properly to obtain relevant answers to the questions of the clinicians. If possible, fractures should be prevented, but excessive drug use should be avoided. There are also national guidelines available on the screening, diagnosis, treatment and follow-up of bone loss in IBD patients. However, some of these protocols are based on results obtained from idiopathic and postmenopausal osteoporotic patients in the general population.

In this editorial, the authors aim to summarize the available epidemiological data, identify the appropriate patients for screening for low bone mass at diagnosis and during follow-up, and review the available therapy.

EPIDEMIOLOGICAL DATA

The prevalence of low bone mass in IBD shows a wide variation in the published literature for several reasons. Of note, even diagnostic criteria for osteoporosis and low bone mass were different in the early epidemiological studies.

The gold standard for the measurement of BMD is dual X-ray absorptiometry (DEXA). BMD values are expressed in relation to the young adult mean (T-score) or age-matched controls (Z-score). Low bone mass (or osteopenia) was defined by the World Health Organisation (WHO) in 1994[4] as the value of BMD more than 1 standard deviation below the young adult mean, but less than 2 standard deviations below this value (T-score < -1 and > -2.5). WHO defines osteoporosis as a value of BMD 2.5 standard deviations or more below the young adult mean (T-score < -2.5). Using the Z-score to define osteoporosis in IBD (Z-score of < -2) seems more logical in clinical practice, because most of the patients are diagnosed with IBD before reaching the peak bone mass. However, epidemiological studies performed more recently use the WHO definitions for evaluating the rate of osteoporosis and low bone mass in IBD.

The prevalence and pathogenesis is very different in the 2 main types of IBD [Crohn's disease (CD) and ulcerative colitis (UC)], but unfortunately, most of the early studies show cumulative epidemiological data[1-3,5]. Osteoporosis and low bone mass or a Z-score less than -2.0 has been found in as many as 30.6% of 75 unselected IBD cases[1]. Similarly, the rate of osteoporosis defined by a T-score below -2.5 was 15% in a very similar IBD population[5]. Further uncontrolled studies reported the incidence of osteoporosis in CD as low as 12%[6,7], but the incidence of osteoporosis was estimated to be as high as 18%-42%[8,9] in unselected cohorts.

Other studies showed that altered bone metabolism was more frequent in CD than in UC[10,11] at diagnosis. Jahnsen *et al*[10] reported that mean Z-scores were significantly lower in patients with CD compared to patients with UC or healthy subjects. Low BMD can be a feature of CD at the time of diagnosis[11], while the impact of steroid treatment leading to low BMD seems to be more significant in UC. The main limitation of both the early and recently performed epidemiological studies is the limited number of patients.

In addition, epidemiological data depend also on the site of BMD measurement. BMD was reported to be lower at the hip than at the spine in most studies[8,9,12]. Therefore, in contrast to postmenopausal and corticosteroid-induced osteoporosis, IBD-associated osteoporosis may be at least as common at the hip. Furthermore, osteoporosis has a north-to-south gradient in the normal population. Therefore, the geographical location of the referred population in the IBD-related bone studies should also be considered as a possible confounder, e.g. low bone mass was found to be 58% in a Dutch cohort[7], while it was 32.4% in a Turkish population[13].

Fracture risk in IBD

The clinical consequence of osteoporosis is increased risk of fractures. Osteoporosis is more predictive of bone fracture than is high cholesterol level in predicting myocardial infarction.

Studies performed in the general postmenopausal osteoporotic population indicate that the risk of fracture approximately doubles for each SD reduction in BMD. The increase in fracture risk for a specific change in BMD depends on the technique used, the site measured, and the fracture type. Measurements at the hip predict hip fracture with greater power than do measurements at the lumbar spine or forearm. An increase in this site-specific relative risk (RR) is estimated to be as high as 1.5 to 3.0 for each SD decrease in the general population[14], but age is also an important predictive factor[15]. Hip fractures have long been associated with an increased mortality rate in the general population but excessive mortality has also been shown to accompany non-hip fractures and low bone mass[16].

There are only a few population-based studies regarding the fracture risk in IBD populations. In a Canadian population-based study the incidence of fracture among persons with IBD has been shown to be 40% greater than in the general population[17] [RR: 1.41, 95% confidence interval (CI): 1.27-1.56]. The RR for hip and spine fractures was 1.47 (95% CI: 1.03-2.10) and 1.54 (95% CI: 1.04-2.3), respectively in CD and 1.69 (95% CI: 1.26-2.28) and 1.9 (95% CI: 1.36-2.65), respectively in UC. In another North American study from Olmsted County, the RR for an osteoporotic fracture was as high as 1.4 (95% CI: 0.7-2.7) in CD patients compared to matched controls[18]. The risk of spine fracture was shown to be even higher (RR: 2.2, 95% CI: 0.9-5.5).

A Danish population-based study[19] evaluated the fracture risk in IBD patients compared to age- and gender-matched controls. The RR of fractures requiring hospitalization was 1.19 (95% CI: 1.06-1.33) in CD patients, and 1.08 (95% CI: 0.97-1.20) in patients with UC. The risk of spine fracture was higher compared to the risk of hip fracture (1.87 *vs* 1.1). The main limitation of this study was that fractures which did not lead to hospitalization (e.g. of the radius) were not taken into account.

All the above-mentioned studies show that IBD patients are exposed to an increased risk of fracture over matched control populations, and the greatest increased risk is found in elderly patients with IBD. A smaller Danish study[20] found that female gender, postmenopausal status, a family history of fracture and current smoking have an impact on fracture risk with RR of 2.5, 1.87, 2.4 and 1.3, respectively. The hazard ratio (HR) increased by 1.3-fold (95% CI: 1.1-1.5) in the Olmsted County study per decade.

Vertebral fractures are frequently asymptomatic; occur spontaneously or after minimal trauma, for example coughing, bending or lifting. Their incidence may be underestimated in all populations. In the general population it is estimated that only one-third of spine fractures are diagnosed. Similarly, approximately 14% of all spine fractures in CD patients were asymptomatic in a European/Israeli study[21]. The fracture rate was very similar in patients with low bone mass compared to patients with normal BMD. The fracture rate correlated with age in females but not in males.

A minority, 4 out of 63 (6.3%) vertebral fractures caused clinical symptoms in a group of 156 CD patients with reduced BMD[22] and, in contrast to the above-mentioned European/Israeli study, lumbar BMD was significantly reduced in patients with fractures compared with those without any fractures, but BMD at the femoral neck did not show any correlation with fracture risk. Approximately one third of patients with fractures were younger than 30 years in this cohort, showing that this complication may affect young patients and deserves further clinical attention.

Another important risk factor is the medical therapy used, especially corticosteroids. There is evidence that even a low dose, e.g. 2-7.5 mg prednisolone daily results in increased fracture risk[23] in any indications. A prominent role of corticosteroid therapy regarding the risk of fractures was proved in a British study. The General Practice Research Database identified all the registered IBD patients (n = 16 550) and created an age and gender matched group for evaluating the RR of fracture. The adjusted HR for hip fracture was 1.68 (95% CI: 1.01-2.78) and 1.41 (95% CI: 1.36-3.18) in CD and UC, respectively. Multivariate analysis identified both current and cumulative use of corticosteroids and the use of opioid analgesics as risk factors. This association was reported by Bernstein *et al*[24] in CD patients.

However, in a recent study of 224 CD patients, 36% had normal BMD, whereas osteopenia and osteoporosis occurred in 51% and 13%, respectively[25]. The same study demonstrated that vertebral fractures in CD patients occurred with an equal frequency in patients with low or normal BMD, regardless of corticosteroid use. Of note, the prevalence of osteoporosis in the general population is estimated to be as high as 15%. Finally, a change in the bone mass in IBD patients during short-term follow-up was shown to be low[26,27].

SCREENING

Screening for low bone mass at diagnosis is not recommended in all IBD patients. However, altered bone mineral metabolism can be observed at the diagnosis of IBD in a considerable proportion of patients, and fractures seem to correlate with BMD in the general population. Current guidelines of The American Gastroenterological Association[28] and the British Society of Gastroenterology[29] suggest determination of the risk of low bone mass and fracture individually to identify patients at risk before performing screening.

Advanced age was described to be one of the most important risk factors for IBD-associated osteoporosis, however some studies showed lower BMD at an earlier age[30,31]. Schoon *et al*[7] observed a greater risk of reduced BMD in patients with CD aged less than 18 years at diagnosis in comparison to those diagnosed at over 18 years, in their Z-score-based evaluation. Of note however, peak bone mass is achieved usually at the third decade of life.

Osteoporosis is more frequently in males with CD and UC as well. The incidence of male hypogonadism was observed to be as high as 6% (3 of 48 CD patients) in an early study[32] by measurement of serum testosterone and gonadotrophin hormone concentrations.

The duration of disease may have a valuable impact on bone metabolism in IBD for several reasons, including disease severity and drug therapy. It has been shown that cumulative steroid dose is associated with low BMD[6,26,30,33]. Corticosteroids are more often given to patients with frequent relapse of the disease, but an increased level of inflammatory cytokines seems to be an independent risk factor for accelerated bone loss[34,35]. Overall, duration, severity of disease, and corticosteroid use are difficult to separate as independent factors associated with reduced BMD.

The UK Consensus Group recommended DEXA in all patients taking 7.5 mg or more of prednisolone daily for 6 mo or more and suggested medical therapy with bisphosphonates if the T-score was < -1.5[36]. Steroid requirement is often unpredictable and bone loss associated with steroids may occur early, thus DEXA screening is recommended in all patients aged < 65 years when steroids are prescribed[29].

Of note, treatment with budesonide was associated with significantly higher BMD compared with prednisolone, in patients with active ileocecal CD[37].

Disease site (small bowel, ileum, colon) had no effect on BMD[6,11,38], and furthermore, the existence of low bone mass was observed in CD with fistulizing behavior[39].

Studies investigating the vitamin D status in patients with IBD reported conflicting results. The physiological concentration of 25(OH)-vitamin D was observed in some studies[11,40,41], while others reported reduced levels[42,43].

In summary, the guidelines suggest identifying at risk patient groups in whom DEXA screening is recommended. Screening densitometry should be performed in all IBD patients who are postmenopausal, male patients older than 50 years, in patients who receive corticosteroid therapy for more than 3 mo and in patients with a history of low trauma fracture or symptoms of hypogonadism[28]. Kornbluth *et al*[44] concluded that implementation of the guidelines led to the detection of low bone mass in a majority of patients who met the guidelines' criteria for DEXA screening.

PREVENTION AND TREATMENT

General and disease-specific risk factors may play a role in IBD-related low bone mass. Some can be modified[45], while others, such as age, genetics[46], and previous bowel resection[38] cannot be altered. Data indicate that CD-associated osteopenia can be correlated with the basic pathology of the disease itself rather than malabsorption or complications of steroid treatment[47]. Elevated local tumor necrosis factor-α (TNF-α) and other systemic inflammatory cytokine concentrations seem to be a common pathological pathway between CD- and IBD-associated osteoporosis[39,48].

Lifestyle changes can modify the BMD in IBD. Smoking cessation[49,50] and avoiding the consumption of excessive amounts of alcohol[51] are beneficial. Benefits of regular, low-impact exercise on bone mass have been proven in a randomized controlled trial[52].

Treatment should be offered if there is a reduced BMD, and other risk factors for fracture are present. However, specific treatment is licensed only for postmenopausal osteoporosis in most countries.

Adequate calcium intake has been suggested to be an important determinant of bone mass[53,54], however there was no correlation between the intake of calcium and BMD in CD patients[55,56].

Efficacy of vitamin D in the prevention of bone loss in IBD was investigated by Vogelsang *et al*[57]. There was no significant change in bone density in patients receiving 1000 IU/d vitamin D for 1 year, but significant bone loss was observed in the control group. Bernstein *et al*[58] analyzed the efficacy of this strategy in patients treated with glucocorticoids. Twenty-four patients were randomized to receive vitamin D and calcium (125 IU and 500 mg, respectively) or no treatment. There were no significant differences in BMD of the femoral neck and the vertebrae at 1 year. Calcium and vitamin D intake was not a predictor of bone status in premenopausal women; however their intake was less than the recommended dose[55]. In our study, calcium and active vitamin D supplementation was beneficial in changing markers of bone turnover (collagen crosslinks and osteocalcin) short-term in patients with active CD[59].

The active form of vitamin D is the hydroxylated 1,25(OH)$_2$-vitamin D. There are only limited data available regarding the presumable advantage of 1,25(OH)$_2$-vitamin D in CD-related osteoporosis. The efficacy of different forms of vitamin D was examined in a small cohort of CD patients in a Hungarian study[59]. The authors could show that 1,25(OH)$_2$-vitamin D had a prominent short-term beneficial effect on bone metabolism compared to 25(OH)-vitamin D.

In summary, editors of the guidelines recommend adequate calcium (1000-1500 mg/d) and vitamin D (400-800 IU/d) supplementation for IBD patients[28,29]. Efficacy of the substitution should be monitored by measuring serum calcium, 25(OH)-vitamin D and parathyroid hormone concentrations, even in CD with extensive small bowel involvement. In addition, the more frequent occurrence of kidney stones should be considered in IBD.

Earlier studies indicated that hormone replacement therapy in postmenopausal women with IBD may be favorable. Clements *et al*[60] showed a beneficial effect of hormone replacement therapy in 47 postmenopausal women with IBD, however 20 who received corticosteroids showed a smaller increase in BMD at the spine. Estrogen as monotherapy or in combination with progestin can be applied, but risk factors of myocardial infarction and stroke should be considered, as well as regular screening for breast cancer.

Bisphosphonates are the most potent anti-resorptive agents and are widely used for the treatment of osteoporosis and prevention of fractures in the general postmenopausal women population. They are also effective in the prevention of steroid-induced osteoporosis. Alendronate, risedronate and ibandronate are all proved to be effective in the therapy of IBD-associated osteoporosis[61-63]. The Royal College of Physicians guidelines[64] recommend that treatment with a bisphosphonate should be considered for all aged over 65 years on commencing steroids (or those under 65 who have already had a an osteoporotic fracture).

Administration of a TNF-α inhibitor was associated with improved BMD in CD. Long-term maintenance therapy improved BMD[65,66], and infliximab improved the bone metabolism in CD with inflammatory[35] and fistulizing behavior CD[39]. These data prove that TNF-α plays a fundamental role regarding CD-related bone loss. In the case of corticosteroid dependency, any corticosteroid-sparing agents (azathioprine, 6-mercaptopurine and methotrexate) may be of value, but a direct beneficial effect has only been proven with anti-TNF-α agents. However, bone loss itself is not an indication for anti-TNF therapy in IBD.

There is a lack of data regarding the therapeutic efficacy of calcitonin, strontium ranelate and recombinant parathyroid hormone administration in IBD patients, but there is no theoretical reason why these treatments would not be as effective as in postmenopausal women.

FOLLOW-UP

DEXA is not only the gold standard for the diagnosis of low bone mass, but it also seems to be the most appropriate method for follow-up. The most important limitation of this modality is that assessing small changes is difficult. The minimum relevant change is 3%-5% at the spine, and 4%-6% at the hip. In addition, the quality of the bone is also important and is not adequately measured by DEXA.

IBD patients who receive optimal calcium and vitamin D supplementation should undergo repeated DEXA measurements every 2 years. In the case of further bone loss despite appropriate supportive therapy, the initiation of antiresorptive therapy should be considered.

Corticosteroid-induced bone loss continues at a slower rate after the first year of therapy[67], therefore DEXA is suggested in each subsequent year of corticosteroid use or until the intervention threshold (e.g. T-score < -1.5) has been reached[29].

Serum osteocalcin, bone specific alkaline phosphatase and carboxyterminal polypeptide of type 1 collagen are used as markers of bone formation, whereas collagen degradation products such as urinary deoxypyridinoline, the carboxypeptidase of type 1 collagen and N-telopeptide cross-linked type 1 collagen are indicators of bone resorption.

Data regarding the usefulness and cost-effectiveness of these markers of bone metabolism in the diagnostic workup and the follow-up are controversial[68,69] because

of the heterogeneity in patients cohorts, methods and markers used in the different trials. Osteocalcin levels have been reported to be reduced by some authors[12,40], but normal concentrations were observed by others[9,70]. Type 1 collagen degradation products were shown to be increased[9,12] or normal[71] or elevated[70] as well. These conflicting data suggest that behavior of the disease, clinical status, medical therapy and some possible other factors may affect the bone turnover in IBD patients. It is possible that bone turnover is increased and resorption is predominant in patients with active disease, whereas low bone turnover is more prevalent in patients with quiescent disease.

None of the above-mentioned studies suggests the use of these serum or urinary markers in the diagnostic or follow-up workup in everyday practice.

The gastroenterologist should keep in mind that patients receiving any of the above-mentioned therapies should undergo appropriate screening examinations. Patients on calcium and vitamin D should be screened for kidney stones and nephrocalcinosis, but the interval of the screening is not well defined. All women receiving hormone replacement therapy should be followed up regularly for gynecological malignancies, and the risk-benefit ratio should also be considered and discussed.

CONCLUSION

Bone turnover is altered in patients with IBD. Many important risk factors (e.g. age, disease severity, medical therapy) have been identified, but a significant proportion of data regarding the diagnosis, therapy and follow-up of low bone mass in IBD have been extrapolated from postmenopausal osteoporosis. General and disease specific risk factors should be considered, particularly in patients with CD, and patients at risk of fractures should be identified and selected for diagnostic procedures. Lifestyle changes and adequate calcium and vitamin D supplementation should be introduced, and cessation of smoking is mandatory. Bisphosphonates should be considered in patients with existing osteoporosis, advanced age and long-term corticosteroid therapy. The vigilance of the physician, appropriate screening and follow-up, supportive therapy and specific control of the bone loss are all important for the optimal treatment of this complication in patients with IBD.

Abstract

In recent years, therapies for follicular lymphoma (FL) have steadily improved. A series of phase Ⅲ trials comparing the effect of rituximab with chemotherapy *vs* chemotherapy alone in treating FL have indicated significant improvements in progression-free survival (PFS) and overall survival. Recent studies have found that prolonged response durations and PFS were obtained with maintenance therapy using rituximab or interferon after completion of first line therapy. For patients with relapsed or refractory FL, phase Ⅱ studies have assessed the effectiveness of combination therapies using a Toll-like receptor-9 agonist (1018ISS), oblimersen sodium (a Bcl-2 antisense oligonucleotide), bendamustine, and rituximab, as well as veltuzumab, a new humanized anti-CD20 antibody, and epratuzumab. In addition, the effectiveness of yttrium-90 ibritumomab tiuxetan and iodine-131 tositumomab as radioimmunotherapies has been reported. Furthermore, three phase Ⅲ studies on an idiotype vaccine are near completion. Unfortunately, these vaccines, which appeared highly effective in phase Ⅰ and Ⅱ trials, do not appear to result in prolonged PFS. This report will summarize the current knowledge on therapies for treatment of FL, and will conclude with a brief discussion of feasible future options for effective treatments. Lastly, we added descriptions of the management of gastrointestinal FL, which is considered to be controversial because it is rare.

Key words: Anti-CD20 monoclonal antibody (rituximab); Follicular lymphoma; Idiotype vaccines; Immunoradiotherapy; Treatment strategies

INTRODUCTION

Indolent lymphoma is a lymphoma that tends to grow and spread slowly, in contrast to an aggressive lymphoma which grows and spreads quickly (Definition of Indolent lymphoma. MedTerms™: the medical reference for Medicine Net.com. http://www.medterms.com/script/main/hp.asp). While the majority of indolent lymphomas, which make up 30%-35% of all non-Hodgkin's lymphoma (NHL) subtypes, are follicular lymphoma (FL)[1], their incidence is low in Western, Asian, and less-developed countries[2]. The incidence of FL accounts for only about 6.7% of all malignant lymphomas in Japan[3]. Its incidence is rapidly increasing in Western and Asian countries[4].

FLs are often detected by the swelling of systemic lymph nodes in adults. FLs are pathologically characterized by medium-sized centrocytes and large-sized centro-

blasts found in normal follicles as proliferative cells. Most FLs are detected at an advanced stage (Ann Arbor stage Ⅲ or Ⅳ), and it was considered difficult to find a better treatment than the "watch and wait strategy" during the asymptomatic phase[5-8]. In recent years, various novel treatment options have been developed for patients with advanced stage FL, including (1) monoclonal antibodies (rituximab, veltuzumab (a new humanized anti-CD20 antibody), and epratuzumab) with conventional chemotherapy; (2) radioimmunotherapy (yttrium-90 ibritumomab tiuxetan and iodine-131 tositumomab); and (3) idiotype vaccines. These therapeutic procedures have a major impact on overall survival (OS) of patients.

Hiddemann *et al*[9] published a review article on the treatment of FL in 2005, however, in recent years, a review article especially on the recent progress in therapeutic procedures for FL has not been published. In this paper, current knowledge regarding therapies for treating FL will be summarized. By reviewing recent publications (in particular, those published in the past 2 years), a variety of treatment options, including novel monoclonal antibodies, immunoradiotherapy, combination therapies of these with conventional chemotherapies, and idiotype vaccines will be discussed. Idiotype vaccines are a nascent treatment alternative for which phase Ⅲ studies are now near completion[10]. If successful, these vaccines can potentially be developed as customized anti-cancer treatments optimized for each patient.

The gastrointestinal (GI) tract is the most common site of extra-nodal NHL, accounting for 30%-40% of primary extra-nodal NHL[11,12]. The histologic subtypes in most primary GI-NHL are mucosal-associated lymphoid tissue (MALT) lymphoma, or high-grade and aggressive B-cell lymphoma[13-16]. GI-FL is rare, and the frequency of this entity accounts for around 2% of GI-NHL[16-18]. However, recently, because capsule endoscopy and double balloon endoscopy of the small intestine were generalized widely in Japan, the number of primary GI-FL patients has tended to increase. In this review manuscript, I describe the treatment strategies for primary GI-FL, which remains controversial.

TREATMENT IS GUIDED BY THE HISTOLOGIC SUBTYPE AND EXTENT OF DISEASE

At present, the following factors are taken into account when deciding the course of treatment for FL: (1) histopathological types and grade of malignancy; (2) lesions where FL developed (in particular, those of extra-nodal origin); and (3) staging classification (Ann-Arbor classification).

Histopathological types and grade of malignancy

In FL, pathological subtypes are classified as grade 1-3a and 3b depending on the number of centroblasts per field of view. FL grade 3b, which is based on the presence or absence of residual centrocytes (3a *vs* 3b), was optional in the 2001 WHO classification[4], but is now mandatory[19]. Details of the grade of malignancy are shown below: grade 1: Number of centroblasts is 0 to 5 per high-power histological view; grade 2: Number of centroblasts is 6 to 15 per high-power histological view; grade 3: Number of centroblasts is more than 15 per high-power histological view; grade 3a: Centrocytes are present; grade 3b: Centroblasts proliferate in sheet formation and no centrocytes are present.

In nodal FL, several studies suggest that this histological grading is a good predictor of prognosis[20,21]. However, the treatment is not decided directly by this histological grading alone, and is decided mainly by staging (extent of disease) or both staging and histological grading[22].

In nodal FL, the proportions of grade 1, grade 2, and grade 3 are 40%-60%, 25%-35%, and 20%, respectively[23], while those of grade 1, grade 2 and grade 3 in GI-FL are 84.4%, 11.3%, and 4.3%, respectively[24]. The proportion of grade 1 in GI-FL accounts for about 85% and commands a majority compared with that in nodal FL. Furthermore, on staging, the proportions of stage Ⅰ and Ⅱ are 66.3% and 26.9%, respectively, and that of stage Ⅰ plus Ⅱ (early stage) is 93.2%. The degrees of grading are considered to be similar to those of staging, which is to say that in early-stage FL, the patients at stage Ⅰ and Ⅱ, and with grade 1 and 2 (Grade 1 and 2 FL is histologically subclassified as "Low-grade" FL[22]) command a majority. With regard to treatment strategies, especially in nodal FL, radiation therapy will be selected first.

In recent years, even if FL patients were found to be in the early stages (stage Ⅰ or Ⅱ), rituximab was included as a treatment strategy in those with nodal or extra-nodal FL to prolong survival, in fact, rather than the so-called "Watch and Wait strategy", aggressive therapies including mainly rituximab tend to be started in the earlier stages in Japan[25].

Lastly, in GI-FL, because the disease lesions are limited, several types of therapeutic options, for instance, surgical resections (plus adjuvant chemotherapy with rituximab, or rituximab alone), or in cases with no symptoms, chemotherapy plus rituximab or the "Watch and Wait strategy" are selected. There is no standard regimen, and the treatment policy is controversial in GI-FL[24]. Conversely, it has been reported that in nodal FL, most cases are found to be in stage Ⅲ or Ⅳ at the diagnosis with FL[22], however, the proportions of grade 1 and 2 are about 50% and 30%, respectively (the proportion of grade 1 plus 2 is 80%)[23], and the degree of grading is considered to be dissimilar to that of staging. The number of patients with stage Ⅲ or Ⅳ and low-risk or low-grade (grade 1 or 2) FL seems to be comparatively high. There is no standard therapy for advanced, but low-grade FL to date[24], however, a combination of classical chemotherapy and rituximab is now considered to be a main therapy for advanced FL, because it has been reported that this combination prolonged survival compared with several classical chemotherapies alone.

The treatments for nodal FL and GI-FL are summarized as follows: Most cases with GI-FL have been found to have focal disease and an early-stage condition at diagnosis, with a histological grading of low-grade, while nodal FL is almost always found at an advanced stage. However, the degrees of cellular malignancies were considered to be divided into two groups of low-grade and high-grade, and the proportions were reported to be about 80% and 20%, respectively. When physicians discuss the treatment strategy for nodal FL and GI-FL, they should consider the differences in the status between these two groups, however, both the treatment regimens for stage Ⅲ-Ⅳ low-grade FL, and stage Ⅲ-Ⅳ high-grade FL do not differ at present.

Furthermore, there is little or no difference in the natural clinical course or the response to treatment between the two groups with histological grade 1 and 2 FL. There is a consensus that physicians initiating different therapeutic options for FL seems meaningless[22].

Biological malignancy is also an important factor which is directly associated with the degree of differentiation of tumor cells, the increased speed of tumor cells themselves, infiltrative growth into the surrounding tissue, and liability to metastasize, which is important for prognosis. With this in mind, the following subjects should be discussed: (1) How many degrees, and how to add the factors with differences in histological grading of the tumor cells themselves, to the factors regarding the selection of therapeutic procedures induced by the differences in staging; and (2) Is the present method of grading FL cells really suitable for FL? This is one of the problems which is very difficult to solve, but very important when discussing the treatment strategies for FL in the future.

Grade 3b FL shows the same clinical features as diffuse, large B-cell lymphoma (malignant lymphoma with a medium grade of malignancy). This grade does not show a slow and indolent course, but rather the same clinical course as an aggressive lymphoma. Some studies have identified biological differences between these 2 subtypes, with most instances of FL Grade 3b being more closely related to diffuse large B-cell lymphoma at the molecular level[26,27]. Consequently, the treatment policy for Grade 3b should be guided in a similar fashion to that of aggressive lymphoma. Given that tumor progression is very different, Grade 3b FL needs to be distinguished from the other grades of FL.

Clinical staging of FL

Clinical staging of nodal FLs is determined using the Ann-Arbor Clinical Staging system[28], while GI-FLs are classified by the Lugano staging classification of GI tract lymphoma[29], which is the modified version of the Ann-Arbor staging system for GI tract lymphomas.

Most indolent lymphomas like FL are discovered at an advanced stage because they grow slowly and only a small number of FL cases have systemic symptoms.

Most FLs are detected at an advanced stage (Ann Arbor stage Ⅲ or Ⅳ), and it was considered difficult to find a better treatment than the "Watch and Wait strategy" during the asymptomatic phase[5-7].

Table 1 Lugano staging classification of gastrointestinal tract lymphoma[29]

Stage	
Ⅰ	Tumor confined to GI tract Stage primary site or multiple, noncontiguous lesions
Ⅱ	Tumor extending into abdomen from primary GI site Nodal involvement
Ⅱ$_1$	Local (paragastric in cases of gastric lymphoma and paraintestinal for intestinal lymphoma)
Ⅱ$_2$	Distant (mesenteric in the case of an intestinal primary; otherwise paraaortic, paracaval, pelvic, inguinal)
ⅡE	Penetration of serosa to involve adjacent organs or tissues [enumerate actual site of involvement, e.g. ⅡE (pancreas), ⅡE (large intestine), ⅡE (post intestinal wall)] Where there is both nodal involvement and penetration involving adjacent organs, the stage is denoted using both a subscript (1 or 2) and E, e.g. Ⅱ$_1$E (pancreas)
Ⅳ	Disseminated extra-nodal involvement, or a GI tract lesion with supradiaphragmatic nodal involvement

GI: Gastrointestinal.

However, randomized controlled trials (RCT) using a new anti-CD20 antibody have shown that combination therapy with traditional chemotherapy plus rituximab prolonged OS in patients compared with conventional chemotherapy alone. Rather than "Watch and Wait", combination therapy with monoclonal antibody and chemotherapy is considered standard therapy even when non-symptomatic FL is discovered. Even if FL patients are found to be in the early stages (stage Ⅰ or Ⅱ), rituximab has been introduced as a treatment strategy in patients with nodal FL to prolong survival, in fact, aggressive therapies including mainly rituximab have recently been initiated in the earlier stages in Japan.

Radiation therapy can treat cases in the limited stage (stage Ⅰ A). Cases need to be assessed to determine whether they are in stage Ⅰ using a PET-CT scan (difficult to detect FL), systemic CT scan, bone marrow puncture, or aspiration.

For FL cases in the limited stage (Ann-Arbor staging Ⅰ A), additional radiation therapy directed at focal lesions after 3 or 4 courses of chemotherapy can be considered in addition to the integral therapy.

In cases where a portion of the tumor remains, additional radiation therapy can be performed after chemotherapy.

Chemotherapy should be performed for cases at a stage ≥ Ⅱ.

The Lugano staging classification of GI tract lymphoma[29] is shown in Table 1.

This is the modified version of the Ann Arbor staging system for GI tract lymphomas. Yamamoto *et al*[24] reported that 128 (66.3%) and 52 (26.9%) of 193 GI-FL cases were at stage Ⅰ and Ⅱ, respectively. Surprisingly, over 90% of all GI-FL cases which have been reported in the English literature were at the early stages, and had localized disease. Yamamoto *et al*[24] suggested that this was because of the low tendency of GI-FL to disseminate outside the GI tract, and the higher frequency of grade 1 lymphoma

in GI-FL cases. Furthermore, the GI-FL cases, in which sufficient examinations and successful treatments were performed due to non-advanced stages and no symptoms, were likely to be reported and submitted for publication in the English literature. The possibility of bias in the selection of the reported cases or case series should be raised. Nodal involvement can be found in GI-FL cases, and this status is classified as stage Ⅱ1 (involvement of local lymph nodes) or Ⅱ2 (involvement of distant lymph nodes).

Disease distribution (unifocal or multifocal) is important for selecting treatments in GI-FL patients.

In recent years, Yamamoto *et al*[24], Kodama *et al*[30] and Higuchi *et al*[31] have claimed that other disease lesions in the small intestine were newly and secondarily found in over 70% of GI-FL patients who had disease lesions in the GI tract except the small intestine in which capsule endoscopy and double-balloon endoscopy were performed. If the patients were found to be multifocal, rituximab with or without conventional chemotherapy may be administered.

THERAPIES FOR NODAL FOLLICULAR LYMPHOMAS

Traditional therapies for FL

FL cases are categorized into pathological grades (1 to 3) based on the proportion of cells comprised by centroblasts. This grading system is an important factor in determining prognosis. For example, grade 3 lymphoma is the most malignant and has the fastest progression, however, chemotherapy can be an effective treatment. In contrast, grade 1 represents the least malignant lymphoma and has a very slow progression where the patient may die 10 years after the time of diagnosis. However, this lymphoma is unaffected by chemotherapy. Thus, prognosis between grades 1 and 3 is strikingly different[32-35].

In cases of NHL not restricted to FL, and in those where GI invasion is observed, patients risk lethal complications if the chemotherapy is too strong. These complications include bleeding or GI perforations due to tumor necrosis. Thus, GI complications must be considered when selecting the appropriate treatment regimen. However, choosing mild chemotherapy or low-intensity radiation therapy due to GI lesions may also result in insufficient treatment of systemic lymphoma. Therefore, the success or failure of a treatment depends on both the grade and degree of disease spread.

Several therapies have been tested for treating GI-FL. In grade 1 and 2 FLs, some treatment options include an alkylating agent alone, a combination therapy with multiple drugs, and high-dose chemotherapy in combination with hematopoietic stem cell transplantation. However, no more than 10% of patients maintain complete remission during the 5-year post-treatment period. Additionally, while the median survival time is seven to 10 years, the survival rate declines progressively and becomes lower than that of aggressive lymphoma after approximately 15 years[36]. Given that the effects of chemotherapy have so far been suboptimal, and disease progression is very gradual even without treatment, some have suggested initiating treatment only after symptoms actually emerge. In the interim, they recommend careful observation. In the early stages (Ⅰ and Ⅱ) of FL, radiation therapy has been effective, resulting in a control rate of 95% and a 10-year progression-free survival (PFS) rate of 40%-52%. In these circumstances, radiation therapy is considered standard treatment because there is promise of healing or remission for an extensive time period. However, the likelihood of radiation therapy actually being performed clinically is low, even in the US[37]. While studies are being conducted to observe the effects of rituximab and irradiation combination therapy, no long-term observational data exist. Recently, therapeutic drug-targeting molecules such as rituximab have played an important role in prolonging the lives of FL patients. In the treatment of systemic FL, 6 cycles of CHOP and rituximab (R-CHOP) combination therapy appear to be the most promising. During a phase Ⅲ RCT, R-CHOP was found to significantly prolong survival compared to CHOP therapy alone[38,39].

Randomized control studies of rituximab plus conventional chemotherapy vs conventional chemotherapy alone

Results of RCTs comparing response rate, duration, disease-free survival (DFS), and OS between patients treated with conventional chemotherapy and those treated with rituximab plus conventional chemotherapy have been reported (Tables 2 and 3). Details are described below.

Rituximab plus chemotherapy trials for previously untreated FL: Several studies have shown that conventional chemotherapy plus rituximab for previously untreated FL prolonged various types of survival (Table 2).

A multicenter randomized phase Ⅲ trial of 321 patients with previously untreated FL compared cyclophosphamide, vincristine, prednisolone (CVP) alone to rituximab plus CVP (R-CVP, $n = 162$)[40]. OS was higher with R-CVP compared to CVP alone (OS, $P = 0.029$; 4-year OS: 83% *vs* 77%, respectively).

The randomized trial conducted by the German Low-grade Lymphoma Study Group involved treating patients with previously untreated FL with 6-8 cycles of CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) combined with rituximab (R-CHOP, $n = 223$) or CHOP alone ($n = 205$). A significantly higher overall response (OR) rate (96% *vs* 90%, respectively, $P = 0.011$) and prolonged duration of remission ($P = 0.001$) were achieved with R-CHOP. The first 3-year OS with 6 deaths in the R-CHOP group was superior to that of 17 deaths in the CHOP group ($P = 0.016$)[38,39].

The FL-2000 randomized trial involved subjecting patients with previously untreated FL to treatment with either CHVP (cyclophosphamide, adriamycin, etoposide and prednisolone) plus interferon-α2a (CHVP+I arm)

Table 2 Results of different randomized trials comparing chemotherapy with chemotherapy plus rituximab in previously untreated patients with follicular lymphoma

Study	No. of patients, pathological types, staging	Median age (yr)	Complete response rate	End point				
				Median progression-free survival	Event-free survival	Median response duration	Time to treatment failure	Overall survival
CVP[40]	n = 321, FL, Stage Ⅱ-Ⅳ	52	$P < 0.0001^b$			$P < 0.0001^b$	$P < 0.001^b$	$P = 0.029^a$
R-CVP	n = 162	Unknown	41%	34 mo		Prolonged than CVP alone (lower relapse rate than CVP alone)	Prolonged than CVP alone	83% (at 4 yr)

CHOP	n = 231	55	15.6%	20.2 mo	71.9% (at 3 yr)

$^aP < 0.05$, $^bP < 0.01$, statistically significant. GLSG: German Low-Grade Lymphoma Study Group; FL: Follicular lymphoma; EORTC: European Organization for Research and Treatment of Cancer; HOVON: Hemato-Oncologie voor Volwassenen Nederland; NCIC: National Cancer Institute of Canada; CTG: Clinical Trial Group (Canada); BNLI: British National Lymphoma Investigation; ALLG: Australasian Leukaemia and Lymphoma Group; NLG: Nordic Lymphoma Group; (R-)CHOP: (Rituximab plus) cyclophosphamide, doxorubicin, vincristine, and prednisone; (R-)FCM: (Rituximab plus) fludarabine, cyclophosphamide, mitoxantrone.

or CHVP combined with rituximab plus interferon (R-CHVP+I arm). After a median follow-up of 5 years, event-free survival was significantly different between the two arms (37% in the CHVP+I arm *vs* 53% in the R-CHVP+I arm, $P = 0.001$). However, the 5-year OS rate between the two arms of CHVP+I and R-CHVP+I was not significantly different[41].

Herold *et al*[42] randomly assigned previously untreated patients with advanced MALT lymphoma, FL, or mantle cell lymphoma (MCL) to one of two groups, either mitoxantrone, chlorambucil, prednisolone plus rituximab (R-MCP, n = 181) or MCP alone (n = 177). All patients who achieved a complete or partial remission were treated with maintenance interferon until they relapsed. They reported the results from the primary analysis population of patients with FL alone, who constituted the majority of patients (56%) recruited to the trial (n = 201; R-MCP, n = 105; MCP, n = 96). OS rate in the R-MCP group significantly improved compared to the MCP alone group (4-year OS rate, 87% *vs* 74%, respectively, $P = 0.0096$).

Table 4 Results of different randomized trials comparing no maintenance with maintenance therapy with rituximab or interferon after first line therapy in patients with follicular lymphoma

Author(s) or studies, maintenance therapy	No. of patients, target disease and randomization to therapies	Median age (yr)	Initial therapy, *n* (%)	CR rate	End point		
					Median PFS	Median response duration	Overall survival
GLSG[43,46]	*n* = 105, relapsed or refractory FL					*P* = 0.035[a]	
R-FCM	*n* = 52	59	R-FCM: 41 (79) FCM: 11 (21)		Not reached	32/41 (78%)	
Observation	*n* = 53	61	R-FCM: 40 (75) FCM: 13 (25)		Not reached	21/40 (53%)	
ECOG1496 study[47]	*n* = 311, stage Ⅲ-Ⅳ indolent lymphoma (282 of 311 had FL)	61	CVP	*P* = 0.00006[b]		*P* = 0.012[a]	All: *P* = 0.05 FL: *P* = 0.08 (trend towards significance)

Observation	*n* = 158		CVP	7%		All: 33% (at 3 yr) FL: 33% (at 3 yr)	All: 86% (at 3 yr) FL: 86% (at 3 yr)

[a]*P* < 0.05, [b]*P* < 0.01, statistically significant. CR: Complete response; PFS: Progression-free survival; FL: Follicular lymphoma; GLSG: German Low-Grade Lymphoma Study Group; (R-)FCM: (Rituximab plus) fludarabine, cyclophosphamide, mitoxantrone; ECOG: Eastern Cooperative Oncology Group; (R-)CVP: (Rituximab plus) cyclophosphamide, vincristine, and prednisone.

Randomized trials of rituximab with chemotherapy in relapsed or refractory FL: A randomized trial which involved fludarabine, cyclophosphamide, mitoxantrone (FCM) alone or rituximab plus FCM (R-FCM)[43] was conducted with 30 FL patients allocated to the FCM and 35 FL patients to the R-FCM treatment groups (total 65 patients). The OR rate [complete response (CR) plus partial response rate] for R-FCM was 94% compared to 70% for FCM alone. The R-FCM arm was significantly superior with respect to PFS ($P = 0.0139$) compared to FCM for FL[43] (Table 3).

In another randomized trial, a total of 465 patients with relapsed or resistant FL were randomly assigned to CHOP or R-CHOP induction therapy groups. Those in complete remission or partial remission were then randomly assigned to maintenance therapy with rituximab or an observation alone group. Median PFS for rituximab maintenance or observation alone after the second randomization was significantly different (51.5 mo *vs* 14.9 mo, respectively). In relapsed or resistant FL, rituximab maintenance improves PFS after R-CHOP induction[44] (Table 3).

Maintenance therapy with rituximab or interferon after first-line therapy

The question as to whether or not maintenance therapy should be carried out has been raised. In one case involving rituximab, Hainsworth *et al*[45] concluded that maintenance therapy is not required because first-line therapy with rituximab was effective in cases without maintenance therapy. Conversely, several studies have shown that rituximab as a maintenance therapy after conventional chemotherapy or interferon as maintenance therapy after conventional chemotherapy plus rituximab prolonged response duration and PFS (Table 4).

Forstpointner *et al*[43,46] reported that maintenance therapy with rituximab was effective after salvage therapy with rituximab along with conventional chemotherapy, and significantly prolonged the response duration in patients with FL. Hochster *et al*[47] also reported the results of the randomized phase Ⅲ ECOG1496 trial, and found that maintenance rituximab after cyclophosphamide, vincristine, and prednisone prolonged PFS in patients with stage Ⅲ-Ⅳ (advanced) untreated indolent lymphoma (282 out of a total of 311 patients had FL). Among patients with FL alone, OS at 3 years in the patients with and without maintenance rituximab was 91% and 86%, respectively; HR = 0.6, log-rank one-sided $P = 0.08$). Further, Herold *et al*[42] reported that rituximab added to first-line MCP, followed by interferon maintenance, prolonged survival in patients with advanced FL.

New anti-cancer agents with rituximab in patients with relapsed or refractory FL

Several studies have recently reported on phase Ⅱ trials involving combination therapy with new anticancer agents plus rituximab for relapsed or refractory FL patients. Friedberg *et al*[48] conducted a Phase Ⅱ trial of a new anticancer agent, Toll-like receptor-9 (TLR-9) agonist, combined with rituximab in patients with relapsed and refractory FL. TLR-9 agonists have pleiotropic effects on both innate and adaptive immune systems, including increased antigen expression, enhanced antibody-dependent cell-mediated cytotoxicity, and T helper cell type 1 shift in the immune response. They reported that clinical responses were observed in 48% of patients and that the overall median PFS was 9 mo. Pro *et al*[49] conducted a Phase Ⅱ multicenter study of combination therapy with oblimersen sodium, a Bcl-2 antisense oligonucleotide, and rituximab in recurrent B-cell NHL patients. They reported an OR rate in relapsed FL patients of 60% (eight complete remissions and four partial remissions out of 20 patients), and that the combination of oblimersen sodium and

rituximab seemed to be most effective in patients with indolent NHL including FL. Further, Robinson *et al*[50] evaluated the phase Ⅱ multicenter study of bendamustine plus rituximab in patients with relapsed indolent B-cell and MCL who showed no resistance to prior rituximab. They reported that OR rate, median duration of response, and median PFS time were 92% (41% CR), 21 and 23 mo, respectively, and concluded that the combination of bendamustine plus rituximab is suitable for relapsed indolent lymphoma centering on FL and MCL.

New anti-CD20 antibody for indolent B-cell lymphoma

Veltuzumab is a humanized anti-CD20 antibody with structure-function differences from chimeric rituximab. Morschhauser *et al*[51] evaluated a multicenter phase Ⅰ / Ⅱ dose-finding trial in relapsed/refractory B-cell NHL evaluating the efficacy of veltuzumab. They reported that in FL, 24 (44%) of 55 patients had objective responses, and CR were seen in 15 (27%) patients. In marginal zone lymphoma, 5 (83%) of 6 patients had OR. Veltuzumab appeared to be safe and active at all doses tested with rituximab, including dose levels less than those typically used, encouraging further study.

New antibodies against targets other than CD20

Epratuzumab, a humanized IgG1 unconjugated anti-CD22 antibody: Leonard *et al*[52] conducted an international multicenter, phase 2 trial in patients with recurrent FL and reported durable CR with a combination of epratuzumab and rituximab. They reported an OR rate of 85% in patients with FL who had Follicular Lymphoma International Prognostic Index (FLIPI) risk scores of 0 or 1 (n = 13), whereas 28 patients with intermediate or high-risk FLIPI scores ($\geqslant$ 2) had an OR rate of 39%.

Inotuzumab ozogamicin (CMC-544), the calicheamicin-conjugated anti-CD22 monoclonal antibody and rituximab: Takeshita *et al*[53] studied the effect of CMC-544, a calicheamicin-conjugated anti-CD22 monoclonal antibody, used alone or in combination with rituximab, and investigated the quantitative alternations on the target molecules of CD20, CD22, CD55and CD59 in cells obtained from patients with B-cell malignancies or Dauji and Raji cells. The reduction in CD55 and the preservation of CD20 after incubation with CMC-544 support the rationale for the combined use of CMC-544 and rituximab[48]. This new antibody may also be used for the treatment of FL in the future.

Galiximab, a human-primate chimeric anti-CD80 antibody: Galiximab is a human-primate chimeric anti-CD80 antibody with excellent tolerability and single-agent effectiveness for recurrent FL[54]. A phase Ⅰ / Ⅱ trial of the combination of rituximab plus galiximab demonstrated a 64% response rate and a 12.1 mo median PFS[55]. A phase Ⅲ trial comparing rituximab with the combination of rituximab plus galiximab in patients with relapsed FL is ongoing.

Other potential new antibodies against targets other than CD20, CD22, or CD80: Phase Ⅰ / Ⅱ trials testing new CD52 (alemtuzumab), CD2 [MEDI-507 (siplizumab)], CD30 [SGN-30 and MDX-060 (iratumumab)], and CD40 (SGN-40)[56] antibodies are now ongoing or have been completed in aggressive lymphoma patients. It is possible that these new antibodies will be used for the treatment of FL in the near future.

Radioimmunotherapy for FL

In 2005, Kanzius *et al*[57,58] provided new systems and methods for radio-frequency-induced hyperthermia plus radioimmunotherapy using ^{90}Yttrium-ibritumomab tiuxetan or ^{131}Iodine-tositumomab for patients with NHL containing FL.

Recently, radioimmunotherapy using ^{90}Yttrium-ibritumomab tiuxetan or ^{131}Iodine-tositumomab, which are produced from anti-CD20 monoclonal antibodies combined with radioactive materials, has been performed for refractory or relapsed FL patients. Recent reports in this field are listed below:

^{131}Iodine-rituximab for relapsed indolent B-cell lymphoma (FL and MALT lymphoma): Illidge *et al*[59] evaluated a novel protocol using 4 weekly infusions of 375 mg/m^2 rituximab followed by 2 fractions of ^{131}Iodine-rituximab, preceded by a 100 mg/m^2 predose of rituximab in patients with relapsed indolent B-cell lymphoma (FL and MALT lymphoma). OR rate was 94%, with a CR rate of 50%. Median time to progression was 20 mo, which is significantly longer than that for the last qualifying chemotherapy (P = 0.001).

^{90}Yttrium-ibritumomab tiuxetan for previously untreated FL: Jacobs *et al*[60] reported on a trial involving patients with previously untreated FL who received CHOP-R (three cycles of CHOP and four additional weekly rituximab cycles). CR rate after CHOP-R, as assessed by CT and PET imaging, was 40% and 46%, respectively. CR rate further improved following ^{90}Yttrium-ibritumomab tiuxetan) to 82% and 89%, respectively.

^{90}Yttrium-ibritumomab tiuxetan for advanced FL after first remission: Morschhauser *et al*[61] described that consolidation of first remission with ^{90}Yttrium-ibritumomab tiuxetan in advanced-stage FL is highly effective with no unexpected toxicities, prolonging PFS by 2 years and resulting in high partial remission-to-complete remission conversion rates regardless of the type of first-line induction treatment.

^{90}Yttrium-ibritumomab tiuxetan for relapsed or refractory indolent B-cell lymphoma (containing FL): Tobinai *et al*[62] reported that radioimmunotherapy with ^{90}Yttrium-ibritumomab tiuxetan is safe and highly effective in patients with relapsed or refractory indolent B-cell lymphoma (small lymphocytic, lymphoplasmacytic, mantle cell, follicular, MALT, and splenic marginal zone lympho-

Table 5 Results of phase Ⅲ clinical trials of idiotype vaccines in follicular lymphoma

Study	No. of patients, target disease	Regimen of induction therapy	Eligibility	Vaccine type	Vaccine production methodology	Primary end point
						Survival types, *P*-value, significance
Biovest	*n* = 177, untreated FL	PACE or R-CHOP	CR	Id-KLH/GM-CSF	Rescue hybridoma	Disease-free survival, $P > 0.05$, not significant
Genitope	*n* = 287, untreated FL	CVP	CR, PR	Id-KLH/GM-CSF	Recombinant DNA	Progression-free survival, $P > 0.05$, not significant
Favrille	*n* = 349, untreated or recurrent FL	Rituximab	CR, PR, SD	Id-KLH/GM-CSF	Recombinant DNA	Time to progression, $P > 0.05$, not significant

FL: Follicular lymphoma; PACE: Prednisolone, doxorubicin, cyclophosphamide and etoposide; R-CHOP: Rituximab plus cyclophosphamide, doxorubicin, vincristine, prednisolone; CVP: Cyclophosphamide, vincristine, prednisolone; CR: Complete response; PR: Partial response; SD: Stable disease; Id-KLH: Idiotype-keyhole limpet hemocyanin; GM-CSF: Granulocyte-macrophage colony stimulating factor.

mas) pretreated with rituximab-based therapy. They also reported OR and CR rates of 83% and 68%, respectively, and a median PFS of 9.6 mo.

Idiotype vaccine

Idiotype vaccines are based on active immunization of patients against their own tumor idiotype, and could lead to an even more effective and sustained anti-tumor response than the passive infusion of anti-idiotype antibodies[10]. Vaccine therapies, which utilize antibodies against the characteristic tumor idiotype for each FL patient, are expected to result in anti-tumor effects, improved response rates, and prolonged survival times. These benefits are anticipated because these vaccine therapies can potentially be developed as personalized anti-cancer treatments optimized for each patient. Several phase Ⅰ / Ⅱ clinical trials for idiotype vaccines in FL have been conducted in the last 20 years, of which about 10 have been published and demonstrate the effectiveness of idiotype vaccines[63-71]. In particular, Inogès *et al*[69] reported that most vaccinated patients with FL had significantly longer DFS after second remission. These encouraging results from phase Ⅰ / Ⅱ trials initiated three phase Ⅲ RCTs (Biovest, Genitope, and Favrille). These phase Ⅲ trials are now essentially completed and have been evaluated (Table 5). While there initially seemed to be a significant prolongation of PFS during the early stages of the trials, all of these phase Ⅲ trials ultimately failed to prolong PFS[10].

McCormick *et al*[72] recently produced patient specific recombinant idiotype vaccines in plants against follicular B cell lymphoma and conducted a phase Ⅰ trial. They reported that more than 70% of patients developed cellular or humoral immune responses, and that 47% of patients developed antigen-specific responses[72]. Results from future phase Ⅱ / Ⅲ trials will be of great interest.

THERAPIES FOR GASTROINTESTINAL FOLLICULAR LYMPHOMAS

Very recently, Yamamoto *et al*[24] performed a literature review of Japanese cases with GI-FL. This review on GI-FL is well written and I believe may help with regard to the recent confusion surrounding the selection of treatment for GI-FL patients.

I would like to summarize this editorial, especially the treatment of GI-FL patients, by focusing on the main points covered in this review article.

Introduction of GI-FL

The GI tract is the most common site of extra-nodal NHL, accounting for 30%-40% of all primary extra-nodal NHL[11,12]. While GI involvement in aggressive NHL (nodal aggressive NHL with involvement of the GI tract) is common, primary GI-NHL is rare, and GI-FL is very rare. It has been reported that the histologic subtypes in most primary GI-NHL are MALT lymphoma or high-grade B-cell lymphoma[13-16]. GI-FL is rare, and this histology represents around 2% of all GI-NHL[16-18]. In addition, over 90% of GI-FL cases which have been published in the English literature to date were early stages (stage Ⅰ and Ⅱ)[24]. Very recently, Yamamoto *et al*[24] performed a review of the literature on patients with GI-FL, and claimed that the diagnosis, prognosis, and treatment of GI-FL remain largely unknown mainly because of its rare frequency. However, recently, because capsule endoscopy and double balloon endoscopy of the small intestine were generalized in Japan, the number of primary GI-FL patients has tended to increase.

Prognosis in patients with GI-FL

The long-term clinical outcome of GI-FL is as yet unclear. Damaj *et al*[73] reported that there was no significant difference between two groups of patients treated by either conventional chemotherapy with rituximab, and patients without therapy based on the "Watch and Wait" concept regarding the median time to disease progression (37.5 mo) and the median relapse-free time (31 mo).

Treatment for GI-FL

Many patients with GI-FL have been identified in the early stages, however, the disease lesion is not unifocal, but multifocal, with another lesion in the small intestine, and rituximab with or without chemotherapy for many non-advanced GI-FL cases may be initiated according to the regimens for nodal FL[24].

However, because it has been reported that there was

little difference in survival between GI-FL patients with and without therapies, and GI-FL itself is very rare, the management of GI-FL remains controversial at present[24].

In recent years as capsule endoscopy and double balloon endoscopy of the small intestine have been generalized in Japan, we have the opportunity to identify GI-FLs, particularly in patients with asymptomatic GI-FL. In addition, the therapeutic options in these patients such as whether conventional chemotherapy with rituximab should be initiated or no therapy with the "Watch and Wait" concept requires careful consideration. This decision may be very important.

Yamamoto *et al*[24] recently performed a literature review and reported the actual numbers in each therapeutic category. Observation without therapy was only about 25%, while some kind of therapy was performed in 75% of all primary GI-FL patients. Chemotherapy (or combination with other therapies) was performed in about 50% of all primary GI-FL patients.

Chemotherapy or other therapies tend to be performed more frequently in patients with GI-FL rather than observation without therapy based on the "Watch and Wait" concept. The reasons why GI-FL patients undergo chemotherapy are as follows: (1) because of increasing acceptability, generalization, dissemination, and recognition of the concepts of primary GI-FL and the chemotherapy regimens as treatment strategies for GI-FL; and (2) because it has been reported that the combination of conventional chemotherapy with rituximab can prolong the survival of nodal FL patients compared with conventional chemotherapy alone, rituximab-containing regimens have been administered to a growing number of GI-FL patients. Future prospective studies on the treatment of GI-FL patients are awaited with great interest.

CURRENT AND FUTURE DEVELOPMENTS

Therapeutic monoclonal antibodies, such as the anti-CD20 antibody, provide significant benefits to patients with NHL. In particular, since 2000 various phase Ⅲ trials have utilized RCTs to compare the treatment effects of conventional chemotherapies *vs* the addition of rituximab to these therapies. The results indicated that the combination of rituximab and conventional chemotherapy was generally superior both in terms of response rates and survival times. Thus, this combination therapy is gradually becoming the standard. Recently, phase Ⅰ and Ⅱ trial results assessing the initial use of a novel anti-CD2 antibody, alone or in combination with rituximab, in patients with recurrent aggressive lymphoma have been published. Determining the usefulness of these new antibodies compared to rituximab requires randomized comparative trials or a demonstration of their effectiveness in rituximab-refractory or relapsed patients after completion of first-line rituximab therapy.

Phase Ⅲ trials comparing galiximab with rituximab combined with galiximab are in progress. Similar studies will be necessary in the future to assess the effectiveness of many novel anti-CD20 antibodies. Some anticipate that rituximab, in combination with these new anti-CD20 antibodies, will improve response rates and prolong PFS.

Radioimmunotherapy with ^{90}Yttrium-ibritumomab tiuxetan or ^{131}Iodine-rituximab is safe and highly effective in patients with relapsed or refractory (resistant to rituximab-based therapy) FL. The effectiveness of these radiolabeled antibodies needs to be compared to other kinds of therapies in randomized trials.

Idiotype vaccines are immunotherapeutic products which have been developed to induce active and long-lasting immune responses against lymphoma cells. Most of these vaccines use the tumor B cell idiotype (the variable region of the surface immunoglobulin) as a tumor-specific antigen. Several phase Ⅰ / Ⅱ clinical trials of idiotype vaccines in FL have been conducted over the last 20 years, of which about 10 have been published and demonstrate the effectiveness of these vaccines. These encouraging results, which seem to indicate that the vaccines prolonged PFS, initiated three phase Ⅲ RCTs (Biovest, Genitope, and Favrille), however, all of these phase Ⅲ trials ultimately failed to prolong PFS.

Primary GI-FL is very rare, and this histology represents around 2% of all GI-NHL. Many patients with GI-FL have been found at the early stages, however, the disease lesion is not unifocal, but multifocal, with another lesion in the small intestine, and rituximab with or without chemotherapy for many non-advanced GI-FL cases may also be initiated based on the regimens for nodal FL. However, it has been reported that there was little difference in survival between GI-FL patients with and without therapies. Furthermore, GI-FL itself is very rare, and the management of GI-FL remains controversial at present. Yamamoto *et al*[24] recently performed a literature review and reported that only about 25% of primary GI-FL patients underwent observation without therapy, and chemotherapy (or combination with other therapies) was performed in about 50% of all primary GI-FL patients. Ongoing research on biomarkers to guide individualized GI-FL therapy may provide invaluable information which will lead to the establishment of a standard therapeutic regimen.

CONCLUSION

This article summarized the existing information on FL treatment through an extensive literature review which included the latest research on drug therapies. The various treatments reviewed included novel monoclonal antibodies, immunoradiotherapy, and the combination of these therapies with conventional chemotherapy. Moreover, idiotype vaccines, a nascent treatment alternative for which phase Ⅲ trials are now near completion, were discussed. If successful, the latter can potentially be developed as personalized anti-cancer treatments optimized for each patient. This article concluded with a brief discussion on potential future developments in the treatment of FL.

ACKNOWLEDGMENTS

I thank Dr. Haruka Hirono, Dr. Katsuhiko Hasegawa, Professor Kenji Soga and Professor Koichi Shibasaki for their help in manuscript publishing. I also thank Ms. Eriko Maruyama for help in language editing. Further, I also thank Ms. Hiromi Yamada and Mr. Tetsuo Higuchi for their help in gathering the necessary references.

Abstract

Radiotherapy with concurrent chemotherapy and surgery represent the main treatment modalities in esophageal cancer. The goal of modern radiotherapy approaches, based on recent technological advances, is to minimize post-treatment complications by improving the gross tumor volume definition (positron emission tomography-based planning), reducing interfraction motion (image-guided radiotherapy) and intrafraction motion (respiratory-gated radiotherapy), and by better dose delivery to the precisely defined planning target volume (intensity-modulated radiotherapy and proton therapy). Reduction of radiotherapy-related toxicity is fundamental to the improvement of clinical results in esophageal cancer, although the dose escalation concept is controversial.

Key words: Esophageal cancer; Intensity-modulated radiotherapy; Positron emission tomography; Image-guided radiotherapy; Proton therapy

INTRODUCTION

Despite many advances in diagnostics and multimodal treatment (surgery, radiotherapy, chemotherapy), esophageal cancer is still generally associated with poor prognosis. The resectability rate in esophageal cancer is reported to be 60%-90%, but the resulting 5-year overall survival rate of resectable disease ranges from 10%-25%[1].

The incidence rate of esophageal cancer varies considerably according to geographical location. The highest rates occur in northern China and northern Iran, where incidence exceeds 1 in 1000 individuals[1]. By contrast, the incidence of esophageal cancer in most European countries and United States does not exceed 1/10 000[2,3].

Histologically, the main tumor types are squamous cell carcinomas and adenocarcinomas. Adenocarcinomas usually occur in the lower third of the esophagus, and this histological type has greatly increased in the last decade in several european countries and in the United States[4].

Currently, radiotherapy has a well-defined role in the management of esophageal cancer. Together with surgery and chemotherapy, it represents the main treatment modality in esophageal cancer. However, recent technological advances in radiation treatment (e.g. intensity-modulated radiotherapy, image guided-radiotherapy, positron emission tomography based radiotherapy planning, *etc.*) have progressively changed the practice, particularly in esophageal cancer. The main goal of these new approaches is the precise irradiation of the tumor while minimizing the risk of damage to healthy tissues.

CURRENT STRATEGIES

Multidisciplinary strategies for treatment

The choice of treatment strategy depends primarily on the patient's performance status, stage and extent of the disease, histology, and location of the primary tumor. The main curative treatment modalities are surgery and concurrent radiotherapy and chemotherapy. In most resectable thoracic esophageal carcinomas (stage ⅡA-ⅣA), concurrent chemoradiotherapy is provided as a preoperative treatment or as definitive treatment[5]. Meta-analyses confirmed that preoperative chemoradiotherapy substantially downstages the tumor[6], and the combination of preoperative chemoradiotherapy and surgery significantly increases 3-year overall survival and reduces the local-regional recurrence rate compared to surgery alone[7]. A recent meta-analysis by Gebski *et al*[8] evaluated ten randomized trials of preoperative chemoradiotherapy compared with surgery alone and suggested a 13% absolute difference in survival at 2 years with the combined treatment. Definitive chemoradiotherapy is the preferred modality for cervical esophageal cancer[5].

Recently, perioperative chemotherapy ECF (combination of epirubicin, cisplatin, and 5-fluorouracil) has become available for adenocarcinomas of the lower esophagus and the gastroesophageal junction, based on the results of the MAGIC trial. This randomized trial compared perioperative chemotherapy plus surgery to surgery alone in patients with adenocarcinoma of the stomach (74%), gastroesophageal junction (11%), and lower esophagus (14%). The 5-year survival rates were 36.3% for the perioperative-chemotherapy group compared to 23.0% for the surgery alone group[9].

The current standard scheme of concurrent chemoradiotherapy is radiotherapy (RT) in a dose of 50-50.4 Gy in 5-5.5 wk and 5-fluorouracil (5-FU) and cisplatin (cDDP) based concurrent chemotherapy. This recommended scheme is based on the results of two randomized trials. RTOG 8501 compared chemoradiotherapy in a dose of 50 Gy plus cisplatin and 5-FU *vs* radiotherapy alone in a dose of 64 Gy. This trial demonstrated the survival advantage of combined treatment (26% *vs* 0% at 5 years, $P < 0.001$), despite the lower dose of radiotherapy[10]. The intergroup study 0123 (RTOG 94-05) compared two arms with the same concurrent chemotherapy regimen (cDDP, 5-FU) and radiotherapy in doses of 64.8 Gy *vs* 50.4 Gy. There was no benefit from the higher dose with respect to the local failure rate (56% *vs* 52% at 2 years) or overall survival (31% *vs* 40% at 2 years)[11].

Standard of radiotherapy planning

The current standard of radiation treatment is a three-dimensional conformal radiotherapy (3D-CRT) based on three-dimensional computer tomography (CT) planning, with volumes delineated according to the International Commision on Radiation Units and Measurements (ICRU) reports 50[12] and ICRU Supplement 62[13].

The gross tumor volume (GTV) is defined on CT slices as a macroscopic primary tumor and involved lymph nodes. Endoscopic evaluation, endoscopic ultrasonography (EUS), and/or barium swallow are helpful. The endoscopic marking of the upper and lower extension of the visible tumor with metallic clips improves the definition of the GTV[14].

The clinical target volume (CTV) includes the GTV and areas at risk of a microscopic spread of the disease. In general, it is recommended to use the cranial and caudal margin of 4 cm due to submucosal spread and 1 cm radially. The same margins were used in the latest Radiation Therapy Oncology Group trials for esophageal cancer[15]. The lymph nodes at risk are included in the CTV according to the location of the primary tumor. For instance, the supraclavicular lymph nodes are included in the CTV in cervical esophageal cancer[16]. The PTV includes the CTV plus a margin for internal movements, mainly respiratory movements, (internal margin - IM; internal target volume - ITV) and for setup uncertainties (setup margin - SM). A margin of 1-2 cm beyond the CTV is used[15].

Dosimetric parameters of toxicity

Modern radiotherapy approaches have to evaluate the probability of organ-specific radiation toxicity. Organs at risk for esophageal cancer radiotherapy include lungs, heart, spinal cord, and for distal esophageal cancer, the liver and kidneys. Current knowledge of radiation toxicity derives from conventional and 3D-CRT data.

Lung toxicity: The dosimetric parameters of lung injury risk were studied mainly on lung cancer irradiation, but a few studies evaluated the risk of lung toxicity in esophageal cancer. In these studies, the increased risk of radiation pneumonitis correlated with heterogeneous parameters, such as mean lung dose (D_{lung} mean), the percentage of lung volume receiving at least 20 Gy (V20), 13 Gy (V13), 10 Gy (V10) or 5 Gy (V5)[17-22].

Graham *et al*[17] found a strong correlation between parameter V20 and the severity of pneumonitis in lung cancer patients. They reported the incidence of grade ⩾ 2 pneumonitis as 7%, 13% and 36% for patients with V20 in the range of 22%-31%, 32%-40%, and > 40%, respectively. Kwa *et al*[18] considered the mean lung dose to

be the most useful predictor of radiation pneumonitis in thoracic tumor radiotherapy. Based on pooled data from 540 patients irradiated for thoracic malignancy, the calculated risk of grade ⩾ 2 pneumonitis was 43%, 18%, and 11% for mean lung doses of 24-36, 16-24 and 8-16 Gy, respectively. Schallenkamp *et al*[19], in a retrospective study, found the strongest predictors of pneumonitis to be the parameters V13 and V10. Lee *et al*[20] found, in 61 patients irradiated preoperatively with concurrent chemotherapy for esophageal cancer, a significant increase of postoperative pulmonary complications in cases with V10 > 40%. A more recent study from the same institution suggested that the factor most strongly associated with postoperative pulmonary complications is the volume of lung spared to doses of ⩾ 5 Gy[21]. Tucker *et al*[22] analyzed 110 patients with preoperative chemoradiotherapy for esophageal cancer and, in that cohort, the mean lung dose and absolute volume of lung volume receiving < 5 Gy were similar predictors of postoperative pulmonary complications.

Other potential risk factors for radiation pneumonitis, besides the heterogenous dosimetric parameters, have been proposed, such as concurrent chemotherapy, age, pretreatment pulmonary functions, presence of chronic pulmonary disease, and others[23-25]. Radiation oncologists have to judge all dosimetric and non-dosimetric risk factors for pulmonary complications of radiotherapy before approval of the treatment plan.

Heart toxicity: The most common manifestation of late radiation injury to the heart is pericardial disease. It may present as acute pericarditis, as chronic pericardial effusion, or can be asymptomatic. The myocardium is involved less frequently, but it develops into more serious cardiomyopathy, usually characterized pathologically as diffuse fibrosis. From long term surviving patients after radiotherapy for Hodgkin's lymphoma or left sided breast cancer, there is evidence that radiotherapy can substantially increase the risk of acute myocardial infarction after radiotherapy. The reason is probably an acceleration of coronary artery disease as a late effect of the radiotherapy[26].

Wei *et al*[27] evaluated the influence of definitive radiochemotherapy on pericardial toxicity. They reported, in 101 patients, a development of pericardial effusion in 27.7 % at a median of 5.3 mo. The pericardium volume irradiated by a dose of 30 Gy or higher (V30) was identified to be a significant predictor of pericardial effusion risk. Tripp *et al*[28] reported a significant reduction of ejection fraction in 20 patients after neoadjuvant chemoradiotherapy (59% *vs* 54 %, $P = 0.01$), but without significant clinical morbidity. Inferior left ventricle ischemia is commonly found in patients having received radiotherapy for distal esophageal cancer. The ischemic segments usually occurr in volumes irradiated to a dose of 45 Gy or more[29].

Spinal cord toxicity: The recommended maximum dose on the spinal cord is 45 Gy[5]. Current data suggests that the probability of myelopathy at 45 Gy is 0.03%, and at 50 Gy, is 0.2%[30]. In this case, the risk of radiation myelopathy in esophageal cancer is low, with a standard prescribed dose of 50.4 Gy as it is easy to comply to the recommended dose limits for the spinal cord. An increased risk of myelopathy can be expected in connection with a dose escalation approach.

Liver toxicity and kidney toxicity: The liver and kidneys are considered to be organs at risk mainly in distal esophageal cancer when the irradiated volume involves the upper abdomen. The risk of radiation injury is minimal when the mean liver dose is < 30 Gy[31] and if at least 50% of the functional kidney parenchyma is spared doses > 20 Gy, which is considered to be the tolerance dose for the human kidney[32].

NEW TECHNOLOGIES IN RADIOTHERAPY

Positron emission tomography/CT based radiation therapy planning

In esophageal cancer there is a high interobserver variability in target volume delineation among tumor sites[33]. The precise definition of the primary tumor and involved lymph nodes is crucial for RT planning.

Positron emission tomography (PET) with 18F-fluoro-2-deoxyglucose (FDG) as a tracer, was documented in several centres as a highly effective diagnostic modality for the initial staging in patients with esophageal cancer, especially in revealing lymph node involvement or distant metastases[34], although the sensitivity for regional lymph node involvement of FDG-PET is controversial[35-38]. FDG-PET imaging became beneficial in radiotherapy planning in several tumor types, mainly in lung cancer, because of the significant impact on target volume delineation[39]. Therefore, the concept of integration of PET into the RT planning process was rational.

Vrieze *et al*[40] added FDG-PET imaging to the RT planning process based on conventional CT and EUS status in 30 patients. In six patients, eight positive lymph nodes were identified on FDG-PET alone, but not on CT/EUS imaging. In three of these patients the target volumes would be enlarged. By contrast, in eight patients, nine positive lymph nodes were identified only on CT/EUS, but not on PET. Therefore, the authors recommended not to reduce the CTV based on negative lymph node FDG-PET status.

In another study, Konski *et al*[41] evaluated the impact of PET and EUS compared with CT alone in radiotherapy planning in 21 patients. Their results showed a low sensitivity of FDG-PET alone to determine regional lymph node metastases. EUS detected significantly more patients with periesophageal and celiac lymphadenopathy compared to PET and CT. Patients with periesophageal lymphadenopathy on PET had a higher primary tumor standard uptake value. The authors also found that the length of the primary tumor (GTV) was significantly longer when determined on CT scans compared with PET scans. The mean length of the GTV, as determined on PET, CT and endoscopy was 5.4, 6.77 and 5.1 cm, respectively.

The sensitivity of FDG-PET alone is considered by some authors to be low[37,38]. Compared to FDG-PET

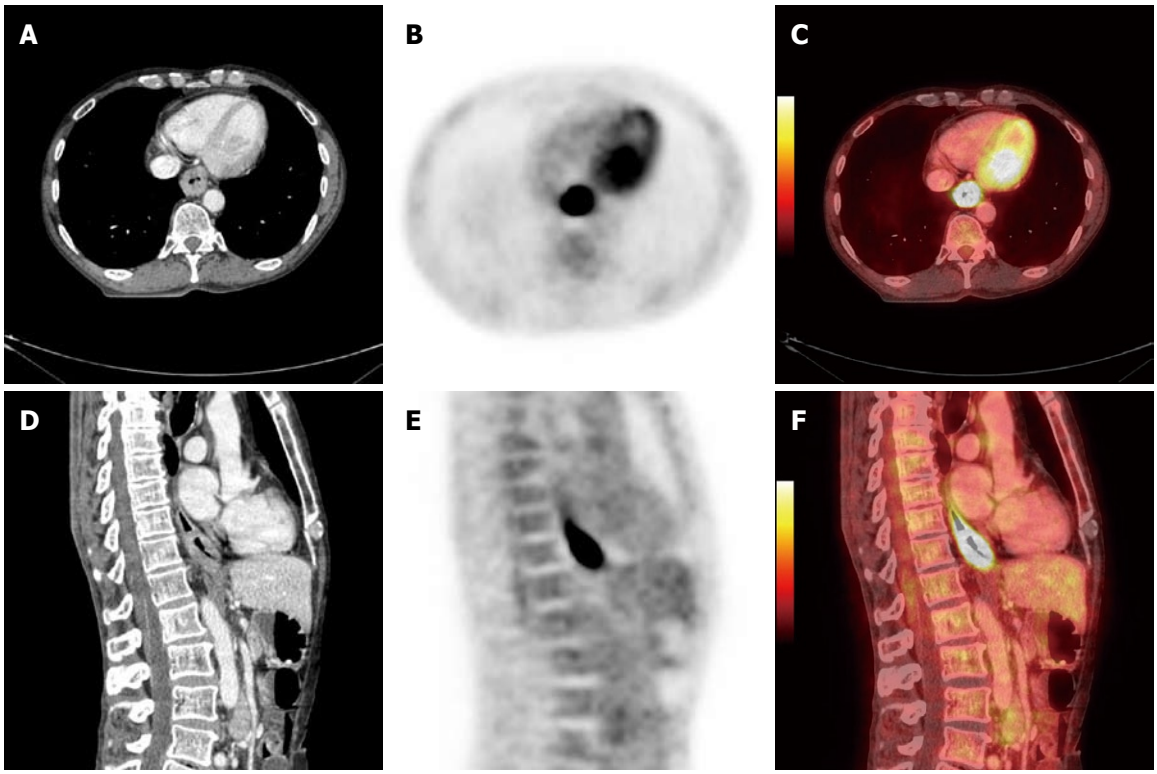

Figure 1 Positron emission tomography/computed tomography images of 61-year-old man with primary squamous cell carcinoma in distal part of the esophagus T3N0M0 prepared in treatment position for radiotherapy planning. A: Computed tomography (CT), axial slice; B: Positron emission tomography (PET), axial slice; C: PET/CT fusion, axial slice; D: CT, sagital slice; E: PET, sagital slice; F: PET/CT fusion, sagital slice.

alone, integrated PET/CT imaging improves the sensitivity and accuracy in the assessment of locoregional lymph nodes in esophageal cancer[42,43]. In a retrospective study by Muijs *et al*[44], target volumes were independently defined based on CT only and based on coregistered PET/CT in 21 patients. In that study, PET/CT-based planning of target volumes was inadequately covered by CT only-based treatment plans in eight patients (38%). In the study of Gondi *et al*[45], PET/CT-based target volumes were compared to CT only-based target volumes in 16 patients with esophageal cancer. In ten of these patients the addition of PET to the planning led to a reduction of the GTV volume.

Leong *et al*[46] evaluated the impact of PET/CT-based planning in a prospective trial. The target volumes based on CT alone and PET/CT were compared in 21 patients. The addition of PET information altered the clinical stage in eight patients (38%). Four patients had a distant metastatic disease and four had an unsuspected regional nodal disease. The PET findings led to a change in the management from radical chemoradiation to treatment with palliative intent in five of these patients (24%). In 16 patients (69%) the PET avid disease was not included in the GTV.

In a similar study by Moureau-Zabotto *et al*[47], the target volumes based on CT alone and subsequently on PET/CT were defined and compared in 34 patients. Unknown metastatic disease was detected by PET/CT in two patients. The GTV was modified in 19 patients (56%); in 12 of these patients the GTV was decreased and in seven patients it was increased by PET/CT. In 18 patients it led to the modification of the PTV. The influence of PET/CT based RT planning on the total lung volume receiving > 20 Gy was also shown.

Recently, Shimizu *et al*[48] published a study of 20 patients who were examined before surgery by PET/CT and EUS. Based on these preoperative diagnostic modalities, the target volumes for radiotherapy were defined and these volumes were compared to the histopathologic findings. Although hybrid PET/CT was used, the CTV was inadequately covered in seven cases out of 20. When EUS was added to PET/CT, inadequate CTV cover occurred in five cases compared to eight cases with CT only- based target volumes.

Therefore, despite the growing popularity of PET/CT based RT planning in esophageal cancer, the recently published International Atomic Energy Agency expert report 2006-2007 classifies esophageal cancer as a diagnosis where the use of PET or PET/CT for RT planning should be cautiously considered, as there is still limited supporting data[49].

An example of PET/CT images performed in treatment position for radiotherapy for esophageal cancer is shown in Figure 1.

Intensity-modulated radiation therapy

Intensity-modulated radiotherapy (IMRT) is an advanced form of conformal radiotherapy that utilizes computer-controlled linear accelerators to deliver precise radiation doses to the PTV (Figure 2). The principal of IMRT is the

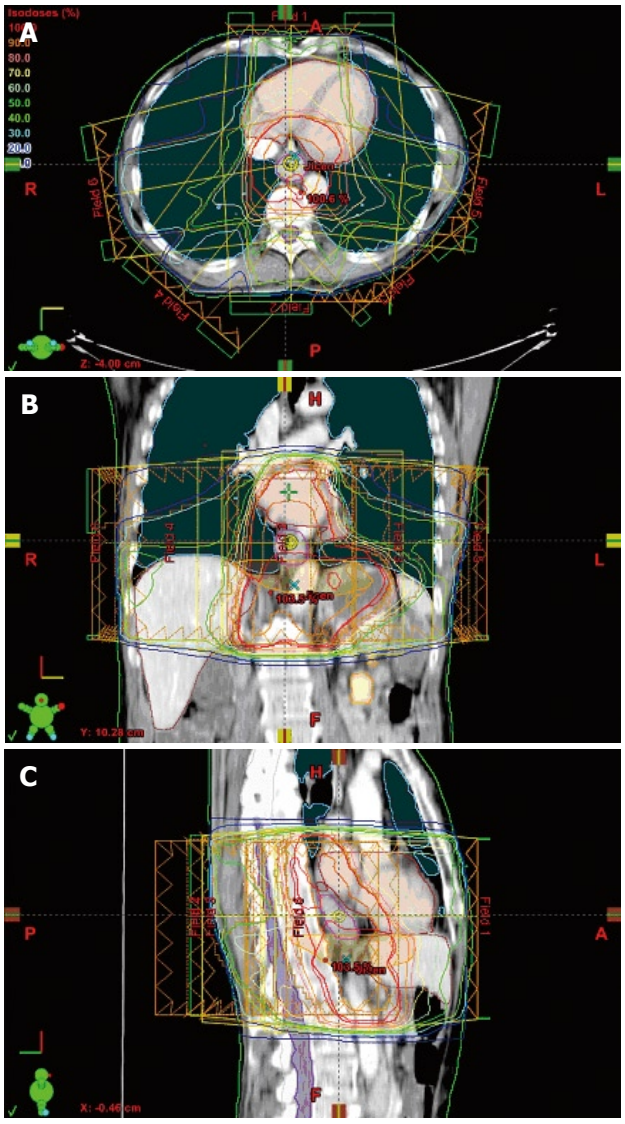

Figure 2 Intensity-modulated radiotherapy plan prepared on a positron emission tomography/computer tomography dataset (Figure 1). Delineated target volumes and organs at risk, beam arrangement and dose distribution in axial (A), coronal (B), and sagittal slices (C).

use of variable radiation fluence patterns from multiple beam angles. The beam fluences are calculated by automated computer-assisted optimization and the combination of optimal beam fluences results in an optimal dose distribution. Current commercial treatment planning software for optimization usually requires only a definition of beam configuration, PTV(s), and dose-volume constraints of organs at risk with varying penalty weights - so called inverse planning.

The main dosimetric advantage of IMRT is the possibility of better sparing of healthy tissues and organs at risk, including shape concavities of the PTV. Therefore, IMRT facilitates a lower risk of late adverse effects of radiotherapy and better local control of the tumor, due to the possibility of safe dose escalation. There has already been much data published worldwide demonstrating dosimetric, and even clinical, improvement of radiation treatment by IMRT, mainly in prostate cancer and head and neck cancer[50,51]. For these reasons, there has been a massive expansion of IMRT worldwide in the last few years.

In addition to the sparing of organs at risk and the possibility of dose escalation in the whole PTV, IMRT offers a dose escalation in every fraction in the subregion with a high risk of local recurrence (primary tumor or tumor bed). This principle is called simultaneous integrated boost (SIB), and it is used mainly in head and neck cancer. The advocates of SIB-IMRT techniques emphasize a better conformality of irradiation in comparison to shrinking volumes technique[52,53].

Several dosimetric studies have been published in esophageal cancer. Nutting *et al*[54] compared IMRT plans with various beam angles and 3D-CRT plans in five patients. They concluded that IMRT using conventional beam angles (two opposed antero-posterior fields and two posterior oblique fields) can provide an acceptable dose homogeneity within the PTV and reduces lung irradiation compared to 3D-CRT. The mean values of the mean lung dose and relative mean lung volume within a dose of 18 Gy were 11.0 Gy and 9.5 Gy (P = 0.001), and 18.8% and 14.1% (P = 0.001), for 4-field IMRT and 3D-CRT, respectively. IMRT plans using nine equispaced fields were not superior to 3D-CRT plan due to the increased lung volume involved with low doses of irradiation.

The reduction of lung dose by IMRT inverse planning in esophageal cancer was subsequently reported by Wu *et al*[55] They prepared IMRT plans using 3-9 equispaced beams and 3D-CRT plans in CT data of 15 patients. The percentage volume of the lung receiving 25 Gy or above (V25) was used as the main dosimetric parameter for the lungs. There was a considerable reduction in V25 in the IMRT plans compared with the inverse planned 3D-CRT (24.6% and 18.2% for the left and right lungs, respectively). The average mean heart dose was not statistically different, but the calculated normal tissue complications probability (NTCP) was significantly lower using IMRT.

The comparison of IMRT *vs* 3D-CRT plans in cervical esophageal cancer was the goal of the dosimetric study in five patients of Fenkell *et al*[56] IMRT plans provided better PTV coverage, higher conformality, a reduction of the maximum dose to the spinal cord and brain stem, and a lower mean dose to the parotid glands.

In another study for upper esophageal cancer, Fu *et al*[57] reported a dosimetric comparison of conformal radiotherapy and SIB-IMRT technique with 3, 5, 7 and 9 beams. The prescribed doses were 67.2 Gy and 50.4 Gy in the primary lesions and electively treated regions; the dose per fraction was 2.4 and 1.8 Gy, respectively. The authors concluded that IMRT-SIB shortens the total treatment time and the primary tumor can receive a higher equivalent dose by SIB. The five equispaced coplanar SIB-IMRT technique produced desirable dose distribution. This regimen is under clinical evaluation in this center.

Chandra *et al*[58] retrospectively compared 4-9 beam IMRT and 3D-CRT plans for distal esophageal cancer in ten patients. The IMRT improved PTV heterogeneity. There was a reduced total lung volume irradiated above 10 Gy and 20 Gy (V10 and V20), and the mean lung dose

using the IMRT plans. However, at low dose levels (below 7 Gy), there was a tendency of increased volume V7 with more beams for IMRT plans.

Mayo *et al*[59] described a technique of combined static and intensity-modulated beams for lung and esophageal cancer radiotherapy. This hybrid IMRT technique reduced the V5, V13, and V20 volumes in a subgroup of esophageal cancer compared to the IMRT only plans. The largest differences were in V13. However, there was an increase in dose to the heart in the hybrid IMRT plans.

The risk of larger volumes of lungs irradiated by lower doses of radiotherapy (⩾ 5 Gy; V5) was mentioned above. The IMRT plans can be associated with higher V5 because of the high number of beams and their configuration, but it can also be partially caused by a leakage of the multileaf collimator during IMRT[60].

Although the dosimetric studies demonstrated the advantage of IMRT in tumors of all parts of esophagus, the clinical results of IMRT for esophageal cancer are still limited to a few small studies. Wang *et al*[61] retrospectively analysed six patients treated by 5-9 beam IMRT with concurrent chemotherapy for locally advanced cervical and upper thoracic esophageal cancer. The prescription dose was 59.7-66 Gy in 28-33 fractions; in five patients a simultaneous integrated boost technique was used. In this study, all six patients achieved complete remission. However, two patients developed local recurrence; one patient had distant metastases and one patient had both regional and distant metastases. Three of the four surviving patients developed an esophageal stricture or fistula.

At Stanford University, 30 patients were treated with preoperative or definitive chemoradiotherapy using IMRT in a median dose of 50.4 Gy (range 34.2-58.8 Gy) for esophageal cancer. 67% of tumors were adenocarcinomas. The 2-year local-regional control was 83% in patients treated preoperatively and 51% in definitively treated patients. One patient died because of a complication following the placement of a gastrostomy tube during the irradiation course (after a dose 34.2 Gy). One patient developed postoperative acute respiratory distress syndrom. Eight patients (27%) developed late esophageal stricture requiring dilatations[62].

Tomotherapy

Helical tomotherapy is a form of intensity-modulated radiotherapy using a helical radiation delivery system. The beam delivery is similar to that of helical computed tomography.

Chen *et al*[63] compared three radiotherapy techniques diametrically - tomotherapy, step-and-shoot method of IMRT, and 3D-CRT - in the CT data of six patients. In the study, tomotherapy was superior to IMRT and 3D-CRT due to better dose conformity, dose homogeneity, and sparing of lung volume from doses ⩾ 20 Gy (V20). Helical tomotherapy and IMRT compared to 3D-CRT spared the heart better (decreased V30 and V45). However, tomotherapy and IMRT plans resulted in a larger V10 of lungs compared to 3D-CRT plans. The same centre also reported the first clinical results of tomotherapy with concurrent chemotherapy in 20 patients with esophageal cancer at the American Society for Radiation Oncology Annual Meeting 2007. The prescribed dose was 50 Gy in the GTV and 45 Gy in the region of a possible subclinical disease. Ten patients were indicated after chemoradiotherapy for surgery, and in eight of them, downstaging was noted with two complete responses. There was a clinically complete response in six patients without surgery. Grade 3 acute toxicity was noted in nine patients (45%) without any specification by the authors. No grade 4 toxicity occured. Two patients developed pneumonitis after surgery[64].

Image guided radiation therapy

The risk of set-up uncertaintities known from megavoltage portal imaging led to a development of modern technological devices integrated into linear accelerators facilitating high precision positioning of a patient before each irradiation (minimizing of interfraction movements). Image-guided radiotherapy (IGRT) generally means the process of two-dimensional or three-dimensional imaging of the patient in the treatment position on the linear accelerator before an irradiation, with the aim of minimizing of the set-up error. Currently, a wide variety of online 2D and 3D imaging is used - megavoltage portal imaging, kilovoltage imaging, kilovoltage CT (commonly cone-beam), megavoltage CT (mainly on helical tomotherapy), and others[65]. The IGRT software allows an image acquisition, matching with the referrence images and individual setup corrections.

The IGRT can be practiced as a daily procedure before each fraction of radiotherapy to minimize random and systemic errors[66]. The second strategy uses an evaluation of random setup errors and, based on the result, the PTV is corrected. This concept, described by Yan *et al*[67,68], was first implemented in prostate cancer radiotherapy and was called by the authors *adaptive radiotherapy*.

Stroom *et al*[69] recommended the size of the CTV-PTV margin which ensures at least 95% of the prescribed dose to 99% of the CTV, to be equal to about $2\Sigma + 0.7\sigma$, where Σ is the standard deviation of the distribution of systemic deviations and σ is the average standard deviation of the distribution of random deviations. Chen *et al*[70] calculated these parameters in ten patients who underwent helical tomotherapy for esophageal cancer. The suggested CTV-PTV margins were 5.0 mm in the anterior-posterior direction, 11.1 mm in the lateral direction and 12.7 mm in the superior-inferior direction. Therefore, the authors recommend a megavoltage CT on tomotherapy before each fraction to minimize setup errors when lesser CTV-PTV margins are used.

Hawkins *et al*[71] recently presented the concept of cone-beam CT-derived adaptive radiotherapy for esophageal cancer treatment at their center. In 14 cases, the standard plan with CTV-PTV margin of 1 cm was prepared. The cone-beam CT was obtained before the first four fractions and, based on this data, the composite CTV with 5 mm margin for the PTV was defined. The same process was subsequently repeated weekly and the plans were compared. The study demonstrated a significant reduction

in the dose received by the heart and lungs because of lesser individualized CTV-PTV margins.

4D-computer tomography and respiratory control techniques

The limitation of the precise dose delivery by 3D-CRT or IMRT in the region of the thorax and upper abdomen are physiologic movements of tumor and organs, mostly due to respiratory or cardiac cycles (intrafraction movements). Therefore, radiation oncologists have to estimate the internal target margin to be adequate to these movements to cover target volumes sufficiently.

The respiratory motion of anatomic structures and target volumes has been investigated in several diagnoses, mainly in lung cancer, breast cancer, and upper abdomen malignancies. Currently, the optimal method for acquiring exact information on movements of structures during the respiratory cycle is respiratory-correlated computed tomography imaging (4D-CT). This technology allows the capture of CT data in separate phases of the respiratory cycle. Their co-registration gives precise information on the amplitude of the structure motion and the position of the structure in each phase of the cycle.

New technologies were evolved to compensate for tumor motion to lower the internal margin for the PTV and, hence, to reduce the volume of surrounding healthy tissues. These include active or passive respiratory gating (respiratory gated radiotherapy) and respiratory tracking techniques.

The principle of active breathing control (ABC) is the monitoring of the respiratory cycle by a special mouth apparatus measuring the airflow (spirometric system). At a preset phase of the cycle (preset volume of expired air), the ABC apparatus temporarily blocks the airflow of the patient and during this period the irradiation is applied[72]. The Real-Time Position Management™ (RPM) System (Varian Medical System, Palo Alto, USA) uses infrared camera monitoring of the movements of a small plastic box with reflective markers placed on the skin in the patient's upper abdomen during free breathing or active breathing.

Real-time respiratory tracking is a method that dynamically moves or shapes the radiation beam to follow the tumor's motion during irradiation. This method was first evolved for CyberKnife System (Accuray, Inc., Sunnyvale, USA), which features a linear accelerator mounted on a robotic arm (Synchrony Respiratory Tracking System).

The evaluation of esophageal tumor movements during the respiratory cycle was studied by Lorchel *et al*[73] in eight patients with various locations of the primary tumor in the esophagus. The cumulative distribution of the GTV and CTV motion in all three directions in absolute terms showed that 95% of the data ranged from 0 to 0.8 cm and from 0 to 1.0 cm, respectively. Therefore, the authors recommended the size of the internal target margin of 1 cm. Zhao *et al*[74] quantified the internal target motion in tumors near the gastroesophageal junction. They found that the tumors exhibited asymmetric and directional changes in shape and volume, mainly for large GTVs. The mean range of the aboral margin of the tumor was greatest in the caudal direction at 0.91 ± 0.36 cm. The mean range of the motion in anterior and posterior directions was 0.68 ± 0.23 cm and 0.36 ± 0.13 cm, respectively. The lateral motion was 0.27 ± 0.09 cm to the right and 0.63 ± 0.20 cm to the left because of movements of the stomach on the left side of the GTV. Based on these results, the authors suggested the use of asymmetric internal target margins: 1.0 cm to the left, 0.8 cm to the right, 1.1 cm anteriorly, 0.6 cm posteriorly, 1.0 cm superiorly, and 1.6 cm inferiorly. The study also evaluated the influence of the heart beat: the largest mean range of motion was 0.56 ± 0.18 cm for the esophageal wall adjacent to the heart.

The optimal approach to respiratory gated radiotherapy was studied by Lorchel *et al*[75]. In a dosimetric study, four spiral scans were performed in eight patients with advanced esophageal cancer: one in the end of expiration, one in the end of inspiration, one in deep inspiration breathhold, and one acquisition was performed in free breathing. Based on the results, the authors suggested the irradiation of esophageal cancer patients in deep inspiration breathhold in the case of using spirometric system and in the inspiration phase in the case of free breathing gating system to reduce a dose to the lungs (reduction in V20) and heart (decreased V40).

Proton therapy

The idea of using proton beam therapy as an effective radiotherapy method was first proposed by Wilson *et al*[76] in 1946. The main advantage of proton radiotherapy is a better dose conformity due to proton beam characteristics. Proton beams are characterized by a narrow penumbra and maximal energy transfer at the end of the range in tissue (Bragg peak). The proton therapy of various malignancies has been discussed in recent years. A few studies on proton therapy for esophageal cancer are also available[77-80].

The dosimetric study of Isacsson *et al*[77] compared the treatment plans with proton beams to plans with photons and combined plans in five patients with esophageal cancer. There was an evident advantage of proton plans in the reduction of dose to organs at risk in all patients. The sparing of the lungs using proton radiotherapy compared to IMRT was noted by Zhang *et al*[78] in a dosimetric study for distal esophageal cancer.

The published clinical studies using proton beam therapy for esophageal cancer applied a dose escalation approach. Koyama *et al*[79] irradiated 30 patients (13 patients with superficial and 17 patients with advanced tumors) with proton beam therapy alone (median fraction dose of 3.2 Gy) or in combination with photons (median fraction dose of 3.1 Gy). Overall mean total doses were 77.7 Gy in superficial carcinomas and 80.7 Gy in advanced carcinomas, respectively. The rates of local recurrence at 5 and 10 years were 0% for superficial cancer, and 56.6% and 78.3%, respectively, for advanced cancer. The radiation-induced esophageal ulcer as a late effect occurred in 66.7% of patients.

Sugahara *et al*[80] reported the clinical results of proton

beam therapy in 46 patients. Forty patients were treated by a combination of photons and protons as a boost to a median total dose of 76.0 Gy (median fraction dose 3.0 Gy), six patients were irradiated only by protons to a median total dose of 82.0 Gy (median fraction dose 3.1 Gy). The local control at 5 years was 57% (83% with stage T1 and 29% with stage T2-T4). Postradiation esophageal ulcers were developed in 48% of patients.

CONCLUSION

The main aim of modern radiotherapy approaches in esophageal cancer is to minimize the post-treatment complications by the improvement of the GTV definition (PET-based planning), reduced interfraction motion (image-guided RT) and intrafraction motion (respiratory-gated RT), and better delivery of the dose to the precisely defined PTV (intensity-modulated RT and proton RT). Another systematic review by Yang *et al*[81] therefore encouraged to utilize and study all technological advances to maximize outcomes in esophageal and gastroesophageal junction cancers.

The reduction of radiotherapy-related toxicity by modern radiation techniques for esophageal cancer is fundamental to the improvement of clinical results of radiotherapy for esophageal cancer, although the dose escalation concept is still controversial.

Abstract

AIM: To investigate chronic stress as a susceptibility factor for developing pancreatitis, as well as tumor necrosis factor-α (TNF-α) as a putative sensitizer.

METHODS: Rat pancreatic acini were used to analyze the influence of TNF-α on submaximal (50 pmol/L) cholecystokinin (CCK) stimulation. Chronic restraint (4 h every day for 21 d) was used to evaluate the effects of submaximal (0.2 μg/kg per hour) cerulein stimulation on chronically stressed rats.

RESULTS: *In vitro* exposure of pancreatic acini to TNF-α disorganized the actin cytoskeleton. This was further increased by TNF-α/CCK treatment, which additionally reduced amylase secretion, and increased trypsin and nuclear factor-κB activities in a protein-kinase-C δ and ε-dependent manner. TNF-α/CCK also enhanced caspases' activity and lactate dehydrogenase release, induced ATP loss, and augmented the ADP/ATP ratio. *In vivo*, rats under chronic restraint exhibited elevated serum and pancreatic TNF-α levels. Serum, pancreatic, and lung inflammatory parameters, as well as caspases' activity in pancreatic and lung tissue, were substantially enhanced in stressed/cerulein-treated rats, which also experienced tissues' ATP loss and greater ADP/ATP ratios. Histological examination revealed that stressed/cerulein-treated animals developed abundant pancreatic and lung edema, hemorrhage and leukocyte infiltrate, and pancreatic necrosis. Pancreatitis severity was greatly decreased by treating animals with an anti-TNF-α-antibody, which diminished all inflammatory parameters, histopathological scores, and apoptotic/necrotic markers in stressed/cerulein-treated rats.

CONCLUSION: In rats, chronic stress increases susceptibility for developing pancreatitis, which involves TNF-α sensitization of pancreatic acinar cells to undergo injury by physiological cerulein stimulation.

Key words: Pancreatitis; Stress; Tumor necrosis factor-α

INTRODUCTION

Stress can be defined as "threatened homeostasis". Stressors can include physical or mental forces, or combinations of both. The reaction of an individual to a given stressor involves the stimulation of pathways within the brain leading to activation of the hypothalamic-pituitary-adrenal axis and the central sympathetic outflow[1]. These can result in visceral hypersensitivity through the release of different substances, such as substance P and calcitonin gene-related peptide from afferent nerve fibers[2].

While it is well established that a previous acute-short-term stress decreases the degree of severity of pancreatitis in several experimental models[3,4], the effects of chronic stress on the exocrine pancreas have received relatively little attention[5,6]. Chronic stress has been proved to increase the susceptibility of different rat organs, such as the small intestine, colon, and brain, to inflammatory diseases[2,7-9], as well as to aggravate atherosclerotic lesions in mice[10].

The pro-inflammatory cytokine, tumor necrosis factor-α (TNF-α), has an important role in various biological functions, including cell proliferation, cell differentiation, survival, apoptosis and necrosis[11], and in stress-related inflammatory disorders[8-10,12]. Secretion of TNF-α by several stressful stimuli has been demonstrated in many cell types, including pancreatic acinar cells[13-20]. Previous reports evaluated the response of pancreatic acinar cells to exogenous TNF-α, showing disruption of the actin cytoskeleton and activation of nuclear factor-κB (NF-κB), a key transcriptional regulator of the expression of inflammatory molecules[21-23]. Interestingly, this TNF-α activation of NF-κB is mediated by the novel protein kinase C δ (PKCδ) and PKCε[23], which have also been shown to modulate cerulein-induced zymogen activation in these cells[24]. Although TNF-α has been shown to participate in the inflammatory cascade that propagates pancreatitis[25], its relevance in the genesis of this multifactor disease was hardly investigated.

We examined the possibility that chronic stress is a susceptibility factor for developing pancreatitis and that TNF-α is a putative sensitizer. We performed studies on both *in vitro* dispersed rat pancreatic acini stimulated with TNF-α and submaximal doses of cholecystokinin (CCK), and in *in vivo* rats under chronic stress induced by restraint and challenged with submaximal doses of the CCK-analogue cerulein.

MATERIALS AND METHODS

Antibodies and reagents

Antibodies used include those against rat TNF-α (R&D Systems, Minneapolis, MN), Na^+/K^+ ATPase (Upstate Biotechnology-Chemicon Int., Temecula, CA), PKCδ and PKCε (Santa Cruz Biotechnology, Santa Cruz, CA), and tubulin (Sigma Chemical Co., St. Louis, MO). Alexa Fluor 488-phalloidin was from Molecular Probes (Burlington, ON, Canada). Recombinant TNF-α was from R&D Systems. Sulfated CCK octapeptide, cerulein, Hoechst dye 33258, N-acetyl-cysteine (NAC), hexadecyltrimethylammonium bromide, and o-dianisidine hydrochloride were from Sigma Chemical Co. Calphostin C, and Gö6976 were from Calbiochem (San Diego, CA). PKCζ myristolated pseudosubstrate inhibitor was from Biosource International (Camarillo, CA). The PKCδ-specific antagonist peptide δV1-1was synthesized by American Peptide Company, Inc. (Sunnyvale, CA) and conjugated to a TAT peptide (PKCδ translocation inhibitor δV1-1). PKCε translocation inhibitor εV1-2 was from Anaspec (San Jose, CA). The protease inhibitor cocktail was from BD Pharmingen (San Jose, CA). BoC-Glu-Ala-Arg-MCA was from Peptides International (Louisville, KY). Amylase, lactate dehydrogenase (LDH), glucose, urea, creatinine, calcium, total proteins, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and quantitative C-reactive protein assay kits were from Wiener Lab (Rosario, Santa Fe, Argentina). The lipase assay kit was from Randox Laboratories Ltd. (Antrim, UK). NF-κB (p65), NF-κB (p50) transcription factor, lipid hydroperoxide (LPO), and malondialdehyde (MDA) Assay Kits were from Cayman Chemical Company (Ann Arbor, MI). TNF-α and macrophage inflammatory protein-1α (MIP-1α) Kits were from R&D Systems. The hypoxia inducible factor-1α (HIF-1α) Kit was from Genxbio Health Science (Delhi, India). The protein assay kit was from Bio-Rad (Hercules, CA). The heat shock protein (HSP) 72 Kit was from StressGen Biotechnologies, San Diego, CA). PKCδ and PKCε Kinase Assay Kits were from Cell Signaling Technology (Beverly, MA). Interleukin (IL)-6 and IL-10 Kits were from Assay Designs (Ann Arbor, MI). The CasPASE Apoptosis Activity Assay Kit was from Genotech (Maryland Heights, MO). The Enliten ATP Assay Kit was from Promega (Madison, WI). The ApoSensor ADP/ATP Ratio Assay Kit was from Enzo Life Science International Inc. (Plymouth Meeting, PA).

Animal model

Male Wistar rats (200-250 g) were housed in standard cages in a climate-controlled room with a temperature of 23 ± 2℃ and a 12 h light/dark cycle (lights on at 08.00 h), with free access to food and water except during restraint times. All animals were maintained under constant conditions for 4 d prior to stress, and they were randomly assigned to non-stress (control) or stress groups. Every day at 09.00 h, animals from both non-stress and stress groups received either 50 μg/kg TNF-α-neutralizing antibodies or an equal dose of control IgG, given as intraperitoneal (ip) injections. Rats in the stress group were exposed to various sessions of restraint (4 h every day for 21 d) between 10.00 and 14.00 h in the animal homeroom. The immobilization was performed using a metallic restraint jacket and was placed inside their home cage during the restraint sessions. Control rats were handled once at 10.00 h

for few seconds and left undisturbed in their home cages. Food and water were removed from their cages to avoid their interference in the parameters determined. Following the 21 d stress protocol, rats from each condition, non-stress (-) and stress (+), were then randomly distributed into three groups of four rats each. One group was treated with six doses of saline-vehicle (Veh groups), and the other two groups were treated with six doses of 0.2 μg/kg cerulein (Cer groups and anti-TNF-α plus Cer groups), given as hourly ip injections. Rats were sacrificed 1 h after the last injection by decapitation, and blood was drained onto heparinized dishes for white blood cell count and determination of hematocrit. Amylase (end-point colorimetric method), lipase (UV turbidimetric method), TNF-α [enzyme-linked immunosorbent assay (ELISA)], LDH (German Society of Clinical Chemistry-DGKC optimized kinetic method), glucose (enzymatic method), urea (enzymatic method), creatinine (end-point colorimetric method), calcium (direct colorimetric method), total proteins (enzymatic method), AST and ALT (IFCC optimized UV method), C-reactive protein (immunoturbidimetric method), HSP-72 (ELISA assay), IL-6 (ELISA assay), IL-10 (ELISA assay), and MIP-1α (ELISA assay) levels were assessed in serum using the respective assay kits. Pancreatic and lung tissues were obtained for determination of levels of NF-κB (p65) and NF-κB (p50) in nuclear extracts, and TNF-α using the respective ELISA assay kit, and myeloperoxidase (MPO) activity. Pancreatic tissue was also evaluated for levels of HIF-1α (ELISA assay), LPO and MDA (colorimetric method) using the respective assay kit, and trypsin activity. Caspases 2, 3, 8, and 9 activity (colorimetric/fluorometric method), and ADP and ATP levels (bioluminescent method) were determined in pancreatic, lung, and stomach tissue using the respective assay kits. All kits were used according to the manufacturer's instructions. All experimental protocols were approved by the Animal Care and Use Committee of the CBRHC Research Center.

Dispersed acini preparation

The preparation of isolated pancreatic acini from rats was performed by a mechanical and enzymatic dissociation technique[26]. The acini were resuspended in oxygenated Krebs-Ringer-HEPES (KRH) buffer, consisting of (in mmol/L): 104 NaCl, 5 KCl, 1 KH_2PO_4, 1.2 $MgCl_2$, 2 $CaCl_2$, 0.2% (wt/vol) bovine serum albumin, 0.01% (wt/vol) soybean trypsin inhibitor, 10 glucose, and 25 2-hydroxyethylpiperazine-2-ethanesulfonic acid (HEPES)/NaOH, pH 7.4, supplemented with minimal essential and non-essential amino acid solution and glutamine.

Cellular models

Hypoxia and reoxygenation treatment: Isolated pancreatic acini were seeded in six-well plates. The hypoxia and reoxygenation (H/R) media were produced by equilibrating Krebs-Henseleit buffer, consisting of (in mmol/L): 118.3 NaCl, 4.7 KCl, 1.2 $MgSO_4$, 1.2 KH_2PO_4, 2.5 $CaCl_2$, 25.0 $NaHCO_3$, and 11.0 glucose, pH 7.4, in 95% N_2/5% CO_2 or 95% air/5% CO_2, respectively. The studies were carried out using two water-jacketed incubators at 37℃ as follows. For H/R treatment, acini were exposed to an anoxic gas mixture (95% N_2/5% CO_2) in a humidified incubator for 30 min. After the hypoxia period, hypoxic media was rapidly replaced with reoxygenation media and the acini were transferred to 95% air/5% CO_2 in a humidified incubator for 3 h. For normoxia (N) control treatment, acini were exposed to 95% air/5% CO_2 in a humidified incubator for the same period of time as the H/R samples. To determine the effect of reactive oxygen species (ROS) inhibition, NAC (30 mmol/L) was added to the cells 1 h before hypoxia, and it was maintained in the media throughout the experiment. TNF-α released into the supernatant was determined using an ELISA assay kit according to the manufacturer's instructions. Values were normalized by DNA content in each sample, which was measured using Hoechst dye 33258.

Hydrogen peroxide stimulation: Isolated pancreatic acini were seeded in six-well plates and incubated with hydrogen peroxide (H_2O_2, 50 μmol/L) for 3 h at 37℃ in a 5% CO_2 humidified atmosphere. To determine the effect of ROS inhibition, NAC (30 mmol/L) was added to the cells 1 h before H_2O_2, and it was maintained in the media throughout the experiment. TNF-α released into the supernatant was determined by the corresponding ELISA assay kit and values were normalized by DNA content in each sample.

TNF-α and CCK stimulation: Isolated pancreatic acini were stimulated with CCK (50 pmol/L) for 1 h at 37℃. Pretreatment with the indicated concentrations of TNF-α in KRH was performed for 1 h prior to and along stimulation. Levels of amylase and LDH release, NF-κB (p65) and NF-κB (p50) in nuclear extracts, caspases 2, 3, 8, and 9 activity, and ADP and ATP, were measured in pancreatic acini using the respective assay kits, according to the manufacturer's instructions. Acini were also assessed for trypsin activity.

Amylase secretion: Amylase released into the supernatant and amylase content of the acini pellet were determined by a colorimetric method as previously reported[27]. "Total amylase" is defined as the summation of the amylase content in the respective cell pellet plus supernatant, and the amylase secreted into the supernatant is expressed as a percentage of total amylase.

Confocal immunofluorescence microscopy: Dispersed acini were placed on glass coverslips and after indicated treatments fixed with 4% paraformaldehyde. Fixed coverslips were permeabilized with 0.1% Triton X-100 for 15 min, followed by incubation with 1% bovine serum albumin for 1 h. Acini were then incubated with Alexa Fluor 488-phalloidin (1:500) for 1 h at 25℃. Coverslips were examined with a 63 × oil immersion objective and conventional laser excitation and filter set, by a laser scanning

confocal imaging system (Zeiss LSM510) equipped with the LSM software version 5.00 (Carl Zeiss, Oberkochen, Germany).

Subcellular fractionation and immunoblotting

Subcellular fractionation: Isolated pancreatic acini, after equilibration (20 min, 37℃), were subjected to the indicated stimulation, and then terminated by adding an excess volume of ice-cold KRH buffer. The acini were then pelleted by centrifugation (300 *g*, 4℃). Whole cell lysates and purified membranes were prepared from the treated dispersed acini by sucrose density gradient centrifugation. Briefly, the sucrose buffer consisted of: 0.3 mol/L sucrose, 0.01% soybean trypsin inhibitor, 0.5 mol/L phenylmethanesulfonyl fluoride, and 5 mmol/L β-mercaptoethanol. The acini were homogenized in a Potter-Elvehjem homogenizer, followed by a five min centrifugation (14 000 *g*, 4℃) to separate the nuclei pellets from supernatants. The supernatant fractions were centrifuged (15 min, 14 000 *g*, 4℃) to separate the zymogen granule pellets, and the resulting supernatants subjected to ultracentrifugation (3 h, 93 000 *g*, 4℃) to obtain the membrane pellet and cytosol supernatant fractions.

Immunoblotting: The protein contents of all samples were determined by Bradford method. Samples of subcellular fractions were dissolved in Laemmli buffer and boiled for five min. Equal amounts of protein were separated by 8% SDS-PAGE and transferred to nitrocellulose membranes (Bio-Rad, Hercules, CA). Blots were blocked for 1 h in Tris-buffered saline containing 5% bovine serum albumin and then incubated with the corresponding primary antibody. The bound antibody was visualized by relevant peroxidase-coupled secondary antibodies using the enhanced chemiluminescence method (Amersham, Arlington Heights, IL). Quantification was performed by densitometry using the NIH-Image software.

Isoform-specific PKC activity

PKCδ and ε activities were determined on lysates from isolated acinar cells using the respective ELISA assay kit, according to the manufacturer's instructions. Activity values were normalized to the basal activity in non-stimulated control cells.

Trypsin activity

Pancreatic tissue and pancreatic acini samples were pelleted, and the cell pellet was resuspended in ice-cold morpholino propylsulfonate (MOPS) buffer, pH 7.0 (containing in mmol/L: 250 sucrose, 5 MOPS, and 1 $MgSO_4$), and then homogenized by hand using a Teflon and glass homogenizer. The resulting homogenate was centrifuged, and the supernatant was used for the assay. Trypsin activity was measured fluorometrically in a stirred cuvette at 37℃ in a Hitachi F-2000 spectrofluorometer with excitation at 380 nm and emission at 440 nm, using BoC-Glu-Ala-Arg-MCA as the substrate. Briefly, the slope of rising fluorescence emission was calculated as arbitrary units and normalized per DNA content in the homogenate of each sample.

Caspases' activity

Caspase 2, 3, 8, and 9 were measured using a colorimetric/fluorometric method as previously reported[28]. Briefly, pancreatic, lung or stomach tissue, or pancreatic acinar cell samples were homogenized in chilled lysis buffer and the lysates were centrifuged at 15 000 *g* for 30 min at 4℃. Caspases' activity was assessed on the supernatants.

ATP and ADP levels

ATP and ADP were measured using a bioluminescent method, as previously reported[28]. Briefly, pancreatic, lung, or stomach tissue, or pancreatic acinar cell samples were homogenized in 6% TCA (trichloroacetic acid) for one min and centrifuged at 6000 *g* for 5 min at 4℃. The TCA in the supernatant was neutralized and diluted to a final concentration of 0.1% with Tris-Acetate buffer, pH 7.75. ATP and ADP were measured in the supernatant. ATP loss was calculated as a percentage of the decrease in values corresponding to control.

MPO activity

Pancreatic and lung tissue were analyzed for MPO activity. Briefly, approximately 50 mg of pancreatic or lung tissue was homogenized on ice with 1 mL of 0.5% hexadecyltrimethylammonium bromide in 50 mmol/L phosphate buffer-pH 6.0. The homogenate was sonicated for 10 s at 200 W, and then centrifuged at 40 000 *g* for 15 min at 4℃. MPO activity in the supernatant was assayed as follows: 0.1 mL of supernatant was combined with 2.9 mL of 5 mmol/L phosphate buffer pH 6.0, 0.167 mg/mL o-dianisidine hydrochloride, and 0.0005% hydrogen peroxide. The change in absorbance at 460 nm was measured spectrophotometrically. One unit of MPO activity is defined as the amount that degrades 1 μmol of peroxide per minute at 25℃. MPO activity was normalized by DNA content in the homogenate of each sample.

Extraction of DNA

The total mass of DNA in the homogenate of each sample was used to standardize the units of enzymatic activity. Approximately 50 mg of tissue was homogenized in 400 μL of lysis buffer consisting of 0.5% SDS, 0.1 mol/L NaCl, 50 mmol/L Tris pH 8, 2.5 mmol/L EDTA, and 100 μg/mL proteinase K, for 1 h at 63℃ and 650 r/min. Seventy-five microliters of 8 mol/L potassium acetate followed by 500 μL of chloroform were then added. Samples were frozen at -20℃ for 15 min and centrifuged at 10 000 r/min for 5 min at 4℃. The DNA was extracted in 1 mL of absolute ethanol and washed in 1 mL of 70% ethanol. The clean DNA pellet was resuspended in distilled water buffer and DNA was measured at 260 nm.

Histological evaluation

Pancreatic, lung, and stomach tissues were graded on a scale of 0 to 4 each for edema, hemorrhage, leukocyte in-

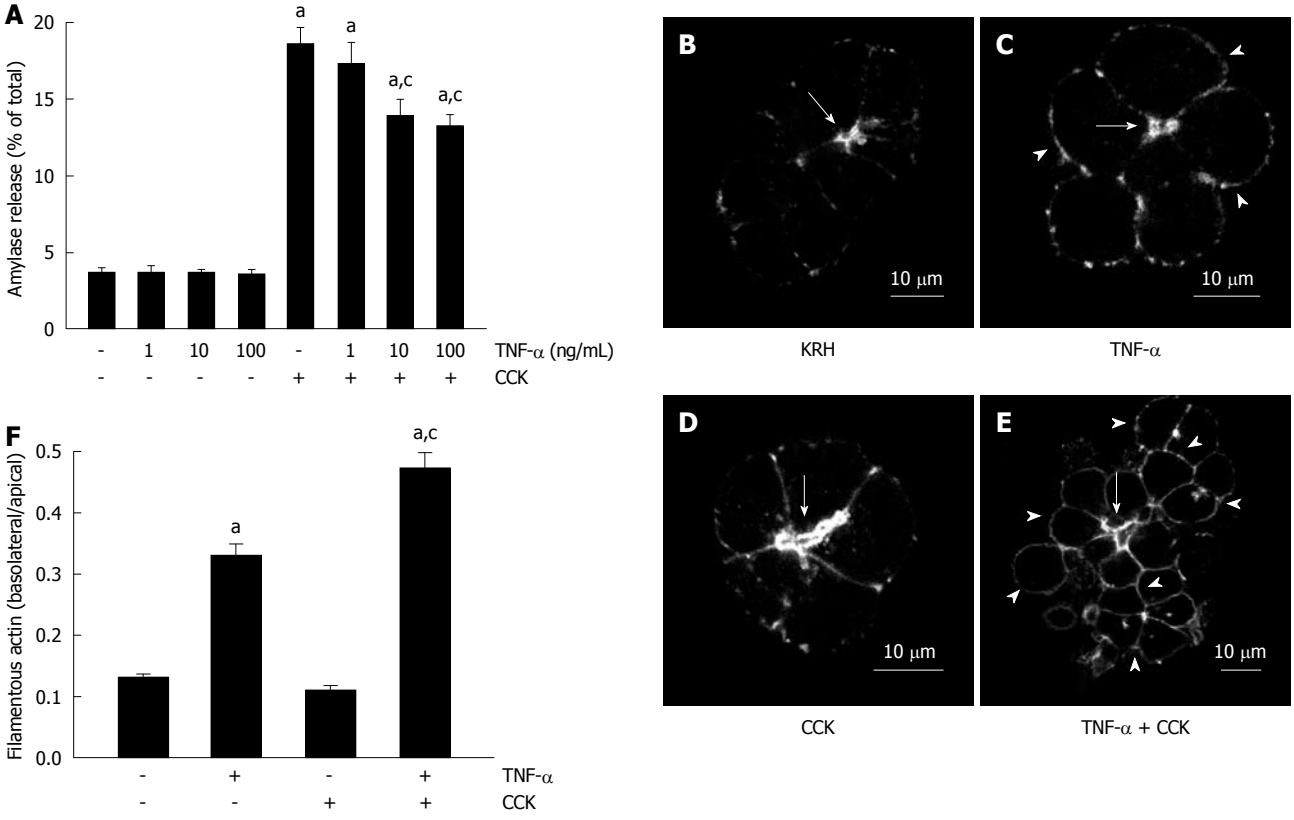

Figure 1 Tumor necrosis factor-α disorganizes the actin cytoskeleton and reduces submaximal cholecystokinin-stimulated amylase secretion. A: Amylase secretion from pancreatic acini. Isolated pancreatic acini were stimulated with either the indicated concentrations of tumor necrosis factor-α (TNF-α) for 2 h, or 50 pmol/L cholecystokinin (CCK) for 1 h, or the indicated concentrations of TNF-α for 1 h followed by the indicated concentrations of TNF-α plus 50 pmol/L CCK for 1 h, or Krebs-Ringer-HEPES (KRH) (vehicle-control) for 2 h. Amylase secreted into the media was determined and expressed as a percentage of the total cellular amylase of the respective sample. Results correspond to the mean ± SE from four independent experiments, with samples performed in triplicate. $^{a}P < 0.05$ *vs* KRH; $^{c}P < 0.05$ *vs* CCK alone; B-F: Filamentous actin distribution; B-E: Confocal images of filamentous actin localization in pancreatic acinar cells. Isolated pancreatic acini were treated with either KRH for 2 h (B), or 10 ng/mL TNF-α for 2 h (C), or 50 pmol/L CCK for 1 h (D), or 10 ng/mL TNF-α for 1 h followed by 10 ng/mL TNF-α plus 50 pmol/L CCK for 1 h (E). Fixed and permeabilized acini were stained with Alexa Fluor 488-phalloidin. Arrows show apical lumens, and arrowheads show basolateral membranes. These are representative images selected from three independent experiments, with samples performed in triplicate; F: Quantification of filamentous actin distribution. Areas of the apical and basolateral membranes in acinar cells treated as in B-E were delineated and the fluorescence intensity was determined. Sixty cells from three independent experiments were analyzed per condition. Values correspond to the intensity in the basolateral area *vs* the apical area, and are expressed as the mean ± SE. $^{a}P < 0.05$ *vs* KRH; $^{c}P < 0.05$ *vs* TNF-α alone.

filtrate, and necrosis. Histological changes were scored in a blinded manner by two independent observers counting frequency of foci per field seen at 40 × (absent, 0; mild, 1; moderate, 2; severe, 3; overwhelming, 4).

Statistical analysis

All data are presented as mean ± SE. The data for each group were subject to analysis of variance followed by Dunnet post hoc test when comparing three or more groups, or evaluated using Student's *t*-test when comparing only two groups. Significant differences were considered with values of $P < 0.05$.

RESULTS

TNF-α reduces submaximal CCK-stimulated amylase secretion

We first examined the effects of TNF-α on amylase secretion from dispersed rat pancreatic acini. Different samples were incubated with different concentrations of TNF-α. Figure 1A shows that none of them stimulated amylase release (3.6% ± 0.5%, 3.5% ± 0.4% and 3.4% ± 0.5% for 1, 10 and 100 ng/mL, respectively) over basal vehicle-control levels (3.6% ± 0.4%). However, two TNF-α concentrations inhibited 50 pmol/L CCK-stimulated secretion (13.8% ± 1.2% and 13.1% ± 0.9% for 10 and 100 ng/mL), which, when compared to CCK alone (18.5% ± 1.2%), represent a reduction of 25.4% and 29.2%, respectively.

TNF-α-induced actin cytoskeleton disorganization is increased during CCK stimulation

TNF-α has been shown to cause actin disorganization in isolated pancreatic acini, which is distinguished by increased filamentous actin along the basolateral membranes and its decrease in the apical area[21]. Here, we showed that both KRH vehicle-control and CCK-stimulated pancreatic acini exhibited the typical actin staining, intense in the apical area, and little and weak in the basolateral area of the acinar cell (Figure 1B and D). However, both 10 ng/mL TNF-α- and 10 ng/mL TNF-α

plus 50 pmol/L CCK-stimulated acini exhibited the previously described actin disorganization pattern, which was more pronounced in acini challenged with TNF-α plus CCK (Figure 1C and E). This disorganization was also observed when using 100 ng/mL, but not with 1 ng/mL TNF-α alone or together with CCK (data not shown). Figure 1F shows the quantification of actin distribution (0.13 ± 0.01, 0.11 ± 0.01, 0.33 ± 0.02 and 0.47 ± 0.03 basolateral/apical actin ratio for KRH, CCK, TNF-α and TNF-α + CCK, respectively).

TNF-α-induced activation of NF-κB is amplified by submaximal CCK

We then evaluated the activation of NF-κB (p65) and NF-κB (p50) in pancreatic acini. Previous reports established that pancreatic acinar cells respond to TNF-α by activating NF-κB in a PKCδ- and PKCε-dependent manner[22,23]. Although submaximal CCK stimulation of pancreatic acini induces the translocation and activation of PKCδ[29], this is not sufficient to activate NF-κB[29,30]. Here, we used the minimal TNF-α concentration (10 ng/mL) that we determined inhibited CCK-stimulated amylase secretion and induced actin disorganization (Figure 1A-F). Figure 2A and B show that CCK alone did not change the activity of NF-κB subunits over basal vehicle-control levels (1.03 ± 0.06 and 1.02 ± 0.05 fold of control for p65 and p50, respectively). However, TNF-α-induced an increase in the activity of both NF-κB subunits (1.52 ± 0.13 and 1.44 ± 0.11 fold of control for p65 and p50, respectively) that was amplified by CCK stimulation (3.28 ± 0.24 and 2.89 ± 0.20 fold of control for p65 and p50, respectively). Furthermore, we found that both TNF-α and TNF-α plus CCK-induced increases in the activities of NF-κB subunits were inhibited, not only by the non-specific PKC inhibitor calphostin C (iPKC∑) (p65, 1.04 ± 0.09 and 1.12 ± 0.11 fold of control for TNF-α and TNF-α + CCK, respectively; p50, 0.98 ± 0.04 and 1.14 ± 0.11 fold of control for TNF-α and TNF-α + CCK, respectively), but by the specific PKCδ translocation inhibitor δV1-1 (iPKCδ) (p65, 0.93 ± 0.07 and 1.05 ± 0.09 fold of control for TNF-α and TNF-α + CCK, respectively; p50, 1.12 ± 0.06 and 1.04 ± 0.11 fold of control for TNF-α and TNF-α + CCK, respectively), and by the specific PKCε translocation inhibitor εV1-2 (iPKCε) (p65, 1.0 ± 0.06 and 1.12 ± 0.10 fold of control for TNF-α and TNF-α + CCK, respectively; p50, 1.00 ± 0.06 and 1.12 ± 0.10 fold of control for TNF-α and TNF-α + CCK, respectively). Neither the specific PKCα inhibitor Gö6976 (iPKCα) nor the PKCζ myristoylated pseudosubstrate inhibitor (iPKCζ) modified the changes in the activities of the NF-κB subunits induced by TNF-α or TNF-α plus CCK.

TNF-α potentiates submaximal CCK-induced trypsin activity

We proceeded to analyze trypsin activity in pancreatic acini. Figure 2C shows that submaximal CCK alone only moderately increased trypsin activity (1.39 ± 0.12 fold of control), as was previously reported for submaximal cerulein[24,31,32]. While basal trypsin activity was not modified by TNF-α alone (1.09 ± 0.04 fold of control), its presence potentiated CCK-induced trypsin activity (2.63 ± 0.24 fold of control). Given that PKCδ and PKCε also modulate trypsin activity in pancreatic acinar cells[24], we further assessed trypsin activity in the presence of PKC inhibitors. We found that both CCK and TNF-α plus CCK-induced increases in trypsin activity were inhibited, not only by iPKC∑ (1.10 ± 0.09 and 1.61 ± 0.14 fold of control for CCK and TNF-α + CCK, respectively), but also by iPKCδ (1.12 ± 0.08 and 1.75 ± 0.15 fold of control for CCK and TNF-α + CCK, respectively). By contrast, iPKCε only inhibited TNF-α plus CCK-induced trypsin activity enhancement (1.38 ± 0.14 and 1.71 ± 0.12 fold of control for CCK and TNF-α + CCK, respectively). Furthermore, neither iPKCα nor iPKCζ modified the increase in trypsin activity induced by CCK or TNF-α plus CCK.

PKCδ and PKCε are translocated and activated by TNF-α plus submaximal CCK

To validate the results obtained with the specific PKC inhibitors, we examined the expression of PKCδ and PKCε in subcellular fractions from isolated pancreatic acini, as well as the respective kinase activity. Previous studies have shown that while PKCδ is translocated from cytosol to membranes and activated by both TNF-α and submaximal CCK, PKCε is only translocated and activated by TNF-α[23,29]. Here, we found similar results (1.35 ± 0.15 and 1.59 ± 0.14 fold of control for TNF-α and CCK, respectively, for PKCδ activity; 1.29 ± 0.09 and 1.02 ± 0.06 fold of control for TNF-α and CCK, respectively, for PKCε activity, Figure 2D-F). Furthermore, we showed that TNF-α plus submaximal CCK also translocated and activated both PKCδ and PKCε, significantly increasing the translocation and activation of PKCδ compared to either TNF-α or CCK alone (1.88 ± 0.12 and 1.41 ± 0.12 fold of control for TNF-α + CCK for PKCδ and PKCε, respectively, Figure 2D-F).

TNF-α does not perturb intracellular calcium oscillations induced by submaximal CCK

Both trypsinogen and NF-κB activation in pancreatic acini require not only PKC activity, but also calcium (Ca^{2+})[24,23,31,33]. To test the possibility that TNF-α could influence CCK activation of trypsinogen and/or NF-κB by directly affecting the Ca^{2+} signal, we studied the effects of TNF-α (10 ng/mL) on changes to the cytosolic free calcium concentration ($[Ca^{2+}]_i$) induced by CCK (50 pmol/L) in pancreatic acini. At submaximal concentrations, CCK induced oscillatory changes in $[Ca^{2+}]_i$ with a typical pattern consisting of base-line spikes[34]. Our results indicate that TNF-α did not affect the basal $[Ca^{2+}]i$ level in pancreatic acini, nor had any significant effects on the CCK-induced $[Ca^{2+}]i$ oscillations (data not shown).

TNF-α pus submaximal CCK induces necrosis in pancreatic acini

The process of necrosis produces damaged plasma mem-

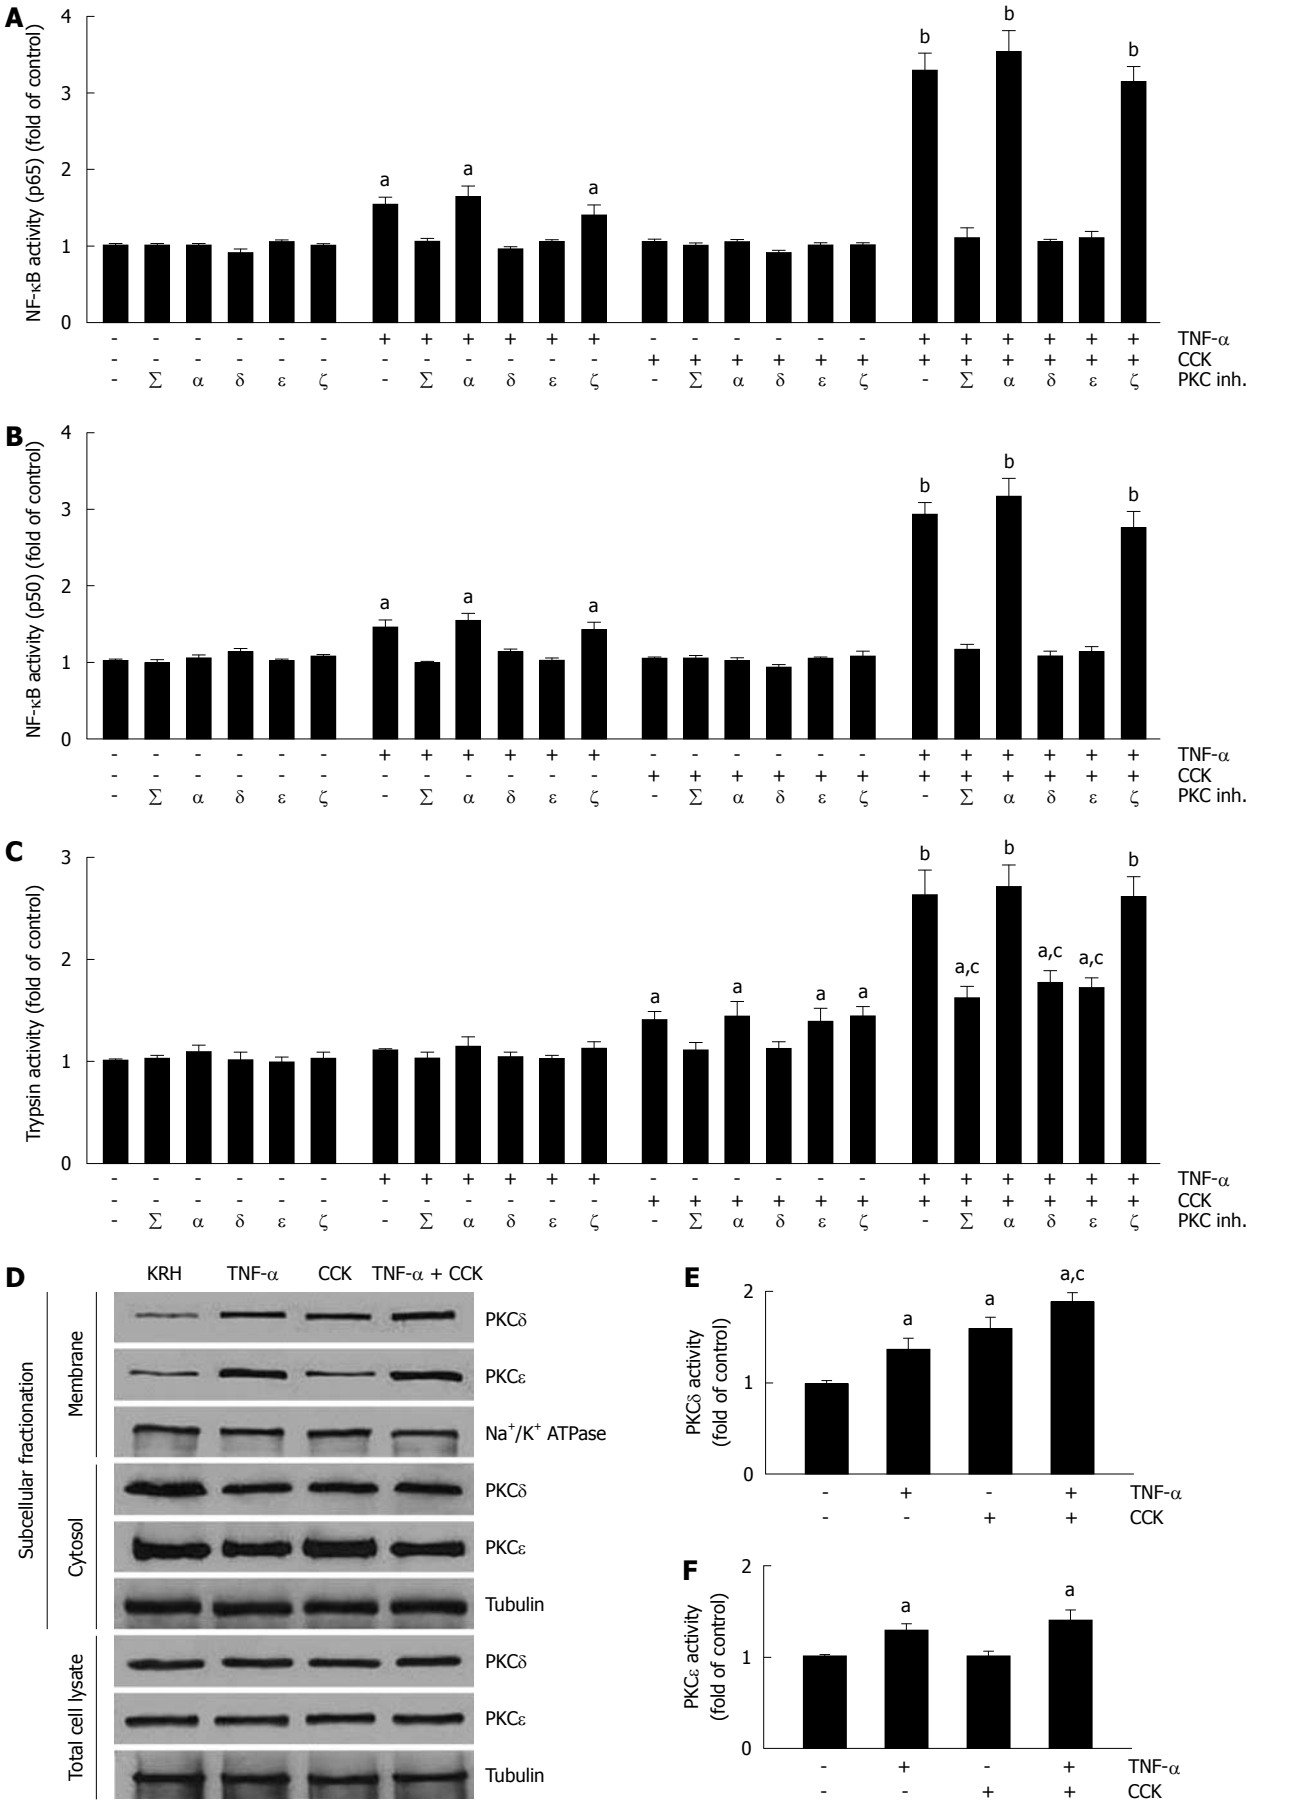

Figure 2 Mutual modulation of tumor necrosis factor-α-induced activation of nuclear factor-κB and cholecystokinin-induced trypsin activity by submaximal cholecystokinin and tumor necrosis factor-α, respectively, involves specific protein kinase C isoforms δ and ε. A-C: Isolated pancreatic acini were incubated in

Krebs-Ringer-HEPES (KRH) (vehicle-control, 3 h), or in KRH (2.5 h) followed by Calphostin C (iPKCΣ, 500 nmol/L, 30 min) or Gö6976 (iPKCα, 200 nmol/L, 30 min), or with the PKCδ translocation inhibitor δV1-1 (iPKCδ, 3 h, 10 μmol/L) or the PKCε translocation inhibitor εV1-2 (iPKCε, 3 h, 10 μmol/L) or the PKCζ myristoylated pseudosubstrate inhibitor (iPKCζ, 3 h, 10 μmol/L). The acini were then stimulated with either 10 ng/mL tumor necrosis factor-α (TNF-α) for 2 h, or 50 pmol/L cholecystokinin (CCK) for 1 h, or 10 ng/mL TNF-α for 1 h followed by 10 ng/mL TNF-α plus 50 pmol/L CCK for 1 h, or KRH for 2 h. Nuclear factor-κB (NF-κB) (p65) and NF-κB (p50) in nuclear extracts (A and B) were measured by enzyme-linked immunosorbent assay (ELISA) using the respective assay kit. Trypsin activity (C) was measured as described in Materials and Methods. A-C: Results are expressed as fold of control and correspond to the mean ± SE from four independent experiments, with samples performed in triplicate. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* KRH without inhibitors; $^{c}P < 0.05$ *vs* TNF-α plus CCK without inhibitors; D-F: Dispersed acini were pre-incubated in KRH for 1 h and then stimulated with either 10 ng/mL TNF-α for 1.5 h, or 50 pmol/L CCK for 30 min, or 10 ng/mL TNF-α for 1 h followed by 10 ng/mL TNF-α plus 50 pmol/L CCK for 30 min, or KRH (vehicle-control) for 1.5 h; D: Subcellular fractionation showing PKCδ and ε translocation from the cytosol to the membrane upon TNF-α and/or CCK stimulation. After stimulation, acini were fractionated into membrane and cytosol fractions, and total cell lysates. 10 μg of protein of each fraction was separated on SDS-PAGE and immunoblotted with the antibodies to the indicated proteins. These blots are representative of three independent experiments; E, F: PKCδ and ε activity assays. Each well was loaded with 10 μg of protein. PKCδ and ε activities were measured by ELISA using the respective assay kit. Results are expressed as fold of control and correspond to the mean ± SE from four independent experiments, with samples performed in triplicate. $^{a}P < 0.05$ *vs* vehicle-control; $^{c}P < 0.05$ *vs* either TNF-α or CCK.

branes, releasing LDH into the extracellular medium. Thus, to evaluate necrosis in the present study, we measured LDH release from pancreatic acini. Figure 3A shows that unstimulated acini exhibited a 6.1% ± 0.5% LDH release, which remained relatively unchanged when acini were stimulated with TNF-α or CCK alone (6.4% ± 0.7% and 6.8% ± 0.8%, respectively). However, acini stimulated with TNF-α plus CCK showed a significant increase of 83.6% for LDH release (11.2% ± 1.1%).

TNF-α plus submaximal CCK potentiates TNF-α-induced caspases' activity

Subsequently, we assessed the activity of caspases in pancreatic acini. Figure 3B shows that TNF-α does augment caspases' activity (1.22 ± 0.05, 1.25 ± 0.11, 1.24 ± 0.09 and 1.21 ± 0.08 fold of control for caspases 2, 3, 8, and 9, respectively). Although CCK alone did not change the activity of these pro-apoptotic proteins (1.02 ± 0.06, 1.03 ± 0.08, 1.04 ± 0.11 and 1.02 ± 0.06 fold of control for caspases 2, 3, 8, and 9, respectively), its combination with TNF-α further increased the activation achieved by TNF-α alone (1.93 ± 0.14, 2.14 ± 0.23, 1.87 ± 0.16 and 1.82 ± 0.19 fold of control for caspases 2, 3, 8, and 9, respectively).

TNF-α plus submaximal CCK depletes ATP and increases the ADP/ATP ratio in pancreatic acini

ATP depletion associated with the percentage of ATP loss and changes in the ADP/ATP ratio allows discrimination of apoptosis from necrosis. Thus, we analyzed ATP and ADP levels in pancreatic acini. Figure 3C shows that neither TNF-α nor CCK alone changed ATP levels compared to basal vehicle-control (10.8 ± 0.7, 11.6 ± 0.7, and 12.5 ± 0.2 μmol/mg protein for TNF-α, CCK and vehicle-control, respectively). However, TNF-α plus CCK significantly decreased ATP levels (4.3 ± 0.6 μmol/mg protein). As shown in Figure 3D, only TNF-α plus CCK significantly increased ATP loss (65.6% ± 4.8% of control), while TNF-α or CCK alone did not (13.6% ± 6.4% and 7.9% ± 5.6% of control, respectively). Figure 3E shows that only TNF-α plus CCK increased the ADP/ATP ratio over basal control (0.85 ± 0.12 *vs* 0.43 ± 0.01, respectively), while TNF-α or CCK alone did not (0.49 ± 0.04 and 0.46 ± 0.03, respectively).

Pancreatic acinar cells secrete TNF-α in response to different stress stimuli

It is well established that pancreatic acinar cells produce TNF-α[22]. Secretion of TNF-α in response to a stressor was previously demonstrated in rat pancreatic acinar cells by their exposure to phorbol-12-myristate-13-acetate (PMA)-primed neutrophils[19,20]. Here, we evaluated the response of pancreatic acini to hypoxia/reoxygenation (H/R) and hydrogen peroxide (H_2O_2) treatments. Figure 4A and B show that both stress stimuli increased TNF-α levels (3.2 ± 0.3 and 7.0 ± 0.6 fold of control for H/R and H_2O_2, respectively). Incubation of acini with the specific ROS inhibitor NAC reduced TNF-α levels (1.7 ± 0.2 and 3.8 ± 0.4 fold of control for H/R and H_2O_2, representing a reduction of 46.9% and 45.7%, respectively), indicating that ROS mediated these stress-induced TNF-α secretions.

Chronic stress plus submaximal cerulein stimulation induces mild to moderate pancreatitis

We then evaluated chronic stress plus submaximal cerulein pancreatitis in a rat model, together with an anti-TNF-α treatment as a putative therapy. First, we examined relevant serum and histological parameters of pancreatitis. Table 1 shows that Stress (+) treatment alone did not affect serum amylase and lipase levels, which were only slightly increased in the Stress (-) plus Cer group. However, this increase did not correlate with pancreatitis, which was confirmed by the completely normal pancreatic histology (Figure 5 and Table 2). In contrast, the Stress (+) plus Cer group exhibited a massive increase in serum amylase (8.4 ×) and lipase levels (85.4 ×) (Table 1) with corresponding histological changes of mild (cytoplasmic vacuoles) to moderate pancreatitis (hemorrhage, leukocyte infiltration, and necrosis) (Figure 5 and Table 2). Of particular relevance for our model, serum TNF-α was not detected in any of the Stress (-) groups (Table 1). Importantly, while TNF-α levels were detected in vehicle-control Stress (+) group, they further increased (3.5 ×) in the Stress (+) plus Cer group, which also demonstrated a marked augmentation (6.5 ×) in serum levels of LDH (Table 1). Of note, relevant serum parameters, as well as the histopathological changes found in the Stress (+) plus Cer group, were all diminished by the anti-TNF-α treatment (Figure 5, Tables 1 and 2).

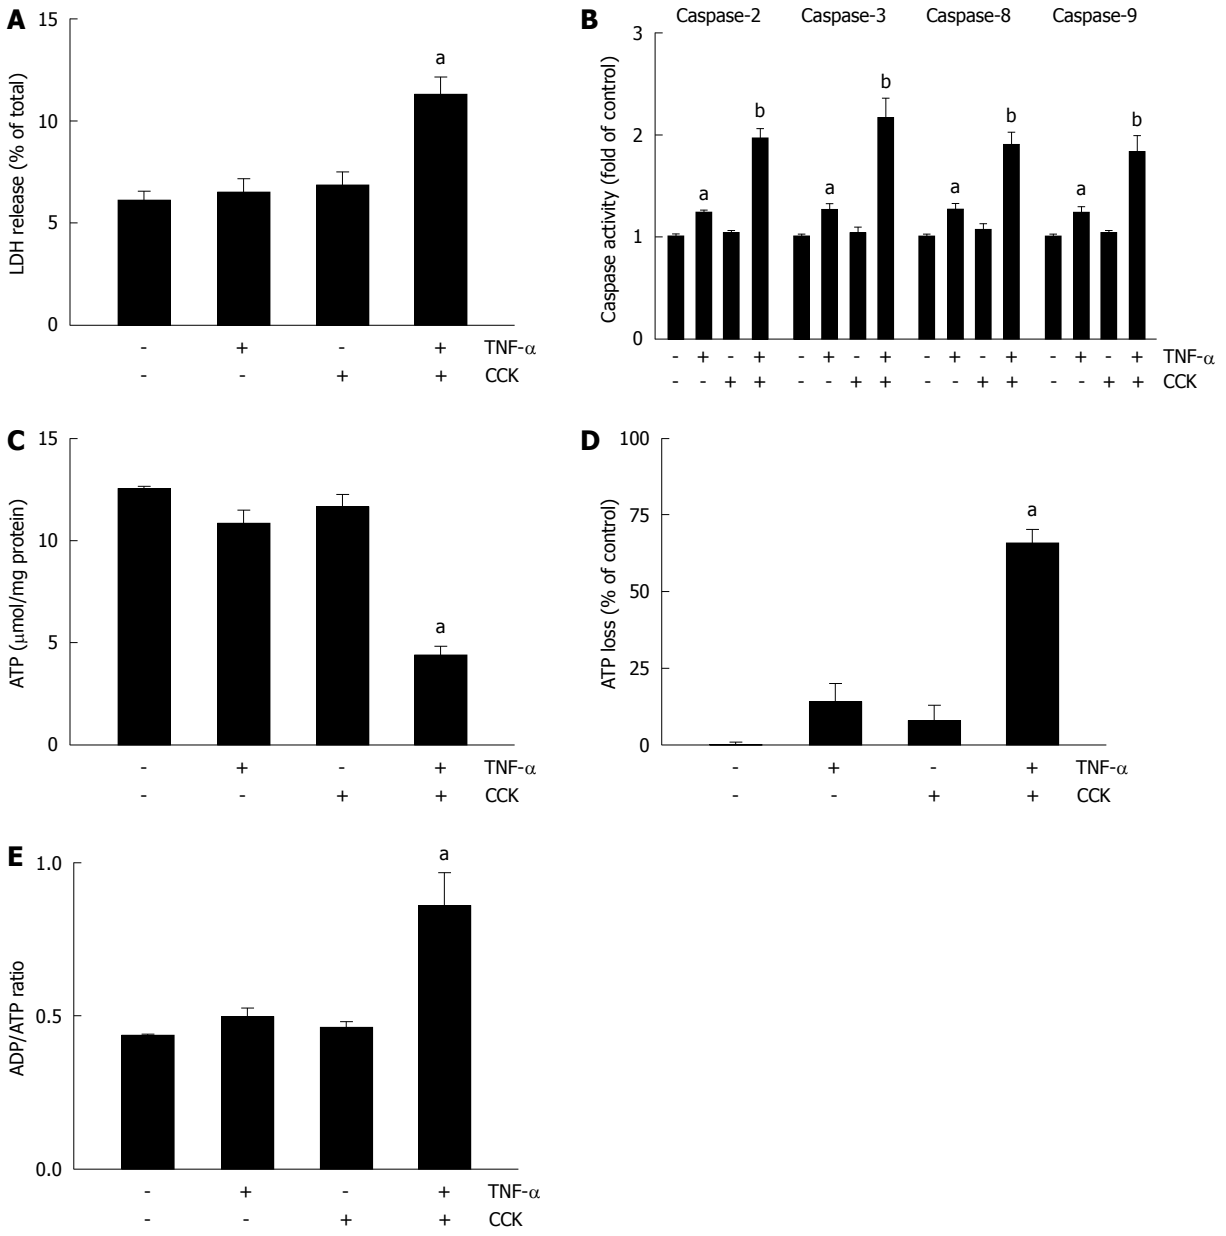

Figure 3 Tumor necrosis factor-α plus cholecystokinin induce apoptosis and necrosis in pancreatic acini. A-E: Isolated pancreatic acini were stimulated with either 10 ng/mL tumor necrosis factor-α (TNF-α) for 2 h, or 50 pmol/L cholecystokinin (CCK) for 1 h, or 10 ng/mL TNF-α for 1 h followed by 10 ng/mL TNF-α plus 50 pmol/L CCK for 1 h, or vehicle-control for 2 h. A: Lactate dehydrogenase (LDH) was measured by the DGKC optimized kinetic method using the respective assay kit. Results are expressed as a percentage of total cellular LDH determined by permeabilizing cells with Triton X-100, and correspond to the mean ± SE from four independent experiments, with samples performed in triplicate. $^{a}P < 0.05$ *vs* vehicle-control; B: Caspases 2, 3, 8, and 9 activity was measured by a colorimetric/fluorometric method using the respective assay kits. Results are expressed as fold of control and correspond to the mean ± SE from four independent experiments, with samples performed in triplicate. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* vehicle-control; C-E: ATP and ADP levels were measured by a bioluminescent method using the respective assay kits. ATP loss was calculated as a percentage of the decrease in values corresponding to vehicle-control. Results correspond to the mean ± SE from four independent experiments, with samples performed in triplicate. $^{a}P < 0.05$ *vs* vehicle-control.

We then analyzed inflammatory parameters in pancreatic tissue. The results are shown in Table 3. As was observed in serum, pancreatic TNF-α was only detected in the Stress (+) groups, where the levels were further increased (3.4 ×) in the Cer subgroup, and were diminished by 63% by the anti-TNF-α treatment. Remarkably, HIF-1α showed a similar trend, being only detected in the Stress (+) groups, where the levels were further increased (4 ×) in the Cer subgroup, and diminished by 58% by the anti-TNF-α treatment. Other assessed parameters (active trypsin, NF-κB (p65) and (p50), MPO, LPO, and MDA) also exhibited increased values in the Stress (+) plus Cer group, which were reduced by the anti-TNF-α treatment.

We also evaluated inflammatory and general biochemical parameters in blood. As shown in Table 4, all the studied inflammatory parameters (leukocyte number, C-reactive protein, HSP-72, IL-6, IL-10, and MIP-1α) were increased in the Stress (+) plus Cer group, whose values correlated with mild to moderate pancreatitis. Im-

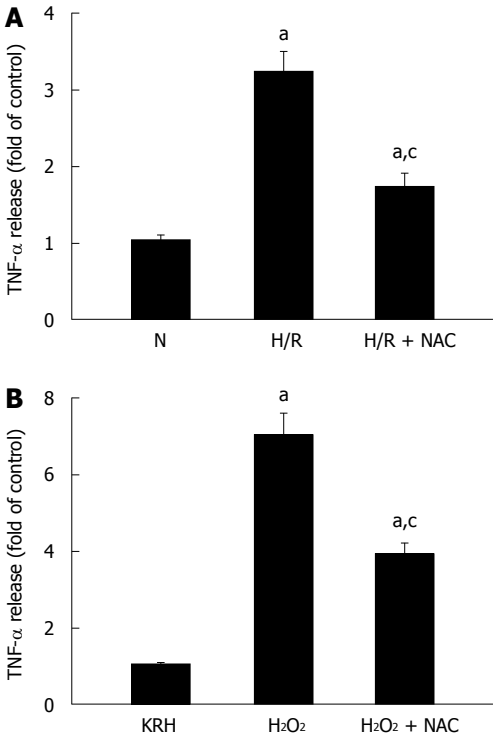

Figure 4 Pancreatic acinar cells secrete tumor necrosis factor-α in response to different stressful stimuli. A: Isolated pancreatic acini were cultured in normoxic (N) conditions for 3.5 h or under hypoxia followed by normoxia-reoxygenation (H/R) for 30 min and 3 h, respectively, in the absence or presence of N-acetyl-cysteine (NAC) (30 mmol/L); B: Isolated pancreatic acini were cultured in Krebs-Ringer-HEPES (KRH) (vehicle-control) or stimulated with H_2O_2 (50 μmol/L) for 3 h in the absence or presence of NAC (30 mmol/L); A and B: TNF-α released into the supernatant was determined by enzyme-linked immunosorbent assay using the respective assay kit. Results are expressed as fold of control and correspond to the mean ± SE from four independent experiments, with samples performed in triplicate. $^aP < 0.05$ *vs* normoxia (A) or to KRH (B); $^cP < 0.05$ *vs* H/R (A) or H_2O_2 (B).

portantly, these elevated values were all attenuated by the anti-TNF-α treatment. Furthermore, Table 5 shows that the studied biochemical parameters (glucose, urea, creatinine, calcium, proteins, AST, ALT, and hematocrit) also evidenced alterations compatible with mild to moderate pancreatitis in the Stress (+) plus Cer group, which were mitigated in the Stress (+) plus anti-TNF-α plus Cer group.

As performed for isolated pancreatic acini, we then investigated pancreatic caspases and energy metabolism in pancreatic tissue. Table 6 shows that caspases 2, 3, 8, and 9 were only augmented in the Stress (+) groups. These values were further increased (6-8 ×) in the Cer subgroup, and diminished by between 21%-37% by the anti-TNF-α treatment. Table 7 shows that the Stress (+) plus Cer group experienced a severe decrease in ATP content (> 70%) and a significant increase in the ADP/ATP ratio (3 ×). Both ATP loss and the ADP/ATP ratio were partially restored by the anti-TNF-α treatment.

Chronic stress plus submaximal cerulein stimulation induces pancreatitis-associated lung injury

A common, and often fatal, systemic complication of acute pancreatitis is acute lung injury, which frequently evolves to acute respiratory distress syndrome[35]. To evaluate this, we examined histological and inflammatory parameters in lung tissue. Figure 6 and Tables 8 and 9 show that histopathological parameters (edema, hemorrhage, and leukocyte infiltrate, Figure 6 and Table 8) as well as MPO, NF-κB (p65), and (p50) (Table 9) were uniformly normal in all Stress (-) groups. In contrast, the Stress (+) plus Cer group exhibited histopathological and inflammatory changes compatible with pancreatitis-associated lung injury (Figure 6, Tables 8 and 9). As was observed in pancreatic tissue, TNF-α levels were only detected in the Stress (+) groups, with increased values in the Cer subgroup (3 ×), which were attenuated by 57% by the anti-TNF-α treatment (Table 9).

Additionally, we measured caspases' activity and energy metabolism in lung tissue. The results are presented in Tables 10 and 11, respectively. As it was found for pancreatic tissue (Tables 6 and 7), caspases 2, 3, 8, and 9 were only augmented in the Stress (+) groups. These values were further increased (8-9 ×) in the Cer subgroup, and diminished between 30%-38% by the anti-TNF-α treatment (Table 10). Table 11 shows that the Stress (+) plus Cer group experienced a severe decrease in ATP content (> 65%) and a significant increase in the ADP/ATP ratio (4 ×). Here, the ATP loss and the ADP/ATP ratio were also partially restored by the anti-TNF-α treatment.

Chronic stress induces gastric lesions

In the general adaptation syndrome described by Selye, the first lesions to appear as a result of stress were found in the stomach. To corroborate that the protocol we have used in our model produces stress, we evaluated histopathological changes together with apoptotic/necrotic parameters in stomach tissue. Tables 12-14 show that our protocol of restraint was effective in generating stress in rats.

DISCUSSION

Although oxidative stress and inflammation each occur in the pancreas during the early stage of supramaximal cerulein-induced acute pancreatitis, oxidative stress or an inflammatory insult alone does not cause the characteristic changes of acute pancreatitis[36]. However, our present study demonstrates that chronic stress leaves the exocrine pancreas susceptible to pancreatitis by submaximal cerulein stimulation.

The main events occurring in the pancreatic acinar cell that initiate and propagate acute pancreatitis include inhibition of secretion, intracellular activation of proteases, and generation of inflammatory mediators[37]. These cellular events can be correlated with the acinar morphological changes (retention of enzyme content, formation of large vacuoles containing both digestive enzymes and lysosomal hydrolases, and necrosis), which are observed in the well-established *in vivo* experimental model of supraphysiological cerulein-induced pancreatitis[38], as well as in human acute pancreatitis[39].

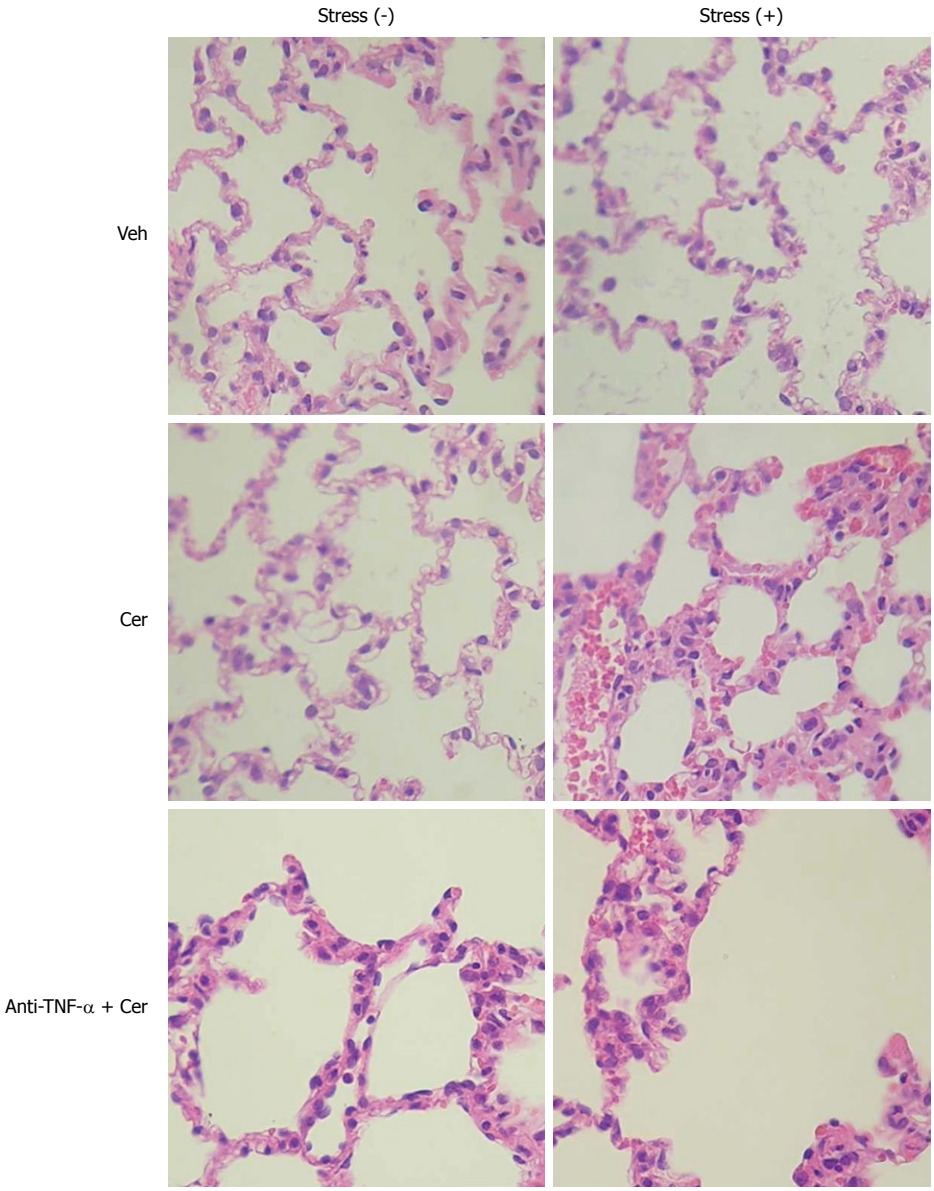

Figure 6 Chronic stress plus submaximal cerulein stimulation induces pancreatitis-associated lung injury. Rats exposed to sessions of restraint (4 h every day for 21 d), Stress (+) groups, and rats in the control, Stress (-) groups, received daily intraperitoneal (ip) injections of either tumor necrosis factor-α (TNF-α)-neutralizing antibody (50 μg/kg) or control IgG, rats were then treated with six hourly ip injections of either saline or cerulein (Cer, 0.2 μg/kg). Here, we employed a new model of chronic stress plus submaximal cerulein stimulation to induce pancreatitis. Furthermore, we studied a new *in vitro* model of TNF-α plus submaximal CCK stimulation, and obtained results that not only reproduced the main pathological events experienced by the acinar cell, but also support the pancreatitis observed in animals exposed to the *in vivo* model.

First, we established that the pro-inflammatory cytokine TNF-α inhibits submaximal CCK-stimulated amylase secretion from pancreatic acini. While TNF-α alone does not stimulate amylase secretion in human pancreas[40] or in isolated rat pancreatic acini, it certainly alters the typical filamentous actin distribution[21]. A similar redistribution of actin from apical to basolateral membranes was observed in pancreatic acini supra-stimulated with CCK[41]. Disorganization of the actin cytoskeleton is associated with dysregulation of pancreatic enzyme secretion[42], which could explain our findings (Figure 1).

Although necessary, the inhibition of pancreatic enzyme secretion alone is not sufficient to induce pancreatitis[37]. Nonetheless, we also demonstrated that the combination of TNF-α and submaximal CCK pathologically activates NF-κB and trypsinogen in pancreatic acini. TNF-α has been shown to regulate the activity of distinct PKC isoforms in diverse cell types, including the pancreatic acinar cell[23,43,44]. PKC consists of a family of at least 12 isozymes differing in tissue distribution and activation requirements. There are three subclasses: classical PKC isozymes (-α, -β1, -β2, and -γ), which require calcium and are activated by diacylglycerol and phorbol ester; the novel PKC isozymes (-δ, -ε, -η, and -θ), which are activated by diacylglycerol and phorbol ester independently of calcium; and the atypical PKC isozymes (-λ, -ι, and -ζ), which are calcium independent and not responsive to phorbol ester. Rat pancreatic acini express the α, δ, ε, and ζ PKC isozymes[45]. Changes in PKC activity are associated with inflammation in a variety of tissues, including skin, kidney, intestine, and pancreas[46-49]. Specifically, PKC-δ and PKC-ε regulate the signal transduction pathways implicated in the pathophysiological activation of NF-κB and trypsinogen in pancreatic acini[23,24]. TNF-α activates both PKC-δ and PKC-ε in pancreatic acini[23], and our study shows

that in turn, these convert physiological CCK concentrations into physiopathogenic concentrations (Figure 2). Different studies have consistently shown that modulation of PKC activity sensitizes acinar cells to physiological CCK and cerulein treatments, resulting in harmful levels of NF-κB and trypsin activity, respectively[29,24]. In agreement with TNF-α-regulated functions[11] and the above discussed results, we found that TNF-α plus submaximal CCK induced both apoptosis and necrosis in acinar cells, as revealed by the increased caspases' activity, increased LDH release, ATP loss, and changes in the ADP/ATP ratio (Figure 3).

Secretion of TNF-α by several stress stimuli has been demonstrated *in vitro* in many cell types, including pancreatic acinar cells[13-20], and *in vivo* in different tissues[10,12,50,51]. We have shown that *in vitro* hypoxia-reoxygenation conditions also induce TNF-α secretion by acinar cells (Figure 4). These conditions are concomitant with ischemia-reperfusion processes, which can be the result of microcirculatory disturbances generated by stress[52]. Indeed, local pancreatic blood flow is reduced by stress[53]. Hence, alternate vasoconstriction and vasodilatation leading to tissue ischemia and reperfusion could reflect the putative local origin of chronic stress-derived TNF-α found in the rat exocrine pancreas, which is supported by the increased levels of HIF-1α observed in the Stress (+) groups (Figure 5, Tables 1-3). HIF-1α is a transcription factor induced by hypoxic conditions and is involved in different inflammatory processes, such as dermatitis, rheumatoid arthritis[54], and also pancreatitis[55].

Our model of chronic stress plus submaximal doses of cerulein produced the hallmark features of pancreatitis (Figure 5, Tables 1-5), and also of its most frequent complication, pancreatitis-associated lung injury (Figure 6, Tables 8 and 9), which characterizes the severity of this disease[34]. Importantly, treatment with a TNF-α antibody greatly protected rats from chronic stress-related pancreatitis (Figures 5 and 6, Tables 1-5, 8 and 9). These results strongly suggest a causative role for TNF-α in the development of pancreatitis induced in chronically stressed animals.

Although anti-TNF-α therapy decreased pancreatitis severity, animals still developed a very-mild form of this disease. The limited protection achieved *in vivo* was probably due to a multiplicity of factors involved in the development of pancreatitis, some of which seem to act independent of TNF-α. Further work will be required to identify the additional molecules and signaling pathways involved in chronic stress as a contributing factor to pancreatitis. Nevertheless, this initial work demonstrates a novel susceptibility mechanism by which chronic stress could predispose the exocrine pancreas to pancreatitis triggered by physiological levels of cerulein stimulation.

COMMENTS

Background

Pancreatitis is an inflammatory disorder of the pancreas characterized by premature activation of pancreatic enzymes leading to pancreatic autodigestion, persistent inflammation, edema, and possible pancreatic necrosis. A wide variety of factors, including gallstones, alcoholism, and a complication of endoscopic retrograde cholangiopancreatography, are thought to contribute to the pathogenesis of this disease.

Research frontiers

Initial inflammation of the pancreas may progress to involve other organs such as the kidney, lungs, and liver. Inflammatory mediators induce complications that can range from local to systemic, leading to a severe form with high morbidity/mortality. Thus, it is critical to identify the precipitating factors of pancreatitis, because treatment will diverge significantly depending on the etiology.

Innovations and breakthroughs

Chronic stress has received little attention as a factor contributing to pancreatitis. Using a new model combining chronic restraint and physiological stimulation of the exocrine pancreas, the authors have established that chronic stress might sensitize the pancreas to pancreatitis. Furthermore, they have begun to elucidate the molecules responsible for the initial events.

Applications

The protective effect shown by anti-tumor necrosis factor-α therapy in this experimental model of pancreatitis indicates a potential clinical application for this antibody in treating this disease. However, the results also indicate that other molecules might be involved in this pathology. This suggests that better results could be obtained by combined therapies, but this requires further experiments to identify additional key contributing molecules.

Peer review

The authors present a study that demonstrates that chronic stress enhances the susceptibility for pancreatic damage produced by physiological cerulein stimulation. It is thought that the authors have produced a good piece of work.

Abstract

AIM: To develop a sensitive assay for screening compounds against hepatitis C virus (HCV).

METHODS: The proteolytic cleavage of NS3/4A on enhanced yellow fluorescent protein (eYFP)-mitochondrial antiviral signaling protein (MAVS) was examined by reporter enzyme secreted placental alkaline phosphatase (SEAP), which enabled us to perform ongoing monitoring of anti-HCV drugs through repeated chemiluminescence. Subcellular localization of eYFP-MAVS was assessed by fluorescence microscopy. Cellular localization and protein levels were examined by Western blotting.

RESULTS: HCV NS3/4A protease cleaved eYFP-MAVS from mitochondria to block the activation of interferon (IFN)-β promoter, thus resulting in downregulation of SEAP activity. The decrease in SEAP activity was proportional to the dose of active NS3/4A protease. Also this reporter assay was used to detect anti-HCV activity of IFN-α and cyclosporine A.

CONCLUSION: Our data show that this reporter system is a sensitive and quantitative reporter of anti-HCV inhibitors. This system will constitute a new tool to allow the efficient screening of HCV inhibitors.

Key words: Mitochondrial antiviral signaling protein; Hepatitis C virus; Interferon-β; Drug screening

INTRODUCTION

Hepatitis C virus (HCV) infection represents a major public health threat because of the chronic nature of the infection, its high prevalence and the significant morbidity of the resultant disease[1-3]. There is no vaccine, and drug treatment is costly and has poor efficacy[4,5]. New treatment regimens that are more efficacious and better tolerated by all patients are needed. Many new antiviral compounds have been synthesized; several of which have shown promising results in early clinical trials[6,7]. However,

development of new drugs is hampered by the lack of appropriate model systems. Therefore, there is an obvious and urgent need to develop a more effective and sensitive assay to facilitate the search for improved antivirals.

HCV is an enveloped virus that contains a single-stranded, positive-sense RNA genome of approximate 9.6 kb. The HCV genome encodes a large open reading frame that is flanked by structured 5' and 3' non-translated regions. There are at least 10 mature proteins that are contained in the polyprotein in the order: NH_2-core/E1/E2/p7/NS2/NS3/NS4A/NS4B/NS5A/NS5B-COOH, which is post-translationally processed. Processing of the nonstructural part of the polyprotein is mediated by the nonstructural NS3/4A protease and helicase[8-10]. Also, NS3/4A blocks the cellular interferon (IFN) response to double-stranded RNA by proteolytic cleavage of mitochondrial antiviral signaling protein (MAVS; also known as IPS-1, VISA, and CARDIF) or of the adaptor molecule Toll/interleukin-1 receptor domain-containing adaptor inducing IFN-β (TRIF)[11-16].

The ability of NS3/4A protease to control the antiviral host response to HCV facilitated our study to develop a new assay for drug screening. Here, we extended the utility of enhanced yellow fluorescent protein (eYFP)-MAVS/IFN-β-secreted placental alkaline phosphatase (SEAP) signaling pathway for anti-HCV drug discovery. Expression of NS3/4A protease in replicon cells disrupted the eYFP-MAVS/IFN-β-SEAP signaling pathway by proteolytic cleavage of eYFP-MAVS, which resulted in the loss of mitochondrial localization and abrogation of the eYFP-MAVS/IFN-β-SEAP signaling pathway. The decrease in SEAP activity was proportional to the dose of active NS3/4A protease. This reporter assay also was used to detect the activity of IFN-α and cyclosporine A (CsA). Our data show that this reporter system is a sensitive and quantitative reporter assay for anti-HCV inhibitors. This system will constitute a new tool to allow the efficient screening of HCV inhibitors.

MATERIALS AND METHODS

Plasmids

Plasmids eYFP-MAVS and pCon1-FL were kindly provided by Martin Baril and Dr. Charles M. Rice of Rockefeller University, respectively. Reporter plasmid of IFN-β-SEAP controlled by the promoter region of IFN-β (from -281 to 20) was constructed based on pTAL-SEAP (Clontech, Mountain View, CA, USA). The NS3/4A sequence derived from HCV type 1b (pCon1-FL) was cloned into pCI Mammalian Expression Vector using *Eco*RI and *Sal*I sites.

Cell culture and transfection

Huh-7.5 and HCV replicon cells that contained full-length HCV sequences of genotype 1b were maintained in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum (FBS; Biochrom AG, Berlin, Germany) and penicillin (100 μg/mL)/streptomycin (100 μg/mL). In 24-well plates, cells were seeded at a density of 6×10^4 cells per well in 500 μL DMEM/10% FBS. After incubation at 37℃ overnight, or until cells were approximately 70% confluent, cells were transfected with various plasmid constructs using Lipofectamine™ 2000 reagent (Invitrogen, Carlsbad, CA, USA). As an internal control for transfection efficiency, 0.02 μg Renilla luciferase plasmid, pRL-TK (Promega, Madison, WI, USA) was co-transfected with 1 μg of each expression vector in each experiment.

Treatment of cells with HCV inhibitors

Huh-7.5 and HCV replicon cells were seeded in 24-well plates at a density of 2×10^4 cells per well. After incubation at 37℃ overnight, cells were treated with various concentrations of IFN-α (Schering-Plough, Kenilworth, NJ, USA) or CsA (Sigma, St Louis, MO, USA). Two or three days later, cells were transfected with eYFP-MAVS and IFN-β-SEAP with the same concentration of drugs, and cells were incubated for one or two more days. Cell culture was collected and SEAP activity was measured by chemiluminescence. NS3 expression level in replicon cells was determined by Western blotting.

SEAP activity

SEAP activity was measured using the Phospha-Light™ assay kit (Tropix, Foster City, CA, USA) according to the manufacturer's instructions.

Western blotting

Protein concentration was estimated by BCA™ Protein Assay Kit from Pierce (Rockford, IL, USA). Cell lysates were separated by SDS-PAGE, and protein expression was detected by Western blotting analysis using antibodies. eYFP was detected using a rabbit polyclonal antibody (Proteintech, Chicago, IL, USA), actin was detected using a rabbit polyclonal antibody (Sigma), NS3 was detected using a goat polyclonal antibody (LifeSpan BioSciences, Seattle, WA, USA), with horseradish peroxidase (HRP)-conjugated secondary antibody followed by detection by chemiluminescent HRP substrate (Millipore, Billerica, MA, USA).

Statistical analysis

All results were expressed as the mean ± SD. Statistical comparisons between two groups were made using Student's *t* test after analysis of variance. The level of significance was set at $\alpha = 0.05$.

RESULTS

Activation of the IFN-β promoter by eYFP-MAVS

We assessed signaling activity of eYFP-MAVS in Huh7.5 cells by co-transfection alongside IFN-β-SEAP. As expected, eYFP-MAVS induced the activation of the IFN-β promoter. As shown in Figure 1, at 48 h post-transfection, eYFP-MAVS gave rise to an approximately 700-fold increase in SEAP activity. Subcellular localization of eYFP-MAVS was also assessed by fluorescence microscopy, with cells expressing eYFP-MAVS proteins. Prior to visualization, mitochondria and nuclei were labeled with

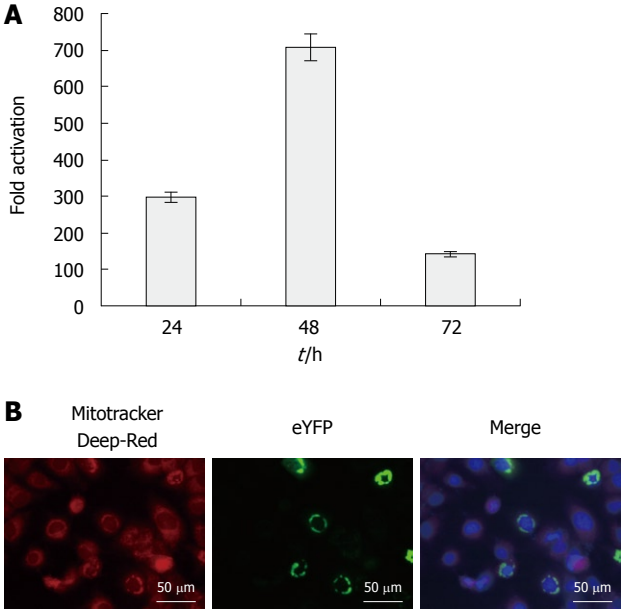

Figure 1 Activation of the interferon-β promoter by enhanced yellow fluorescent protein-mitochondrial antiviral signaling protein and subcellular localization of enhanced yellow fluorescent protein-mitochondrial antiviral signaling protein. A: Activation of the interferon (IFN)-β promoter by enhanced yellow fluorescent protein (eYFP)-mitochondrial antiviral signaling protein (MAVS). Expression vector of eYFP-MAVS was co-transfected with IFN-β-secreted placental alkaline phosphatase (SEAP) in Huh7.5 cells. pRL-TK was co-transfected to normalize transfection efficiency. SEAP activity in cell culture was measured at 24, 48 and 72 h post-transfection. Results are expressed as activation levels of the promoter compared to those in cells transfected with an empty expression vector. The error bars represent the SDs from the mean values obtained from three independent experiments performed in duplicate; B: Fluorescence microscopy of Huh7.5 cells transfected with eYFP-MAVS at 48 h post-transfection. Mitochondria were stained with Mitotracker deep red (red) and nuclei were labeled with 4',6-Diamidino-2-phenylindole (blue). Yellow labeling in the merged image indicates co-localization of eYFP-MAVS with mitochondria.

Mitotracker deep red and 4',6-Diamidino-2-phenylindole (DAPI), respectively. Figure 1 shows eYFP-MAVS localized to the mitochondrial membrane.

HCV NS3/4A protease disrupts eYFP-MAVS/IFN-β-SEAP signaling pathway by proteolytic cleavage of eYFP-MAVS in a dose-dependent manner

Our assay was used to assess HCV replication in Huh7.5 cells that stably expressed full-length HCV replicons. The replicon cell lines were co-transfected with eYFP-MAVS and IFN-β-SEAP, and naive Huh7.5 cells were simultaneously transfected to serve as a control. SEAP activity in HCV replicon cells was approximately 20% relative to that in the control group ($P < 0.05$, Figure 2A). In the presence of HCV NS3/4A protease, eYFP-MAVS was proteolytically cleavaged as reported previously[11,16]. The proteolytically cleaved eYFP-MAVS, named ΔeYFP-MAVS, only could be detected in HCV replicon cells (Figure 2C), whose localization shifted from the mitochondrial membrane to the cytoplasm (Figure 2B).

The sensitivity of this assay was examined by co-transfecting eYFP-MAVS and IFN-β-SEAP with various concentrations of pNS3/4A, or with the control empty vector. SEAP activity was evaluated 24, 48 and 72 h post-transfection. The expression of NS3/4A protease in trans-

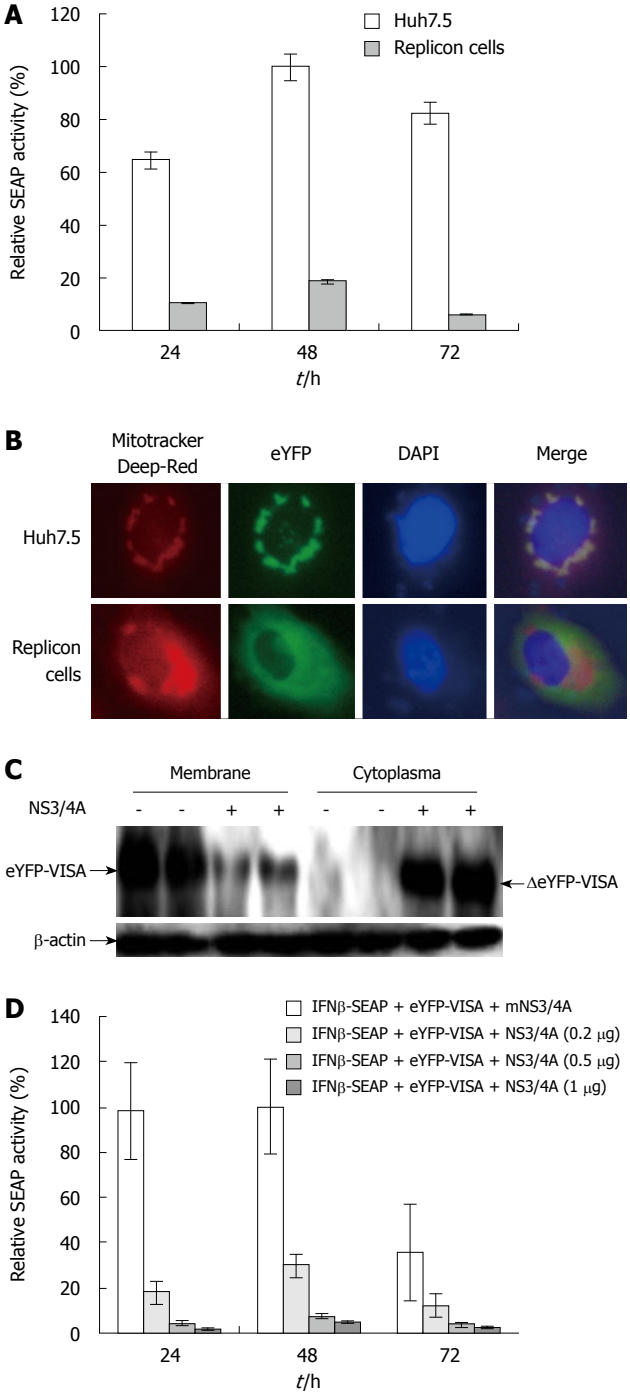

Figure 2 Hepatitis C virus NS3/4A protease activity impairs the enhanced yellow fluorescent protein-mitochondrial antiviral signaling protein/interferon-β-secreted placental alkaline phosphatase signaling pathway. A: Validation of the reporter assay system in Huh7.5 cells that contain full-length hepatitis C virus (HCV) replicons ($P < 0.05$). Huh7.5 and replicon cells were co-transfected with enhanced yellow fluorescent protein (eYFP)-mitochondrial antiviral signaling protein (MAVS) and interferon (IFN)-β-secreted placental alkaline phosphatase (SEAP). pRL-TK was co-transfected to normalize transfection efficiency. SEAP activity was examined at 24, 48 and 72 h after transfection. Bars indicate SD ($n = 3$); B: Localization of eYFP-MAVS. Subcellular localization of eYFP-MAVS was assessed by fluorescence microscopy 48 h post-transfection in Huh7.5 and replicon cells; C: Western blotting analysis of eYFP-MAVS cleaved by NS3/4A protease. Lysates of Huh7.5 and replicon cells treated as above were harvested at 48 h post-transfection and analyzed by Western blotting. Arrows indicate the positions of eYFP-MAVS and Δ eYFP-MAVS, respectively; D: Huh7.5 cells were co-transfected with eYFP-MAVS, IFN-β-SEAP and increasing amounts of expression plasmid pNS3/4A that encoded HCV NS3/4A protease (0, 0.2, 0.5 and 1 μg). pRL-TK was co-transfected to normalize transfection efficiency. SEAP activity in cell culture was measured at 24, 48 and 72 h post-transfection. Bars indicate SD ($n = 3$).

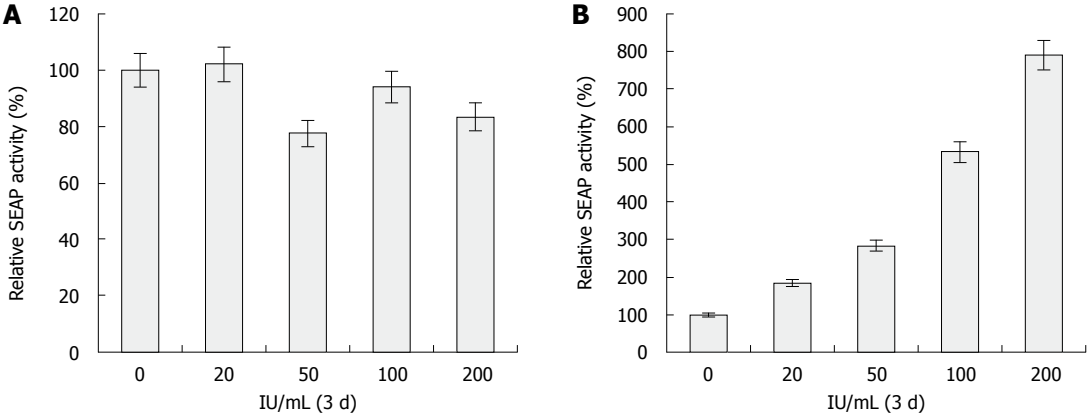

Figure 3 Secreted placental alkaline phosphatase reporter correlates with the anti-hepatitis C virus activity of interferon-α. A, B: Increase of secreted placental alkaline phosphatase (SEAP) activity in enhanced yellow fluorescent protein (eYFP)-mitochondrial antiviral signaling protein (MAVS) and interferon (IFN)-β-SEAP co-transfected Huh7.5 ($P > 0.05$) and replicon cells ($P < 0.05$) treated with IFN-α. Before transfection, Huh7.5 and replicon cells were incubated in the absence or presence of 20, 50, 100 and 200 IU/mL IFN-α for 72 h. SEAP activity was measured at 48 h post-transfection in the presence of IFN-α. The percentage increase in luciferase activity relative to the untreated controls was plotted. Bars indicate SD ($n = 3$).

fected cells resulted in the expected downregulation of the eYFP-MAVS/IFN-β-SEAP signaling pathway in a dose-dependent manner ($P < 0.05$, Figure 2D). These results indicated that this reporter system could be used for quantitative analysis of NS3/4A protease activity.

Feasibility of this system to reflect the activity of HCV inhibitors

To show the feasibility of this reporter system for characterizing HCV inhibitors, Huh-7.5 and HCV replicon cells incubated with various concentrations of IFN-α, ranging from 0 to 200 U/mL for 72 h were transfected with eYFP-MAVS and IFN-β-SEAP. At 48 h, SEAP activity of replicon cells was proportional to the extent of anti-HCV treatment ($P < 0.05$, Figure 3A). Meanwhile, Western blotting analysis of these samples revealed the amount of NS3 protease that was encoded by the HCV replicon was proportionally reduced by treatment with increasing concentrations of IFN-α (Figure 3B). The increase in SEAP activity was inversely proportional to the dose of active NS3/4A protease. No difference was observed with Huh-7.5 cells. These results indicate that this reporter system could be used for quantitative analysis of HCV-inhibitory compounds in cell culture systems.

Inhibitory effect of CsA on HCV replication and its combination effect with IFN-α

CsA is a well-characterized anti-HCV reagent that strongly suppresses viral replication in cell culture[17-19]. We evaluated the inhibitory effect of CsA on HCV replication and its combination effect with IFN-α. Huh-7.5 and replicon cells treated with increasing doses of CsA (Figure 4A) for 48 h were transfected with eYFP-MAVS and IFN-β-SEAP. At 24 h post-transfection, cells treated with 0.4 and 0.6 μg/mL CsA had significantly higher SEAP activity compared with cells treated with vehicle or 0.05 and 0.2 μg/mL CsA, whereas no difference was observed with Huh-7.5 cells (Figure 4A). As shown in Figure 4B, IFN-α in combination with CsA therapy enhanced its inhibitory effect. Cells treated with both agents had significant enhancement in SEAP activity compared with cells treated with a single agent. Determination of SEAP activity revealed that 0.2 μg/mL CsA-treated cells had a minimal increase in SEAP activity compared to untreated cells (Figure 4A), whereas, in combination with IFN-α, 0.2 μg/mL CsA-treated cells had a 5-6-fold increase. Cells treated with CsA and IFN-α showed a > 7-fold increase in SEAP activity.

DISCUSSION

To date, the only available therapy for chronic hepatitis C is IFN-α, either alone or in combination with the nucleoside analogue ribavirin. However, many patients are discouraged from IFN-based treatment because of severe side effects. In the past few years, much progress has been made in the development of small-molecule-based therapeutics for the treatment of HCV infection, such as inhibitors of HCV enzymes, as well as nucleic-acid-based agents that attack the viral RNA. However, the lack of appropriate model systems for drug evaluation has hampered their clinical use.

Although the replicon systems and the infectious HCV cell culture system have served as extremely valuable tools for *in vitro* study of HCV replication, and for screening and evaluation of new antiviral drugs against HCV that specifically target the protease activity of NS3 or the polymerase activity of NS5[20-26], the level of viral multiplication is not satisfactory, because in all cases, the detection of viral RNA and protein has to rely on reverse transcriptase-polymerase chain reaction and antibody labeling, which have some inherent technical problems that are difficult to overcome. To date, many different HCV replicons have been generated with other reporter genes such as firefly luciferase or fluorescent proteins, which allow screening of a high number of compounds in a fast and reproducible way[27-31]. However, the results from these systems should be interpreted with care because some adaptive mutations

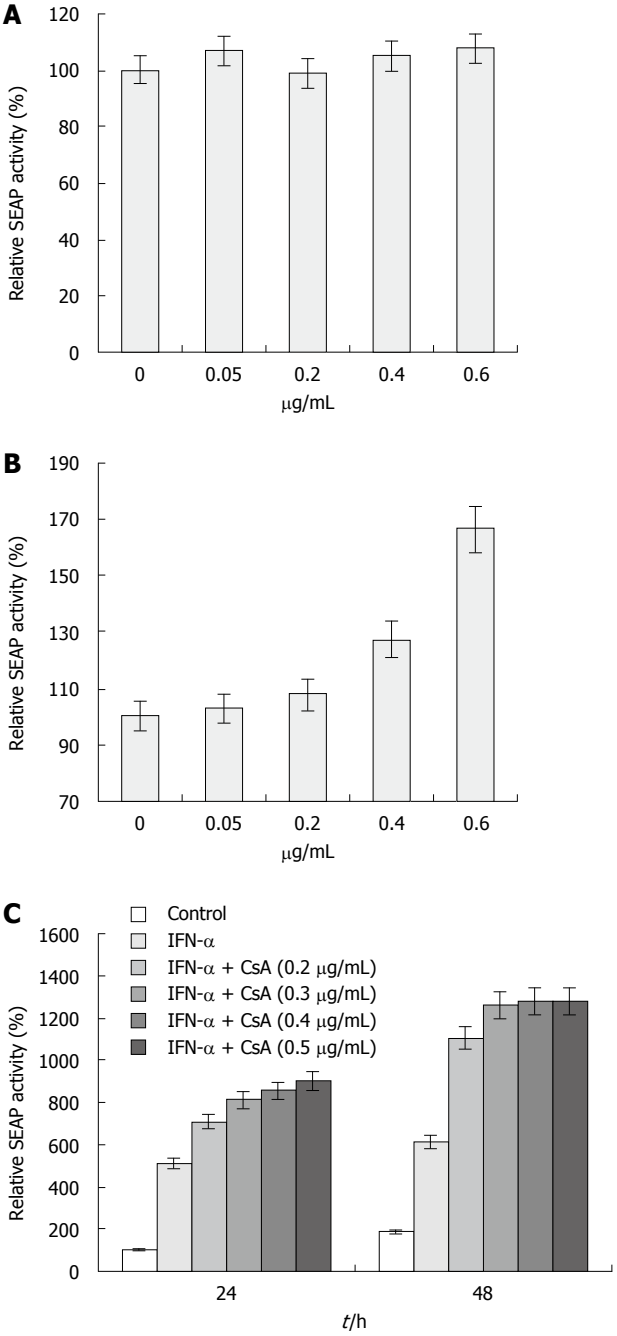

Figure 4 Inhibitory effect of cyclosporine A on hepatitis C virus replication and its combination effect with interferon-α. A, B: Increase of secreted placental alkaline phosphatase (SEAP) activity in enhanced yellow fluorescent protein (eYFP)-mitochondrial antiviral signaling protein (MAVS) and interferon (IFN)-β-SEAP co-transfected Huh7.5 ($P > 0.05$) and replicon ($P < 0.05$) cells treated with cyclosporine A (CsA). Before transfection, Huh7.5 and replicon cells were incubated with CsA at 0, 0.05, 0.2, 0.4 and 0.6 μg/mL for 48 h. SEAP activity was measured at 24 h post-transfection in the presence of CsA. The percentage increase in SEAP activity relative to the untreated controls was plotted. Bars indicate SD ($n = 3$); C: IFN-α in combination with CsA therapy enhanced its inhibitory effect. Replicon cells were incubated with IFN-α (100 IU/mL) in combination with CsA at 0, 0.2, 0.3, 0.4 and 0.5 μg/mL for 48 h, and co-transfected with eYFP-MAVS and IFN-β-SEAP; pRL-TK was co-transfected to normalize transfection efficiency. SEAP activity was measured at 24 and 48 h post-transfection in the presence of IFN-α and CsA. The percentage increase of SEAP activity relative to the untreated controls was plotted. Bars indicate SD ($n = 3$).

that mediate efficient replication *in vitro* might result in non-replicative replicons *in vivo*.

It has been previously reported that HCV NS3/4A protease cleaves MAVS from mitochondria to block the activation of IFN-β and nuclear factor-κB and the induction of antiviral effector genes in infected cells. In the present study, using the eYFP-MAVS/IFN-β-SEAP signaling pathway and HCV replicon model, we established a rapid and sensitive cell-based assay system to identify regulators of HCV replication. It allowed us to monitor HCV replication both qualitatively and quantitatively, using an easy, rapid and inexpensive system. HCV replication can be measured by the reporter enzyme SEAP, which enabled us to perform ongoing monitoring of anti-HCV drugs through repeated chemiluminescence. The cell lysates need not be prepared in our assay, and the SEAP protein is very stable and highly sensitive in enzymatic assays. SEAP activity in culture medium obtained from control cells transfected with eYFP-MAVS and IFN-β-SEAP was approximate 700 times greater than that obtained from replicon cells. Another reporter, eYFP-MAVS, which was localized to the mitochondrial membrane, but in the presence of HCV NS3/4A protease, it was proteolytically cleaved and shifted from the mitochondrial membrane to the cytoplasm, which can be dynamically monitored by fluorescence microscopy. Time- and dose-dependent studies have revealed that a decrease of SEAP activity and cleavage of eYFP-MAVS occur under conditions in which NS3/4A is active. Valuation of this reporter assay was verified through detecting the activity of IFN-α and CsA, which have been reported to be capable of modulating HCV replication. Although not investigated here, we believe that this reporter system could be of significant benefit in studies of HCV infection. This system will enable development or enhancement of therapeutic protocols by providing a platform to investigate dosing, scheduling, or the efficacy of combination therapies.

COMMENTS

Background

Advances in hepatitis C virus (HCV) replicon and infectious cell models provide systems for screening compounds against HCV. However, methods for detection of HCV protein or RNA require fixation or cell lysis, such as immunofluorescence, Western blotting and quantitative reverse transcriptase-polymerase chain reaction, and are insensitive or complex and time-consuming.

Research frontiers

Overexpression of mitochondrial antiviral signaling protein (MAVS) strongly activates interferon (IFN)-β promoter. MAVS self-association mediates innate immune signaling that can be blocked by HCV NS3/4A cleavage. Recent studies have highlighted the mechanism by HCV escapes the innate antiviral immunity mediated by HCV NS3/4A cleavage of MAVS. In this study, the authors developed a sensitive, simple assay for screening compounds against HCV based on HCV NS3/4A cleavage of the MAVS/IFN-β signaling pathway.

Innovations and breakthroughs

Although many studies have focused on the mechanism by which HCV escapes the innate antiviral immunity mediated by HCV NS3/4A blockage of the MAVS/IFN-β signaling pathway, its application for HCV detection has seldom been studied. The assay reported here based on HCV NS3/4A blockage of the MAVS/IFN-β signaling pathway converts the theoretical research into applied science. The reporter system provides a quantitative approach for detection of HCV replication based on measurement of secreted reporters in the medium, which is more sensitive and simpler compared with the methods described in background.

Applications

The reporter system here is a simple, sensitive and quantitative assay for anti-

HCV compounds and will provide another alternative efficient means for screening HCV inhibitors.

Terminology

Measurement of reporter expression level regulated by IFN-β promoter is an indicator for IFN-β promoter activation. Overexpression of MAVS strongly activates IFN-β-promoter-regulated reporter expression. However, in the presence of HCV NS3/4A, IFN-β promoter activation induced by MAVS was inhibited. By contrast, compounds against HCV will recover IFN-β promoter activation induced by MAVS.

Peer review

Fu *et al* have described concisely an HCV replicon model that is suitable to test the efficacy of anti-HCV compounds by means of checking the activity of the MAVS/IFN-β pathway. The materials and methods are clearly presented, although they could be explained in more detail. Results are demonstrative and conclusive and the English is also good, with only minor changes being necessary.

Abstract

AIM: To evaluate whether the ABO blood group is related to pancreatic cancer risk in the general population of the United States.

METHODS: Using the University of Pittsburgh's clinical pancreatic cancer registry, the blood donor database from our local blood bank (Central Blood Bank), and the blood product recipient database from the regional transfusion service (Centralized Transfusion Service) in Pittsburgh, Pennsylvania, we identified 274 pancreatic cancer patients with previously determined serological ABO blood group information. The ABO blood group frequency was compared between these patients and 708 842 individual, community-based blood donors who had made donations to Pittsburgh's Central Blood Bank between 1979 and 2009.

RESULTS: The frequency of blood group A was statistically significantly higher amongst pancreatic cancer patients compared to its frequency amongst the regional blood donors [47.63% *vs* 39.10%, odds ratio (OR) = 1.43, P = 0.004]. Conversely, the frequency of blood group O was significantly lower amongst pancreatic cancer patients relative to the community blood donors (32.12% *vs* 43.99%, OR = 0.60, P = 0.00007). There were limited blood group B (n = 38) and AB (n = 17) pancreatic cancer patients; the overall P trend value comparing patient to donor blood groups was 0.001.

CONCLUSION: The ABO blood group is associated with pancreatic cancer risk. Future studies should examine the mechanism linking pancreatic cancer risk to ABO blood group.

Key words: ABO blood group; Pancreatic adenocarcinoma; Surveillance; Risk reduction; Epidemiology

INTRODUCTION

Pancreatic adenocarcinoma is the fourth most common cancer in the United States among men and women and has the highest case-fatality rate of any of the major cancers, due to its late stage at diagnosis and poor response to traditional therapies[1]. The median survival of pancreatic cancer patients is about 6 mo, and the majority of patients do not have resectable disease at the time of their diagnosis[2]. Pancreatic cancer increases in likelihood with advancing age and predominates in certain ethnic/racial groups, such as African-Americans, Ashkenazi Jews, Pacific Islanders, and the New Zealand Maori[3]. The elevated risk among certain populations appears to be multifactorial in nature and likely is due to a combination of environmental and inherited factors. The most significant genetic variables that are associated with the development of pancreatic cancer remain to be identified, although various cancer syndromes and hereditary pancreatitis place individuals at significantly increased risk[4]. Cigarette smoking, chronic pancreatitis, diabetes mellitus and obesity are well-established risk factors for pancreatic cancer[5].

Mounting evidence has demonstrated that the ABO blood group may also be associated with pancreatic cancer. A Spanish study of 108 cases and 374 controls found a non-significantly elevated risk of pancreatic cancer among individuals with blood group A [relative risk (RR) = 1.52, 95% confidence interval (CI): 0.87-2.67][6]. An Italian series of 224 patients with histologically-confirmed pancreatic adenocarcinoma compared the ABO blood group distribution with two control groups: 7086 patients with various diseases (Group 1) and 7320 voluntary blood donors (Group 2). The researchers noted an increased incidence of pancreatic cancer among the blood group B patients (RR = 1.5 *vs* Group 1, $P = 0.021$; RR = 1.7 *vs* Group 2, $P = 0.0025$) and a decreased number in blood group O patients, when compared with the two control groups[7]. Additionally, a combined, prospective cohort study of over 107 000 US health professionals observed that blood groups A, B, and AB were associated with an overall increased risk of developing pancreatic cancer[8]. More recently, a genome-wide association study (GWAS) of 1896 individuals with pancreatic cancer and 1939 controls - validated using an additional 2457 affected individuals and 2654 controls - identified a single nucleotide polymorphism (SNP) in intron 1 of the *ABO* gene (rs505922) as a genetic risk factor for pancreatic cancer [odds ratio (OR) = 1.20; 95% CI: 1.12-1.28][9]. In an effort to further discern how pancreatic cancer and the ABO blood group might be associated, we investigated the relationship of pancreatic cancer incidence with ABO blood group in our Western Pennsylvania regional population. We compared the serologically-determined ABO blood group of pancreatic cancer patients with the ABO group of greater than 700 000 blood donors to the Central Blood Bank in Pittsburgh.

MATERIALS AND METHODS

To estimate the ABO frequencies in our local area, the donor database of the Central Blood Bank in Pittsburgh, Pennsylvania was queried for the ABO group of individual donors. The Central Blood Bank collects blood mainly in southwestern Pennsylvania. This database includes all individuals who have made a blood donation to the Central Blood Bank over the past approximately 30 years. Between 1979 and 2009, there were 708 842 unique blood donors. Pancreatic cancer patients from the University of Pittsburgh's affiliated hospitals - Presbyterian University Hospital and the University of Pittsburgh Cancer Institute's Hillman Cancer Center - who had provided informed consent to be part of their pancreatic cancer research registry were included in this study. Of 359 eligible pancreatic cancer patients in the registry, 274 had a historical or current ABO blood group available after querying the Centralized Transfusion Service's database. The Centralized Transfusion Service's database includes all patients who have a type and screen performed at Pittsburgh area hospitals. Blood donors were screened for infectious diseases according to Food and Drug Administration (FDA) and American Association of Blood Banks (AABB) regulations. FDA approved manual and automated ABO grouping methods and reagents were employed both at the Central Blood Bank and at the Centralized Transfusion Service. Proportions of ABO blood groups for pancreatic cancer cases and regional blood donors were compared using Chi-squared analysis. Data analysis was performed using R Project software (www.r-project.org).

RESULTS

Table 1 shows the OR of the ABO blood group distribution of the 274 pancreatic cancer patients in comparison with the ABO groups of the 708 842 unique blood donors to the Central Blood Bank in the Pittsburgh area over approximately the past 30 years. The frequency of blood group A was statistically significantly higher amongst the pancreatic cancer patients compared to the frequency amongst the regional blood donors. Conversely, the frequency of blood group O was statistically significantly lower amongst the pancreatic cancer patients relative to the community blood donors.

Statistically significant associations were not revealed among the limited number of blood group B ($n = 38$) and AB ($n = 17$) pancreatic cancer patients and regional blood donors; the overall P trend value comparing patient to donor ABO blood groups was 0.001.

DISCUSSION

Our study demonstrates that pancreatic cancer patients

Table 1 Odds ratio of pancreatic cancer patients stratified by ABO group in relation to the ABO groups of regional unique blood donors

Blood group	Unique blood donors, *n* (%)	Pancreatic cancer patients, *n* (%)	Odds ratio *vs* other blood groups
Group A	277 133 (39.10)	131 (47.63)	1.43 (0.004)
Group B	87 252 (12.31)	38 (13.87)	1.15 (0.41)
Group AB	32 662 (4.61)	17 (6.20)	1.37 (0.19)
Group O	311 795 (43.99)	88 (32.12)	0.60 (0.000070)
Total	708 842	274	*P* trend patients *vs* donors = 0.001

treated at a large, US institution are significantly more likely to be blood group A than regional blood donors and are significantly less likely to be blood group O than regional blood donors; the proportions of patient *vs* donor ABO blood groups were statistically different from what would be expected by chance alone. We examined this relationship among over 700 000 unique individuals who made blood donations to the Central Blood Bank in Pittsburgh between 1979 and 2009. Although there was a trend for risk of pancreatic adenocarcinoma in association with blood groups B and AB, a statistically significant effect was not observed, likely due to limited study power for detecting differences in these small subpopulations of individuals.

In a prospective cohort study published in 2009 of 107 503 US residents derived from the Nurses' Health Study (77 360 eligible female nurses) and the Health Professionals Follow-up Study (30 143 eligible male health professionals), individuals with blood group A, B and AB were noted overall to have an elevated risk of pancreatic cancer compared to those participants with blood group O[8]. However, taking each study separately, only blood group B was associated with increased cancer risk. Notably, blood group was self-reported in that prospective study, although a validation analysis displayed a greater than 90% concordance rate between reported and actual ABO blood group. In our study, the presence of serologically-determined blood group information from the blood bank was an entry criterion; thus, there was no possibility of recall bias influencing our results.

The *ABO* locus is located on chromosome 9 and there are three main alleles in the system: *A101*, *B101*, and *O01*[10]. The *A101* allele encodes a glycosyltransferase that adds a terminal α-N-acetylgalactosamine to H antigen, producing the A antigen. Similarly the *B101* allele encodes a glycosyltransferase that adds a terminal α-D-galactose to H antigen, thus creating the B antigen. The most common types of *O* alleles contain a critical 1-bp deletion compared to the consensus *A101* allele and, if translated, would give rise to non-functional enzymes[10,11]. In a group O individual, the H antigen is not modified. In addition to studies of pancreatic cancer, numerous past studies have shown that blood group A is related to gastric cancer[12,13]. The precise biological reasons as to why there is a relationship between ABO blood group and certain cancers are unknown, although two recent GWAS demonstrated that particular SNPs at the *ABO* locus were associated with the inflammatory cytokines tumor necrosis factor[14] and intercellular adhesion molecule 1[15]. The ABO blood group has also been shown to be related to other biological processes; for example, although a definitive mechanism has not yet been elucidated, levels of von Willebrand factor (vWF) antigen have been statistically shown to correlate to the ABO group with group AB individuals demonstrating the highest average vWF levels and group O individuals having the lowest average vWF levels[16].

The ABO blood group is genetically-determined and therefore is not a modifiable risk factor as are cigarette smoking, body mass index, diet or other lifestyle-related variables. The risk of pancreatic cancer for individuals with blood group A has been replicated in several studies. Nonetheless, the magnitude of risk is not high enough to warrant clinical screening, especially considering that these approaches are still in the developing stages[17]. However, the risk of pancreatic cancer in individuals with blood group A (and likely B or AB) is nearly as strong as the risk of developing pancreatic cancer as a consequence of cigarette smoking; thus, the combination of multiple moderate risk factors (such as age and family history[18]) could be used to calculate whether some individuals are at high enough risk to warrant counseling for risk reduction strategies or inclusion in pancreatic cancer screening trials.

The importance of the ABO blood group in assessing pancreatic cancer risk is also highlighted by the lack of other global genetic risk factors identified in the GWAS by Amundadottir *et al*[9]. This study indicates that the etiology of pancreatic cancer is more complex than previously believed and likely represents an array of deleterious pathways. Although the mechanisms of pancreatic cancer oncogenesis have not been fully deciphered, the association of ABO blood group with pancreatic cancer risk has been confirmed.

COMMENTS

Background

Pancreatic adenocarcinoma has the highest case-fatality rate of any of the major cancers. Because there are no accepted population-based screening methods, identifying individuals at greatest risk of developing this lethal form of cancer is paramount to developing risk reduction strategies. Previous evidence has indicated that ABO blood group may influence the risk of developing pancreatic cancer.

Research frontiers

Blood groups A, B, and/or AB have been associated with pancreatic cancer in a limited number of past studies. Genome-wide association studies have also identified a risk locus in the *ABO* gene.

Innovations and breakthroughs

This study compared the frequency of ABO blood groups in a cohort of pancreatic cancer patients to the blood group distributions in greater than 700 000 community-based blood donors. The authors demonstrated that blood group A was statistically significantly higher and blood group O was significantly less frequent among pancreatic cancer patients than in community blood donors. In contrast to many past studies, the authors used serologically-confirmed blood group information.

Applications

ABO blood group information is valuable in predicting who may be at risk of developing pancreatic adenocarcinoma and should be incorporated into risk stratification and surveillance studies.

Peer review

The authors report an interesting study about the connection of ABO blood group and the development of pancreatic cancer. The paper is written well and good to read, the data presented clearly and the whole paper of relevance.

Abstract

AIM: To assess linear endoscopic ultrasound (L-EUS) and magnetic resonance imaging (MRI) in biliary tract dilation and suspect small ampullary tumor.

METHODS: L-EUS and MRI data were compared in 24 patients with small ampullary tumors; all with subsequent histological confirmation. Data were collected prospectively and the accuracy of detection, histological characterization and N staging were assessed retrospectively using the results of surgical or endoscopic treatment as a benchmark.

RESULTS: A suspicion of ampullary tumor was present in 75% of MRI and all L-EUS examinations, with 80% agreement between EUS and histological findings at endoscopy. However, L-EUS and histological TN staging at surgery showed moderate agreement (κ = 0.54).

CONCLUSION: L-EUS could be a useful adjunct as a diagnostic tool in the evaluation of patients with suspected ampullary tumors.

Key words: Ampullary tumors; Endoscopic ultrasound; Magnetic resonance imaging

INTRODUCTION

Ampullary tumors are infrequent entities that represent about 0.2% of gastrointestinal malignancies[1]. However, these neoplasms are considered as diagnostic challenges, because they display a wide array of pathological features, from mild dysplasia to high-grade dysplasia and invasive

carcinoma[2]. Clinical presentation includes vague abdominal pain, liver enzyme elevation, jaundice, recurrent pancreatitis, or uncommon symptoms such as gastrointestinal bleeding or duodenal obstruction[3,4].

Although endoscopic papillectomy represents a possible treatment[5], most ampullary tumors still undergo a surgical approach[6,7]. Thus, the diagnostic evaluation must be as careful as possible[8], because ampullary carcinoma is difficult to diagnose at an early stage and multiple imaging techniques should be carried out appropriately to establish a diagnosis and improve prognosis[9]. In fact, neither definitive methods for early diagnosis nor specific markers are available for this disease[10].

In recent years, endoscopic ultrasound (EUS) has been shown to be superior to computed tomography (CT)[11] and conventional ultrasound scans[12], and equivalent to magnetic resonance imaging (MRI) for tumor detection and T and N staging of ampullary tumors[13].

Echoendoscopes are classified into radial and linear instruments[14]: to date, almost all information available on detection and staging of ampullary tumors has been obtained with radial echoendoscopes, and there are no studies with linear EUS (L-EUS) for this purpose.

The aim of the present study was to compare L-EUS and MRI in the diagnostic evaluation of patients with suspected ampullary neoplasms.

MATERIALS AND METHODS

In a consecutive series of 1205 L-EUS biliopancreatic examinations carried out in the period July 2007 to August 2009, there were 44 symptomatic patients (referred for increasing liver enzymes, jaundice, abdominal pain or dilation of the biliary tract) who were evaluated for suspicion of ampullary tumors. In 20 of these, the ampullary tumor was excluded by L-EUS that revealed other causes for their symptoms (four stones, four mediocholedocal stenoses, and 12 pancreatic cephalic small cancer). In the remaining 24 patients, data were collected prospectively and the accuracy of detection, histological characterization, and N staging were assessed retrospectively using the surgical or endoscopic results as a benchmark.

The following inclusion criteria were adopted: (1) cholestatic syndrome with previous negative or uncertain conventional US and CT imaging; (2) absence of previously known biliary and/or pancreatic diseases; (3) absence of advanced ampullary tumors; (4) histological diagnosis of the resected specimen; (5) MRI (axial, coronal and radial sequences, T2 single-shot, performed by a radiologist with experience of the biliary tree); and (6) L-EUS. Exclusion criteria included previously known biliary or pancreatic disease, and the presence of evident, large ampullary tumors at endoscopy.

L-EUS was carried out by means of a linear array echoendoscope (Pentax EG 33830UT or Pentax EG 3870UTK; Hamburg, Germany) that was inserted into the second part of the duodenum after intravenous midazolam and meperidine titrated to obtain conscious sedation. Keeping the tip of the echoendoscope in touch with the duodenal mucosa, the echoendoscope was torqued counterclockwise and slowly withdrawn into the duodenal bulb[14], and after visualization of the papilla of Vater, its endoscopic aspect was considered and recorded.

Ampullary carcinoma visualized by EUS was staged according to the TN classification[15]: T1 if the tumor echo was limited to the main duodenal papilla; T2 if the tumor echo invaded the duodenal muscularis propria layer; T3 if the tumor echo invaded the pancreas; and T4 if the tumor echo invaded peripancreatic soft tissues or other adjacent organs or vascular structures. EUS criteria for lymph node metastasis, classified as N1, were circularity, at least 10 mm in size, and hypoechogenicity.

Ethical considerations

This was a retrospective study and no study-driven clinical intervention was performed. Simplified Institutional Review Board approval for retrospective studies was obtained.

Statistical analysis

Differences in percentage of detection of ampullary tumors between MRI and L-EUS and between L-EUS and histology were assessed by the χ^2 test. Values of $P < 0.05$ were chosen for rejection of the null hypothesis. Moreover, a κ value for agreement between endoscopic and surgical histology and L-EUS and histological TN staging was calculated. The value was scored according to standard criteria[16].

RESULTS

Data from 24 patients (17 men and seven women, aged 60 ± 12 years, range: 42-88 years) fulfilled the entry criteria and were evaluated. Demographic data, referral reasons, clinical, radiological and histological features are summarized in Tables 1 and 2. Abdominal pain was the common symptom in all patients; jaundice was present in 13 (54%) and liver enzyme elevation was detected in 12 (50%). One patient was evaluated due to dilation of both extrahepatic and main pancreatic ducts. Multiple endoscopic forceps biopsies were taken from all cases during L-EUS evaluation. In one case, it was impossible to analyze the sample due to material not being available in the test-tube. Agreement between endoscopic and histological results was very good ($\kappa = 0.81$).

All patients underwent surgery except for two (stage T1N0) who were treated by endoscopic ampullectomy, and histological results were available for the entire group (Figure 1). Average diameter of the ampulla was 2 ± 0.8 cm (range: 1.5-2.6 cm).

MRI examination was negative in 6 (25%) cases, showed indirect signs (dilatation of intrahepatic and extrahepatic bile ducts) of space occupying lesions of the ampulla in

Table 1 Demographic data and reasons for referral of patients with ampullary tumors

Patient No.	Sex/age (yr)	Referral reason
1	M/53	Liver enzymes elevation + jaundice
2	F/47	Abdominal pain
3	M/71	Liver enzymes elevation + jaundice
4	M/62	Liver enzymes elevation + jaundice
5	F/53	Liver enzymes elevation
6	F/67	Liver enzymes elevation
7	M/45	Liver enzymes elevation
8	M/73	Liver enzymes elevation
9	M/80	Liver enzymes elevation
10	F/44	Liver enzymes elevation
11	F/50	Liver enzymes elevation + jaundice
12	M/48	Liver enzymes elevation + jaundice
13	M/66	Liver enzymes elevation
14	M/67	Liver enzymes elevation + jaundice
15	M/59	Liver enzymes elevation
16	M/67	Liver enzymes elevation + jaundice
17	F/60	Liver enzymes elevation
18	M/63	Liver enzymes elevation + jaundice
19	F/54	Liver enzymes elevation + jaundice
20	M/65	Liver enzymes elevation
21	M/64	Liver enzymes elevation + jaundice
22	M/42	Liver enzymes elevation + jaundice
23	M/47	Liver enzymes elevation + jaundice
24	F/88	Liver enzymes elevation + jaundice

17 (71%) cases, and an actual space occupying lesion of the ampulla in 1 (8%) case (Figure 2).

L-EUS detected ampullary tumors in all 24 (100%) patients ($P < 0.03$ *vs* MRI) (Figure 2).

In 19 (80%) cases, Histological analysis revealed intestinal-type adenocarcinoma in 19 (80%) cases (stage T2N0 in 14 and T2N1 in five) CDX2 positive, adenoma with high-grade dysplasia in 2 (8%), and adenoma with low-grade dysplasia in the remaining 3 (12%) (Figure 3).

No biliary/pancreatic-type tumors were found. Thus, L-EUS was able to detect malignant lesions in 87% of ampullary lesions ($P = 0.21$ *vs* histological results), with sensitivity of 87.5% and specificity of 100% and a moderate agreement ($\kappa = 0.54$) between L-EUS and TN histological staging.

DISCUSSION

Although MRI is regarded as the most reliable noninvasive diagnostic imaging modality for the evaluation of pancreatobiliary lesions[17,18], and is considered as a substitute for diagnostic endoscopic retrograde cholangiopancreatography[19], it cannot provide biopsy samples and rarely identifies whether the obstruction is benign or malignant, especially when lesions are small. The ampulla of Vater is a possible blind spot for MRI because of its small size and the tapering of the intramural ducts that contain little fluid[9,18,20]. Thus, other investigative modalities have been added to the diagnostic armamentarium; among these, EUS has proved to be useful and reliable. Generally, radial EUS is considered the gold standard[17,18] whereas L-EUS performance has never been studied.

Figure 1 Endoscopic aspect (A) and resected surgical specimen (B) of a small ampullary tumor.

This is believed to be the first study to report L-EUS as a useful diagnostic tool for detection and staging of small ampullary tumors. In our experience, also supported by histological findings, this technique was able to raise a suspicion of ampullary neoplasm when other imaging techniques, including MRI, were not. Indeed, a suspicion of ampullary neoplasms was observed in 75% of MRI investigations compared with 100% of L-EUS scanning; the latter proved to be accurate, identifying > 80% of these lesions as malignant. The accuracy of EUS in the TNM staging of ampullary tumors remains controversial[17,21]. Histological grade is the gold standard, with the possibility to differentiate between ampullary tumor of intestinal type and those originating from the biliary or pancreatic ducts; however, it is worthy of note that a discrete correlation was found between L-EUS and histological TN staging in the present study. The discrepancies were due more to overstaging in 6 (25%) patients than to understaging in 3 (12%) patients. Overstaging can occur in the presence of peritumoral inflammation, whereas understaging can occur in the presence of minimal malignant infiltration of the pancreas[9,22]. Other recent experience also suggests that EUS is an accurate diagnostic test and exhibits a high level of agreement with surgical pathology[23].

However, L-EUS provided several advantages compared to MRI, such as the possibility of obtaining direct endoscopic visualization of the major duodenal papilla, and to depict the layered structures of the periampullary area. Thus, it is often possible to give a judgment on a pos-

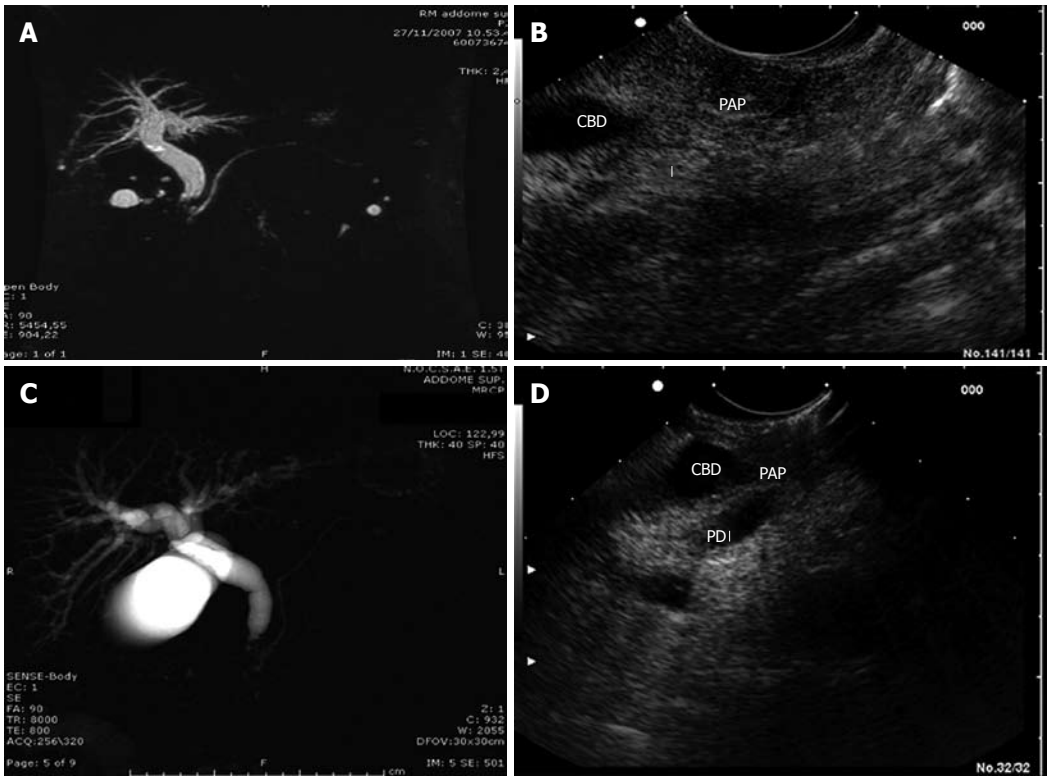

Figure 2 Ampullary tumor, stage 1. A: Magnetic resonance imaging (MRI) showed dilation of the common bile duct and Wirsung's duct, without space-occupying lesions of the ampulla; B: Linear endoscopic ultrasound (L-EUS) of the same patient. Ampullary tumor, stage 2; C: MRI showed dilation of the common bile duct and normal appearance of Wirsung's duct; D: L-EUS scan of the same patient, which showed duodenal wall disruption without pancreas invasion. CBD: Common bile duct; PAP: Papilla (Vater's papilla); PD: Pancreatic duct.

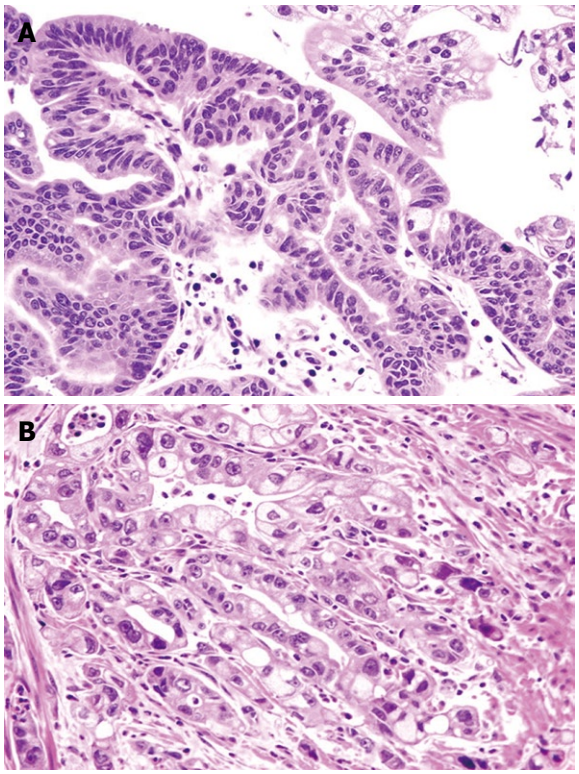

Figure 3 Ampullary tumor, low-grade dysplasia (A) and ampullary adenocarcinoma (B). Hematoxylin and eosin (HE), original magnification 40 ×.

sible endoscopic approach, because it also demonstrates intracholedochal growth. Limitations of this technique include inability to differentiate early malignant from benign tumors and to demonstrate distant metastases, in addition to being an invasive method.

The present study had some limitations. It was retrospective, the patient cohort was relatively small, and it was carried out in a setting with particular expertise in EUS. It remains to be established whether these results can be translated to a more general setting.

In conclusion, L-EUS appears to be a valid diagnostic tool to identify and stage small ampullary tumors, and might yield results that are superior to those of other diagnostic techniques. Further prospective studies are clearly needed to confirm these observations.

COMMENTS

Background

Ampullary tumors are rare and difficult to diagnose. The correct diagnosis is often reached after serological, radiological and/or endoscopic tests. Recently, endoscopic ultrasound (EUS) has been demonstrated as being as useful as magnetic resonance imaging (MRI) for detection of these neoplasms.

Innovations and breakthroughs

No previous study has been previously conducted with L-EUS in this setting, and this study by Manta *et al* showed that this appears to be a valid diagnostic tool to identify and stage small ampullary tumors, and might yield results that are superior to those with other diagnostic techniques.

Terminology

EUS and L-EUS: techniques that combine endoscopic and echographic approaches for detecting lesions of the gastrointestinal tract. MRI: a technique that employs nuclear resonance imaging to visualize abdominal sections without exposing the subject to radiation.

Peer review

This is a retrospective study with a small sample size. Despite this, it is a novel and well-designed study that is likely to influence clinical practice.

Abstract

AIM: To give an overview of the literature on left-sided acute appendicitis (LSAA) associated with situs inversus totalis (SIT) and midgut malrotation (MM).

METHODS: We present a new case of LSAA with SIT and a literature review of studies published in the English language on LSAA, accessed *via* PubMed and Google Scholar databases.

RESULTS: Ninety-five published cases of LSAA were evaluated and a 25-year-old female, who presented to our clinic with left lower abdominal pain caused by LSAA, is reported. In the reviewed literature, fifty-seven patients were male and 38 were female with an age range of 8 to 82 years and a median age of 29.1 ± 15.9 years. Sixty-six patients had SIT, 23 had MM, three had cecal malrotation, and two had a previously unnoted congenital abnormality. Fifty-nine patients had presented to the hospital with left lower, 14 with right lower and seven with bilateral lower quadrant pain, and seven subjects complained of left upper quadrant pain. The diagnosis was established preoperatively in 49 patients, intraoperatively in 19, and during the postoperative period in five; 14 patients were aware of having this anomaly. The data of eight patients were not unavailable. Eleven patients underwent laparoscopic appendectomy, which was combined with cholecystectomy in two cases. Histopathological examination of the appendix specimens revealed adenocarcinoma in only two of 95 patients.

CONCLUSION: The diagnosis of left lower quadrant pain is based on well-established clinical symptoms, physical examination and physician's experience.

Key words: Diagnostic dilemma; Left lower quadrant pain; Left-sided appendicitis; Midgut malrotation; Situs inversus totalis

INTRODUCTION

Acute appendicitis is probably the most common intraabdominal condition requiring emergency surgery. The diagnosis is based on well-established clinical symptoms, basic radiologic findings and surgeon experience[1,2]. Approxi-

mately one third of patients with acute appendicitis have pain localized outside of the right lower quadrant because of the various positions of the appendix vermiformis, i.e. retrocecal, pelvic, subcecal, preileal and postileal, while subhepatic, meso-celiac, mid-inguinal and left-sided are seen more rarely[1,2].

Appendicitis causing pain in the left lower quadrant is extremely rare and can occur with congenital abnormalities that include true left-sided appendix or as an atypical presentation of right-sided, but long appendix, which projects into the left lower quadrant[2]. Left-sided acute appendicitis (LSAA) develops in association with two types of congenital anomalies: situs inversus totalis (SIT) and midgut malrotation (MM)[1-65]. Herein, we report an unusual case of SIT with acute appendicitis presenting as left lower quadrant abdominal pain. We also reviewed 95 published cases of LSAA with congenital anomalies retrieved from the Google Scholar and PubMed databases.

MATERIALS AND METHODS

We report a new case of LSAA with SIT. Additionally, for the review, a search of the English medical language literature in PubMed and Google Scholar was conducted for every case report, series, letter to the editor, original article and literature review relating to left-sided appendicitis. In addition, reference lists of the articles obtained and previous reviews were examined. Key words used were left lower quadrant pain, LSAA, appendicitis with left lower quadrant pain, SIT and appendicitis, acute left-sided appendicitis, and MM and appendicitis. The search included all articles from 1893 to July 2010. The articles containing adequate information such as patient age, sex, localization of the symptoms, time of the diagnosis, type of congenital anomalies, choice of incision and surgery were included in the study, while studies and comment articles with insufficient clinical and demographic data were excluded.

RESULTS

Case report

A 25-year-old female presented to the emergency unit on June 18, 2010 with severe abdominal pain, which started the previous night. The patient stated that the pain has begun first in the epigastric area and later expanded through the left lower quadrant. Besides the pain, she complained of inappetence and mild nausea. Patient history revealed no previous illness or surgery. On physical examination, rebound tenderness was observed in the left lower quadrant. Laboratory tests, including leukocyte count (9100 K/UL), were normal. Based on the patient's clinical status and our previous experience, we considered LSAA in the differential diagnosis; accordingly, relevant analyses were performed. Chest X-ray revealed dextrocardia (Figure 1) and abdominal ultrasonography (USG) demonstrated SIT and blind intestinal loop consistent with acute appendicitis in the left lower quadrant. The patient was immediately taken to surgery and as the laparoscopic device was out of order, a left McBurney's incision was performed. She was discharged on the second postoperative day with no complications (Figure 2). Contrast-enhanced thoraco-abdominal computed tomography (CT) in the postoperative period confirmed the diagnosis of SIT (Figure 3).

Figure 1 Chest X-ray showing dextrocardia.

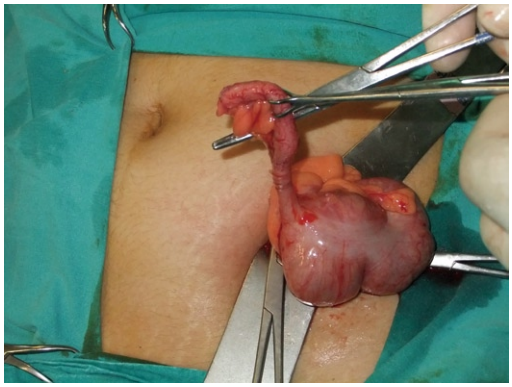

Figure 2 Intraoperative photograph showing an appendix together with cecum in the left lower quadrant.

Figure 3 Coronal contrast-enhanced multidetector computed tomography of the thorax, abdomen and pelvis. Computed tomography showed situs inversus totalis including dextrocardia, right-sided gastric bubble and reversed spleen and liver (postoperative view).

Analysis of literature about left-sided appendicitis

The English medical literature published to July 2010 in PubMed and Google Scholar databases was reviewed, and 64 reports concerning 95 cases of LSAA meeting the above-

Table 1 Summary of 95 reported cases of left-sided acute appendicitis with situs inversus totalis and midgut malrotation *n* (%)

Patient characteristics	Results
Mean age (yr, range)	29.1 ± 15.9 (8-82)
Sex	
Male	57 (60)
Female	38 (40)
Pain location	
Left-lower quadrant	59 (62.1)
Right-lower quadrant	14 (14.7)
Bilateral lower quadrant	7 (7.3)
Pelvic	2 (2)
Left-upper quadrant	7 (7.3)
Peri-umbilical	6 (6.3)
Congenital anomaly	
Situs inversus totalis	66 (69.4)
Midgut malrotation	23 (24.2)
Cecal malrotation	3 (3)
Unnoted	2 (2)
Other	1 (1)
Time of diagnosis	
Preoperative	49 (51.5)
Intraoperative	19 (20)
Known	14 (14.7)
Postop	5 (5.2)
Unnoted	8 (8.4)

mentioned criteria were included in this review[1-64]. The article types were as follows: case report - 48, case report and a review of the literature - 7, imaging for surgeon - 5, letter to the editor - 2, and abstract - 2. The clinicopathologic characteristics of the 95 patients are summarized in Table 1. The patients were aged from 8 to 82 years (mean: 29.1 ± 15.9 years). Fifty-seven were male (mean: 30.9 ± 15.2 years, range: 9-82 years) and 38 were female (mean: 26.5 ± 16.4 years, range: 8-76 years). Sixty-six patients had SIT, 23 had MM, 3 had cecal malrotation, in two the anomaly was previously unnoted and in one case, the end of the appendix running along the anterior side of sacrum was found in the left side. According to localization of the symptoms, 59 patients presented with left and 14 with right lower quadrant pain, 7 with bilateral lower quadrant pain, 7 with left upper quadrant pain, 6 with peri-umbilical, and two presented with pelvic pain. With regard to the diagnosis, 49 patients were diagnosed with appendicitis during the pre-operative period, in 19 patients, the diagnosis was established intraoperatively and in 5 postoperatively; 14 patients were previously known to have SIT and/or MM. No information was available in eight patients. Of 95 patients included in this literature review, 13.6% of patients underwent laparoscopic surgery. Laparoscopic appendectomy was performed in eight cases[6,10,12,13,15,21,24,58], and was combined with cholecystectomy in two[3,41] and with ablation of endometriosis implants in one patient[7]. In the remaining two patients, the intervention was switched to laparotomy due to technical reasons[8,25].

DISCUSSION

There are two anatomic abnormalities which result in LSAA - the first being SI, and the second, less common abnormality, is MM[6,7]. MM is the term used to describe a spectrum of congenital positional anomalies of the intestine caused by nonrotation or incomplete rotation of the primitive loop around the axis of the superior mesenteric artery (SMA) during fetal life. Although about 80% of cases are diagnosed in patients younger than 1 mo, malrotation has also been reported in older children and adults[8]. The incidence of MM cited in the literature varies from 0.03% to 0.5% in live births[1,3,9,10]. SI is an uncommon condition, which is caused by a single autosomal recessive gene with incomplete penetrance and occurs in 1 per 5000 to 1 per 10000 live births[7]. This condition may be complete (SIT), when both thoracic and abdominal organs are transposed, or partial, when only one of those cavities is affected[1]. The incidence of SIT reported in the literature varies from 0.001% to 0.01% in the general population[12-14], whereas the incidence of acute appendicitis associated with SIT is reported to be between 0.016% and 0.024%[5,13,14].

According to published reports in the literature, LSAA occurs between the age of 8 and 63 years and is 1.5-fold more frequent in men than in women[3,13]. In our review, we determined the mean age of the patients as 29.3 ± 16.1 (range: 8-82) years and the male/female sex ratio as 3/2[1].

The differential diagnosis of left lower quadrant abdominal pain includes: diverticulitis, renal colic, ruptured ovarian cyst, Meckel's diverticulitis, epididymitis, incarcerated or strangulated hernia, bowel obstruction, regional enteritis, psoas abscess, and right- and left-sided appendicitis (LSAA)[1,4].

LSAA is a diagnostic dilemma, because the appendix is located in an abnormal position. The differential diagnosis of LSAA may not be promptly established in the emergency setting and is often delayed due to lack of uniformity in the clinical signs[11,58]. It is assumed that even though the viscera are transposed, the nervous system may not show the corresponding transposition, which may result in confusing symptoms and signs. In about 18.4%-31% of patients with SIT and MM, the pain caused by LSAA has been reported in the right lower quadrant[1,5,11-13]. In this literature review, it was observed that 14.7% of patients had pain localized in the right lower quadrant, which indicates the importance of accurate preoperative diagnosis in order to avoid incorrect incision.

The diagnosis of acute appendicitis in patients with SIT or MM can be based on physical examination, electrocardiogram, chest X-ray, barium studies, USG, CT scan and diagnostic laparoscopy[1,2].

Plain radiographs are usually not helpful for establishing the diagnosis of appendicitis. However, the detection of dextrocardia on chest X-ray and right-sided gastric bubble on abdominal plane X-ray is of considerable value in establishing the diagnosis of SIT. Barium enema with gastrografin can reveal MM or SIT, when there are difficulties in making the diagnosis of acute left lower quadrant pain[11]. Over the last two decades, there has been an increasing use of imaging modalities, such as USG and

CT, in the diagnosis of acute appendicitis. USG is widely used in cases of appendicitis, however, it has significant limitations: it is operator-dependent, and examination of the lower quadrant can be compromised in patients with large body habitus or by overlying bowel gas. The value of CT in the diagnosis of acute appendicitis has been well-documented, with a reported accuracy of 90%-98%[2,13]. USG and CT may also be helpful in the detection of SIT and MM. Of the patients included in this literature review, CT has been used in the diagnosis of 28 patients and USG in 22 patients since 2000[1,6,8,17-24,26,27].

After establishing the diagnosis of SIT or MM, the surgical options are the same as for normal patients[1]. According to the reviewed literature, we observed that many open and a few laparoscopic procedures have been performed[1,6,8,15]. Laparoscopic appendectomy was first carried out in 1998 by Contini *et al*[58] in a 34-year-old male patient with SIT. Since then, laparoscopic appendectomy has been performed in a total of 20 cases (12 with MM and 8 with SIT), of which two have undergone cholecystectomy at the same surgical session[3,6,7,10,12,13,15,21,24,41,58,65]. We believe that laparoscopy may be very useful both in establishing the differential diagnosis and in performing the definitive surgery[1].

As in patients with normally localized appendix, appendectomy specimens in LSAA should be sent for pathological evaluation. To our knowledge, in the literature, only two of 95 patients (59 male, 76 female), who underwent appendectomy due to LSAA, were pathologically diagnosed with malignancy. Ascendent hemicolectomy was performed in both patients after pathological evaluation, which revealed mucinous adenocarcinoma and mucinous cystadenocarcinoma[19,26].

In conclusion, LSAA should be considered in the differential diagnosis of young patients presenting with pain localized in the left lower quadrant. Chest X-ray, abdominal USG and CT provide quite useful information. Diagnostic laparoscopy is the gold standard in cases with complicated differential diagnosis.

COMMENTS

Background

Acute appendicitis is a surgical condition, which manifests itself as pain usually localized in the lower right quadrant and can be diagnosed easily due to its clinical findings. Besides the surgeon experience, blood tests, radiological investigations, and in some circumstances, diagnostic laparoscopic techniques, should be used in the diagnosis of atypically localized appendicitis.

Research frontiers

Left-sided appendix is a rarely seen condition, which is frequently associated with situs inversus totalis (SIT) and midgut malrotation (MM). In this study, the authors performed an overall evaluation of management approaches and diagnostic processes in cases of left-sided acute appendicitis (LSAA) related to SIT and MM published in the English language literature to date, and presented the experience.

Innovations and breakthroughs

This study is the largest literature screening on LSAA to date.

Applications

This brief literature review demonstrates the importance of radiologic assessment and diagnostic laparoscopy along with surgical experience in the differential diagnosis of LSAA.

Peer review

The authors described a case of left sided appendicitis in the setting of situs inversus and a corresponding literature review. Over all, this paper is well written, concise and information.

Abstract

AIM: To investigate whether fresh frozen plasma (FFP) transfusion affects outcomes following hepatic resection for hepatocellular carcinoma (HCC) in terms of liver function, postoperative complications and cancer prognosis.

METHODS: We retrospectively compared the incidence of postoperative complications between 204 patients who underwent hepatectomy for HCC with routine FFP transfusion in an early period (1983-1993, Group A) and 293 with necessity for FFP transfusion during a later period (1998-2006, Group B), and also between two subgroups of Group B [22 patients with FFP transfusion (Group B1) and 275 patients without FFP transfusion (Group B2)]. Additionally, only in limited patients in Group B1 and Group B2 with intraoperative blood loss $\geqslant$ 2000 mL (Group B1$_{\geqslant 2000\ mL}$ and Group B2$_{\geqslant 2000\ mL}$), postoperative complications, liver function tests, and cancer prognosis were compared.

RESULTS: No mortality was registered in Group B, compared to 8 patients (3.9%) of Group A. The incidence of morbidity in Group B2 [23.2% (64/275)] was not significantly different from Group B1 [40.9% (9/22)] and Group A [27.0% (55/204)]. The incidence of complications and postoperative liver function tests were comparable between Group B1$_{\geqslant 2000\ mL}$ *vs* Group B2$_{\geqslant 2000\ mL}$. Postoperative prognosis did not correlate with administration of FFP, but with tumor-related factors.

CONCLUSION: The outcome of hepatectomy for HCC is not influenced by FFP transfusion. We suggest FFP transfusion be abandoned in patients who undergo hepatectomy for HCC.

INTRODUCTION

Surgical resection is the established optimal treatment for hepatocellular carcinoma (HCC) associated with hepatitis B virus or hepatitis C virus infection. Since HCC usually develops in patients with liver cirrhosis, most such patients present with bleeding tendencies based on chronic liver dysfunction[1,2]. Accordingly, bleeding is a major problem in liver surgery for HCC, and it also affects postoperative mortality and morbidity[3-5].

Fresh frozen plasma (FFP) is human donor plasma, and contains near normal levels of many plasma proteins, including procoagulants and inhibitory components of the coagulation cascades, acute phase proteins, immunoglobulins and albumin. The clinical use of FFP has increased steadily over the last two decades in many countries[6-8]. Furthermore, in the surgical treatment of HCC, FFP has been frequently administered to supply coagulation factors, maintain serum albumin level and circulating blood volume, and prevent postoperative hepatic failure[9-12]. On the other hand, FFP transfusion is reported to induce adverse effects in some patients: transmission of infection, allergic reactions, hemolysis, anaphylaxis, and transfusion-related acute lung injury (TRALI)[13-15]. Moreover, some studies have reported a relationship between perioperative transfusion and postoperative HCC recurrence[16,17]. In addition to these adverse effects, the amount of FFP is limited because of its source from human donation. Therefore, appropriate use of FFP is needed in terms of application and volume, as stated in the guidelines of the Japanese Ministry of Health, Labour and Welfare[18]. Regarding surgery for HCC, recent advances in both surgical and anesthetic techniques that have led to a reduction in intraoperative blood loss, have resulted indirectly in a gradual decrease in the need for FFP perioperatively[19,20]. Considering the reduction in intraoperative blood loss and the aforementioned potential adverse effects of FFP transfusion, we believe there is no need for FFP in surgery for HCC. In order to discuss this need, we first should investigate whether FFP transfusion affects outcomes following hepatic resection for HCC.

In this study, we retrospectively investigate whether FFP transfusion affects outcomes following hepatic resection for HCC in terms of liver function, postoperative complications and cancer prognosis.

MATERIALS AND METHODS

Trends in transfusion

Until 1993, FFP was routinely administered to patients after hepatectomy for HCC at the Department of Surgery, Osaka University Hospital. In 1994, HCC patients began to donate their blood preoperatively for autologous blood transfusion during or after surgery. Between 1994 and 1997, the use of autologous blood transfusion and FFP transfusion was determined by the surgeon. However, in 1998, the use of autologous blood transfusion was implemented in our institution to cover all HCC patients with hemoglobin of ≥ 11.0 g/dL. FFP was administered only to patients with extensive bleeding intraoperatively and low levels of coagulation factors. After the publication of Guidelines by the Japanese Ministry of Health and Welfare, we adhered to these guidelines in the use of FFP[18].

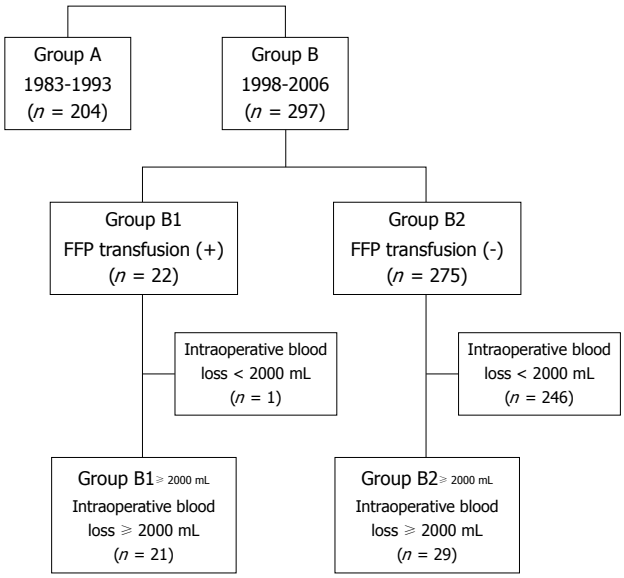

Figure 1 Distribution of the enrolled patients according to the clinical background of hepatectomy for hepatocellular carcinoma. FFP: Fresh frozen plasma.

Patients

Between 1998 and 2006, 297 patients underwent curative hepatic resection for HCC in our institution. In this study, we retrospectively compared the incidence of postoperative complications and postoperative cancer prognosis in the 297 patients with those of 204 patients with HCC who underwent curative hepatic resection with the routine use of FFP between 1983 and 1993. These 204 patients and 297 patients were categorized into Group A and Group B, respectively. The 297 patients of Group B were also divided into two groups depending on their history regarding perioperative FFP transfusion: 22 patients (7.4%) with FFP transfusion (Group B1) and 275 patients (92.6%) without FFP transfusion (Group B2). The distribution of patients enrolled in this study is illustrated accordingly in Figure 1. In patients of Group B1, FFP transfusion was performed either during the surgery or within 3 d after surgery. The median number of total units of transfused FFP was 10 (range, 4-40). In these groups, the need and validity of routine FFP transfusion were retrospectively evaluated based on the following postoperative complications and cancer prognosis.

Surgery and postoperative complications

In our institution, indication for hepatectomy for HCC is based on the value of indocyanine green retention rate at 15 min, and five factors included in the Child-Pugh classification: albumin, prothrombin time (PT), total bilirubin

(T-Bil), presence of ascites, and presence of encephalopathy. The selected surgical procedure was based on tumor location and predicted residual liver function, according to the classification system of the Liver Cancer Study Group of Japan[21]. The indication for surgery and selection of surgical procedure were not different between Group A and Group B. Death within 30 d after surgery was considered operative mortality. Morbidities were represented by the following complications that required additional treatment: cardiopulmonary complications, hepatic failure, bleeding, bile leakage, ascites and/or pleural effusion, ileus, and wound infection. PT and T-Bil [preoperative, postoperative day (POD) 1, 3, 5, 7] were used as representative markers of postoperative liver function.

Statistical analysis and ethical considerations

Differences between groups were assessed by the χ^2 test, Fisher's exact test or the Mann-Whitney *U* test. Survival rates were calculated according to the Kaplan and Meier method and compared using the log-rank test. Statistical analysis was performed using StatView (version 5.0, SAS Institute Inc., Cary, NC). A *P* value < 0.05 was considered statistically significant. The study was approved by the Human Ethics Review Committee of Osaka University Hospital and a signed consent form was obtained from each patient.

RESULTS

Table 1 lists the differences in perioperative characteristics between Group A and Group B. Patients classified as Child-Pugh A were significantly more common among Group A than Group B (*P* = 0.0176). Intraoperative blood loss in Group A was significantly greater than in Group B (*P* < 0.0001). While the postoperative mortality was 3.9% (8/204) in Group A, no mortality was recorded in Group B (*P* = 0.0007). The incidence of postoperative complications was 27.0% (55/204) in Group A and 24.6% (73/297) in Group B, and the incidence did not significantly differ between the two groups.

Various perioperative parameters were compared between Group B1 and Group B2 (Table 1). The preoperative factors were similar in the two groups. The incidence of hepatectomy equal to or more than Hr 2 was significantly higher in Group B1 than in Group B2 (*P* = 0.0436), and a significantly greater intraoperative blood loss was recorded in Group B1 than in Group B2 (*P* < 0.0001). There was no operative mortality in either of the two groups. The incidence of postoperative complications was 40.9% (9/22) in Group B1 and 23.2% (64/275) in Group B2, and the incidence did not significantly differ between the two groups. No adverse events related to FFP transfusion were found in Group B1. Postoperative complications and liver function were compared between Group B1 and Group B2 only in patients with intraoperative blood loss of ≥ 2000 mL (Group B1≥ 2000 mL: *n* = 21, Group B2≥ 2000 mL: *n* = 29). Comparison of clinical features of patients in these two groups is summarized in Table 2. There were no significant differences in the preoperative factors. Intraoperative blood loss and the frequency of administra-

tion of red cell concentrates (RCC) in Group B1≥ 2000 mL were significantly more than those in Group B2≥ 2000 mL ($P < 0.0001$ and $P = 0.0004$, respectively). Operative mortality was not encountered in the two groups. The incidence of postoperative complications was 42.9% (9/21) in Group B1≥ 2000 mL and 31.0% (9/29) in Group B2≥ 2000 mL. Table 3 lists the types of complications. Neither postoperative hepatic failure nor postoperative bleeding occurred in the two groups.

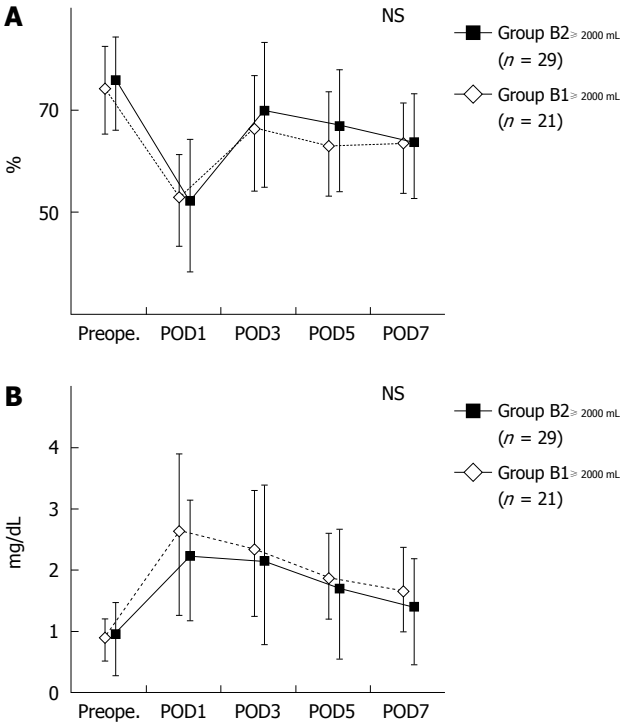

Figure 2 Perioperative changes in (A) serum prothrombin time, and (B) total bilirubin levels in Group B1≥ 2000 mL and Group B2≥ 2000 mL. NS: Not significant; Preope.: Preoperative; POD: Postoperative day.

Figure 2 demonstrates the perioperative changes in PT and T-Bil in patients with intraoperative blood loss of ≥ 2000 mL. The levels of PT and T-Bil were not significantly different between the two groups, irrespective of the POD.

Long-term postoperative outcomes, including disease-free survival (DFS) and overall survival (OS) after hepatic resection, were also examined in patients with intraoperative blood loss of ≥ 2000 mL (Table 4). Vascular invasion (absent/present), FFP transfusion (transfused/non-transfused), tumor size (< 5 cm/≥ 5 cm), RCC transfusion (transfused/non-transfused) were significant factors in univariate analysis of DFS among the clinicopathological factors tested ($P = 0.0101$, 0.0276, 0.0288, and 0.0343, respectively). Multivariate analysis for DFS using the four factors identified vascular invasion as the only significant independent factor ($P = 0.0299$). The DFS in Group B2≥ 2000 mL was significantly better than in Group B1≥ 2000 mL ($P = 0.0276$), though the factor was not significant on multivariate analysis (Figure 3A). Next, univariate analysis for OS using various clinicopathological factors demonstrated that vascular invasion (absent/present) and number of nodules (single/multiple) were significant factors ($P = 0.0024$ and $P = 0.0150$, respectively). Multivariate analysis for OS using the two factors, identified vascular invasion as the only significant independent factor ($P = 0.0185$). There was no significant difference in OS between Group B2≥ 2000 mL and Group B1≥ 2000 mL (P = not significant) (Figure 3B).

DISCUSSION

The present study was designed to investigate whether the outcomes of hepatectomy for HCC are influenced by FFP transfusion. Firstly, we compared the incidence of mortality and morbidity between Group A and Group B, indicating no significant difference in the incidence between the two groups. However, the comparison is considered to be difficult because of differences in the background of each period such as surgical and anesthetic techniques. For example, there were significant differences in liver function evaluated by Child-Pugh classification, and in intraoperative blood loss, between the two groups. Therefore, for more justified analysis, we next compared the outcomes between Group B1 and Group B2. The result showed the incidence of mortality and morbidity to be comparable between Group B1 and Group B2. However, since there were significant differences in the surgical procedure and intraoperative blood loss between the two groups, we also compared the postoperative complications between Group B1≥ 2000 mL *vs* Group B2≥ 2000 mL. The results showed equal rates of postoperative complications in the two groups. In particular, hepatic failure (prevention of which is one of the purposes of FFP administration) was not identified in the two groups. Postoperative residual liver function, represented by PT and T-Bil, was also equal in the two groups. Furthermore, the incidences of postoperative mortality and morbidity in Group B1 and Group B2 were similar to those reported in other studies[5,22-24]. For example, Imamura *et al*[5] reported the surgical result of 1056 hepatic resections including 532 HCC cases, with incidences of postoperative mortality and morbidity of 0% and 39.0%, respectively. However, they did not report the number of patients who received FFP. FFP was reported to be administered at a rate that exceeded the amount of blood loss by 10% to 20% during surgery; it substituted the amount of protein lost so as to maintain serum total protein level at 6.0 g/dL in that study. Based on our results and those of early studies, it cannot be concluded that FFP administration would contribute to the incidences of postoperative mortality and morbidity, including hepatic failure.

Although some previous studies have reported postoperative complications after hepatectomy for HCC, there are no reports comparing postoperative complications between patients with FFP transfusion and those without FFP transfusion. Martin *et al*[25] reported the use of FFP after hepatic resection and suggested criteria for FFP transfusion to deal with postoperative complications after treatment of liver metastasis from colorectal cancer, but not for HCC with liver cirrhosis. Accordingly, their criteria should not be necessarily generalized to the use of FFP in hepatectomy for HCC. Therefore, this study is the first report in which the incidence of postoperative complications in HCC patients was compared between patients who received FFP and those who did not receive FFP transfusion.

To date, FFP has been traditionally used at hepatectomy for the purpose of hemostatic effect by correction of deficiency of coagulation factors and maintenance of circulating blood volume by supplementation of albumin, which is mainly responsible for the colloid osmotic pressure of plasma; in addition to the aforementioned purpose of prevention of hepatic failure[6-8]. Firstly, with regard to the hemostatic effect, recent improvements in surgical techniques allow hepatectomy to be performed with minimal bleeding[19,20]. Moreover, coagulopathy requiring FFP transfusion is generally reported to occur at a PT value of more than 2.0 times the control, whereas the mean PT level of patients of Group B1≥ 2000 mL and Group B2≥ 2000 mL in the present study did not drop to the applicable level, even though it was measured after hepatectomy[26-28]. Furthermore, the incidence of postoperative bleeding was low and was not different in the two groups. Taking these results into consideration, routine administration of FFP is not necessary in terms of the hemostatic effect. Secondly, the maintenance of appropriate circulating blood volume is important in order to prevent certain complications such as pulmonary edema and prerenal type of renal dysfunction. However, albumin products, which can be administered safely compared to FFP, can be substitutes for FFP in terms of maintenance of circulating blood volume. In fact, albumin products were administered perioperatively instead of FFP in this study, especially in the non-transfused group, and the incidence of these complications was not different between Group B1≥ 2000 mL and Group B2≥ 2000 mL. In this context, routine FFP administration is also suggested not to be necessary in terms of maintenance of the circulating blood volume. Thus, we suggest that the routine administration of FFP for the purpose of prevention of hepatic failure, hemostatic effect, and maintenance of circulating blood volume is not necessary.

Many adverse effects related to FFP transfusion have been identified, such as infection, allergic reactions, hemolysis, anaphylaxis, and TRALI[13-15]. In particular, TRALI, which is a rare and serious complication characterized by sudden onset of respiratory distress due to noncardiogenic pulmonary edema during or following transfusion, can be life-threatening. Fortunately, none of these transfusion-related complications occurred in our patients. However, since some of the reported adverse events can be life-threatening, one should refrain from inappropriate use of FFP.

Since an initial report by Foster *et al*[29] about survival advantages in patients undergoing colectomy for colon cancer, several other reports have shown that perioperative homologous blood transfusion to be an independent prognostic factor in many kinds of cancers[16,17,30-33]. However, a few suggested that homologous blood transfusion has no significant effect on the prognosis of cancer patients[34,35]. Thus, the association between transfusion and postoperative prognosis is still under debate. In the present study, postoperative prognosis did not correlate with FFP administration, but rather with tumor-related factors. Although the result was not powerful evidence to resolve the controversy, we can at least confirm that FFP administration does not improve prognosis of patients undergoing hepatectomy for HCC.

In fact, the guidelines of the Japanese Ministry of Health, Labour and Welfare state that administration of FFP should be limited only to supplement coagulation factors in those patients with a PT of more than 2.0 times normal or coagulation factor activity of ≤ 30%, and that the use of FFP for supplementation of circulation blood volume is inappropriate[18]. The guidelines do not mention administration of FFP for the prevention of hepatic failure. Thus, our suggestion is to obey the guidelines. Recently, Kaibori *et al*[36] reported the clinical value of FFP in surgery for HCC. They suggested that FFP transfusion was useful and recommended on the grounds of the results obtained from their analysis that the incidence of postoperative complications in patients with FFP transfusions was lower than that of patients with FFP and RCC transfusions, and was equal to that of non-transfused patients; long-term survival in patients with FFP transfusions was almost equal to that in non-transfused patients. However, their suggestion is perceived as groundless for the following reasons. To begin with, although there were some significant differences in many factors such as liver function and tumor progression among the groups in their study, they simply suggested that the difference in postoperative complications and long-term outcome resulted from the RCC and FFP transfusions. Secondly, since details of postoperative complications were not shown, especially for hepatic failure, postoperative bleeding, pulmonary edema and renal dysfunction, the examination of correlations between complications and FFP transfusions was insufficient. In addition, their suggestion completely ignored the recent guidelines of Japan.

The present analysis did not include HCC patients who underwent liver transplantation for treatment of liver cirrhosis. Therefore, the result of this study is not applicable to liver transplantation surgery. Considering that transfusion is performed for concomitant liver dysfunction at almost all liver transplantation surgery, it seems to be still too early to discuss the necessity of transfusion in such surgery.

In summary, FFP transfusion did not affect outcomes following hepatic resection for HCC in terms of liver function, postoperative complications and cancer prognosis. Considering the previously reported FFP transfusion-related adverse effects in addition to the results of the present study, we suggest that FFP transfusion be abandoned in patients who undergo hepatectomy for HCC.

COMMENTS

Background

Fresh frozen plasma (FFP) has been frequently administered in the surgical treatment for hepatocellular carcinoma (HCC). Today, appropriate use of FFP is needed in terms of application and FFP transfusion-related potential adverse events. However, to our knowledge, there have been few reports investigating whether FFP transfusion affects outcomes following hepatic resection for HCC or any discussion of the need for FFP in surgery for HCC.

Research frontiers

The incidence of mortality and morbidity, postoperative liver function, and postoperative cancer prognosis were comparable between patients with intraoperative blood loss ⩾ 2000 mL who had FFP transfusion and who did not have FFP transfusion.

Innovations and breakthroughs

This study showed that FFP transfusion did not affect outcomes following hepatic resection for HCC in terms of liver function, postoperative complications and cancer prognosis.

Applications

Considering the results of the present study, there is a suggestion that FFP transfusion should be abandoned in patients who undergo hepatectomy for HCC.

Peer review

The manuscript is a well-written paper that is adequately discussed with a reasonable number of literature references. Moreover, the topic is a current and popular one. Conclusions are well supplied by the results and literature.

Abstract

AIM: To track intravascularly transplanted mesenchymal stem cells (MSCs) labeled with superparamagnetic iron oxide (SPIO) by using magnetic resonance imaging (MRI) in an experimental rabbit model of hepatic failure.

METHODS: Human MSCs labeled with FDA-approved SPIO particles (Feridex) were transplanted *via* the mesenteric vein into rabbits (n = 16) with carbon tetrachloride-induced hepatic failure. Magnetic resonance (MR) examinations were performed with a 3.0 T clinical scanner immediately before and 2 h and 1, 3, and 7 d after transplantation. Signal intensity (SI) changes on T2*-weighted MRI were measured, and correlation between MR findings and histomorphologic findings was also investigated.

RESULTS: SI on T2*-weighted MRI decreased significantly in the liver 2 h after injection of human MSCs and returned gradually to the levels found before injection in 7 d. Changes in SI in the liver at 2 h, 1, 3, and 7 d were 41.87% ± 9.63%, 10.42% ± 4.3%, 5.12% ± 1.9%, 3.75% ± 1.2%, respectively (P < 0.001). Histologic analyses confirmed the presence of MSCs in the liver, localized mainly in the sinusoids in early period (2 h and 1 d) and concentrated to the border zone in late period (3 and 7 d). The number of iron-positive cells in the liver at 2 h and on 1, 3 and 7 d after transplantation was 29.2 ± 4.8, 10.1 ± 3.7, 6.7 ± 2.2, and 5.8 ± 2.1, respectively (P = 0.013).

CONCLUSION: Intravascularly injected SPIO-labeled MSCs in an experimental rabbit model of hepatic failure can be detected and followed with MRI.

Key words: Stem cell; Liver failure; Magnetic resonance; Nanoparticle; Transplantation

INTRODUCTION

As a potential treatment, liver cell transplantation provides an effective strategy for the treatment of liver failure[1]. Transdifferentiation of stem cells of various types into functional hepatocytes has been demonstrated, including embryonic stem cells, hepatoblasts, hepatic oval cells, pancreatic progenitor cells, bone marrow hematopoietic stem cells, and mesenchymal stem cells (MSCs)[2-7]. The use of MSCs as a potent potential source for hepatocytic transdifferentiation has been tried[8,9] and bone marrow-derived MSCs protected against carbon tetrachloride-induced liver fibrosis in rats[10].

In the past several years, a great deal of research has been focused on stem cell therapy. However, there remain many important issues to be addressed regarding cell therapy, and noninvasive and repeated monitoring of *in vivo* transplanted stem cells is an important topic in these days. Therefore, more recent research activities have focused on *in vivo* real-time tracking and detecting the fate of transplanted stem cells by using appropriate imaging technologies[11,12].

The use of magnetic resonance imaging (MRI) is well suited to evaluate the ability of cells to migrate and engraft to target organs, as MRI can provide a detailed anatomy of target organs with excellent spatial resolution. Paramagnetic or modified dextran-coated superparamagnetic iron oxide (SPIO) contrast agents have been used to label cells, allowing investigators to monitor cellular migration using MRI[12,13]. However, few studies have been undertaken to determine the feasibility of the use of *in vivo* MRI of cell therapy in models of hepatic failure. The aim of the present study is to assess *in vivo* MRI with the use of a clinical 3-Tesla MRI unit for the depiction of SPIO-labeled MSCs in a rabbit model of hepatic failure.

MATERIALS AND METHODS

Cell culture and labeling

The method of cell culture and labeling was previously reported[14] and is only briefly described here. Human MSCs (Bio-Whittaker, Walkersville, MD) were grown in mesenchymal stem cell basal medium (MSCBM, Bio-Whittaker) at 37℃ and in a 95% air, 5% CO_2 atmosphere. Human MSCs were cocultured in MSCBM containing FDA-approved SPIO particles (Feridex; Berlex, Wayne, NJ). The iron concentrations of the SPIO preparations were 125 μg/mL. Poly-L-Lysine (PLL) (Sigma-Aldrich, St. Louis, MO) was used as a transfection agent.

Animal models

All animal work was conducted in accordance with the guidelines provided by the Institutional Animal Control and Utilization Committee. The experiments were performed with 24 New Zealand white rabbits weighing 2.5-3.2 kg. The average age of rabbits was 10 wk. The rabbits were allowed food and water *ad libitum* and were kept in 44 cm × 68 cm × 39 cm sized cage with 22 ± 2℃ of temperature and 40%-60% of humidity.

Hepatic fibrosis was induced by intragastric administration of carbon tetrachloride (CCl_4) twice a week for 2 wk with 0.1 mL/kg in olive oil (at a 1:1 ratio). One day after the fourth administration of CCl_4, rabbits were anesthetized with intramuscular injection of 25-50 mg/kg ketamine hydrochloride (Yuhan Yanghang) and 10-20 mg/kg 2% xylazine hydrochloride (Bayer). After the abdomens of the rabbits were opened to expose the mesenteric vein, 1×10^6 SPIO-labeled human MSCs were slowly injected into the mesenteric vein in the experimental group (16 rabbits). One milliliter normal saline was injected into the mesenteric vein in control group (8 rabbits).

MRI

In all 24 rabbits MRI was performed with a 3.0 T MRI scanner (Signa Excite; GE Healthcare, Milwaukee, WI) with a knee coil. MRI of the rabbit liver was carried out immediately before, and 2 h, and 1, 3, and 7 d after injection of these stem cells. Transverse T2*-weighted gradient-echo (repetition time msec/echo time msec, 600/20; flip angle, 30°; section thickness, 3 mm; FOV, 18 cm; matrix, 256 × 160; number of signals acquired, two) sequences were employed.

Changes in signal intensity (SI) were characterized by use of region of interest (ROI) analysis on a well-centered slice with an area of 1 mm^2. A minimum of 15 pixels was required per region as displayed on a picture archiving and communication system (PACS) workstation (Maroview; Marotech). The value of the ROI was determined as the mean ± SD after an estimated three times, and was normalized to that of back muscle[15]. SI changes in each rabbit were calculated according to the use of the following formula: [SI (pre) - SI (post)]/SI (pre) × 100; SI (pre) and SI (post) are the normalized SI values as compared to back muscle before and after labeled cell injection.

Histological analysis

Two hours, and 1, 3, and 7 d after MRI, 4 rabbits each time in the experimental group and 2 rabbits each time in the control group were sacrificed for histological examination. Rabbit liver tissue blocks were fixed in 4% paraformaldehyde and were processed for paraffin embedding. Microsections (4 μm) were prepared with a microtome and were used for Prussian blue staining to detect labeled iron particles in the cells. An experienced board-certified pathologist calculated the number of Prussian blue stain positive cells per high power field (HPF) in each group. Prussian blue stain positive cells were counted in at least three HPFs per section and a minimum of six sections were examined.

Statistical analysis

The Kruskall-Wallis test was used to evaluate differences in SI changes and Prussian blue stain positive cells. *P* value of less than 0.05 was considered to indicate a statistical significance, and statistical computer software (SPSS 12.0; SPSS, Chicago, Ill) was used.

RESULTS

In the experimental group (n = 16), axial T2*-weighted

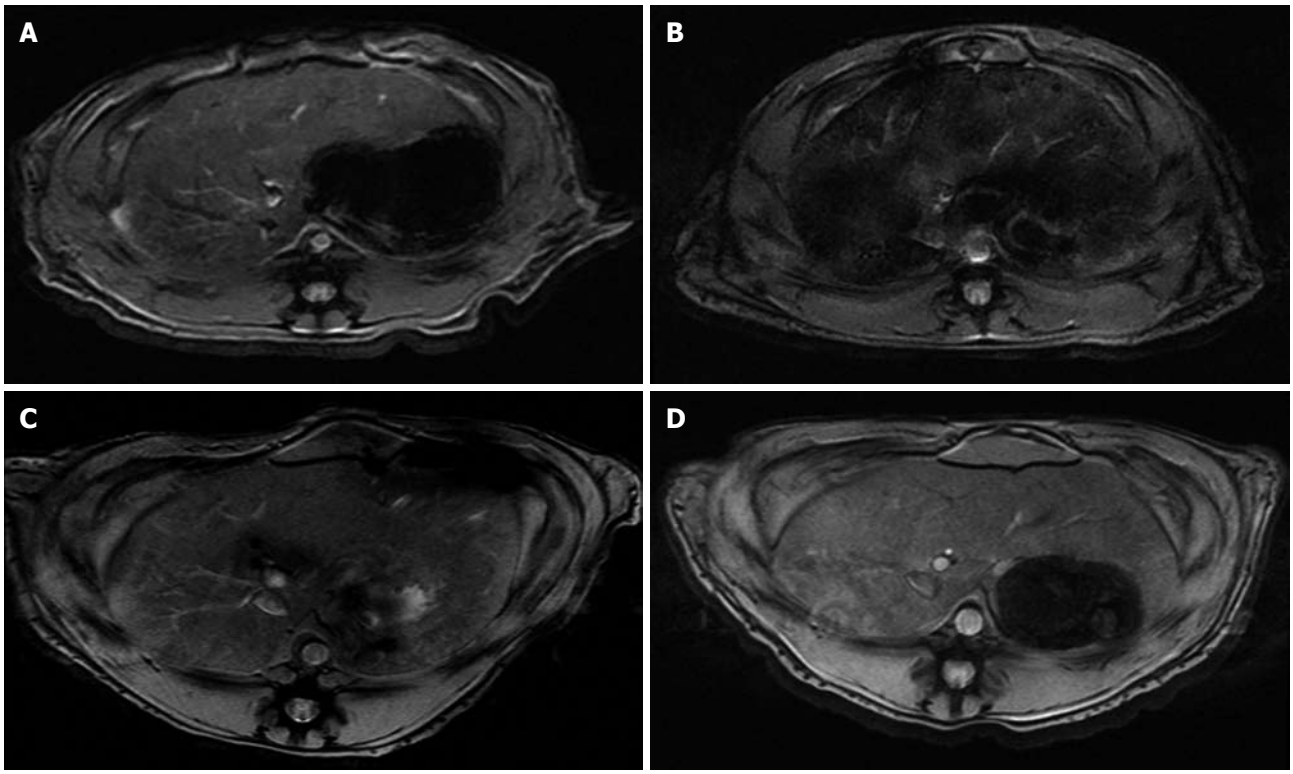

Figure 1 T2*-weighted gradient-echo magnetic resonance images show signal intensity changes of the liver after injecting superparamagnetic iron oxide-labeled human mesenchymal stem cells immediately before (A), 2 h (B) and 1 d (C), 7 d (D) after injection. Changes in signal intensity in the liver normalized to that of back muscle at 2 h, 1 d, and 7 d were 41.87% ± 9.63%, 10.42% ± 4.3%, and 3.75% ± 1.2%, respectively ($P < 0.001$). Note a significant signal drop of the liver at 2 h after injecting superparamagnetic iron oxide-labeled mesenchymal stem cells and gradual return of signal intensity compared with signal intensity before transplantation.

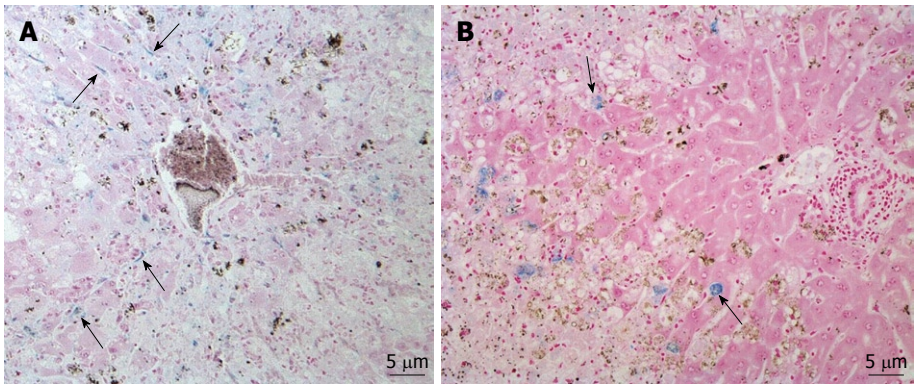

Figure 2 Photomicrographs of rabbit liver obtained after superparamagnetic iron oxide-labeled human mesenchymal stem cells injection *via* the mesenteric vein. A: Section obtained on day 1 shows distributions of Prussian blue stain-positive mesenchymal stem cells (MSCs) (arrows) in the liver parenchyma along the sinusoids; B: Section obtained on day 7 shows the localization of superparamagnetic iron oxide-labeled MSCs (arrows) in the border zone between normal liver parenchyma and hepatic injury areas.

images of the liver demonstrated a significant signal loss of fine granular signal voids 2 h after intravascular administration of SPIO-labeled cells in comparison to baseline (Figure 1). The change in SI of the liver on T2*-weighted images peaked at 2 h after injection and subsequently declined. Changes in SI in the liver at 2 h, 1, 3 and 7 d were 41.87% ± 9.63%, 10.42% ± 4.3%, 5.12% ± 1.9%, 3.75% ± 1.2%, respectively ($P < 0.001$). In the control group ($n = 8$), no overt signal changes of the liver were observed.

CCl4 treatment of rabbits induced typical histopathological changes indicative of persistent damage and fibrotic changes in the liver. Prussian blue staining studies showed that the iron-containing cells were mainly distributed in the portal triad regions throughout the liver 2 h and 1 d after injection of human MSCs. These cells showed amorphous shapes with positive iron staining in their cytoplasms and tended to localize along the sinusoids (Figure 2A). However, the iron-positive cells in the experimental group mainly appeared in the border zone between normal liver parenchyma and hepatic injury areas 3 and 7 d after injection (Figure 2B). The number of iron-positive cells in the experimental group at 2 h and on 1,

3 and 7 d after injection was 29.2 ± 4.8, 10.1 ± 3.7, 6.7 ± 2.2, and 5.8 ± 2.1, respectively (P = 0.013). In the control group, Prussian blue positively stained cells were absent from the liver.

DISCUSSION

It is widely accepted that efficient monitoring of the distribution, migration, and differentiation of transplanted stem cells holds the key to the development of effective methods in stem cell therapy[16]. Because of its high resolution and sensitivity, MRI has been regarded as a method of first choice compared to other imaging modalities. MRI can be broadly defined as a non-invasive and repetitive modality of imaging for targeted cells and cellular processes[17], which entails proper labeling of cells with appropriate magnetic resonance (MR) contrast agents.

In most reports that have described MRI of grafted stem cells, local implantation has been used as the route for cell grafting into the rat brain and spine[18,19]. After implantation, these cells are concentrated in a localized area rather than dispersed throughout the target organ, as occurs after intravascular injection. These locally implanted stem cells were observed to migrate only at a rate of a few millimeters a week[18-20]. This stereotactic method can hardly be applied in a hepatic failure model because liver damage often has a widespread distribution. Thus, we injected MSCs into the mesenteric vein, as a large number of MSCs could be directly transferred to the whole liver.

Our results and others[21] demonstrate that MSCs are particularly present along the sinusoids where the cells can be mechanically trapped after injection into the portal vein. Recently, the process of migration of stem cells from the spleen to the liver in rats was tracked *in vivo* by labeling stem cells with superparamagnetic particles[12], which showed that the majority of iron-positive cells appeared in the liver at 3 h of post-transplantation. This is similar to our findings. The results together suggest that direct intravascular transplantation is an efficient way of delivering MSCs to the liver.

The histological data obtained in the present study showed that Prussian blue stain-positive cells were found mainly in the border zone between normal liver parenchyma and the hepatic injury areas 3 and 7 d after injection. The exact reason why MSCs were concentrated in the border zone in liver damage is not known. This phenomenon may be caused by secreted cytokines such as hepatocyte growth factor which is secreted by mesenchymal cells and has a major role in adult organ regeneration and in wound healing[22]. We speculate MSCs might contribute the healing process of liver damage.

SI on T2*-weighted images decreased substantially in the liver 2 h after injection of MSCs and gradually returned to the levels found before injection. The gradual increase of SI in the liver may be the result of mobilization of labeled cells out of the liver, dilution of intracellular iron as a result of cell division, or cell death resulting from immune rejection[12]. In our study, SI decreased more quickly than that reported in other study[12] and this was probably due to the use of human MSCs in our study that induces more potent immune rejection than previous study.

There are some limitations to this study. First, we used only commercially available human MSCs, and not rabbit MSCs, because we focused on the validity of MRI for the depiction of SPIO-labeled MSCs in hepatic failure model rather than to access recovery of hepatic function. Second, we did not perform immunohistochemical analysis on human MSCs under the conditions that we tested with the rabbit model, and therefore could not confirm whether Prussian blue stained positive cells were associated with SPIO-labeled MSCs *in vivo*.

In conclusion, SPIO-labeled MSCs could be detected *in vivo* by the use of a clinically available 3-Tesla MR unit after intravascular injection in a rabbit model of hepatic failure.

COMMENTS

Background

Stem cell transplantation provides an effective strategy for the treatment of liver failure. Noninvasive and repeated monitoring of *in vivo* transplanted stem cells is one of important topics in these days.

Research frontiers

In vivo real-time tracking and detecting the fate of transplanted stem cells by magnetic resonance imaging (MRI) would be a good way to evaluate the ability of cells to migrate and engraft to target organs. However, few studies have been undertaken to determine the feasibility of the use of *in vivo* MRI of cell therapy in models of hepatic failure.

Innovations and breakthroughs

This study showed the possibility of stem cell tracking by the use of a clinically available 3-Tesla magnetic resonance unit.

Applications

In vivo real-time tracking transplanted stem cells by MRI might facilitate clinical use of stem cell.

Terminology

Mesenchymal stem cells: multipotent stem cells that can differentiate into a variety of cell types including osteoblasts (bone cells), chondrocytes (cartilage cells) and adipocytes (fat cells).

Peer review

It is a well-written but moderately designed study, with interesting and important scientific merit.

Abstract

AIM: To evaluate the efficacy of endoscopic diagnosis and therapy for jejunal diverticular bleeding.

METHODS: From January 2004 to September 2009, 154 patients underwent double-balloon enteroscopy (DBE) for obscure gastrointestinal bleeding. Ten consecutive patients with jejunal diverticula (5 males and 5 females) at the age of 68.7 ± 2.1 years (range 19-95 years) at Chang Gung Memorial Hospital, Academic Tertiary Referral Center, were enrolled in this study.

RESULTS: Of the 10 patients, 5 had melena, 2 had hematochezia, 2 had both melena and hematochezia, 1 had anemia and dizziness. DBE revealed ulcers with stigmata of recent hemorrhage in 6 patients treated by injection of epinephrine diluted at 1:10 000, Dieulafoy-like lesions in 4 patients treated by deploying hemoclips on the vessels, colonic diverticula in 2 patients, and duodenal diverticula in 3 patients, respectively. Of the 2 patients who underwent surgical intervention, 1 had a large diverticulum and was referred by the surgeon for DBE, 1 received endoscopic therapy but failed due to massive bleeding. One patient had a second DBE for recurrent hemorrhage 7 mo later, which was successfully treated with a repeat endoscopy. The mean follow-up time of patients was 14.7 ± 7.8 mo.

CONCLUSION: DBE is a safe and effective treatment modality for jejunal diverticular bleeding.

INTRODUCTION

Jejunal diverticulum, first described by Sir Astley Cooper in 1807, is a rare lesion of the small intestine seen in 2%-2.3% of small-bowel contrast studies[1,2] and 1.3%-4.6% of autopsy studies[3,4]. Most jejunal diverticula are asymptomatic, but they are usually complicated by diverticulitis with or without bowel perforation, intestinal obstruction, and bleeding, once they become symptomatic[5,6]. Massive gastrointestinal bleeding secondary to jejunal diverticulosis

is extremely rare, and only less than 50 cases have been reported[7]. Most of them present with obscure gastrointestinal bleeding.

In the past, jejunal diverticular bleeding was surgically treated[8], with associated operative morbidity and mortality, as well as postoperative ileus[9]. Double-balloon enteroscopy (DBE), a new technique developed by Yamamoto *et al*[10], using the push-and-pull method, enables optimal to-and-fro observation as well as therapeutic intervention[11]. Herein, we describe our clinical experience with this new technique in the diagnosis and treatment of jejunal diverticular bleeding at one academic tertiary-referral center in Taiwan.

MATERIALS AND METHODS

Patients

From January 2004 to September 2009, 154 patients with obscure gastrointestinal bleeding were referred for DBE at our tertiary referral center. Ten (6.5%) consecutive patients with jejunal diverticular bleeding (5 males and 5 females) at the age of 68.7 ± 2.1 years (range 19-95 years) at Chang Gung Memorial Hospital, Academic Tertiary Referral Center, were enrolled in this study. Obscure gastrointestinal bleeding is defined as the absence of an identified bleeding source after standard endoscopic evaluation[12,13]. The demographics of these patients are shown in Table 1. Of the 10 patients, five had melena, two had hematochezia, two had both melena and hematochezia, and one had microcytic anemia and dizziness.

Informed consent was obtained each patient prior to the endoscopic procedure.

DBE system and technique

The DBE system (Fujinon Inc., Japan) developed by Yamamoto *et al*[10] was used. A Fujinon EN-450 T5-type enteroscope with a 2.8-mm working channel and a 9.4-mm outer diameter was used, permitting easier and greater instrument access where necessary. Two soft latex balloons were fitted at tip of the enteroscope and overtube. An air pump controller (Fujinon PB-10) was used to measure and control the pressure in both balloons. Insertion route was selected based on the information obtained from pre-DBE. Peroral route examination was performed first, in the event of insufficient localization clues, because of the direction of peristalsis in the small intestine, which could thus reduce interference from blood in the small intestine. If no bleeder was identified, tattooing with pure carbon was performed at the most distal point during the examination. A second examination was performed a few days later. No special preparation was needed for the peroral examination other than an 8-12 h fasting. For the perianal examination, bowel preparation was performed as in colonoscopy. Mild sedation was accomplished *via* intravenous injection with meperidine (0.5-1.0 mg/kg) and midazolam (0.05 mg/kg). An Olympus rotary reusable delivery system, HX-110UR (2300 mm in length) with an EZ clip, was used for Dieulafoy-like lesions, and local injection with epinephrine diluted at 1:10 000 was applied to lesions with stigmata of recent hemorrhage (SRH).

RESULTS

Three patients were treated with non-steroidal anti-inflammatory drugs, one was treated with coumadin, and one was treated with clopidogrel. Esophagogastroduodenoscopy, colonoscopy or DBE showed colonic diverticula in two patients and duodenal diverticula in three patients, respectively. Other imaging studies including computed tomography (CT), barium study, angiography, and capsule enteroscopy (CE) were performed before DBE (Table 1). Five patients underwent CT scan with no positive CT finding found in any patient. Four patients underwent CE with diverticular bleeding detected in one patient. Eight patients underwent barium study and the results are shown in Table 1. Three patients underwent angiography with no positive finding observed in any patient.

All the 10 patients underwent peroral DBE, which was chosen according to the presenting clinical symptoms and signs, estimation of bleeding sites, and the results of previous studies.

Six patients (Table 2) had ulcers with SRH on the margin of diverticulum, which were treated by injection of 1-3 mL epinephrine diluted at 1:10 000 (Figure 1). Four patients had Dieulafoy-like lesions on the fold of diverticulum, which were treated by deploying hemoclips (Figure 2) on the vessels. The lesions were roughly estimated in the proximal to middle jejunum.

Of the two patients who underwent further surgical intervention, one had a large diverticulum (2.3 cm × 1.5 cm × 1.2 cm in size) and was referred by the surgeon for DBE, one experienced failure of endoscopic therapy due to massive bleeding. One patient underwent a second DBE for recurrent hemorrhage 7 mo later, and was successfully treated with a repeat endoscopy. The mean follow-up time of patients was 14.7 ± 7.8 mo. Occult blood testing was negative in stools of these patients, and no significant decrease was observed in hemoglobin during the follow-up period.

DISCUSSION

Gastrointestinal bleeding is frequently encountered by the endoscopist in his/her daily medical practice. Ninety-five percent of the bleeders can be identified by conventional upper endoscopy or colonoscopy. However, 5% of bleeders cannot be found even on repeat conventional upper endoscopy or colonoscopy. This phenomenon is known as obscure gastrointestinal bleeding, and can be further divided into frank bleeding (overt bleeding) and iron-deficiency anemia with guaiac-positive stools (occult bleeding)[12,13]. The bleeding site of most obscure gastrointestinal bleeders is in the small intestine. Lesions in potential bleeders can be further classified into 3 types: vascular lesions, neoplastic lesions, or inflammatory lesions, including diverticula[14].

Table 1 Demographics of 10 patients with jejunal diverticular bleeding

No.	Age (yr)/sex	Symptoms	Hb (g/dL)	Drugs	CT	CE	Barium	Angiography
1	64/M	Melena and hematochezia	8.9	-	Negative	-	Diverticulosis	-
2	61/F	Melena and hematochezia	9.8	NSAIDs -		-	Diverticula	-
3	80/M	Melena	11	NSAIDs	Negative	-	Diverticula	Negative

Table 2 Enteroscopy and double-balloon enteroscopy findings

No.	Route	Findings	Management	Follow-up timed (mo)	Outcome
1	Per-oral	Ulcer with SRH on the margin	Injection therapy	16	Recurrent bleeding after 7 mo, second DBE therapy performed
2	Per-oral	Ulcer with SRH on the margin	Injection therapy	14	Surgical intervention for large diverticulum
3	Per-oral	Dieulafoy-like lesion on the fold	Hemoclipping	9	Surgical intervention for failure of endoscopic treatment
4	Per-oral	Ulcer with SRH on the margin	Injection therapy	19	No recurrence
5	Per-oral	Ulcer with SRH on the margin	Injection therapy	22	No recurrence
6	Per-oral	Ulcer with SRH on the margin	Injection therapy	9	No recurrence
7	Per-oral	Dieulafoy-like lesion on the fold	Hemoclipping	8	No recurrence
8	Per-oral	Dieulafoy-like lesion on the fold	Injection therapy and hemoclipping	9	No recurrence
9	Per-oral	Ulcer with SRH on the margin	Injection therapy	32	No recurrence
10	Per-oral	Dieulafoy-like lesion on the fold	Hemoclipping	9	No recurrence

SRH: Stigmata of recent hemorrhage.

It has been reported that most patients with jejunal diverticular hemorrhage are treated with surgical intervention[7,15]. Jejunal diverticula are frequently seen in the sixth and seventh decades of life, as an acquired lesion with no muscularis layer on the mesenteric side. Patients undergoing surgery for duodenal diverticula are at risk for operative mortality and morbidity, as well as postoperative ileus and complications of general anesthesia[9].

Many modalities have been introduced to evaluate obscure gastrointestinal bleeding, including barium contrast study, CT scan, angiography, and CE. However, they have some limitations. The yield of CT scan for jejunal diverticula is only 2%[1]. Although the yield of CE for obscure gastrointestinal bleeding is 30%-80%[14], CE is not a therapeutic modality for obscure gastrointestinal bleeding and may result in retention of the capsule in diverticulum[16], as occurred in two of our patients. Barium contrast study has a high yield for detection of jejunal diverticula, but it is not a therapeutic modality for gastrointestinal bleeding. It has been reported that angiography plays a role in the diagnosis and treatment of small-bowel bleeding[17,18]. However, this procedure has limitations, including the risk of ischemic damage to the small-bowel wall, and failure to detect all bleeders.

It has been recently reported that DBE, a novel and unique technique, can successfully treat jejunal diverticular bleeding[19,20], and allow to-and-fro observation of the small intestine, and more importantly, permits tissue diagnosis and therapeutic intervention[11,21,22]. Thus, the aim of our study was to evaluate the efficacy of DBE therapy for jejunal diverticular bleeding.

Since endoscopic injection in treatment of nonvariceal hemorrhage was first described by Soehendra *et al*[23] in 1985, many endoscopic therapeutic modalities including contact or noncontact thermal therapy, and mechanical therapy by deploying a hemoclip on the feeding vessel have been developed for upper and lower gastrointestinal hemorrhage[24].

To our knowledge, this is the first case series report of patients with jejunal diverticular bleeding treated *via* endoscopy with diluted epinephrine local injection or hemoclips. The complication of injection therapy for small intestine lesions has been reported by Yen *et al*[25] who reported a case of intestinal wall necrosis after injection therapy. In addition, he reminds us that advanced age, atherosclerotic vascular disease, anemia, hypoxemia, shock and thinner intestinal wall are the risk factors. The amount of diluted epinephrine used in this study ranged 1-3 mL and no intestinal necrosis was found in patients. Nevertheless, further study is needed to determine the ideal amount of diluted epinephrine.

In this study, the mean follow-up time of patients was 14.7 ± 7.8 mo, during which only two patients had surgical intervention due to the large diverticulum and massive bleeding. One patient had recurrent ulcer bleeding after 7 mo, and was successfully treated with a repeat DBE by local injection therapy. No additional bleeding occurred in the other seven patients during the most recent follow-up.

In conclusion, DBE is a safe and effective treatment modality for jejunal diverticular bleeding. If rebleeding occurs, a repeat endoscopic therapeutic procedure should be attempted in addition to surgical intervention.

COMMENTS

Background

Jejunal diverticular massive bleeding is a rare complication of small bowel disease which usually takes the form of obscure gastrointestinal bleeding. Double-balloon enteroscopy (DBE) has been documented to be an effective tool for diagnosing and treating obscure gastrointestinal bleeding.

Research frontiers

The efficacy of endoscopy in diagnosing and treating jejunal diverticular bleeding was evaluated.

Innovations and breakthroughs

According to the findings in this study, DBE is a safe and effective treatment modality for jejunal diverticular bleeding.

Applications

DBE should be considered as the primary treatment modality for small intestine bleeding including jejunal diverticular bleeding.

Terminology

DBE uses 2 soft latex balloons fitted on tip of the enteroscope and overtube to complete the whole small bowel study.

Peer review

This is an interesting study describing the use of double-balloon-enteroscopy for hemorrhage from small bowel diverticula.

Abstract

AIM: To study the value of neoadjuvant chemotherapy (NAC) for advanced gastric cancer by performing a meta-analysis of the published studies.

METHODS: All published controlled trials of NAC for advanced gastric cancer *vs* no therapy before surgery were searched. Studies that included patients with metastases at enrollment were excluded. Databases included Cochrane Library of Clinical Comparative Trials, MEDLINE, Embase, and American Society of Clinical Oncology meeting abstracts from 1978 to 2010. The censor date was up to April 2010. Primary outcome was the odds ratio (OR) for improving overall survival rate of patients with advanced gastric cancer. Secondary outcome was the OR for down-staging tumor and increasing R0 resection in patients with advanced gastric cancer. Safety analyses were also performed. All calculations and statistical tests were performed using RevMan 5.0 software.

RESULTS: A total of 2271 patients with advanced gastric cancer enrolled in 14 trials were divided into NAC group (n = 1054) and control group (n = 1217). The patients were followed up for a median time of 54 mo. NAC significantly improved the survival rate [OR = 1.27, 95% confidence interval (CI): 1.04-1.55], tumor stage (OR = 1.71, 95% CI: 1.26-2.33) and R0 resection rate (OR = 1.51, 95% CI: 1.19-1.91) of patients with advanced gastric cancer. No obvious safety concerns were raised in these trials.

CONCLUSION: NAC can improve tumor stage and survival rate of patients with advanced gastric cancer with a rather good safety.

INTRODUCTION

Gastric cancer is still a major health problem and a leading cause of cancer-related death although its incidence is decreased worldwide[1]. Surgery is the only curative treatment modality for gastric cancer and the overall survival (OS) rate of early-stage gastric cancer patients is up to 90%[2]. However, as the majority of gastric cancer patients are at the advanced stage at the time of diagnosis, their overall prognosis is suboptimal despite aggressive treatment, with an overall survival rate of 20%-30% after radical surgical

resection in Europe and about 60% in Japan[3,4]. Clearly, effective adjuvant therapy is needed to improve the outcome of patients with advanced gastric cancer.

Adjuvant therapy for gastric cancer has been extensively studied[2,5,6]. The effect of adjuvant chemoradiation therapy and perioperative chemotherapy has been demonstrated in well designed, multicenter and randomized clinical trials. It was recently reported that adjuvant chemotherapy has an affirmative effect on locally advanced gastric cancer[5]. S-1, an oral fluoropyrimidine (Taiho Pharmaceutical) used as an adjuvant chemotherapeutic agent, can increase 10% 3-year overall survival rate of patients with gastric cancer[6]. Among the potential strategies for adjuvant therapy, preoperative chemotherapy may provide an equal therapeutic efficacy as postoperative chemotherapy for gastric cancer[7]. Chemotherapy delivery may be more efficient if given prior to surgical disruption of vasculature, tumor down-staging may substantially facilitate surgical resection[8], and preoperative chemotherapy can be used to evaluate tumor chemosensitivity to cytotoxic medications. Furthermore, gastric cancer patients may tolerate preoperative cytotoxic treatment better than postoperative treatment, as performance status is usually negatively impacted by surgery[9]. However, lack of response to neoadjuvant chemotherapy (NAC) may delay curative surgery and chemotherapy-induced toxicity may increase surgical complications[10].

The effect of NAC on gastric cancer has been studied in several prospective trials[11-14]. However, no definite conclusion has been drawn from these trials. The underlying reasons included insufficient statistical power due to a limited sample size, an extended period of time for patient accrual, imbalanced treatment arms, and non-protocol treatment strategy. A well-designed randomized clinical trial is therefore needed to define the effect of NAC on advanced gastric cancer. A relatively effective alternative to provide clinical evidence under such circumstances is to perform a meta-analysis of the published clinical trials[15]. The current meta-analysis was to evaluate the role of NAC in treatment of gastric cancer and explore the optimal strategy for chemotherapy delivery.

MATERIALS AND METHODS

Inclusion criteria

All published controlled trials comparing NAC *vs* no treatment before surgery in patients with locally advanced gastric cancer were included in our analysis. Blindness of the trial was not necessary. The inclusion criteria were patients with pathologically diagnosed gastric adenocarcinoma and no history of prior treatment before entering the trial but a history of potentially curative surgery. A study was chosen if it was updated. NAC was performed through oral or intravenous (IV), intraperitoneal (IP) and intra-arterial (IA) infusion. Studies on preoperative radiotherapy or immunotherapy were excluded. Postoperative therapies were not included in our study.

Outcome

Primary outcome was the odds ratio (OR) of intervention with overall survival rate. Secondary outcome was the OR of R0 resection rates and tumor down-staging, which was represented as the percentage in stage pT0-2 after surgery. If the 95% confidence interval (CI) of the OR included 1.0, no difference was considered between the groups. Subgroup analysis was used to explore and explain the differences in results of different studies. Sensitivity analysis was also performed to show the publication bias.

Search method

Cochrane archives of clinical comparative trials, MEDLINE, Embase and American Society of Clinical Oncology meetings were retrieved from 1978 to 2010, with a censor date up to April 2010. The search strategy terms used in the English databases were "neoadjuvant chemotherapy OR preoperative chemotherapy" AND "gastric cancer OR stomach cancer OR stomach neoplasm OR gastric carcinoma" AND "clinical trial". Trials published in journals or published as meeting abstracts with essential data were included. Non-controlled trials were excluded. Randomized controlled trials with three or more arms were retained if at least two arms addressed an eligible comparison. Studies on patients with metastatic gastric cancer at enrollment were excluded.

Data checking

Methodological quality of trials was evaluated according to the Jadad quality scores[16], which include secure method of randomization, allocation concealment, patient and observer blinding, and losses to follow-up. Based on these criteria, the studies were divided into high quality group (score $\geqslant$ 4) and low quality group (score < 4). Two reviewers independently assessed the eligibility of each trial.

Data extraction

Authors, year of publication, country of investigators, sample size (total, eligible, and per arm), chemotherapy regimen, cycles of chemotherapy, follow-up period, curative effect (survival rate, rate of macroscopic radical resection cancer stage at pathological examination), and adverse events of each eligible trial were recorded. Two reviewers independently made extracts from each study.

Statistical analysis

RevMan software 5.0 was employed for the meta-analysis[17]. Continuous data were expressed as weighted mean difference. OR for dichotomous parameters including overall survival rate, tumor down-staging, and R0 resection rate was recorded. Results were reported as 95% CI. All meta-analyses appraised inter-study heterogeneity using χ^2-based Q statistics for statistical significance and I^2 statistics for the degree of heterogeneity. $P < 0.10$ was considered statistically significant and $I^2 > 50\%$ showed a large heterogeneity. If there was no heterogeneity, a fixed-effect model was used. Otherwise, a random-effect model was used. The number needed to treat (NNT) was applied for outcomes with a statistical difference. Publishing bias was tested using the funnel plot. Sensitivity analysis was performed to investigate the possible influence of the study quality on the results. The main outcome of high-

quality trials was analyzed. Subgroup analysis was used to explore and explain the diversity in results of different studies for collecting information with different characteristics, such as tumor grade, chemotherapy regimen, and race.

RESULTS

Eligible trials

A total of 354 studies were retrieved. After abstracts were read, 335 studies were found to be unrelated to our selection criteria and it was impossible to extract data from another 5 studies. Thus, only 14 studies[18-31] were eligible for our meta-analysis. The enrolled 2271 gastric cancer patients in the studies were divided into NAC group (n = 1054) and control group (n = 1217). Of the 14 studies, 9 were from Asian and 5 from Western countries. NAC routes were IV, IA, IP, and oral in 7, 2, 1, and 4 studies, respectively. The median follow-up time of the patients across the studies was 54 mo (Table 1). The quality of included studies was assessed according to the Jadad quality scores[16] for the 4 requirements (method of randomization, allocation concealment, blindness, and completeness of follow up). Accordingly, 6 studies had a score greater than 4 (high quality, low risk of bias)[18-21,24,30] (Table 2).

Overall survival rates

Twelve studies[18-25,27,29-31] with 1868 patients (878 in NAC group and 990 in control group) reported survival rates at the end of follow-up. The median follow-up time in these studies was over 3 years. The NAC group had a marginal survival benefit compared to the control group (48.1% *vs* 46.9%, respectively), with an OR of 1.27 (95% CI: 1.04-1.55, fixed-effect model) and a NNT of 84 (Figure 1A).

Three-year progression-free survival rate

Three studies[18-20] compared the 3-year progression-free survival (PFS) rates for the two groups. The 3-year PFS

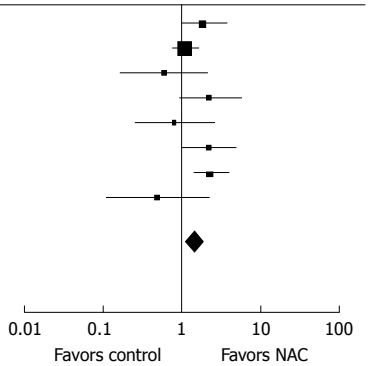

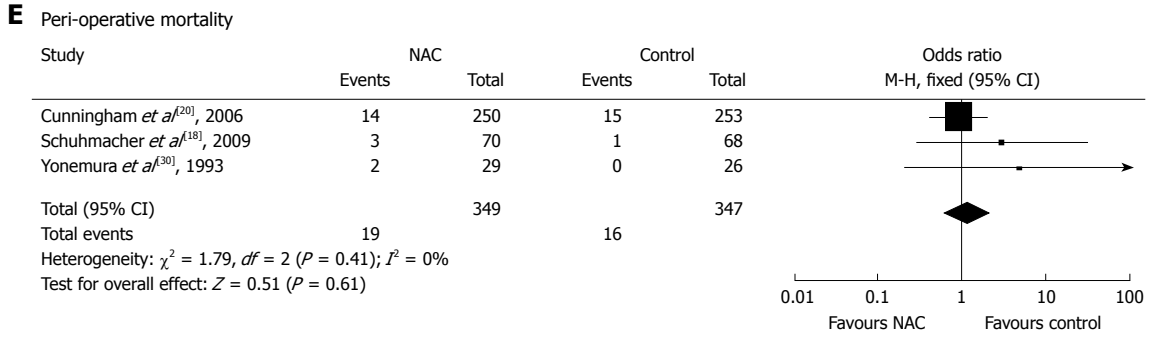

Figure 1 Overall survival rates of patients with advanced gastric cancer in 12 studies (A), 3-year progression-free rates in 3 studies (B), tomor down-staging rates in 6 studies (C), R0 resection rates in 8 studies (D), and adverse effects of neoadjuvant chemotherapy (E). NAC: Neoadjuvant chemotherapy; PFS: Progression-free survival; CI: Confidence interval.

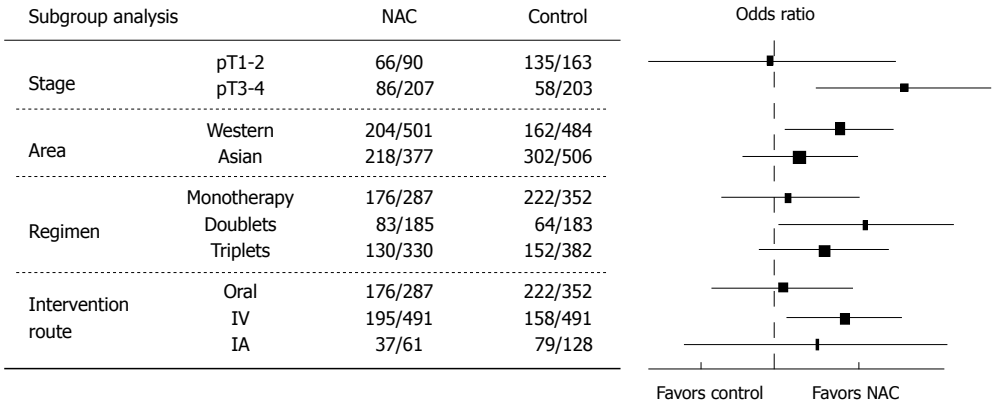

Figure 2 Subgroup analysis showing different overall survival rates of patients with advanced gastric cancer in trials from Western and Asian counties. NAC: Neoadjuvant chemotherapy; IV: Intravenous; IA: Intra-arterial.

rate was higher for NAC group than for control group (41.1% *vs* 27.5%), with an OR of 1.85 (95% CI: 1.39-2.46, fixed-effect model) and a NNT of 8 (Figure 1B).

Tumor down-staging rate

Six studies[18,20-22,27,28] described the pathological staging of gastric cancer after resection. Except for one study[22] showing non-comparative staging data at baseline from the two groups, the other 5 studies involving 718 patients (355 in NAC group and 363 in control group) were included in the final analysis. The rate of pT0-2 was higher for NAC group than for control group (49.9% *vs* 37.5%), suggesting that NAC has a significant down-staging effect on gastric cancer with an OR of 1.71 (95% CI: 1.26-2.33) and a NNT of 9 (Figure 1C).

R0 resection rate

The resection rate of gastric cancer was reported in 8 trials[18-21,26-28,30]. Since no obvious heterogeneity was observed in these studies (P = 0.08, I^2 = 45%), the fixed-effect model was used. The R0 resection rate of gastric cancer was higher for NAC group than for control group (75.2% *vs* 66.9%) with an OR of 1.51 (95% CI: 1.19-1.91, fixed-effect model) (Figure 1D).

Safety analysis

Safety analysis included both chemotherapy-induced adverse effects (grade 3/4, defined according to the Common Toxicity Criteria of the National Cancer Institute, version 2.0) and perioperative morbidity and mortality. Three studies[20,22,30] reported grade 3/4 adverse effects of NAC, including gastrointestinal (GI) problems in 8.8% (31/353) and leukopenia in 18.1% (62/343) of gastric cancer patients. Three studies[18,20,30] reported perioperative mortality with no statistically significant difference (P = 0.61) between the two groups (5.4% *vs* 4.6%, Figure 1E).

Subgroup analysis

Different factors that might be related to the different results between the two groups were studied (Figure 2). When the overall survival rate was set as the end point, gastric cancer patients at a later stage (pT3-4) benefited more from NAC than those at an earlier stage (pT1-2) (OR = 1.91, 95% CI: 1.24-2.96, NNT = 8). Trials from Western countries showed more solid data favoring NAC than those from Asian countries (OR = 1.39, 95% CI: 1.07-1.80). Monotherapy regimens were inferior to doublet or triplet chemotherapy regimens (OR = 1.05, 95% CI: 0.75-1.48). IV route of NAC was better than other routes (OR = 1.42, 95% CI: 1.08-1.85).

DISCUSSION

Our current meta-analysis demonstrated the feasibility

of NAC for locally advanced gastric cancer. NAC could down-stage (NNT = 9) and increase the R0 rate of gastric cancer. However, whether NAC improves the overall survival rate of gastric cancer patients is still controversial[5]. To examine the role of NAC alone in improving the overall survival rate of gastric cancer patients who did not receive postadjuvant chemotherapy, data from the 5 trials[18,21,23,25,29] were further analyzed, showing that NAC has no effect on the overall survival rate of gastric cancer patients (OR = 1.20, 95% CI: 0.8-1.80). Since all the included studies had a very small sample size (17-123 patients in the NAC arms) with a different follow-up time, no clear conclusion could be reached on the effect of NAC alone on overall survival rate of gastric cancer patients.

Our meta-analysis showed that gastric cancer patients could well tolerate NAC. Preoperative chemotherapy was feasible as over 80% patients with advanced gastric cancer completed all treatment courses, except for one trial where only 55.6% of the patients completed all courses[21]. Grade 3/4 GI adverse events of NAC occurred in 8.8% (31/353) of gastric cancer patients, which is considerably lower than that (25%) induced by postoperative adjuvant chemotherapy[32]. The tolerance to postoperative adjuvant chemotherapy was often marred by surgery-related GI effects. No severe and obvious postoperative complications, such as anastomotic leakage, infection, or death, occurred after NAC, indicating that NAC is a safe modality for gastric cancer.

Overtreatment of early gastric cancer with NAC is a potential concern. Whether later stage gastric cancer (T3-4) is the optimal group for NAC was analyzed. A Japanese trial[2] on serosa-negative cancer including node-positive disease showed that the 5-year disease-free survival rate and overall survival rate are 83% and 86%, respectively for gastric cancer patients receiving D2 surgery (gastrectomy with extended lymph-node dissection), indicating that early-stage gastric cancer patients may be cured with adequate surgical therapy alone rather than with NAC. Subgroup analysis also showed that the outcome of NAC for gastric cancer was better in trials from Western countries than in those from Asian countries. Of the 14 trials included in the present study, 6 were from Japan that included more patients with gastric cancer diagnosed at an earlier stage, thus possibly influencing the final results.

One of the questions concerning NAC for gastric cancer is its best regimen. Great efforts have been made on finding the optimal NAC for gastric cancer. In our current meta-analysis, few data were available to answer this question. However, our analysis showed that combination regimen and IV route of NAC had a high efficiency on advanced gastric cancer. Theoretically, NAC with a high response rate can be recommended for metastatic gastric cancer. For example, docetaxel-based[33] or epirubicin-based triple therapy[34] is a good option for metastatic gastric cancer. Regimens with a rapid and high response rate help to down-stage tumors to the greatest extent and increase the probability of R0 resection, thus improving the survival rate for patients with gastric cancer.

Disease progression during NAC is another potential concern due to a loss of opportunity for surgery. In our meta-analysis, two trials[18,22] showed a disease progression rate of 2.9% (4/138). Of the 402 patients with gastric cancer, 108 (26.9%) in NAC group underwent palliative resection (n = 76) or with their tumor unresectable (n = 32), which was lower than that (33.8%) in control group[18,20-22,30], indicating that disease progression after NAC is not a major concern for its resection.

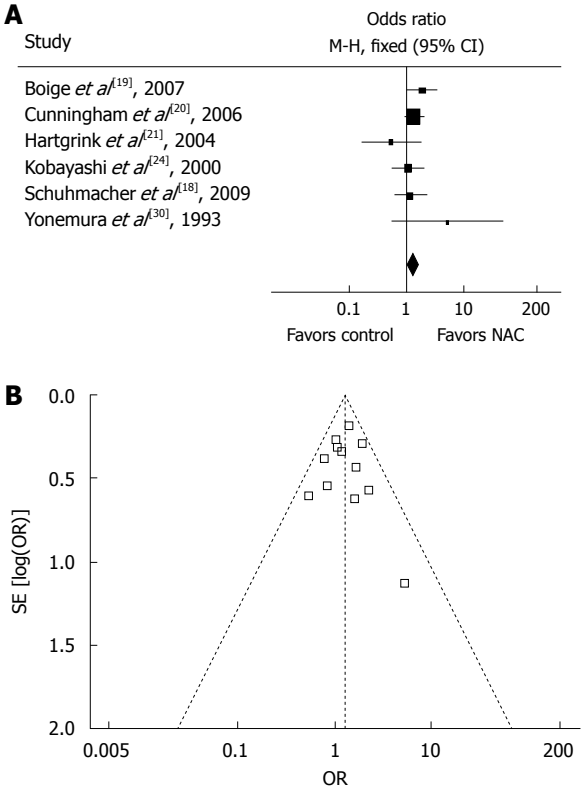

Figure 3 Odds ratio (A) and publication bias (B) in studies included in this study. A: Sensitivity analysis for overall survival: high-quality studies (Jadad score ⩾ 4); B: Funnel plot analysis of potential publication bias.

A major concern in our meta-analysis was the quality of studies included. Since no sufficient randomized controlled trials were available on NAC for gastric cancer, our current meta-analysis included quasi-randomized or non-randomized but controlled trials with basic data that could be used for comparison. Sensitivity analysis was therefore performed to determine the effect of trial quality on the final results. Six high-quality trials with a Jadad score ⩾ 4[18-21,24,30] reported the overall survival rate with an OR of 1.35 (95% CI: 1.06-1.73) compared to that with an OR of 1.27 (95% CI: 1.04-1.55) in all the studies (Figure 3A), indicating that the results are consistent with those in all the trials and are therefore independent of trial quality. Furthermore, the symmetrical shape of 'funnel plot' when drawing together survival rate and sample size for all the studies indicated that no obvious publication bias was found in our meta-analysis (Figure 3B).

NAC has been proven effective against some cancers, such as breast cancer[35]. However, it is not generally recommended for gastric cancer, primarily because of differences in treatment modalities for gastric cancer

between Asian and Western countries. A Western study demonstrated that D2 surgery can effectively remove lymph nodes[36], whereas a Japanese study showed that D2 surgery is highly effective and safe, and recommended as a routine surgery[4]. It was reported that chemoradiotherapy is the standard therapy for gastric cancer after operation in USA[37] and most appropriate for the D0 dissection population. Whether post-chemoradiotherapy benefits D2 dissection patients lacks strong evidence. It has been shown that perioperative chemotherapy can prolong the survival time of locally advanced gastric cancer patients who tolerate preoperative chemotherapy better than postoperative chemotherapy[20]. Therefore, NAC is a hopefully good option for locally advanced gastric cancer, although further studies are required to determine its best regimen.

Our meta-analysis provided the up-to-date evidence for the positive effect of NAC on locally advanced gastric cancer. A number of new trials have been registered to examine the role of NAC in treatment of advanced gastric cancer, such as S-1 plus cisplatin[38]. Our meta-analysis should therefore be further updated whenever new and strong evidence is available. With the increasing acceptance of the concept of NAC, additional studies on new regimens and well-designed powerful trials are highly encouraged in patients with locally advanced gastric cancer.

COMMENTS

Background

Over 50% of patients with newly diagnosed gastric cancer have advanced disease. Even after surgery, their prognosis remains poor. The effect of chemotherapy on advanced gastric cancer has been proven. Neoadjuvant chemotherapy (NAC) plays a role in improving the prognosis of advanced gastric cancer patients, but its value remains controversial because of lack of well-powered trials.

Research frontiers

Meta-analysis was used to evaluate the value of NAC for advanced gastric cancer in this study.

Innovations and breakthroughs

The meta-analysis provided the up-to-date evidence for the positive effect of NAC on locally advanced gastric cancer. NAC improved the R0 resection rate (95% CI: 1.19-1.91), tumor down-staging (95% CI: 1.26-2.33) and survival rate (95% CI: 1.04-1.55) for the 2271 patients enrolled in 14 trials. No obvious safety concerns were raised in these trials. These findings suggest that NAC can improve the survival rate of patients with advanced gastric cancer.

Applications

With the increasing acceptance of the concept of NAC, additional studies on new regimens and well-designed powerful trials are highly encouraged in patients with locally advanced gastric cancer.

Terminology

MAGIC trial: A phase Ⅲ clinical trial conducted by the Medical Research Council Adjuvant Gastric Infusional Chemotherapy, showing the effect of perioperative chemotherapy on advanced gastric cancer. INT-0116 study: The Intergroup-0116 study reporting that postoperative chemoradiotherapy is effective against gastric adenocarcinoma or gastroesophageal junction. D2 surgery: D2 lymphadenectomy which was defined according to the rules of the Japanese Research Society for Gastric Cancer and, therefore, included all lymphnodes of levels N1 and N2. Adverse events: Assessed according to the Common Toxicity Criteria of the National Cancer Institute (version 2.0) and defined as grade 0-4. Tumor stage: Assessed according to the International Union against Cancer: TNM classification of malignant tumors. "pT" indicates the pathological stage after surgery and "cTNM" indicates the clinical pretreatment tumor stage. S-1: An orally active combination of tegafur (a prodrug that is converted by cells to fluorouracil), gimeracil (an inhibitor of dihydropyrimidine dehydrogenase, which degrades fluorouracil), and oteracil (which inhibits the phosphorylation of fluorouracil in the gastrointestinal tract, thereby reducing the gastrointestinal toxic effects of fluorouracil) with a molar ratio of 1:0.4:1.

Peer review

This is an important analysis of NAC for advanced gastric cancer. The meta-analysis of all available controlled trials on NAC conduced by the authors may provide the up to date evidence of NAC for advanced gastric cancer.

Abstract

AIM: To evaluate the anti-*Helicobacter pylori* (*H. pylori*) activity of 50 traditional Chinese herbal medicines in order to provide the primary evidence for their use in clinical practice.

METHODS: A susceptibility test of water extract from 50 selected traditional Chinese herbal medicines for *in vitro H. pylori Sydney strain 1* was performed with broth dilution method. Anti-*H. pylori* activity of the selected Chinese herbal medicines was evaluated according to their minimum inhibitory concentration (MIC).

RESULTS: The water extract from Rhizoma Coptidis, Radix Scutellariae and Radix isatidis could significantly inhibit the *H. pylori* activity with their MIC less than 7.8 mg/mL, suggesting that traditional Chinese herbal medicines have anti-inflammatory and antibacterial effects and can thus be used in treatment of *H. pylori* infection.

CONCLUSION: Rhizoma Coptidis, Radix Scutellariae and Radix isatidis are the potential sources for the synthesis of new drugs against *H. pylori*.

Key words: Chinese herbal medicines; *Helicobacter pylori*; Minimum inhibitory concentration; Gastric; Oral

INTRODUCTION

Helicobacter pylori (*H. pylori*), a microaerophilic, Gram-negative spiral bacterium which was first detected in 1984 by Marshall *et al*[1], is one of the most common chronic bacterial pathogens in humans. Approximately 50% of people in the world are infected with it, and its prevalence is significantly higher in developing countries than in developed countries[2]. *H. pylori* infection is an important etiologic impetus usually leading to chronic gastritis, gastroduodenal ulcer and low grade gastric mucosa-associated lymphoid tissue lymphoma. Epidemiological data show that a high *H. pylori* infection rate is related to the high incidence of gastric cancer and gastric adenocarcinoma[3]. World Health Organization has categorized *H. pylori* as

a class 1 carcinogen[4]. Fortunately, its eradication with antibiotics can result in ulcer healing, prevent peptic ulcer recurrence and reduce the prevalence of gastric cancer in high-risk populations[5]. However, it is not always successful because of its resistance to one or more antibiotics and other factors such as poor patient compliance, undesirable side effects of the drugs and significant cost of combination therapy. Worrel *et al*[6] reported that over 15% of the patients undergoing antibiotics therapy would experience therapeutic failure. In developing countries, since the application of antibiotics is still under a poor management as a whole, there is a growing need for finding new anti-*H. pylori* agents that can hopefully eradicate the invasion and presence of survived *H. pylori* strains to avoid relapse of gastric ulcer. Hence, a considerable variety of studies involving tests for medicinal plants showing antimicrobial activity and discrepant susceptibility test results are available due to variations in the methods and conditions used for its susceptibility testing. It was reported that Garlic extracts exhibit a weak or modest anti-*H. pylori* activity[7,8]. Pteleopsis suberosa[9], Cinnamon[10], Cranberry juice[11], Aristolochia paucinervis Pomel[12], black Myrobalan[13], *etc.,* have also been found to have anti-*H. pylori* activities. Ndip *et al*[14] reported that Ageratum conyzoides, Scleria striatinux and Lycopodium cernua show a very potent antibacterial activity. Fifty-four herbal medicines from Korea have been screened for their anti-*H. pylori* activity, of which, Rheum palmatum, Rhus javanica, Coptis japonica and Eugenia caryophyllata have a strong anti-*H. pylori* activity[15]. Extracts and fractions from 7 Turkish plants also demonstrate anti-*HP* activities[16]. Traditional medicinal plants from Pakistan and Psoralea corylifolia L. demonstrate a strong anti-*H. pylori* activity[17]. Some compounds even have been isolated and their anti-*H. pylori* activity has also been testified, for example, Myroxylon Peruiferum from the Brazilian medicinal plants[18]. In addition, some flavonoids and isoflavonoids isolated from licorice, such as licochalcone A and licoisoflavone B, have been reported to exhibit inhibitory activities against *H. pylori*[19].

In China, traditional Chinese medicine and pharmacology play an indispensable role in the health care system, especially in prevention and management of chronic diseases. Studies[20,21] revealed that some traditional herbal medicines are efficient against gastrointestinal diseases, including chronic gastritis and peptic ulcer disease, a major outcome of *H. pylori* infection, indicating that the medicinal plants may contain constituents, which have antibacterial and anti-inflammatory activities. The present study was to evaluate the anti-*H. pylori* activity of some selected medicinal plants to identify the potential sources for synthesis of new drugs against *H. pylori*. In this study, 50 traditional Chinese medicinal herbs (Table 1) were examined and screened for their anti-*HP* activity according to their minimum inhibitory concentration (MIC).

MATERIALS AND METHODS

Extract of medicinal plants

A total of 50 traditional Chinese medicinal herbs, purchased from Tongren Drugstore, were identified by Professor Chang-Qing Wang, Beijing Academy of Agriculture and Forestry Sciences. Medicinal herbs were selected according to their traditional use in Chinese pharmacology as anti-inflammatory or antibacterial drugs. Radix Scutellariae Baicalensis (20 g) was soaked for 2 h in about 1000 mL distilled water at room temperature, decocted for 1 h (first quickly, then slowly), and filtered through filter paper. Their residue was decocted for a second time and filtered. The filtrate was collected and centrifuged at 3500 r/min for 15 min. Finally, the liquid was concentrated to 10 mL (2 g/mL) in a rotary vacuum evaporator, then capped and autoclaved for 15 min at 121℃. Under the sterile environment, 12 sterile 7.5 cm × 1.3 cm capped tubes were arranged in a row in the rack, marked with No. 1, No. 2, …, No. 12 tubes, then 1 mL sterile distilled water was transferred to each tube with a fresh transferpettor and decocted. A Radix Scutellariae Baicalensis stock solution (2 g/mL) was added into No. 1 tube and mixed thoroughly. Then 1 mL solution was transferred from No. 1 tube to No. 2 tube, diluted twice until no extract dilution solution was added into the No. 10, No. 11 and No. 12 tubes as controls. After that, 1 mL two-fold concentration of modified brucella broth (control of diarrheal diseases in China Research, Shanghai Regent Supply) supplemented with 10% sterile fetal calf serum (Guangzhou Ruite Ltd., China) was added into each of the tubes. The final concentration of medicinal plants reached 500, 250, 125, 62.5, 31.2, 15.6, 7.8, 3.9, 2.0 and 1.0 mg/mL in No. 1-10 tubes, respectively. Extraction was performed in duplicate from other medicinal plants and their extracts were stocked at 4℃ prior to use.

Inocula

H. pylori Sydney strain 1 (*SS1*), obtained from Laboratory of Medical Microbiology, Southern Medical University, was stored in brain-heart infusion broth supplemented with 20% (v/v) glycerol and 1% yeast extract at -70℃. After freeze thawing under a superclean bench (Shanghai Anting Scientific Instrument Ltd., China), a drop of *H. pylori* was inoculated into a single-fold concentration of modified sterile brucella broth (as above), cultured at 37℃ in a shaking incubator containing 5% O_2, 10% CO_2, and 85% N_2 at 150 r/min for 3 d. *H. pylori SS1* was identified with routine diagnostic procedures, according to their colony morphology, Gram-staining, test of oxidase, catalase and urease reaction, as well as molecular identification based on the amplified species-specific sequences of 16s rRNA by polymerase chain reaction (PCR). Bacterial suspension was transferred quickly into 0.9% sterile physiological saline and diluted to the McFarland standard 0.5 (1×10^8 cfu/mL) as the standardized bacterial suspension. The turbidity was verified by spectrophotometrically measuring the absorbance of the suspension ($A_{625\ nm}$).

Susceptibility testing

Ten microliters of standardized bacterial suspension (1×10^8 cfu/mL) was inoculated into No. 1-11 tubes within

Table 1 Fifty anti-*Helicobacter pylori* traditional Chinese herbal medicines

Chinese name	English name	Pharmaceutical name	Botanical name	MIC (mg/mL)
Huanglian	Coptis Rhizome	Rhizoma Coptidis	Coptis chinensis Franch.	3.9 < MIC ≤ 7.8
Huangqin	Baikal skullcap Root	Radix Scutellariae	Scutellaria Baicalensis Georgi.	3.9 < MIC ≤ 7.8
Banlangen	Indigowoad Root	Radix isatidis	Isatis tinctoria L.	3.9 < MIC ≤ 7.8
Jinyinhua	Honeysuckle Flower	Floslonicerae Japonicae	L. Similis Hemsl	7.8 < MIC ≤ 15.6
Qinpi	Largeleaf Chinese Ash Bark	Cortex Fraxini	F. Bungeana DC.	7.8 < MIC ≤ 15.6
Zihuadiding	Tokyo Violet Herb	Herba Violae cum Radice	Viola yedoensis Mak.	15.6 < MIC ≤ 31.2
Huangbai	Chinese Corktree Bark	Cortex Phellodendri	Chinese Schneid	15.6 < MIC ≤ 31.2
Daqingye	Indigowoad Leaf	Foliun isatidis	Isatis	15.6 < MIC ≤ 31.2
Pugongying	Dandelion	Herba Taraxaci Mongolici cum Radice	Taraxacacum mongolicum	15.6 < MIC ≤ 31.2
Dahuang	Rhubarb	Rhizoma Rhei	R. Officinale baill	31.2 < MIC ≤ 62.5
Shandougen	Tonkin sophora Root	Radix Sophorae Tonkinensis	Sophora Subprostrata Chun et T. Chen	31.2 < MIC ≤ 62.5
Longdancao	Chinese Gentian Root	Radix Gentianae Scabrae	Gentiana Scabra Bge. In	31.2 < MIC ≤ 62.5
Hezi	Medicine Terminalia Fruit	Fructus Terminaliae Chebulae	Terminalia chebula Retz.	31.2 < MIC ≤ 62.5
Machixian	Purslane Herb	Radix Sophorae Subprostratae	Sophora Subprostrata Chun et T. Chen	62.5 < MIC ≤ 125
Banzhilian	Barbed Skullcap Herb	Herba Scutellariae Barbatae	Scutellaria Barbata D. Don	62.5 < MIC ≤ 125
Yuxingcao	Heartleaf Houttuynia Herb	Herba Houttuyniae Cordatae	Houttuynia cordata Thunb.	62.5 < MIC ≤ 125
Tufuling	Glabrous Greenbrier Rhizome	Rhizoma Smilacis Glabrae	Simlax glabra Roxb.	62.5 < MIC ≤ 125

MIC: Minimum inhibitory concentration.

15 min. No. 11 tube was used as a growth control (broth with bacterial inoculum, no extract) and No. 12 tube was used as a sterility control (broth only). All tubes were cultured in a shaking incubator containing 5% O_2, 10% CO_2, and 85% N_2. At the same time, 10 μL bacterial suspension from No. 11 tube was diluted quickly with 10 mL 0.9% sterile physiological saline at 1:1000, then 100 μL 0.9% sterile physiological saline was transferred onto the surface of three Campylobacter plates [control of diarrheal diseases in China Research, Shanghai Regent Supply; each liter containing bio-polyone (10 g), bio-lysat (10 g), bio-myotone (3 g), corn starch (1 g), sodium chloride (5 g), agar (13.5 g), pH 7.3, autoclaved at 121℃ for 15 min] containing 5% (v/v) of sterile defibrinated sheep blood (Guangzhou Ruite Ltd., China), cultured at 37℃ in a jar system (Refrigerating Machine Factory, Yiwu City, Zhejiang Province, China) containing 5% O_2, 10% CO_2, and 85% N_2 to verify the absence of contamination and calculate the colonies. Susceptibility test for other medicinal plants was performed in duplicate.

RESULTS

After incubation, the tubes were visually examined to determine whether the *H. pylori* strains grew. *H. pylori* strains in No. 11 tube grew well and no bacterial growth was observed in No. 12 tube. The colonies in 3 agar plates grew well with an average number of about 50. The lowest concentration (highest dilution) of extract that inhibited the visible growth of *H. pylori* strains (no turbidity) was defined as MIC. For further confirmation, 10 μL of bacterial suspension from the clearly visible tubes was diluted quickly with 10 mL 0.9% sterile physiological saline at 1:1000, then 100 μL 0.9% sterile physiological saline was transferred onto the surface of three Campylobacter plates and cultured for 3 d. When the average number of colonies in the 3 agar plates was less than 5 or no colony was found, the MIC was considered less than or equal to the concentration. When the growth of *H. pylori* strains occurred in all dilutions containing the extract, the MIC was considered greater than the highest concentration. When no growth of *H. pylori* strains occurred in any concentration tested, the MIC was considered less than the lowest concentration. When a tube with visible growth of *H. pylori* strains, e.g. growth at 500, 250 and 62.5 mg/mL, but not at 125 mg/mL, was called a skipped tube and ignored. Growth of *H. pylori* strains in isolated tubes indicated contamination, the test should be repeated. The results are listed in Table 1. The MIC of Rhizoma Coptidis, Radix Scutellariae and Radix Isatidis was less than 7.8 mg/mL. The MIC of Floslonicerae Japonicae and Cortex Fraxini was less than 15.6 mg/mL. The MIC of Herba Violae cum Radce, Cortex Phellodendri and Foliun Isatidis, Herba Taraxaci Mongolici cum Radice was less than 31.2 mg/mL. The MIC of Rhizoma Rhei, Radix Sophorae Tonkinensis, Radix Gentianae Scabrae, Frutus Terminaliae Chebulae was less than 62.5 mg/mL. The MIC of Radix Sophorae Subprostratae, Herba Scutellariae Barbatae, Herba Houttuyniae Cordatae and Rhizoma Smilacis Glabrae was less than 125 mg/mL. The MIC of Fructus Arctii Lappae, Flos Chrysanthemum Morifolii, Herba Whiteflower Patrinia Herb, Radix Thichosanthis and Fructus Brucae Javanicae was less than 250 mg/mL. The MIC of Calculus Bovis, Frucifictio Lasiosphaerae, Folium Periliac Frutescentis, Radix Bupleuri, Caulis Lonicerae, Radix Sophorae Flavscentis was less than 500 mg/mL, and the MIC of other medicinal herbs was greater than 500 mg/mL. Authority books, such as Pharmacopoeia of People's Republic of China (Committee of National Pharmacopoeia, 2005 edition), Chinese Herbal Medicine (Gong-Wang Liu, Li-Ya Gao, 2000, Hua Xia Publishing House), Modern Clinical Chinese Herbal Medicines (Dong Kun-Shan, Wang Xiu-Qin, Dong Yi-Fan, 2001, Chinese Traditional Medicine Press), acclaimed that most selected medicinal plants have an activity against microscopic organisms, including various Gram-negative or -positive bacteria, fungi, viruses or parasites. In fact, many of them are the constituents of Chinese patent medicines used in treatment of stomach discomfort-related diseases. More importantly, most of them demonstrate a significant anti-*H. pylori* activity.

DISCUSSION

In this study, the MIC in 50 traditional Chinese herbal medicines was detected. Although a considerable variety of plants showing an antimicrobial activity have also been reported in other studies[7-19], variation of MIC still exists due to the bioassay methods employed in different studies, the sources and age of the plants, the solvent used for extraction, and *H. pylori* strains. The susceptibility of *H. pylori SS1* to water extracts was examined and screened in this study with broth dilution diffusion, a quantitative assay method, which is less time-consuming and less labor-intensive than agar dilution method, and cheaper than *E* test. All selected herbal medicines are the commonly used traditional Chinese herbal medicines prescribed by physicians of traditional Chinese medicine. Some plants are even recommended as a dietetic therapy for health preserving, such as Radix Isatidis, Herba Houttuyniae Cordatae. More importantly, all the selected herbal medicines have a same standard from the TonRen Corporation. Although the susceptibility of only an isolated *H. pylori* strain to such medicines was tested, the susceptibility of other clinical strains to these medicines should also be tested.

In this study, the water extract from Rhizoma Coptidis, Radix Scutellariae and Radix Isatidis had a stronger anti-*H. pylori* activity than that from other plants, indicating that the three plants can be used as useful sources for the synthesis of novel drugs against *H. pylori*. Traditional medical practitioners and biomedical specialists play an important role in pharmacodynamics and pharmacokinetics research. In order to find scientific evidence and rationalize the utility and efficacy of traditional Chinese medicines, they have tried to extract and analyze the active compounds of medicinal plants with various biomedical analytical techniques and assay methods, and evaluated their antibacterial and anti-inflammatory mechanism in animal experiments.

Rhizoma Coptidis contains berberine. Several protoberberine alkaloids of berberine, palmatine, coptisine and aporphinoid alkaloid of magnoflorine have been confirmed to be the major pharmacologically active constituents, and these alkaloids demonstrate a significant antimicrobial activity against a variety of organisms including bacteria, viruses, fungi, protozoans, helminthes, and Chlamydia[22,23]. The pharmacological antibacterial activity of the 3 berberine alkaloids is berberine > coptisine > palmatine[24]. An animal experiment suggested that the total alkaloid is a potent protective agent against *H. pylori* LPS which induces gastric mucosal inflammation[25].

Radix Scutellariae contains over 30 kinds of flavonoid, such as baicalin, baicalein, wogonin, wogonin7-glucuronide, oroxylin A, and oroxylin A 7-O-glucuronide[26]. Active flavonoids, including baicalin, baicalein, wogonin, and wogonoside, have a variety of pharmacological activities, such as anti-inflammation, free radical scavenging and anti-oxidation[27], and antibacterial action[28]. All active flavonoids exert their anti-inflammatory effect mainly by inhibiting the inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (*COX-2*) gene expression[29]. It was

reported that Radix Scutellariae inhibits LPS-induced production of proinflammatory mediators, including NO, IL-3, IL-6, IL-10, IL-12p40, IL-17, IP-10, KC, and VEGF in mouse macrophages[30].

Radix Isatidis is also officially documented. Organic acids, including syringic acid, 2-amino-benzoic acid, salicylic acid and benzoic acid among the main chemical active components, have been segregated and purified as a crystal[31]. Some authors have even tested the potency sequence of the 4 organic acids (syringic acid > 2-amino-benzoic acid > salicylic acid > benzoic acid)[32]. Furthermore, the 4 organic acids share a basic molecular structure, and the number, position and type of their functional groups on phenyl ring have great impacts on antibacterial activities. Extracts from Radix Isatidis can decrease the production of inflammatory mediators, such as nitricoxide, prostaglandin E2, and pro-inflammatory cytokines[33].

Traditional Chinese medicines have a long history, due to their effectiveness and relatively low toxicity, and herbal medicines have drawn more and more attention during the past decades. Chemical compositions of Rhizoma Coptidis, Radix Scutellariae and Radix Isatidis have been extensively studied, some of which can act on *H. pylori* LPS and inhibit the production of proinflammatory mediators. In our study, water extracts from the medicinal plants demonstrated a strong anti-*H. pylori* activity, and a wide range of phytochemistry materials from medicinal plants could reduce the inflammatory response, indicating that the 3 herbal drugs can be used as anti-inflammatory or antibacterial agents. However, the strong *in vitro* anti-*H. pylori* activity of these water extracts does not necessarily imply that they have a strong *in vivo* anti-*H. pylori* activity. On the other hand, some of these plants may be more potent *in vivo* due to metabolic transformation of their components into highly active intermediates. However, further study is needed to confirm the effect of Rhizoma Coptidis, Radix Scutellariae, Radix Isatidis and other traditional Chinese medicines on alimentary tract diseases due to *H. pylori* infection.

It is well known that human beings are the main reservoir of *H. pylori*. World Health Organization pointed out that most subjects infected with *H. pylori* have no clinical symptoms, peptic ulceration and superficial chronic gastritis, but peptic ulcer, ulcer complications, and progression to gastric cancer will occur in approximately 17%, 4.25% and 1% of *H. pylori*-infected subjects, respectively[34]. Besides, extragastric diseases involving the cardiovascular, hepatobiliary, dermatological, immunological, hematological systems[35] are also related with *H. pylori* infection. Moreover, since *H. pylori* was isolated from human dental plaque[36], *H. pylori* has been detected in oral cavity, suggesting that oral cavity diseases such as halitosis, glossitis, burning mouth syndrome, recurrent aphthous stomatitis, dental caries, are related with oral *H. pylori* infection. Anand *et al*[37] reported that the prevalence of *H. pylori* is higher in dental plaque of patients with gastric *H. pylori* infection than in that of patients without gastric *H. pylori*. It has been shown that patients with poor oral hygiene have the most frequent recurrence of gastric *H. pylori* infection[38]. Oral cavity is a potential reservoir of *H. pylori* and oral *H. pylori* may influence the relapse of gastric *H. pylori* infection. It was reported that *H. pylori* in dental plaque is hardly eradicated by triple therapy[39,40], suggesting that oral antibiotics have almost no effect on *H. pylori* in oral cavity.

With the better recognition of *H. pylori*, more diseases have been found to be related to *H. pylori*. Since oral cavity, as a residence of *H. pylori*, is as important as stomach, prevention and treatment of oral *H. pylori* infection should be put on the agenda. Antibiotics have been the main drugs against *H. pylori* since the bacterium was discovered. Further study is needed to solve the problems such as drug resistance, poor patient compliance, undesirable side effects and the significant cost of combination therapy. Traditional Chinese medicines have shown their advantages over Western drugs, including a lower price, a low toxicity and less adverse reactions.

It is exciting that Rhizoma Coptidis, Radix Scutellariae, Radix isatidis and other herbs with a strong anti-*H. pylori* activity may provide the potential sources of new drugs, thus reducing the morbidity of oral cavity diseases and improving the eradication rate and relapse of gastric *H. pylori* infection.

COMMENTS

Background

Many diseases are related to *Helicobacter pylori* (*H. pylori*) infection. Although antibiotics can eradicate gastric *H. pylori*, antibiotics treatment can lead the problems, such as drug resistance, poor patient compliance and undesirable side effects. It has been reported that some herbal medicines have an anti-*H. pylori* activity. The herbal medicine resources are rich in China with a long history of practicing traditional Chinese medicine. However, few studies are available on the anti-*H. pylori* activity of herbal medicines. Herbal medicines may be potential sources of new drugs.

Research frontiers

Human beings are the main reservoir of *H. pylori*. World Health Organization estimates indicate that *H. pylori* infection is closely related with gastric and extragastric diseases involving the cardiovascular, hepatobiliary, dermatological, immunological, and hematological systems. *H. pylori* has been detected in oral cavity. Oral cavity diseases such as halitosis, glossitis, burning mouth syndrome, recurrent aphthous stomatitis, dental caries, may be related with *H. pylori* infection.

Innovations and breakthroughs

In vitro susceptibility test was performed for water extract from 50 selected traditional Chinese herbal medicines and their anti-*H. pylori* activity was evaluated according their MIC values. The active compounds of Rhizoma Coptidis, Radix Scutellariae and Radix Isatidis, were detected and their anti-*H. pylori* activity was analyzed.

Applications

Since Rhizoma Coptidis, Radix Scutellariae and Radix Isatidis have a strong anti-*H. pylori* activity, with a low toxicity, a low price and less adverse reactions, they can be used in preventing and treating gastric and/or oral *H. pylori* infection.

Peer review

This study described the strong anti-*H. pylori* activity of Rhizoma Coptidis, Radix Scutellariae and Radix Isatidis, thus adding some novel herbal medicines for preventing and treating gastric and/or oral *H. pylori infection*.

Abstract

AIM: To explore the association between mothers against decapentaplegic homolog 4 (*SMAD4*) gene polymorphisms and gastric cancer risk.

METHODS: Five tagging single nucleotide polymorphisms (tSNPs) in the *SMAD4* gene were selected and genotyped in 322 gastric cancer cases and 351 cancer-free controls in a Chinese population by using the polymerase chain reactionrestriction fragment length polymorphism method. Immunohistochemistry was used to examine SMAD4 protein expression in 10 normal gastric tissues adjacent to tumors.

RESULTS: In the single-locus analysis, two significantly decreased risk polymorphisms for gastric cancer were observed: the SNP3 rs17663887 TC genotype (adjusted odds ratio = 0.38, 95% confidence interval: 0.21-0.71), compared with the wild-type TT genotype and the SNP5 rs12456284 GG genotype (0.31, 0.16-0.60), and with the wild-type AA genotype. In the combined analyses of these two tSNPs, the combined genotypes with 2-3 protective alleles (SNP3 C and SNP5 G allele) had a significantly decreased risk of gastric cancer (0.28, 0.16-0.49) than those with 0-1 protective allele. Furthermore, individuals with 0-1 protective allele had significantly decreased SMAD4 protein expression levels in the normal tissues adjacent to tumors than those with 2-3 protective alleles (P = 0.025).

CONCLUSION: These results suggest that genetic variants in the *SMAD4* gene play a protective role in gastric cancer in a Chinese population.

Key words: Mothers against decapentaplegic homolog 4; Genetic variation; Gastric tumor; Molecular epidemiology

INTRODUCTION

Gastric cancer is the fourth most common cancer and the second leading cause of cancer-related death worldwide; about 934 000 new cases were diagnosed and approximately 700 000 people died of the disease in 2002[1]. The incidence of gastric cancer varies within countries. In China, it was predicted that, in 2005, 300 000 deaths and 400 000 new cases from gastric cancer, which ranks it as the third most common cancer[2]. Epidemiological studies have identified many risk factors for gastric cancer, such as *Helicobacter pylori* (*H. pylori*) infection, low fiber intake, and tobacco smoking[3,4]. However, only a fraction of individuals exposed to these factors develop gastric cancer during their lifetime, which suggests that genetic susceptibility plays an important role in gastric carcinogenesis.

Transforming growth factor (TGF)-β signaling is one of the most important tumor suppressor pathways. Mothers against decapentaplegic homolog (SMAD) proteins serve as crucial components of TGF-β signaling, which negatively regulates cell growth and promotes apoptosis of epithelial cells. According to the specific functions, Smads can be classified into the receptor-regulated Smads (R-Smads: Smad 1, 2, 3, 5 and 8), inhibitory Smads (anti-Smads: Smad 6 and 7), and the common mediator Smads (Co-Smads: Smad 4), which is apparently common to all of the ligand-specific Smad pathways and plays a central role in TGF-β signaling[5]. In 1996, *SMAD4* was identified as a candidate tumor suppressor gene[6].

The loss of SMAD4 expression is a common feature of most human malignancies, including gastric cancer[7-11]. In 1997, Powell *et al*[10] firstly reported inactivation of SMAD4 in gastric carcinoma. Then, Xiangming *et al*[12] further demonstrated that the reduced expression of SMAD4 was 75.1% in advanced gastric cancer. Wang *et al*[13] has found that the loss of SMAD4, especially loss of nuclear SMAD4 expression, is involved in gastric cancer progression. A more recent study by Leng *et al*[14] has shown that SMAD4 expression in gastric cancer tissue is dramatically lower than that in peri-tumoral tissue. *In vitro* and *in vivo* studies have shown that mutations in *SMAD4* play a significant role in SMAD4 inactivation. For example, mutation-related loss of SMAD4 is most prevalent in pancreatic and colorectal cancer[8,15]. *SMAD4* mutations have also been observed in seminoma[16] and head and neck cancer[17], which give rise to the complete loss of SMAD4. Notably, germline mutations in *SMAD4* are found in > 50% of patients with familial juvenile polyposis syndrome[18,19], which predisposes individuals to develop gastrointestinal cancer. Although mutations in *SMAD4* are not seen frequently in gastric cancer (2.9%)[10], the gene is highly polymorphic in the dbSNP database.

Given the role of SMAD4 in tumor suppression, we hypothesized that genetic variants in the *SMAD4* gene are associated with the risk of gastric cancer. In the present study, five tagging single nucleotide polymorphisms (tSNPs) were selected to evaluate the association between these common genetic variants in *SMAD4* gene and risk of gastric cancer in our ongoing, hospital-based, case-control study in a Chinese population.

MATERIALS AND METHODS

Study subjects

The study included 322 gastric cancer patients and 351 cancer-free controls. All subjects were recruited from an ongoing study that started in March 2006. The detailed inclusion criteria have been described previously[20]. The participation rate of cases was about 95%. The cancer-free controls were genetically unrelated to the cases, had no individual history of cancer, and were recruited from the hospital where they were seeking health care or undergoing routine health examination. All the 351 control subjects were matched with the cases by age (± 5 years) and sex. Informed consent was obtained from each of the eligible subjects before recruitment. A questionnaire was used to obtain demographic and risk factor information about the study subjects. For gastric cancer patients, the clinicopathological variables, including tumor site, tumor histotype, invasion, and lymph node status, were obtained from the medical records of patients. The classification criteria of the clinicopathological variables were previously reported[20]. The response rate of the eligible controls was about 85%. Those subjects who smoked daily for > 1 year were defined as regular smokers. Individuals who consumed one or more alcoholic drinks per week for at least 1 year were considered regular drinkers. The research protocol was approved by the institutional review board of Nanjing Medical University.

SNP selection and genotyping

The *SMAD4* gene, which is 49.5-kb long and is located on chromosome 18q21.1, contains 13 exons and 12 introns. There have been at least 197 SNPs reported in the dbSNP database. Based on the HapMap database (http://www.hapmap.org/) (from chr1846807425 to 46868845), tSNPs were selected from common variants (minor allele frequency > 0.10) in the Han Chinese in Beijing (CHB) population sample. As a result, six tSNPs were selected using a pairwise Tagger method[21] with an r^2 cutoff value of 0.8 to capture all the common SNPs in *SMAD4* and the mean r^2 was 0.980. The genotype frequencies of the SNPs can be influenced by population differences and sample sizes[22,23], therefore, we genotyped these six tSNPs in 100 Chinese control subjects. Of these, one was not in agreement with the Hardy-Weinberg equilibrium (HWE) ($P < 0.01$). Thus, this tSNP was not included in further analyses. The rs number and relative position of selected five tSNPs are shown in Table 1.

The selected tSNPs were genotyped in all 673 subjects by the polymerase chain reaction (PCR)-restriction fragment length polymorphism method. The tSNPs information, primers, and restriction enzymes are all listed in

SNP: Single nucleotide polymorphism; 3′-UTR: 3′-untranslated region.

Supplementary Table 1. The genotype analysis was done by two persons independently in a blind fashion. About 1% of PCR products were randomly selected and confirmed by sequencing (data not shown), and > 10% of the samples were randomly selected for repeated genotyping. The results were 100% concordant.

Immunohistochemical staining and evaluation

Immunohistochemical study was performed on the 10 normal gastric tissues adjacent to tumors. Immunohistochemical staining was performed by using the Boster SABC (rabbit IgG)-POD Kit (Wuhan, China) according to the manufacturer's instructions. After deparaffinization and rehydration, the sections were microwaved for 10 min for antigen retrieval and then washed in PBS. Sections were incubated with normal goat serum for 30 min to block nonspecific antibody binding. The primary antibody anti-Smad4 (1:100; ab40759; Abcam Ltd., Hong Kong, China) was used to incubate sections overnight at 4℃, followed by three successive rinses with PBS, and incubation with secondary antibody for an additional 20 min. After rinsing, tissue sections were incubated with streptavidin-biotin-peroxidase (SABC) (Boster) for 20 min at room temperature. Slides were washed and visualized using 3,3'-diaminobenzidine. Slides were counterstained with hematoxylin, dehydrated, and mounted with balsam for examination.

A positive reaction was indicated by a reddish brown precipitate in the cytoplasm. Specifically, the percentage of positive cells was divided into five grades (percentage cores): (0) ≤ 5%; (1) 6%-25%; (2) 26%-50%; (3) 51%-75%; and (4) > 75%. Intensity of staining was divided into four grades (intensity scores): (0) no staining; (1) light brown; (2) brown; and (3) dark brown. SMAD4 staining positivity was determined by the formula: overall scores = percentage score × intensity score. Overall score of ≤ 3 was defined as negative, > 3 but ≤ 6 as weakly positive, and > 6 as strongly positive[24].

Statistical analysis

The χ^2 test was used to compare the differences in frequency distributions of selected demographic variables, smoking status, alcohol use, as well as each allele and genotype of the *SMAD4* polymorphisms between the cases and controls. The difference between *SMAD4* genotypes and clinicopathological characteristics was assessed by χ^2 test. The crude and adjusted odds ratios (ORs) and 95% confidence intervals (CIs) were obtained to assess the association between the *SMAD4* polymorphisms and gastric cancer risk using, unconditional univariate and multivariate logistic regression models. The multivariate adjustment included the age, sex, tobacco smoking, and alcohol use. HWE of the genotype distribution among control groups was tested by a goodness-of-fit χ^2 test. The combined genotypes data were further stratified by subgroups of the age, sex, smoking status, and alcohol use. The Mann-Whitney *U* test was used to compare the SMAD4 expression levels between individuals with 0-1 protective allele and 2-3 protective alleles. All tests were performed with SAS software (version 9.1.3; SAS Institute, Inc., Cary, NC, USA) with two sides, unless indicated otherwise. $P < 0.05$ was considered statistically significant.

RESULTS

The characteristics of the study population are shown in Table 2. There was no significant difference in the distribution of age ($P = 0.354$), sex ($P = 0.516$), or alcohol use ($P = 0.846$) between the case and control subjects. However, there were more regular smokers among the cases (43.8%) than among the controls (35.0%) ($P = 0.020$). Furthermore, there were 149 (48.1%) and 161 (51.9%) patients with cardia and non-cardia gastric cancer, respectively. The histological types were 162 (52.3%) intestinal and 148 (47.7%) diffuse type gastric cancer; positive lymph nodes were identified in 148 (47.1%) cases. For depth of tumor infiltration, 80 (25.8%), 68 (22.0%), 112 (36.1%) and 50 (16.1%) cases were T1, T2, T3 and T4, respectively.

The primary information of the five tSNPs in CHB patients is shown in Table 1. The observed genotype frequencies of the five tSNPs among the control subjects were all in agreement with HWE (all $P > 0.05$). The allele frequencies of the genotyped tSNPs in the controls were consistent with those of the International HapMap Project database for CHB. The single SNP allele analysis indicated that the allele frequencies of two tSNPs, SNP3 rs17663887 and SNP5 rs12456284, were significantly different between the cases and controls ($P < 0.001$ for SNP3 rs17663887, and $P = 0.017$ for SNP5 rs12456284).

The genotype frequencies of these five tSNPs and

[1]Two-sided χ^2 test for the frequency distribution of selected variables between gastric cancer cases and cancer-free controls; [2]No. of subjects in cases (n = 310 for tumor site, n = 310 for histological types, n = 310 for depth of tumor infiltration, and n = 314 for lymph node metastasis) were less than the total number (n = 322) because some information was not obtained.

their associations with gastric cancer risk are summarized in Table 3. The single locus analysis revealed that the genotype frequencies of two tSNPs, SNP3 rs17663887 and SNP5 rs12456284, were significantly different between the cases and controls ($P < 0.001$ for SNP3 and $P = 0.003$ for SNP5, respectively). Multivariate logistic regression analyses indicated that the variant TC genotype of SNP3 was associated with a significantly decreased risk of gastric cancer compared with the wild-type TT genotype (adjusted OR = 0.38, 95% CI: 0.21-0.71). For the SNP5, compared with the wild-type AA genotype, the variant GG genotype was associated with a statistically significantly decreased risk of gastric cancer (adjusted OR = 0.31, 95% CI: 0.16-0.60) (Table 3).

Considering the potential interactions of the tSNPs on risk of gastric cancer, we combined these two tSNPs based on the numbers of the protective alleles (i.e. SNP3 C and SNP5 G alleles). As shown in Table 4, the combined genotypes with zero and one protective allele were more common (0.429 and 0.518, respectively) and that with two and three protective alleles was less common (0.053 and 0.000, respectively) among the cases than the controls (0.362, 0.423, 0.154 and 0.011, respectively), and these differences were statistically significant ($P < 0.001$). When these combined genotypes were dichotomized into two groups (i.e. 0-1 *vs* 2-3 protective alleles), their distributions differed significantly between the cases and controls ($P < 0.001$).

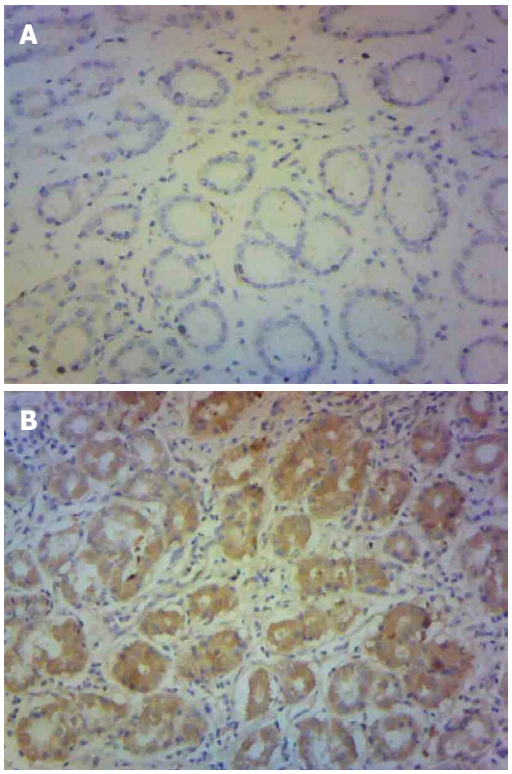

Figure 1 Immunohistochemical staining for SMAD4 in gastric tissues adjacent to tumor. HE, original magnification, 100 ×. A: Individuals with *SMAD4* 0 or 1 protective allele; B: Individuals with *SMAD4* 2 or 3 protective alleles.

In the association analyses, we found that the individuals with 2-3 protective alleles had a significantly decreased risk of gastric cancer (adjusted OR = 0.28, 95% CI: 0.16-0.49) than those with 0-1 protective allele (Table 4). Further stratification analysis showed the same results as the main protective effect among subgroups of age, sex, smoking status, and drinking status (data not shown). However, no statistical evidence was observed for interactions between the combined genotypes and the variables (i.e. age, sex, tobacco smoking, and alcohol use) (data not shown).

Based on the results of the genetic association studies of the *SMAD4* combined genotype (0-1 *vs* 2-3 protective alleles) and gastric cancer, the SMAD4 protein expression of gastric cancer patients with 0-1 or 2-3 protective alleles was analyzed using immunohistochemistry. Four of the 10 patients had 2-3 protective alleles and six had 0-1 protective allele. SMAD4 was mainly expressed in the cytoplasm. Individuals with 0-1 protective allele had significantly decreased SMAD4 expression compared with those with 2-3 protective alleles ($P = 0.025$) (Figure 1).

To explore whether genetic variation in SMAD4 is associated with clinicopathological characteristics and disease progression, we performed additional stratified analysis of association between *SMAD4* combined variant genotypes and risk of gastric cancer by the tumor sites (cardia and non-cardia), histological types (intestinal and diffuse), tumor infiltration (T1-T4), and lymph node metastasis (negative and positive). However, no significant association was observed (data not shown).

[1]0-3 represent the number of variants within the combined genotypes (0 = no variant and 1-3 = 1-3 variants); the variant (protective) alleles used for the calculation were the SNP3 C and SNP5 G alleles; [2]Two-sided χ^2 test for the frequency distribution; [3]Odds ratios (ORs) were obtained from a logistic regression model with adjustment for age, sex, smoking status, and alcohol use. SNP: Single nucleotide polymorphism; CI: Confidence interval.

DISCUSSION

In this case-control study of gastric cancer, we investigated the associations of five tSNPs located in the intron (SNP1-4) and 3'-untranslated region (3'-UTR) (SNP5) of the tumor suppressor gene *SMAD4* with risk of gastric cancer in a Chinese population. Among these five tSNPs, we found that two variant genotypes (SNP3 TC and SNP5 GG) were associated with a significantly decreased risk of gastric cancer. When the protective alleles (SNP3 C and SNP5 G alleles) were evaluated together, we found that individuals with 2-3 alleles had a significantly decreased risk of gastric cancer compared with those with 0-1 protective allele. Furthermore, individuals with 0-1 protective allele had a significantly decreased SMAD4 protein expression level in normal tissues adjacent to tumors compared with those with 2-3 protective alleles. To the best of our knowledge, no published studies have investigated the role of *SMAD4* polymorphisms in gastric cancer.

It has been shown that the loss of SMAD4 is a common feature of most human malignancies, and is associated with cancer progression[13]. Smad4 complete knockout mice can generate tumors throughout the gastrointestinal tract[25,26]. Experimental data also suggest that SMAD4 participates in immunosuppression. Absence of SMAD4 expression in thymic epithelial cells leads to functional change, and the number of early T-lineage progenitors is markedly reduced[27]. Selective loss of SMAD4 in T cells also leads to epithelial cancers throughout the gastrointestinal tract in mice[28]. SMAD4 appears to be a key regulatory protein of the SMAD4-dependent signaling in tumor carcinogenesis.

In the present study, we found an association of *SMAD4* tSNPs with risk of gastric cancer. Moreover, SMAD4 protein expression levels were significantly different between individuals with 0-1 and 2-3 protective alleles. Although the underlying mechanism by which the mutated intron allele or 3'-UTR allele in the gene is associated with cancer risk remains elusive, there are two possible explanations. First, the mutant C allele of SNP3 rs17663887 that is located in intron 9 might produce/alter *cis* elements that allow/alter binding of transcription factors and thereby change *SMAD4* expression. Using the Alibaba program (http://www.gene-regulation.com/cgi-bin/pub/programs/alibaba2), we found the transcription factors are altered when the SNP3 T allele mutates to C allele [i.e. T allele: C/EBPα (CCAAT/enhancer binding protein α), HNF-3 (fork-head homolog 3), and AP-1

(activator protein 1); C allele: C/EBPβ (CCAAT/enhancer binding protein β) and HSF (heat shock factor)]. Second, the mutant G allele of SNP5 rs12456284 that is located in the 3'-UTR might influence the potential miRNA binding and ultimately influence *SMAD4* expression. Our immunohistochemistry assay partly supported these assumptions *in vivo*. However, the experiment needs to be done in normal gastric tissues and with larger sample sizes.

In this study, we found that *SMAD4* polymorphisms might jointly provide protection against gastric cancer risk; individuals with 2-3 protective alleles had a significantly decreased risk of gastric cancer compared with those with 0-1 protective allele. This putatively supports the notion that a single polymorphism only contributes a modest effect and the combined variants of a gene might provide a more comprehensive evaluation of genetic susceptibility in candidate genes with low penetration. To date, few published epidemiological studies have investigated the associations between *SMAD4* polymorphisms and human cancer. Only one case-control study has reported an association between the *SMAD4* tSNPs and testicular germ cell tumor susceptibility in the US Servicemen's Testicular Tumor Environmental and Endocrine Determinants Study[29]. Although they also selected the two tSNPs in the *SMAD4* gene (i.e. rs9304407 and rs12456284) in their study, no association was found.

Kim *et al*[30] have reported that loss of SMAD4 protein expression is significantly associated with intestinal type gastric cancer. Later, they further reported that expression of SMAD4 was significantly lower in diffuse than intestinal-type gastric cancer[31]. Nevertheless, our analysis failed to find an association of *SMAD4* polymorphisms with tumor histological types. Besides, Xiangming *et al*[12] and Kim *et al*[30] have reported that reduced expression of SMAD4 is related to the depth of tumor invasion. Our results did not find any correlation between the polymorphisms and tumor infiltration of gastric cancer. This could be attributable to different ethnicity and our relatively small sample size. Larger studies with different ethnic populations are needed.

Several limitations in our study need to be addressed. (1) The study design was hospital-based, which could have had inherent limitations that introduced selection bias, compared with population-based or cohort studies. However, the allele frequency in control subjects is close to that reported in the HapMap database for the CHB population; (2) We did not obtain enough information on *H. pylori* infection, and future studies with such information are needed; and (3) The relatively small sample size of 322 cases and 351 controls in the present study might not be large enough to identify significant gene-environment interactions, although we had > 85% power to detect an OR of $\geqslant$ 1.6 and $\leqslant$ 0.6, with an exposure frequency of 30% under the current sample size.

In conclusion, we found two tSNPs within the *SMAD4* gene that were associated with a decreased risk of gastric cancer in a Chinese population. This is believed to be the first report of *SMAD4* polymorphisms and gastric cancer, therefore, additional larger investigations and functional studies with more detailed environmental exposure data are warranted to validate these findings.

ACKNOWLEDGMENTS

We thank Dr. Jian-Wei Zhou (Nanjing Medical University) for the help in part of the sample collection.

COMMENTS

Background

Gastric cancer is the fourth most common cancer and the second leading cause of cancer-related death worldwide. Epidemiological studies have identified many risk factors for gastric cancer that are involved in genetic susceptibility.

Research frontiers

Mothers against decapentaplegic homolog 4 (SMAD4) is a central mediator of the transforming growth factor β signaling pathway, which acts as a tumor suppressor in numerous cancers. The relationship between *SMAD4* gene polymorphism and gastric cancer needs to be addressed.

Innovations and breakthroughs

This is believed to be the first study to examine the potential role of *SMAD4* genetic variants in the occurrence of gastric cancer in a Chinese population. Two tSNPs within the *SMAD4* gene were found to be associated with a decreased risk of gastric cancer. Protein expression assays also support the association study results.

Applications

These findings might be of value in the explanation of gastric carcinogenesis. The observations also could be used as for further investigation of SMAD4 and gastric cancer.

Peer review

This paper is generally well prepared.

Abstract

AIM: To explore the regulator of G-protein signaling 5 (RGS5) expression in gastric carcinoma and its association with differentiation and microvascular density (MVD).

METHODS: Expression of RGS5 and CD34 were examined in 76 cases of gastric carcinoma, including 22 cases with lymph node metastasis and 54 cases without lymph node metastasis determined by immunohistochemistry (IHC). MVD was assessed using CD34 monoclonal antibody. The presence of RGS5 and CD34 was analyzed by IHC using the Envision technique.

RESULTS: The RGS5 expression in gastric carcinoma was positively correlated with the differentiation of the tumor (r = 0.345, P < 0.001), but not related with age, gender, tumor size, clinical stage and lymph node metastasis (P > 0.05). The average MVD in the group with lymph node metastasis was significantly higher than that in the group without lymph node metastasis (P < 0.05). RGS5 expression was negatively correlated with the average MVD (P < 0.05).

CONCLUSION: RGS5 expression level in gastric carcinoma is associated with the differentiation and MVD of the tumor, and may be used as an important parameter for determining the prognosis of gastric carcinoma patients.

Key words: RGS5 expression; Gastric carcinoma; Differentiation; Microvascular density

Relationship between RGS5 expression and differentiation and angiogenesis of gastric carcinoma. *World J Gastroenterol* 2010; 16(44): 5642-5646 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i44/5642.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i44.5642

INTRODUCTION

Gastric carcinoma is one of the most common malignant tumors, and lymph node metastasis is the most common and the earliest transfer channels. Regulator of G-protein signaling 5 (RGS5) is a member of the RGS superfamily and acts as a negative regulator of heterotrimeric G-protein-mediated signaling through G-protein-coupled recep-

tors (GPCRs)[1,2]. Recently, RGS5 has been found involved in tumor angiogenesis and metastasis[3-6]. We used immunohistochemical technique to examine the expression of RGS5 and CD34 in 76 cases of gastric carcinoma in order to explore the relationship between RGS5 expression and differentiation and angiogenesis of gastric carcinoma.

MATERIALS AND METHODS

Samples, histological examination and reagents

We studied 76 patients with gastric adenocarcinoma who underwent operation without radiotherapy and chemotherapy in the Nanjing General Hospital of Nanjing Military Command, from March 2005 to October 2009, including 46 men and 30 women, with an average age of 55.95 years. There were 42 stage Ⅰ, 12 stage Ⅱ and 22 stage Ⅲ cases; the tumors were highly differentiated in 22, moderately differentiated in 30 and poorly differentiated in 24 cases. Two senior pathologist reviewed the morphologic classification of the tumors according to the WHO specifications and evaluated the adequacy of biopsy specimens for further tests. Specimens were promptly fixed and embedded, and the slices were made with a thickness of 2-4 μm.

The antibody used for RGS5 was rabbit polyclonal (Sigma Inc., USA) at 1:80 dilution. The antibody used for CD34 was mouse monoclonal (Neo Markers Inc., USA) at 1:200 dilution. The diaminobenzidine tetrahydrochloride was obtained from DAKO Company.

Immunohistochemistry

The presence of RGS5 and CD34 was analyzed by Immunohistochemistry (IHC) using the Envision technique. Antigen retrieval was carried out by high temperature and pressure cooking of the slices in 15 mL EDTA. The slices were rinsed in phosphate buffered solution (PBS) (0.01 mol/L, pH 7.4) for three times, incubated with the primary antibody overnight at 4℃ and washed again in PBS for three times. They were then incubated with the anti-rabbit and mouse horse radish peroxidase polymer reagent for 12 min at room temperature, and washed in PBS three times as above. The reaction product was developed using diaminobenzidine tetrahydrochloride. Finally, the slices were counterstained with hematoxylin, dehydrated and mounted in resinous mountant. Negative controls with PBS (0.01 mol/L, pH 7.4) replacing the primary antibody were also included.

Any brown cytoplasmic staining of cells was taken as positive expression for RGS5. The tissue sections were screened at a high power (× 200) and five areas with the most intense expression were selected. Briefly, a mean percentage of positive cells was determined in at least five areas (× 200) and assigned to one of the following five categories: < 5% (-); 5%-25% (+); 25%-50% (2+); 50%-75% (3+); and ≥ 75% (4+). A mean percentage of positive cells < 50% was considered as having low expression, and that ≥ 50% was considered as having high expression. Microvascular density (MVD) was assessed using CD34 monoclonal antibody. Any brown cytoplasmic or membranous staining of vascular endothelial cells was taken as positive expression for CD34. The tissue sections were screened at a low power (× 40) and three areas with the most intense neovascularization were selected. Microvessel counting was performed at a high power (× 400) in these areas.

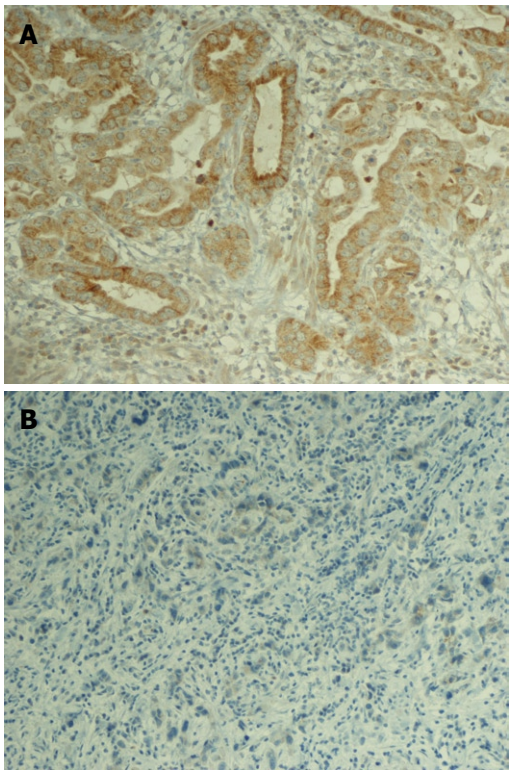

Figure 1 Expression of regulator of G-protein signaling 5 (× 200). A: High regulator of G-protein signaling 5 (RGS5) expression in highly differentiated gastric adenocarcinoma; B: Low RGS5 expression in poorly differentiated gastric adenocarcinoma.

Statistical analysis

Statistical analyses were performed using the Software Packages for Social Science 13.0 for Windows (SPSS, Inc, Chicago, IL, USA). Associations of RGS5 expression with clinical parameters of patients were described by the Chi-square test. Fisher's exact test was also used when necessary. Relationship between expression of RGS5 and clinical parameters of patients was analyzed using the Spearman rank correlation analysis. Average MVD was calculated and analyzed using the independent-samples *T* test. *P* values < 0.05 were considered significant.

RESULTS

Expression of RGS5

RGS5 was mainly expressed in the cytoplasm of gastric carcinoma cells, and the strong positions were in the regions infiltrated by the tumor cells (Figure 1). The RGS5 expression level in gastric carcinoma was positively correlated with the differentiation ($r = 0.345$, $P < 0.001$, Table 1),

but not correlated with age, gender, tumor size, clinical stages and lymph node metastasis ($P > 0.05$, Table 1).

CD34 was expressed in the cytoplasm or membrane of vascular endothelial cells. The staining of cells was uniform. And the areas with intense microvascularization were the regions infiltrated by the tumor cells (Figure 2). The average MVD in the group with lymph node metastasis group was significantly higher than that in the group without lymph node metastasis ($P < 0.05$, Table 2), but not correlated with age, gender and tumor size ($P > 0.05$, Table 2).

Relationship between RGS5 expression and MVD in gastric carcinoma

The average MVD in high RGS5 expression group was significantly lower than that in low RGS5 expression group ($P < 0.05$, Table 2, Figure 2).

DISCUSSION

G protein-coupled biological processes are important for an ever-increasing number of human diseases[7]. RGS5 is a member of the RGS superfamily, and is involved in a number of processes of diseases, such as atherosclerosis[8]. In normal tissues, RGS5 was found to be highly up-regulated in PDGFR-β^+ pericytes and played an important role in developmental processes of blood vessels[9-12]. Recently, it has been indicated that RGS5 expresses in the early stages of blood vessel maturation and regulates the development of vascular pericytes[13-23]. However, there have been fewer studies about RGS5 expression in tumors. Chen *et al*[3] and Furuya *et al*[4] discovered that RGS5 highly expressed in vascular pericytes of both hepatocellular carcinoma and renal cell carcinoma. In addition, tumor metastasis depends on the newborn blood vessels, and RGS5 was found involved in tumor angiogenesis[24]. However, the function of RGS5 in development or angiogenesis of gastric carcinoma is still unclear.

We used IHC method for the first time to examine the expression of RGS5 protein in gastric carcinoma. The results showed that expression of RGS5 protein varies in different gastric carcinoma patients, indicating that the function of RGS5 protein in occurrence of gastric carcinoma is manifold. Forty-six (61%) cases had low RGS5 expression, and most of them had poorly differentiated gastric carcinoma ($P < 0.001$). Tumor occurrence and development are associated with multiple genes, and RGS5 protein is only a part of the signal transduction pathway. RGS5 acts as a negative regulator of heterotrimeric G-protein-mediated signaling through GPCRs[1]. RGS5

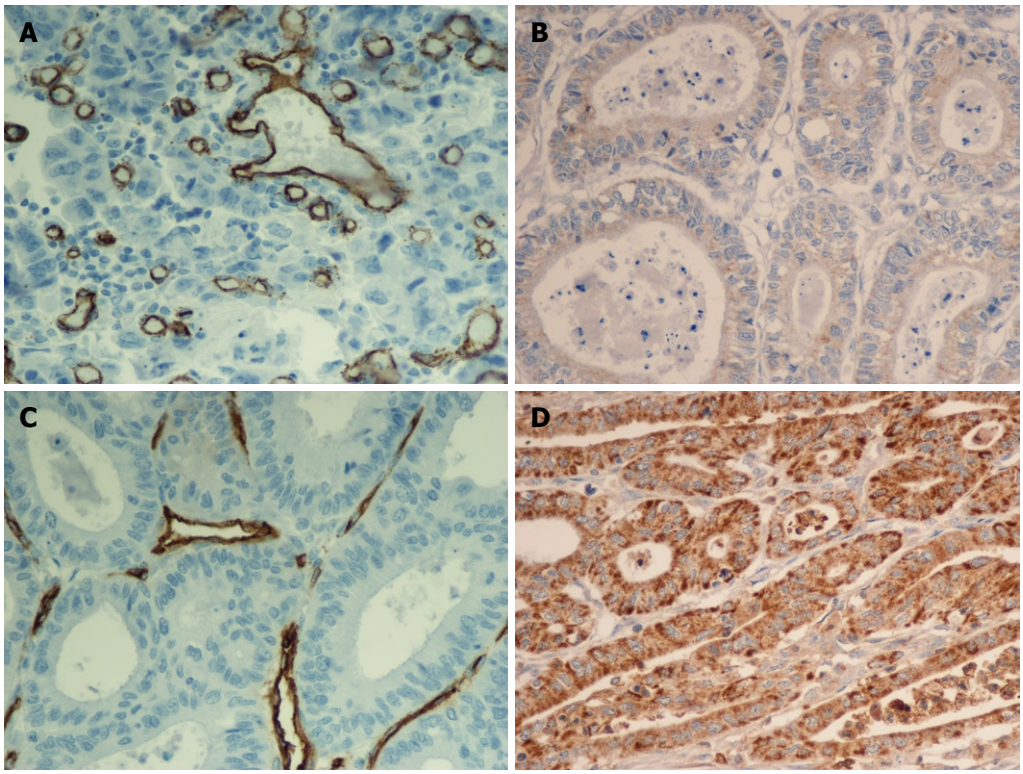

Figure 2 High microvascular density in gastric adenocarcinoma with low regulator of G-protein signaling 5 expression (A, B) and low microvascular density in gastric adenocarcinoma with high regulator of G-protein signaling 5 expression (C, D). Envision, × 400.

was found to be involved in tumor angiogenesis, and perhaps regulate tumor progress.

We found that the RGS5 expression level in gastric carcinoma was negatively correlated with the average MVD. The average MVD in the group with lymph node metastasis was significantly higher than that in the group without lymph node metastasis, but the RGS5 expression level in gastric carcinoma was not correlated with lymph node metastasis. This may be related to the number of samples and methods of detection. In addition, in the aspect of regulation of the tumor growth, we have found that the tumor blood vessels of RGS5 gene knockout mice tended to be mature and differentiated[25-28], indicating that expression of RGS5 is a factor of tumor blood vessel abnormalities and may play a certain role in regulating the invasion and metastasis of tumor cells.

In addition, RGS5 expression can be used to determine the prognosis of renal clear cell carcinoma together with a number of other indicators[8,29,30]. Our study suggested that RGS5 expression level in gastric carcinoma was significantly associated with the differentiation and MVD of the tumor, also indicating the trend of disease development. Many researches have confirmed that the differentiation, MVD and some other clinical pathological parameters are important factors for the prognosis of gastric carcinoma. Therefore, RGS5 protein may be an effective indicator for evaluating the malignant degree of gastric carcinoma.

However, there have been fewer studies about the relationship between RGS5 and tumors reported in literature. The function of RGS5 in tumor development or tumor angiogenesis needs to be further studied.

COMMENTS

Background

G protein-coupled biological processes are important for an ever-increasing number of human diseases. Regulator of G-protein signaling 5 (RGS5) is a member of the RGS superfamily and acts as a negative regulator of heterotrimeric G-protein-mediated signaling through G-protein-coupled receptors. Recently, RGS5 has been found involved in tumor angiogenesis and metastasis.

Research frontiers

High RGS5 expression has been found in the vascular pericytes of hepatocellular carcinoma and renal cell carcinoma. In addition, tumor metastasis depends on the newborn blood vessels, and RGS5 is involved in tumor angiogenesis. The expression of RGS5 is a factor of tumor blood vessel abnormalities and may play a certain role in regulating invasion and metastasis of tumor cells.

Innovations and breakthroughs

The authors used immunohistochemical method for the first time to examine the expression of RGS5 protein in gastric carcinoma.

Applications

There have been fewer studies about the relationship between RGS5 and tumors. The function of RGS5 in tumor development or tumor angiogenesis needs to be further studied.

Peer review

In this manuscript, Wang *et al* examined the expression of RGS5 and its relationship with differentiation and microvascular density (MVD) in a panel of gastric tumors. They found that RGS5 expression is associated with differentiation,

and negatively correlated with average MVD. These findings have not been described and are potentially important. The quality of representative pictures is high.

Abstract

Celiac disease (CD) is a common autoimmune condition. Previously it was considered to be a rare childhood disorder, but is actually considered a relatively common condition, present at any age, which may have multiple complications and manifestations. Hematological disorders of the disease are not uncommon. Among these disorders, the most frequently reported are anemias as a result of iron deficiency, often associated with folate and/or B12 deficiency. Anemias caused by hemolysis are very rarely reported in celiac patients. An 11-year-old girl with a previous uneventful medical history presented with severe hemolytic anemia. Hemolysis was Coombs negative, accompanied by inappropriate low reticulocyte count, despite exaggerated bone marrow hyperplasia of the erythroid precursors which showed normal maturation. Serology for recent infections, including Epstein-Barr virus, parvovirus B19, cytomegalovirus and mycoplasma, were all negative. Levels of serum IgA, IgG and IgM, were all within normal ranges for age. Screening for anti-DNA, antinuclear, antineutrophil cytoplasmic, antimicrosomal, antithyroglobulin, and antimitochondrial antibodies and lupus anticoagulants, was negative. She was also negative for human immunodeficiency virus. Conventional therapy with corticosteroids and intravenous immunoglobulin failed. CD was serendipitously discovered upon screening for anti-tissue transglutaminase autoantibodies. The disease was confirmed by biopsy of the small intestine mucosa. The patient recovered with gluten-free diet. A unique case of CD is presented. CD should be serologically screened in each patient with Coombs negative "immune" hemolytic anemia, particularly if accompanied by "reticulocytopenia". A new hemolytic mechanism and very speculative explanation for "reticulocytopenia" are discussed.

INTRODUCTION

Celiac disease (CD) is a common autoimmune condition, induced by the intake of prolamines, alcohol soluble proteins, rich in glutamine and proline present in wheat, barley and rye, in genetically susceptible persons. Histologically, the disease produces a spectrum of upper small intestinal mucosa changes, ranging from an increase in

the number of intraepithelial lymphocytes to mucosal remodeling with crypt hyperplasia and flattening of the villi. Contrary to common belief this disorder is a systemic protean disease, rather than merely a pure digestive dysfunction. Previously, it was considered to be a rare childhood disorder, but is actually considered a relatively common condition, present at any age, and may have multiple complications and manifestations[1]. Among these, hematological disorders at presentation of the disease, and/or as manifestations during the course of the disease are not uncommon. The most frequent are anemias, including iron-deficiency anemia often associated with folate and/or B_{12} deficiency[2]. Other, less common hematological disorders seen in CD are leucopenia/neutropenia, thrombocytopenia, thrombocytosis, and vitamin K deficiency, manifested as coagulopathy and/or thromboembolism[2]. Hemolytic anemia, as an integral part of the clinical picture of CD, is extremely rare. We describe a child whose CD presented with severe hemolytic anemia with inappropriate reticulocytosis. A new mechanism of hemolysis, specific for CD and a very speculative explanation for "reticulocytopenia" are discussed.

CASE REPORT

An 11-year-old girl, with no previous gastrointestinal or other complaints, presented with acute, severe hemolytic anemia. This was preceded by slight flu-like illness of 2 d duration. On admission she was found to be pale, with mild icteric discoloration of the sclera. She was above the 25th percentile for weight and height. The spleen was slightly enlarged. Initial laboratory testing disclosed an elevated sedimentation rate of 100/146, hemoglobin 4.3 g/L, red blood cell count 1.5×10^{12}/L, and white blood cell count 9.8×10^{6}/L. A peripheral blood smear showed normal white cells and differential, normochromic and normocytic red cells. Neither abnormal red cells, nor normoblasts were seen. The platelet count was 355×10^{9}/L, mean corpuscular volume 83 fL, reticulocyte percentage 3.0%, total bilirubin level 46 μmol/L (normal range 1.7-20.0 μmol/L), direct bilirubin level 13 μmol/L (normal range 1.7-8.6 μmol/L), lactate dehydrogenase 980 U/L, slightly elevated serum transaminases activities (alanine transaminase 67 U/L, aspartate transaminase 72 U/L), and almost undetectable haptoglobin level (< 0.07 g/L). Bone marrow examination revealed hyperplasia of the erythroid precursors with normal maturation. Serology for recent infections, including Epstein-Barr virus, parvovirus B19, cytomegalovirus and mycoplasma, were all negative. A direct antiglobulin test (DAT) with anti-IgG, anti-IgM and anti-C3b was negative. An indirect antiglobulin test was also negative. The ceruloplasmin level was 46.1 g/L. Levels of serum IgA, IgG and IgM, were all within the normal ranges for age. Screening for anti-DNA, antinuclear, antineutrophil cytoplasmic, antimicrosomal, antithyroglobulin, and antimitochondrial antibodies and lupus anticoagulants, was negative. She was also negative for human immunodeficiency virus.

A diagnosis of idiopathic DAT-negative autoimmune hemolytic anemia (AIHA) was established. For the first 7 d, in expectation of spontaneous recovery, she was treated with transfusions of red packed cells only. Hemolysis was so severe that she had to receive at least 500 mL of red packed cells daily to maintain the hemoglobin level just above 50 g/L. On the 7th day, 3 mg/kg per day of prednisone was started with 1 g/kg of intravenous immunoglobulin (IVIG) on 2 consecutive days. She did not improve during the following 14 d. Then we started to taper prednisone, and serendipitously[3] the patient's blood was sampled for anti-tissue transglutaminase antibodies (anti-tTGAbs) and a gluten-free diet (GFD) was introduced. A gradual improvement ensued. The need for blood transfusion started to decrease 7 d after introduction of the GFD and a steady increase in hemoglobin level followed, accompanied by exaggerated reticulocytosis (> 20%). Ten days after blood sampling for anti-tTGAbs testing, we were informed that the anti-tTGAb titer was elevated (45.8 U/mL, normal < 8 U/mL). Thereafter a peroral intestinal enterobiopsy was performed. CD grade Ⅲ was confirmed. Now, 5 years later, on a GFD, she has normal development, normal blood counts, and normal anti-tTGAbs titer.

DISCUSSION

There is no doubt that our patient has CD, which was previously unrecognized. The patient had an uneventful medical history, until a severe, life-threatening hematological disorder appeared. There is also no doubt that the nature of the hematological disorder was anemia caused by a hemolytic mechanism. Until recently we thought that the patient had classical AIHA with negative DAT. AIHA is very rare event in CD and in the general population as well[4]. AIHA is not even included in the hematological spectrum of CD[2], despite the existence of 4 well documented reports of patients having CD and AIHA, (2 had Evans syndrome)[5-7]. These patients, contrary to the presented case were: (1) symptomatic before CD was diagnosed; (2) their hemolysis was DAT positive suggesting that the hemolysis was IgG and/or C3b mediated; (3) hemolysis in these patients was accompanied by exaggerated reticulocytosis; and finally (4) each of these patients responded to corticosteroid treatment. Our patient was (1) asymptomatic before hemolysis appeared; (2) hemolysis was resistant to corticosteroids and IVIG; (3) DAT was negative, meaning that the hemolysis was not mediated by IgG, IgM or C3b; and finally (4) despite the large number of erythroid precursors in the patient's bone marrow, reticulocytes were only marginally elevated (3%).

In an attempt to explain these unusual phenomena in our patient, like The Three Princes[3], we set out on a trip, and kept making unexpected discoveries along our way through the medical literature. Thus, we reached the wonderful world of transglutaminases (TGs)[8], especially the world of tissue transglutaminase (tTG), and their "enemies", the anti-tTGAbs[9]. Anti-tTGAbs found in CD[9]

have special properties which may play a role in the disease, at both local and systemic levels, reflecting the role of tTG in many crucial biological processes. It was shown that anti-tTG-Abs from celiac patients inhibit the enzymatic activity of human tTG both *in vitro*, and *in situ*[10]. Very recent studies showed that *in vivo* targeting of tTG in CD also occurs in the form of *in situ* endomysial, reticulin, and jejunal subepithelial anti-tTGAbs binding[11]. Furthermore, the same study[11] showed IgA deposition on extracellular tTG in the liver, lymph nodes, and muscles indicating that the CD autoantigen is widely accessible to the intestinally-produced circulating autoantibodies throughout the body.

Finally, we were able to elucidate the mystery of our patient. Anti-tTGAbs were produced in her small intestine upon continuous exposure to gluten and distributed *via* the circulation throughout the body. They targeted the erythrocytic TG, so called band 4.2[12] and disabled its anchor function. As a consequence, the patient's erythrocytes became fragile and hemolysis ensued in the very hostile spleen environment (acidosis, hypoglycemia, slowed circulation).

This case should not be classified as classical IgG or C3b mediated AIHA. It should be rather considered as a "celiac type of immune hemolysis", because we believe it was mediated by autoantibodies, which were generated in the intestinal mucosa in gluten intolerance and exerted an anti-tTG activity. This kind of hemolysis could be designated as an enzymatic inhibition induced hemolysis. One could argue that the hemolysis in our patient could be IgA mediated. Unfortunately, at the time in Serbia kits for anti-IgA DAT were not available. Because our patient was not IgA deficient, it could be presumed that the patient's circulating anti-tTGAbs which belong to IgA, targeted the erythrocytic TG (band 4.2). One can also argue that our patient could have AIHA with a low titer of anti-erythrocytic antibodies to explain the negative Coombs test. Having in mind the severity of the hemolysis, we can argue with the question: can low anti-erythrocyte autoantibodies cause such severe hemolysis?

The failure of our patient to respond to corticosteroids and IVIG could be explained by the fact that the patient was fed, i.e. continuously challenged, with gluten and the production of anti-tTGAbs was unrestrained, until the introduction of a GFD.

Finally, we will try to explain the most mysterious phenomenon of our patient and that is the inappropriate low reticulocytes (3%), despite the exaggerated erythroid bone marrow hyperplasia which ensued as a physiologic answer to severe hemolysis.

Fibronectin is a glycoprotein associated with the extracellular matrix of many tissues[13] and is a major component of the interstitial matrix in the bone marrow[14]. Fibronectin is tightly bound to the surface of many cells, including bone marrow precursors. Migration of mature reticulocytes from the bone marrow into the circulation is associated with the loss of fibronectin adhesion from the marrow precursors (mature reticulocytes). This process is probably physiologically mediated by at least 2 bone marrow tTGs. The first one is cell surface tTG, a ubiquitously expressed, potent integrin-binding adhesion coreceptor involved in the binding of cells to fibronectin[15]. Its role would be retention of early erythroid marrow precursors in the bone marrow hematopoietic nests, until their full maturation. After that another tTG, an extracellular tTG, would modulate fibronectin adhesion affinity. This tTG switches fibronectin adhesion from the mature reticulocyte membrane toward the extracellular matrix, *via* tight cross-linking of fibronectin with extracellular matrix proteins[16]. Thus, reticulocytes are liberated and migrate into the circulation.

We suggest that, in our patient, anti-tTGAbs targeted this extracellular bone marrow tTG, and fibronectin adhesion affinity could not be switched, which resulted in trapping of reticulocytes in the bone marrow. This is a very speculative explanation. We cannot offer any other explanation for the low reticulocyte count in our patient, despite the bone marrow erythroid hyperplasia.

This case represents one of the many atypical presentations of CD, and the first one whose CD started with hemolytic anemia. CD should be serologically screened in every patient with DAT-negative immune hemolytic anemia, particularly if accompanied by "reticulocytopenia". This case also confirms the value of antibody screening in early diagnosis of CD. Finally, we believe that we have probably described a new mechanism of hemolysis, which we would designate as an "enzymatic inhibition hemolysis".

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Non-steroidal anti-inflammatory drugs (NSAIDs) constitute a family of drugs, which taken as a group, represents one of the most frequently prescribed around the world. Thus, not surprisingly NSAIDs, along with anti-infectious agents, list on the top for causes of Drug-Induced Liver Injury (DILI). The incidence of liver disease induced by NSAIDs reported in clinical studies is fairly uniform ranging from 0.29/100 000 [95% confidence interval (CI): 0.17-051] to 9/100 000 (95% CI: 6-15). However, compared with these results, a higher risk of liver-related hospitalizations was reported (3-23 per 100 000 patients). NSAIDs exhibit a broad spectrum of liver damage ranging from asymptomatic, transient, hyper-transaminasemia to fulminant hepatic failure. However, under-reporting of asymptomatic, mild cases, as well as of those with transient liver-tests alteration, in conjunction with reports non-compliant with pharmacovigilance criteria to ascertain DILI and flawed epidemiological studies, jeopardize the chance to ascertain the actual risk of NSAIDs hepatotoxicity. Several NSAIDs, namely bromfenac, ibufenac and benoxaprofen, have been withdrawn from the market due to hepatotoxicity; others like nimesulide were never marketed in some countries and withdrawn in others. Indeed, the controversy concerning the actual risk of severe liver disease persists within NSAIDs research. The present work intends (1) to provide a critical analysis of the dissimilar results currently available in the literature concerning the epidemiology of NSAIDS hepatotoxicity; and (2) to review the risk of hepatotoxicity for each one of the most commonly employed compounds of the NSAIDs family, based on past and recently published data.

Key words: Non-steroidal anti-inflammatory drugs; Side effects; Fulminant hepatic failure; Cholestasis; Liver damage; Liver injury; Hepatitis; Hepatotoxicity

Bessone F. Non-steroidal anti-inflammatory drugs: What is the actual risk of liver damage? *World J Gastroenterol* 2010; 16(45): 5651-5661 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i45/5651.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i45.5651

INTRODUCTION

Non-steroidal anti-inflammatory drugs (NSAIDs) are consumed massively worldwide and, along with antimicrobial agents, are the most frequent causes of drug-induced liver injury (DILI)[1-3]. Indeed, roughly 10% of total drug-induced hepatotoxicity is NSAIDs related. Recent data from England indicates that the relative frequency of NSAIDs prescription has changed, i.e. a 4% decline in the consumption of diclofenac and a parallel 5% increase in the use of naproxen are probably due to an increase in the awareness of both gastrointestinal and cardiovascular serious adverse events[4]. The current policy concerning the use of NSAIDs recommends that patients take "the lowest effective dose for the shortest duration" needed to control symptoms. In this particular

setting evidence indicates that naproxen is associated with a lower thrombotic risk than coxibs, and that ibuprofen has a good thrombotic safety profile for daily doses of up to 1200 mg[5]. Noticeably, 6% of the US population consumes at least one of these products in a month. Information regarding ibuprofen indicates that 24% is sold as over the counter medication[6].

The paradox is that even when it has been known historically and widely accepted that the use of these NSAIDs is associated with a low rate of hepatic adverse events, it is severe liver damage that is the main adverse event through which these drugs are eventually withdrawn from the market[7]. On the other hand, 50% of fulminant hepatic failure (FHF) in the USA is due to hepatotoxicity[8]. Antimicrobial drugs are the most often involved[9].

Hepatotoxicity is more frequently encountered in post-marketing studies or even after, once the drug has already been launched due to the fact that premarketing recruits a relatively low number of patients, frequently insufficient to fully judge the true incidence of hepatotoxicity[10]. One of the most representative examples of this situation is that of bromfenac-related severe liver damage. Bromfenac was withdrawn from the market in 1998 as a result of multiple reports of FHF within the year of its approval (1 case for every 10000 exposed individuals)[11,12]. Frequent severe liver damage associated with nimesulide had also been reported[13]. Although nimesulide is currently approved in 50 countries worldwide, national health authorities of several countries have withdrawn nimesulide from the market and others have never approved it[14-16]. EMEA (European Medicines Evaluation Agency) currently recommends a restricted length of treatment (15 d) and a maximal drug dosage (100 mg/d) for nimesulide therapy, which in addition should be avoided in children.

Interestingly, NSAIDs-induced hepatotoxicity may be associated with liver injury six to nine times more frequently in patients who are taking other potentially hepatotoxic medications concomitantly. (i.e. amoxicillin-clavulanic acid, proton pump inhibitor, phenobarbitol, isoniazid)[17,18].

According to a recent study, hepatic steatosis and metabolic syndrome might predispose to an NSAIDs-induced liver toxicity[19], a similar situation to that already proven for methotrexate and halothane.

Finally, chronic alcohol abuse during treatment with paracetamol was associated with an increase in liver injury induced by acetaminophen including those patients who were taking doses not higher than 4 g daily[20].

Our attempt in the present work is two-fold (1) to analyze the clinical impact regarding severity of NSAIDs hepatotoxicity based on a critical analysis of the conflicting epidemiological approaches currently available in the literature; and (2) to review the individual expected risk of hepatotoxicity for NSAIDs most commonly employed in clinical practice based on past and recently published data.

EPIDEMIOLOGY

Epidemiological studies evaluating severe NSAID liver toxicity take into consideration hospitalization and death of the exposed population. One important pitfall to demonstrate the risk of liver damage induced by NSAIDs resides in the epidemiological study design.

Generally speaking, the strengths of randomized control trials (RCT) are the close patient follow up, the comparison with a control group and an accepted design in order to prove specific therapeutic actions. However, RCT frequently represent just a sample of the general population seldom truly representative, particularly as evidence of the incidence of hepatotoxicity[6]. In addition, trials frequently fail to be informative concerning populations under 18 years of age because this group of individuals is usually underrepresented when not openly excluded[21]. On the other hand, data regarding incidence of liver toxicity from cohort, case-control studies and trials are not free from bias. Environmental factors, alcohol abuse, viral infections and metabolic factors coexist with DILI constituting confounding factors**.** Likewise, retrospective studies have important drawbacks such as researcher unawareness of concurrent drug intake other than the study drug. Other important limiting factors affect both pre- and post-marketing hepatotoxicity studies. Among these is the fact that mild and reversible cases are underreported. The other frequent source of error is the lack of a reliable "denominator" (defined as the number of patients potentially exposed) for calculations. We may also consider an additional source of underestimation of hepatotoxicity which is the report lag - the delay between the occurrence of adverse events and case communication. The latter should be taken into account when the alert is associated with severe liver damage. The incidence of liver disease induced by NSAIDs reported in most studies is fairly uniform ranging from 1 to 9 cases per 100000 persons exposed[21,22]. In spite of these results, epidemiologists analyzing the real risk of liver disease induced by different NSAIDs usually face difficulties, such as different study designs, different populations (ethnic groups, age and sex) and adjustment variable control methods that add complexity to the data analysis.

Traversa and co-workers analyzed a retrospective study from 1997 through 2001 in a region of Italy (850000 inhabitants). About 2 million prescriptions corresponding to NSAIDs-treated patients through a 5-year period follow-up were analyzed[23].

One of the main conclusions drawn from this study is that the risk of NSAIDs induced hepatotoxicity is very small (if the number of prescriptions is taken as the denominator, the incidence of liver injury was 1.7 per 100000 exposed individuals). In contrast, a higher rate of hepatotoxicity was observed among people older than 75 years old (5.7-fold increased risk of liver disease when compared with people under 45 years). Interestingly, it was observed that nimesulide showed both a slightly higher incidence of liver damage and a higher hospitalization rate than that observed with the other NSAIDs (33 per 100000 patient-years *vs* 22 per 100000 patient-years respectively). The authors were unable to find severe liver damage and deaths related to NSAIDs. While the positive features of this study were the high number of patients

Table 1 Results of population-based studies showing liver toxicity induced by non-steroidal anti-inflammatory drugs

Authors	Study design	Incidence rate of hepatotoxicity (ALT ⩾ 3 ULN) per 100 000 patient-years (95% CI)
García Rodríguez *et al*[22], 1992	Retrospective cohort study, cross over design	9/100 000 (6-15)
Traversa *et al*[23], 2003	Retrospective cohort	1.4/100 000 (1.0-2.1)
de Abajo *et al*[24], 2004	Retrospective population-based case-control study	2.4/100 000 (2.0-2.8)
Rubenstein *et al*[26], 2004	Systematic review (hospitalization or death)	3.1 to 23.4/100 000
Rostom *et al*[21], 2005	Systematic review	0.29/100 000 (0.17-0.51)
Laine *et al*[25], 2009	Long-term prospective trial	2.1/100 000 (1.9-2.3)

ALT: Alanine transaminase; ULN: Upper limit of normal; CI: Confidence interval.

enrolled and the extended follow-up, the major limitations were that the database monitoring system neither included the reason for prescription nor NSAIDs doses.

In contrast, a case-control study that included prescriptions of all market-approved NSAIDs highlighted diclofenac as the only drug associated with an increased risk of liver damage (95% confidence interval: 1.9-8.8)[24]. Laine and co-workers recently reported the largest prospective, randomized double-blind study comprising four times more patients than the largest previous trials. They evaluated the incidence of diclofenac-induced hepatotoxicity in 17 289 patients, showing that patients who suffered diclofenac-associated adverse drugs reactions seldom required hospital admission (23/100 000 patients). They also observed that symptoms of diclofenac-related liver disease developed either early or late after starting drug therapy[25]. The conclusions were: a low rate of occurrence of diclofenac-related admissions, and a very low rate of diclofenac-associated FHF. Indeed, only one patient required liver hospitalization for every 132 patients with aminotransferase > 3 × upper limit of normal (ULN).

Rostom and co-workers investigated bibliographic databases MEDLINE and EMBASE and public FDA archives in order to identify randomized controlled trials of diclofenac, naproxen, ibuprofen, celecoxib, rofecoxib, valdecoxib, or meloxicam in adults with osteoarthritis or rheumatoid arthritis. The authors analyzed aminotransferase elevations > 3 ULN, liver-related drug discontinuation, serious hepatic adverse events, liver-related hospitalizations, and liver-related deaths[21]. After analyzing 65 database articles and 67 FDA submitted studies, they concluded that diclofenac and rofecoxib had a higher level of transaminases both compared with placebo and with the other studied NSAIDs. Interestingly, none of these studies had a high rate of serious hepatic adverse events, hospitalizations or death.

The authors found only 1 hospital admission (naproxen) observed among 37 671 patients included in studies reporting hospitalization. This very low hospitalization rate represents 3 per 100 000 patients (0.5-15 per 100 000 patients). One patient died due to naproxen liver toxicity among 51 942 patients consuming NSAIDs, which in turn also represents a low death rate: 2 per 100 000 patients (0.3-11 per 100 000 patients).

These results are in concordance with those reported by Rubenstein and Laine who also analyzed several epidemiologic studies designed to determine the incidence and risk of serious liver-related NSAIDs toxicity[26]. Seven studies met the inclusion criteria proposed by the authors. They observed an incidence of liver toxicity associated with hospital admission ranging from 3.1-23.4/100 000 patient-years related to current use of NSAIDs, with an excess risk compared with past NSAIDs users of 4.8-8.6/100 000 patient-years of exposure. Moreover, these researchers documented zero mortality associated with NSAIDs when cumulative exposure of liver damage was analyzed in 396 392 patients/year.

Most of the information regarding the incidence and relative risk of hepatotoxicity associated with NSAIDs comes from cohort or case control studies and usually shows a low incidence of hepatotoxicity (Table 1).

Great efforts have been made to identify those clinical factors predictive of severe liver damage induced by drugs. Several years ago the FDA along with Representatives of Pharmaceutical Research and Manufacturers of America (PhRMA) and the American Association for the Study of Liver Disease (AASLD) constituted a working group to study how to minimize the risk of hepatotoxicity[27]. Despite valuable effort, expert consensus could not be achieved concerning: (1) biochemical markers of liver injury to applied used in pre-marketing studies; and (2) clinical parameters able to predict severe liver injury. Yet today we still continue using transaminases level higher than three times the ULN as a marker of significant hepatocellular injury[28].

CHARACTERISTICS OF NSAIDS INDUCED LIVER TOXICITY

The discovery of aspirin in 1946 followed by that of phenylbutazone was the beginning of the NSAIDs era. However, not until 1960 was indomethacin marketed. On the other hand, during the 1950s, ibuprofen was the second drug (along with aspirin) approved to be sold as over the counter medication. Interestingly, most of these substances were employed during the 60s, before the prostaglandin era.

The NSAIDs chemical classification recognizes four major groups of molecules: (1) carboxylic acids; (2) oxicams carboxamides; (3) sulphonanilides diaryl-substituted; and (4) pyrazole/furanones[29]. From the clinical stand point NSAIDs induced hepatotoxicity is associated with

Table 2 Liver-related hepatotoxicity induced by non-steroidal anti-inflammatory drugs

Drug	Pattern of liver damage	Proposed mechanism	Incidence
Aspirin	Acute and chronic hepatitis Reye's syndrome	Dose dependent > with high dose	Low
Diclofenac	Acute and chronic hepatitis Mixed damage and pure cholestasis	Metabolic Immunologic	Low
Sulindac	Acute hepatitis and mixed injury	Hypersensivity	Moderate
Ibuprofen	Acute hepatitis, ductopenia	Metabolic	Low
Naproxen	Cholestatic, mixed damage	Metabolic	Low
Coxibs	Acute hepatitis, mixed damage	Probably metabolic	Low
Oxicams	Acute hepatitis, massive and submassive necrosis, cholestasis and ductopenia	Metabolic	Low
Nimesulide	Acute hepatitis, pure cholestasis	Probably metabolic	Moderate

different patterns of clinical presentation, several mechanisms of liver damage and various pathological patterns.

We will only describe below the clinical characteristics of several NSAIDs that may be associated with a potential liver injury (Table 2).

Acetaminophen was not taken into account because most cases of liver damage are due to suicide attempts but a minority of cases are accidental and related to use of paracetamol as a therapeutic prescription. Acetaminophen-induced hepatotoxicity should be described separately and not within this topic.

ASPIRIN

Although liver toxicity induced by aspirin is considered to be dose-dependent, there is evidence that rheumatic patients may have predisposing conditions that may increase individual risk of liver damage. Hypoalbuminemia in patients with systemic lupus erythematosus and juvenile rheumatoid arthritis are two well documented risk factors for increased susceptibility to liver injury[30,31]. In addition, studies in rats have shown that aspirin hepatotoxicity is more common in animals with experimentally-induced rheumatoid arthritis compared to that observed in those without arthritis[32]. The clinical presentation of liver toxicity is often anicteric (jaundice at less than 5%) and transaminase levels correlate with serum salicylate levels (> 25 mg/100 mL)[33]. Focal nonspecific necrosis, hepatocellular degeneration and hydropic changes are commonly seen in liver histology[34]. Aspirin can also produce a mitochondrial dysfunction pattern that may lead to a liver free fatty acid accumulation and subsequently develop into a severe metabolic disorder associated with hepatic massive micro-steatosis. This syndrome, known as Reye's Syndrome, is characterized by metabolic acidosis, hepatic encephalopathy, hypoglycemia, coagulopathy and azotemia. Reye's disease induced by aspirin is a rarity since aspirin is currently avoided in pediatric patients and replaced by ibuprofen and paracetamol.

A recent experimental study in rats suggests that salicylic acid could trigger mitochondrial dysfunction causing a marked fall in intracellular ATP which in turn leads to a lethal hepatocellular injury mediated by a lipid peroxidation mechanism[35].

DICLOFENAC

Diclofenac is the most widely used NSAID in the world[36,37]. The vast majority of data related to hepatic reactions comes from retrospective studies. There were no more than 60 cases of diclofenac hepatotoxicity reported in the literature until Banks and co-workers in 1995 reported their analysis of 180 cases referred to FDA from 1988 through 1991. The authors observed evidence of liver disease in 85% of the patients within the first 6 mo after drug intake. Interestingly, a higher latency (after 6 mo) was observed in 12% of cases[38]. The long latency period observed in a large number of cases in addition to the absence of hypersensibility support a metabolic mechanism of hepatotoxicity. Jaundice was a very common sign present in 90 out of 120 patients. A total of 7 jaundiced patients died as a result of liver disease. In this analysis liver function tests (LFTs) showed a mixed (hepatocellular and cholestatic) pattern in 66% of cases, cholestatic in 8% and indeterminate in the remainder of the group. In contrast to Jick's point of view which suggests that hepatotoxicity induced by diclofenac is an uncommon event[39], the study by Banks proposed for the first time that diclofenac is a much more common cause of liver damage than so far suspected[38]. This concept was reinforced in a recent report from Laine who conducted the longest and largest liver-related diclofenac study so far ever reported [Multinational Etoricoxib and Diclofenac Arthritis Long-Term (MEDAL) program][25]. They conducted a prospective, randomized and double-blind study analyzing the frequency of diclofenac induced liver reactions in 17 289 patients. The authors randomized only those osteoarthritis or rheumatoid arthritis patients over 50 years of age who were going to receive diclofenac therapy (150 mg daily) or etoricoxib (60 or 90 mg daily). They also excluded cases with previous liver disease or more than 14 weekly alcohol drinks. Hypertransaminasemia > 3 × ULN was observed in over 3% of arthritic patients with a regular intake of diclofenac. It is interesting to point out that alanine transaminase (ALT) values higher than 10 × ULN were only identified in 0.5% of cases[25]. The incidence of diclofenac liver-related hospitalizations in this study was 16 per 100 000 patient-years. Through these results, the authors provide evidence that diclofenac is a very safe drug. The

small number of related hospitalizations (0.023%), and Hy's cases (transaminases > × 3 ULN and bilirubin > 2 ULN or a fatal outcome or liver transplantation) (0.012%) are the strongest evidence showing that diclofenac bears a low liver toxicity rate.

These data are in concordance with those observed by Traversa and co-workers showing ibuprofen and naproxen also displayed a low hepatotoxicity rate. However, in this latter study nimesulide had a higher hospitalization rate when compared with a past control cohort (33 per 100 000 patient-years)[23]. In a systematic analysis of several randomized studies, Rostom and co-workers also found a very low frequency of hospital admissions due to NSAIDs related-liver disease in 4261 patients (3 per 100 000 patient) and 0% when diclofenac was evaluated separately[21].

Diclofenac is a typical example of the combination of factors resulting in hepatotoxicity (e.g. drug metabolism, reactive metabolite formation and clearance) determining the actual development and the severity of liver damage. Moreover, diclofenac might produce liver injury through either metabolic idiosyncrasy or an immunological mechanism generated by drug adduct formation[8].

SULINDAC

Sulindac (SLD) is associated with an increased incidence of liver toxicity and serious hepatic reactions (5-10 times) when compared with other NSAIDs. Besides its recognized anti-inflammatory mechanism through the inhibition of cyclooxygenase (COX 1 and 2), SLD became very popular due to its antiapoptotic effect in colonic polyposis treatment[40]. SLD induced hepatotoxicity was more frequently encountered among people over 50 years old. Regarding the mechanism of hepatotoxicity, SLD associated DILI is one other example of a combination of factors as judged by the conflicting results present in the literature. Indeed, in a series of 91 documented cases reported to FDA a predominantly cholestatic pattern was present in 43% while hepatocellular-related changes were found in 25% of patients[41]. Moreover, a hypersensitivity mechanism of liver injury was present in 60% of cases. Zou *et al*[42] recently reported an interesting pilot study showing that co-treatment of SLD and lipopolysaccharide (LPS) caused liver injury in rats. In this context they also found a selectively clotting system activation and fibrinolytic system inhibition in rats treated with SLD/LPS. These changes were also associated with tisular hypoxia and fibrin clot deposit in the hepatic sinusoids[42]. Researchers suggest that these results may be extrapolated to humans with the disease. Furthermore, they hypothesize that hypoxia in the frame of the SLD/LPS association may underlie the idiosyncratic model where the sulfide metabolite probably plays a central role.

Another experimental study carried out by the same authors shows that tumor necrosis factor (TNF)-α augmented the cytotoxicity of SLD sulfide in primary hepatocytes and HepG2 cells. These results suggest that TNF-α can enhance SLD sulfide-induced hepatotoxicity, thereby contributing to liver injury in SLD/LPS-cotreated rats[43].

Regrettably the current coexistence of conflicting and heterogeneous results precludes us from reaching valid conclusions regarding SLD DILI.

IBUPROFEN

Ibuprofen has a recognized anti-inflammatory, analgesic and antipyretic property and is one of the most commonly NSAIDs used worldwide. It is characterized by a high safety profile and very low liver toxicity incidence. Along with paracetamol and aspirin, ibuprofen has become one of the largest ever selling over the counter drugs. It was first introduced to the UK market in 1969 and due to the low rate of gastrointestinal adverse events, it has ever since almost replaced aspirin, indometacin and phenylbutazone in arthritic patients[44]. A scarce number of hepatotoxicity reports involving ibuprofen were published, associated to both hepatocellular and cholestatic liver damage. Indeed, one of the latter cases was linked to vanishing bile duct syndrome[45,46]. It has also been suggested that ibuprofen may increase the risk of liver injury when administered to patients with chronic hepatitis C. An ibuprofen associated increase of transaminases > 5 × UNL was recently reported in three patients with chronic hepatitis C, eventually confirmed by re-challenge[47].

Traversa *et al*[23] in their cohort study that recruited thousands of patients receiving various NSAIDs confirmed that ibuprofen has a very low liver toxicity rate: Only two patients showed ibuprofen-associated liver injury (out of 126 cases that had NSAIDs). Despite the massive use of this drug worldwide, a low rate of ibuprofen liver toxicity along with a low incidence of gastrointestinal, renal and cardiovascular serious events characterizes the safety profile. This is probably based on the fact ibuprofen has a short plasma half life and does not form pathological metabolites.The absence of reports including ibuprofen induced liver injury in several studies and meta-analyses, strongly suggests that ibuprofen is an unlikely cause of liver disease[48-50].

COXIBS

Coxibs are NSAIDs designed to selectively inhibit COX-2. Lately, this group of drugs has been gaining worldwide popularity due to a much better gastrointestinal safety profile when compared with nonselective NSAIDs[25]. However, NSAIDs-induced cardiovascular adverse events have generated significant controversy[51,52]. Due to increased risk of myocardial infarction and arterial hypertension, rofecoxib was removed from the market by Merck in 2004[53]. Valdecoxib was also voluntarily discontinued by manufacturer Bextra, Pfizer Canada Inc and by FDA in 2005 because of severe allergic skin lesions including cases of Stevens-Johnson syndrome and also because of an increased risk of heart and stroke attack[54]. On the other hand, celecoxib continues to be marketed in many countries. Laine and coworkers recently published a comprehensive evaluation of the literature up to 2007

analyzing controlled trials, meta-analyses and reviews related to the safety profile of selective inhibitors of COX-2 in patients with osteoarthritis (OA)[55]. Their results are truly encouraging and show that coxibs have a therapeutic efficacy comparable to other NSAIDs and higher than that of acetaminophen. This was observed when patients with OA were treated for moderate to severe degree of pain. Through meta-analysis the authors documented that coxibs have a 74% lower risk of gastro-duodenal ulcer complications. In contrast, they found a double risk of myocardial infarction vs placebo and naproxen treated patients. There were no significant differences in cardiovascular risk between coxibs compared with non-naproxen NSAIDs. Despite these encouraging results, FDA reported an alert related to the increase of cardiovascular risk induced by coxibs.

Coxib-induced liver injury is an uncommon event and the annual reported incidence of hepatotoxicity is 1 in 100 000 exposed persons[56]. A long term study evaluating the safety profile of celecoxib in arthritics patients (Celecoxib Long-term Arthritis Safety Study-CLASS) found increased transaminase level in 0.6 % patients[57].

A rise of transaminase level was also reported and associated with rofecoxib (2%) and with higher doses of lumiracoxib (3%). In this study, a higher frequency of clinical hepatitis was found in patients receiving 400 mg of lumiracoxib when compared with ibuprofen and naproxen treated patients[58]. In another survey, lumiracoxib was linked to severe hepatocellular necrosis[59]. Health authorities from United Kingdom subsequently removed it from the market. Scottish authorities reported 20 cases of severe liver disease probably associated with lumiracoxib. FHF was documented in 14 out of 20 patients (two patients died and three patients needed liver transplantation). In addition, recent postmarketing reports from Australia of severe hepatic reactions with lumiracoxib at doses of at least 200 mg (two patients died and 2 underwent liver transplantation) led also to its withdrawal from the market in that country[60].

On the other hand, rofecoxib was associated with a low rate of hepatic reactions and an increase of ALT $\geqslant$ 3 × UNL was documented in 1.8/100 000 exposed persons[55], but despite this excellent safety profile, Yan and colleagues reported two well-documented cases of cholestatic hepatitis induced by rofecoxib[61]. The first patient showed a high level of alkaline phosphatase (APH) associated with hepatocellular injury in zone 1 whereas in the other case a significant increase in ALT associated with a minimum increase of APH was documented. In this latter patient mild liver damage in both acinar zones 1 and 3 was described. In contrast, four other published cases of rofecoxib induced liver toxicity were characterized by predominant cholestatic presentation[62,63].

To our knowledge no case of etoricoxib severe hepatotoxicity has ever been published. However, transaminase elevation (3 × ULN) has been reported in 1% of patients treated with etoricoxib for up to one year[21,64].The mechanism of liver damage induced by coxibs has not yet been completely elucidated. Kung and co-workers recently suggested that the bioactivation of lumiracoxib and its metabolite [4'-hydroxylumiracoxib (M5)] may produce GSH depletion, covalent binding to proteins and oxidative stress, that in turn may lead to liver injury[65].

Nevertheless, hepatotoxicity caused by non-selective NSAIDs has been more extensively studied. Furthermore, mitochondrial injury, cholestasis and oxidative stress induced by a reactive metabolite formation constitute the most conspicuous molecular reported disorders. An attractive hypothesis suggests that NSAIDs inhibition of COX-2, might cause liver damage through a prostaglandin (PGs) pathway. Regarding this concept the authors proposed that the inhibition of PGE2 could down regulate the antiapoptotic mitochondrial protein Bcl-2, which protects against bile acid induced apoptosis[66].

OXICAMS

Oxicams induced hepatotoxicity is an uncommon clinical situation. Piroxicam induced severe hepatocellular necrosis was the most frequent reported clinical pattern[35,67,68]. Uneventful recovery, death and need of liver transplantation have all been reported[69,70]. On the other hand, a clinical and histological pattern of hepatocellular plus cholestatic (mixed) injury was also associated with piroxicam in one single case. LFTs normalization was observed in this patient within 4 mo after starting the clinical disease[71], Interestingly, a case of severe intrahepatic cholestasis linked to a long period of piroxicam intake, was originally described 20 years ago[72].

Only two patients with piroxicam-induced liver toxicity were admitted to our liver unit during the last three decades (unpublished data). The first patient was a 44-year-old woman with clinical and histological evidence of submassive necrosis. The patient developed ascites and liver failure after 28 d of drug intake and uneventfully recovered without liver transplantation in 95 d from clinical onset. The other case was a 42-year-old man admitted with clinical and biochemical manifestations of severe cholestasis after piroxicam treatment as the single medication for 58 d. Liver histology showed a typical hepato-canalicular cholestasis associated with ductopenia (Figure 1). This latter case progressively evolved to prolonged cholestasis with asthenia, anorexia and intolerable itching. He underwent corticosteroids therapy for 30 d. We were able to document a complete biochemical recovery 120 d from the clinical onset.

Other oxicam derivatives were also occasionally implicated in cases of acute cholestatic hepatitis included isoxicam and droxicam[73].

The mechanism of oxicams-induced hepatotoxicity appears to be idiosyncratic and dose independent. Due to the absence of immunoallergic features in most of the reported cases, it is very difficult to support an immune-mediated mechanism of liver injury[74].

NIMESULIDE

Nimesulide has analgesic, anti-inflammatory and anti-

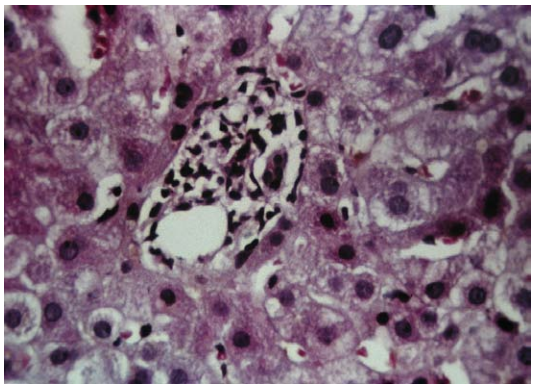

Figure 1 Piroxicam induced hepato-canalicular cholestasis associated with ductopenia (notice absence of bile duct in the portal tract).

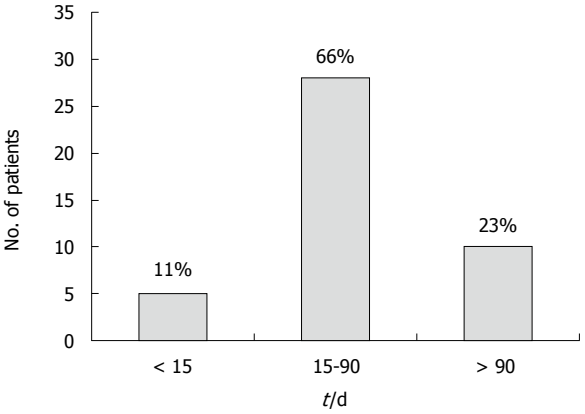

Figure 2 Latency (time from nimesulide intake to clinical onset) in 43 patients.

pyretic activity due to potent inhibitory effects on the COX-2 enzymes. Nimesulide bears a good gastro-intestinal tolerance. The mechanism of action has been attributed to a unique chemical structure of the sulphonanilides class of NSAIDs[75].

Our group in Argentina reported the first observation linking nimesulide with liver toxicity in 1997[76]. Since then, a steady flow of reports confirmed severe forms of hepatotoxicity, to the point that national health authorities of several countries withdrew nimesulide from the market[77-88]. Despite this, nimesulide commercialization is still maintained in several European countries, although the EMEA reports recommend a length of therapy restricted to 15 d and maximal dosage of 100 mg/d[13]. Controversy regarding nimesulide persists due to the fact that clinical series reports and epidemiological trials continue to involve nimesulide in severe liver damage[19,89,90]. On the other hand, health institutions conclude that nimesulide-induced-liver injury is statistically comparable to that of the remainder of the NSAIDs[91,92].

In our institution, 5 out of 30 cases (17%) had severe liver injury[93]. In 2009 our series included 43 well documented cases of nimesulide-induced liver damage associated to a wide clinical and histological spectrum of hepatotoxicity[94]. To our knowledge this constitutes the largest series of nimesulide hepatotoxicity ever reported. The

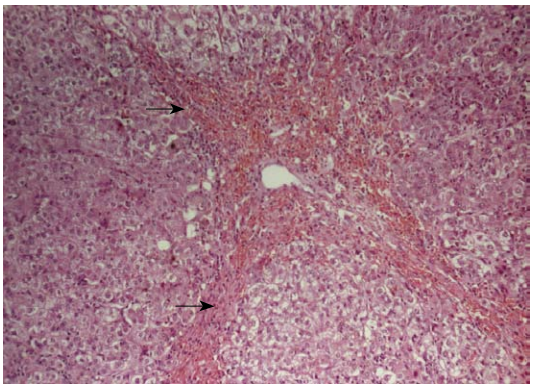

Figure 3 Acute hepatitis induced by nimesulide (hepatocellular collapsed areas are shown with arrows).

main clinical symptoms at presentation are jaundice (70%), malaise (65%) and pruritus (50%). Interestingly, two thirds of patients start liver toxicity 15 to 90 d after drug intake. Relevant to drug safety, in only 11% latency was shorter than 15 d (Figure 2). On the other hand, normalization exceeded 90 d in 27% of cases[94]. In cholestatic liver injury, normalization of alkaline phosphatase serum level usually takes more time than transaminases (i.e. more than 1 year)[95].

Nine patients in our series developed severe liver disease and FHF was observed in 6 cases. In agreement with the recent publication by Walker *et al*[96], this subpopulation was composed predominantly of females older than 50 years. Two patients died before liver transplant due to multiorgan failure, while a 9-year-old girl successfully underwent orthotopic liver transplantation.

We observed a wide range of variations of ALT/aspartate transaminase level in concordance with Bjarnason who analyzed 33 case reports documenting an elevation of ALT of at least 2-fold in 100%, and a 5-fold elevation in 89% of patients[97].

Nimesulide hepatotoxicity shows a wide spectrum of liver damage including acute hepatitis, cholestasis, mixed forms, massive and submassive hepatic necrosis. We found hepatocellular necrosis (Figure 3) in 64%, cholestatic hepatitis in 27% and pure cholestasis in 9 %[94].

The mechanism of nimesulide induced hepatotoxicity remains unknown. It has been suggested that it could be due to the formation of a reactive metabolite. On the other hand, individual genetic variations in drug metabolism have also been proposed.

Acknowledging the true impact of nimesulide on the liver is not an easy task. Despite the proliferation of reports describing nimesulide-induced severe liver injury (mainly Argentina, Ireland and Finland), the epidemiological studies have almost unanimously concluded that severe hepatotoxicity is of low incidence determining a positive risk-benefit-ratio. Inquiring about nimesulide intake should be incorporated into standard anamnesis of liver disease, especially when acute liver damage is being investigated.

Addendum

Other than the previously analyzed drugs, indomethacin,

naproxen, meloxican, tenoxican and etodoloc have also been associated with various hepatic reactions[73].

CONCLUSION

Aspirin was the first discovered NSAID. Dose dependent liver injury is accepted as the prevalent mechanism. Liver toxicity rate is very low currently since aspirin has been replaced by paracetamol and ibuprofen in pediatric patients and in various rheumatic diseases.

Diclofenac is probably the most used NSAID in rheumatology. Severe liver reactions and diclofenac hospitalization rate are uncommon. An increase in ALT levels of 3-10 × ULN is observed in 3% of cases.

Sulindac induced hepatotoxicity was documented more than fifty years ago. Liver damage occurrence was reported to be 5-10 times higher than that of other NSAIDs. A hypersensivity mechanism of liver injury was the most prevalent liver reaction.

Ibuprofen has the highest liver safety profile among NSAIDs and showed no severe liver injury in larger studies. Along with paracetamol and aspirin, it is considered one of the most common over the counter NSAIDs sold in the world.

Coxibs have currently replaced several NSAIDs due to safer GI profile. However, the high rate of cardiovascular events associated to rofecoxib is the main drawback related to drug marketing. Despite liver damage being a rare clinical situation, lumiracoxib has been discontinued in several countries due to severe hepatotoxicity.

Oxicams are associated with a well-documented hepatic safety profile. Uncommonly, piroxicam may cause severe hepatocellular damage. The clinical and histological pattern may be mixed or associated to clinical and biochemical prolonged cholestasis with or without ductopenia. Isoxicam and droxicam were only linked to liver toxicity in sporadic reports. The mechanism of liver damage appears to be an idiosyncratic one.

Nimesulide was removed from the market in several countries due to severe liver damage described in clinical series, but various epidemiological surveys do not document these findings. EMEA recommends that nimesulide should only be used for short periods at daily doses not higher than 200 mg/d in adults.

In summary, neither documenting the possibility of the causative role of a drug when confronting liver damage in an individual patient nor determining the true incidence of NSAIDs induced hepatotoxicity in the general population, are easy tasks. Rigorous data collecting, caution and clinical commitment are required when judging potential hepatotoxicity. The clinician always needs to critically evaluate the possibility whether other factors may play a role in the actual findings.

Despite the shortage of well-designed epidemiological studies, there is evidence showing that most of the NSAIDs are safe drugs with low risk of liver injury (mostly ranging from 0.29-3.1/100 000 exposed individuals when recent based-population studies were analyzed).

Both sulindac and nimesulide have been linked to a higher frequency of liver damage. NSAIDs induced liver injury which might potentially lead to a fatal outcome or need liver transplantation. As in other forms of DILI, jaundice entails poor prognosis with 25% of jaundiced patients developing severe liver disease. Drugs with an increased risk of liver damage should undergo close LFTs monitoring in order to prompt drug withdrawal to avoid severe hepatotoxicity.

ACKNOWLEDGMENTS

I would like to thank Professor Luis Colombato for his support and for reviewing this manuscript and to Professor Miguel Bruguera for his counsel and advice.

Abstract

Laparoscopically assisted colorectal procedures are time-consuming and technically demanding and hence have a long steep learning curve. In the technical demand, surgeons need to handle a long mobile organ, the colon, and have to operate on multiple abdominal quadrants, most of the time with the need to secure multiple mesenteric vessels. Therefore, a new surgical innovation called hand-assisted laparoscopic surgery (HALS) was introduced in the mid 1990s as a useful alternative to totally laparoscopic procedures. This hybrid operation allows the surgeon to introduce the non-dominant hand into the abdominal cavity through a special hand port while maintaining the pneumoperitoneum. A hand in the abdomen can restore the tactile sensation which is usually lacking in laparoscopic procedures. It also improves the eye-to-hand coordination, allows the hand to be used for blunt dissection or retraction and also permits rapid control of unexpected bleeding. All of those factors can contribute tremendously to reducing the operative time. Moreover, this procedure is also considered as a hybrid procedure that combines the advantages of both minimally invasive and conventional open surgery. Nevertheless, the exact role of HALS in colorectal surgery has not been well defined during the advanced totally laparoscopic procedures. This article reviews the current status of hand-assisted laparoscopic colorectal surgery as a minimally invasive procedure in the era of laparoscopic surgery.

INTRODUCTION

Since its introduction in 1991, the number of performed laparoscopic colorectal surgery has remained a minority[1-3]. This was attributed to the fact that such procedures are time-consuming, technically demanding and have a long steep learning curve[4]. In the technical demand, surgeons need to handle a long mobile organ, the colon, and has to operate on multiple abdominal quadrants most of the time with the need to secure multiple mesenteric vessels. However, the most important deterring reason was the fear that laparoscopic colectomy was considered oncologically unsound in the management of colorectal cancers[5]. Therefore, a new surgical innovation called hand-assisted laparoscopic surgery (HALS) was introduced in the mid 1990s as a useful alternative to totally laparoscopic procedures[6-8]. This hybrid operation allows the surgeon to introduce the non-dominant hand into the abdominal cavity through a special hand port while maintaining the

pneumoperitoneum[6,7]. This innovative technique met with fierce resistance and its validity was questioned. Nevertheless, there has been an upsurge in the performance of both laparoscopic and hand-assisted laparoscopic colectomy (HALC) over the past 5 years. The reasons are the introduction of more versatile laparoscopic instruments, the introduction of new vessel-sealing devices like the harmonic scalpel and Ligasure, and various laparoscopic endo-staplers. This has enabled surgeons to perform laparoscopic colorectal procedures without the need for a single intracorporeal knot or suture. Another important factor that has contributed tremendously to this upsurge is the emergence of a level I evidence confirming that the laparoscopic colorectal technique is as oncologically sound as the open procedure[9,10]. The European Cooperation in Science and Technology (COST) multi-institutional study suggested that the laparoscopic approach is an acceptable alternative to open surgery for colon cancer with a similar rate of recurrent cancer after laparoscopically assisted colectomy (LAC) and open colectomy[9]. However, the questions remain: is HALC an alternative to LAC? Is it second best? Or are they complementary to each other? This article reviews the current literature in an attempt to demonstrate the status of hand-assisted laparoscopic colorectal surgery as a minimally invasive procedure in the era of laparoscopic surgery.

ARGUMENT FOR HALC

The proponents of HALC claim that a hand in the abdomen will restore the tactile sensation which is usually lacking in laparoscopic procedures. It also improves the eye-to-hand coordination, allows the hand to be used for blunt dissection or retraction and also permits rapid control of unexpected bleeding[6-8,11,12]. All of those factors can contribute tremendously in reducing the operative time. Moreover, HALC is also considered as a hybrid procedure that combines the advantages of both minimally invasive and conventional open surgeries. It is also strongly argued that if an incision is needed to extract the resected specimen at the end of the laparoscopic procedure, then such an incision may be inflicted earlier in the procedure and be utilized as a hand port. However, this new innovation was not quickly embraced and has been fiercely rejected by the surgical community.

ARGUMENT AGAINST HALC

The opponents argued that introducing a hand in the abdomen during any laparoscopic procedure violates the fundamental principles of minimally invasive surgery (MIS) and makes maintenance of pneumoperitoneum difficult. Furthermore, if this new surgical innovation is adopted, one may witness the birth of a new generation of surgeons who is reluctant to learn totally laparoscopic techniques; a generation who will be offering their patients a "second" best procedure[13]. Also, this new innovation is more aggressive and traumatic as the incision for the hand insertion and specimen extraction is inflicted earlier in the operation with persistent and continuous stretch and compression on the wound. It is also speculated that the increased handling and mobilization of the bowel will result in the development of postoperative ileus and intra-abdominal adhesions. Moreover, there is uncertainty about the long-term results such as development of adhesive small bowel obstruction and ventral hernias, *etc*. Other arguments focused on the cost incurred by the use of the hand port, the comparatively larger size of the hand port and the extraction incision, obstruction of the operative view by the inserted hand and the ergonomics of this technique as up to 20% of surgeons reported forearm fatigue and wrist pain at the end of the procedure[14]. Hence, it is difficult to convince experienced laparoscopic surgeons to introduce a hand in the abdomen in order to speed up the procedure and it remains questionable whether there is actually a need for them to do so[13].

INDICATIONS AND CONTRAINDICATIONS OF HALC

HALC can be offered to all patients who are undergoing any form of colorectal resection for benign as well as malignant conditions. The procedure is best suited for the obese especially those with body mass index (BMI) of 40 or more, as the conversion rate is high if the procedure is conducted laparoscopically[13]. HALC is also indicated in cases where the pathology is bulky and whenever the laparoscopic surgeon is contemplating conversion of the laparoscopic procedure to an open technique due to unexpected difficulties during the procedure[13]. Similarly, it can be utilized whenever the surgeon encounters difficulty or wants to speed up the operation pace in areas where there is laparoscopic technical difficulties such as taking down the splenic or hepatic flexures. It can also be considered in cases of total colectomy when an hour saving in the operating time can be gained[13]. However, there is a doubtful advantage of HALC in low rectal surgery over the laparoscopic technique.

Therefore, generally speaking, HALC should be avoided in patients with low BMI, thin patients with a small abdomen, and in pediatric patients. It is also contraindicated when the pathology is non-bulky and the surgeon's hand is huge.

HAND PORTS

Hand ports facilitate the hand insertion; act as specimen retrieval site and also as a wound protector. They further serve as portals for construction of extracorporeal anastomoses and can also serve as laparoscopic trocar sites. The latter permits selective use of HAL and laparoscopically assisted (LA) techniques at various times during the same operation. The first generation of hand ports was cumbersome, and allows loss of pneumoperitoneum due to gas leak. This gave HALS a bad reputation in its early days. However, newer hand ports devices have better sealing mechanisms and are more user friendly abolishing

Figure 1 An operative picture showing the placement of the hand port and other trocars.

the initial criticism of the old hand ports. Currently, there are varieties of hand ports, but the most commonly used are LapDisc (Johnson and Johnson Endosurgery, USA) (Figure 1) and Gelport (Covidien, Autosuture, USA)[14,15].

Some new special finger mounted surgical instruments that may help some delicate steps of surgical procedures such as intracorporeal dissection and cutting, have been designed for HALS. However, there have been few reports about their efficiency and usefulness in clinical practice.

HALS *VS* OPEN COLECTOMY

There is no doubt that HALC is far superior to open colectomy (OC) as it preserves the advantages of MIS. There are three randomized controlled trials (RCT) that compared HALC and OC surgery[16-18]. The first RCT that compared two well matched groups: 41 patients with HALC *vs* 40 with OC undergoing elective management of right-sided colonic cancer[16] found that HALC took significantly longer time to perform (110 min *vs* 97.5 min, $P = 0.003$), but resulted in significantly less blood loss (35 mL *vs* 50 mL, $P = 0.005$) and was associated with significantly less pain, less parenteral and enteral analgesia[16]. Moreover, patients receiving HALC recovered faster, and had a shorter length of hospitalization (7 d *vs* 9 d, $P = 0.004$). The 5-year survival rate was similar between the two groups (83% *vs* 74%, $P = 0.90$)[16].

The second RCT evaluated the postoperative recovery after HAL ($n = 30$) *vs* open ($n = 30$) restorative proctocolectomy with ileal pouch anal anastomosis for ulcerative colitis and familial adenomatous polyposis[17]. The operating time was longer in the HAL group compared with the open group (210 and 133 min, respectively; $P < 0.001$). However, there were no significant differences in either narcotics requirement or morbidity or postoperative hospital stay (20% *vs* 17%, and 10 d *vs* 11 d, respectively). Moreover, there was no difference between the two procedures in quality of life (QOL) assessment score in the 3 mo after surgery. However, the HAL procedure was more costly than the open procedure[17].

In the third RCT, Kang *et al*[18] randomized 60 patients into two well-matched groups: HALC ($n = 30$) and OC ($n = 30$) for the management of benign or malignant colorectal diseases. The patients undergoing HALC had a significantly shorter hospital stay and incision length, faster recovery of gastrointestinal function, less analgesic use and blood loss, and lower pain scores on the 1st, 3rd and 14th postoperative days. Moreover, there were no significant differences in operating time, complications, or time to recover to normal[18].

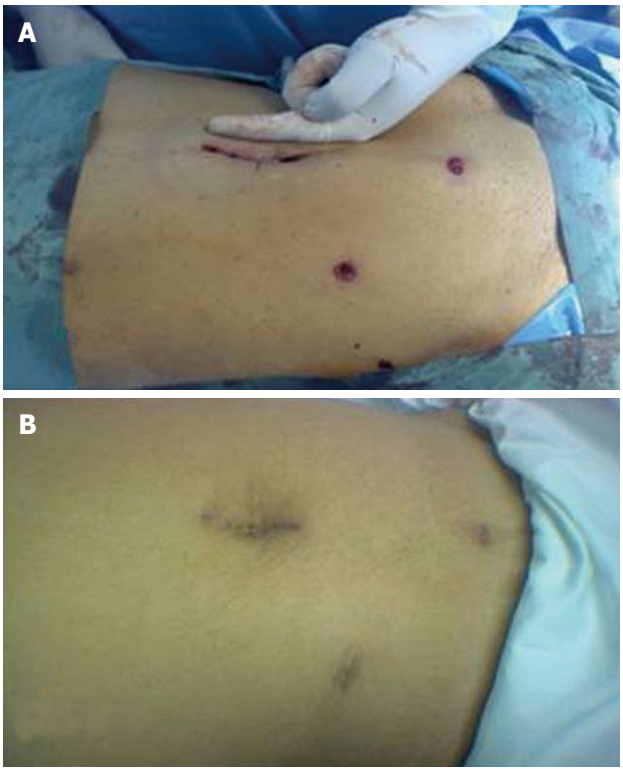

Figure 2 Cosmetic results after hand-assisted laparoscopic colectomy. A: It shows the hand port site closure and the trocar sites at the conclusion of hand-assisted laparoscopic sigmoid colectomy; B: It shows the operative wounds 2 mo after the procedure. Note the shrinkage of the port site scar and the acceptable cosmesis.

A fourth comparative study that aimed to compare the QOL, functional outcome, body image, and cosmesis after hand-assisted laparoscopic (HALRPC) *vs* open restorative proctocolectomy (ORPC) in 53 patients who completed the QOL and functional outcome questionnaires[19] found no differences in the functional outcome, morbidity, or QOL between the two groups. However, at a median of 2.7 years after surgery, the body image and cosmoses scores of female patients were significantly higher in the HALRPC group[19].

In summary of the above RCTs (Table 1), HALC takes longer time, but is associated with less blood loss, less pain, faster postoperative recovery with a shorter length of hospital stay and incision than OC. Furthermore, there is no difference in the complication occurrence, and HALC is associated with higher body image and cosmesis scores in female patients (Figure 2A and B), but is more costly than OC.

HALC *VS* LAC

A review of the literature yielded 8 important studies which compare HALC and LAC; 4 randomized trials[14,20-22], 2 prospective non-randomized[23,24] and 2 large retrospective studies[10,25]. The HALS study was conducted by 10 surgeons from Europe and America and included only 40 patients who were randomized into HALC (18 patients) and LAC (22 patients)[14]. This study, though small in size,found no significant difference between the two groups in term of operating time (142 min *vs* 151 min), length of incision (7.4 cm *vs* 7.0 cm), rate of major complications and length of hospital stay (7 d *vs* 6 d). However, there were fewer conversions in the HALC group (14% *vs* 22%). The HALS study group concluded that HALC retains the benefits of MIS[14]. The second study by Targarona *et al*[20] included a larger number of patients: 54 patients randomized equally into HALC and LAC groups. The operating time and clinical outcome were similar. However, the conversion rate was much higher in the LAPC group (23% *vs* 7%). Of interest, 4 of 6 conversions in the laparoscopic group were completed with the hand-assisted technique. There is another interesting finding in this study that the inflammatory (tissue injury) markers such as interleukin-6 and C-reactive proteins were increased in the hand-assisted group. This may lead us to believe that HALC is a more aggressive procedure than LAC, but preserved the features of MIS. This has also opened the door for using HALC as a halfway house procedure and adjunct to LAC when difficulties are encountered and when conversion to the open procedure is contemplated during laparoscopic colectomy[13].

The Minimally Invasive Therapy and Technology (MITT) group study[21] consisted of a multi-centre (5 hospital, 11 surgeons), unblinded RCT which compared HALC and LAC for segmental (SC) and total colectomy/proctocolectomy (TC). The HALC group (47 patients: 33 SC and 14 TC) and LAC group (48 patients: 33 SC and 15 TC) were both matched for age, sex, diagnosis, BMI and previous surgery. There was no significant difference in the complication rates (19% *vs* 21%) and long-term clinical outcome, but the extraction incision was bigger (8.2 cm *vs* 6.1 cm) and the conversion rate was lower (2% *vs* 12.5%) in the HALC group. Moreover, there were no apparent differences in the time for bowel function recovery, tolerance of diet, length of hospital stay, postoperative pain scores, or narcotic use between the two groups. Another interesting finding in this study is that the operating time can be reduced by more than 30 and 60 min in SC and TC, respectively if the procedure is conducted by HALC instead of LAC[21]. The last RCT compared 35 HALRPC and 30 LARPC[22]. There were neither conversions nor intraoperative complications, and the median operating time was longer in LAPRPC group (298 min *vs* 214 min, $P < 0.001$). Morbidity and reoperation rates were comparable (29% *vs* 20% and 17% *vs* 10%, respectively). The median hospital stay was 9 d in the laparoscopic group compared with 10 d in the HAL group. Moreover, there were no differences in QOL and the total costs[22].

A prospective non-randomized case control study on ultra-low anterior resection was reported by Tjandra *et al*[23] with an equal number of patients (32 HALC and 31 LAC). There were no conversions in both groups with similar oncological harvest in term of tumor clearance and number of lymph nodes retrieved. The length of hospital stay was the same (5.9 d *vs* 5.8 d). But, the operating time was significantly shorter in the HALC group (170 min *vs* 188 min). The duration needed for postoperative narcotics was significantly longer (3.0 d *vs* 1.5 d) and the bowel function recovery and flatus passage were delayed (3.4 d *vs* 1.9 d) in the HALC group. This study has confirmed some difference in recovery in favor of the laparoscopic group. This difference is, however, of doubtful clinical significance as the length of hospital stay is unaffected[23].

Also a prospective comparative study analyzed 258 well-matched patients undergoing HALS ($n = 109$) or LAC ($n = 149$)[24]. A significantly greater proportion of HALS patients underwent complex procedures and extensive resections. However, there were no differences in the conversion rates (15% *vs* 11%, $P = 0.44$), intraoperative complications (4% *vs* 1%, $P = 0.17$), the 30-d morbidity (18% *vs* 11%, $P = 0.12$) and surgical reinterventions (2% *vs* 1%, $P = 0.58$). There was no difference in the recovery judged by days to pass flatus (mean 3 d *vs* 3 d), however HALS took a longer operating time (276 min *vs* 211 min, $P < 0.0001$) and resulted in 1 d longer stay in hospital (6 d *vs* 5 d, $P = 0.0009$). It was concluded that HALS facilitates the expansion of a minimally invasive colectomy practice to include more challenging procedures while maintaining the short-term benefits of LAC[24].

A large retrospective single institution study from the Lahey clinic[25] comparing HAL sigmoid colectomy ($n = 66$) with LA sigmoid colectomy ($n = 85$) revealed no

Table 2 Published studies comparing hand-assisted laparoscopic colorectal surgery with laparoscopically assisted colorectal surgery

Study, yr	Patients (HALC *vs* LAC)	OT (min)	Incision length (cm)	Complications (%)	Conversion rate (%)	LOS (d)	Bowel function (d)	Comments and conclusion

Ringley *et al*[10], 2007	22 *vs* 18	120 *vs* 156	7 *vs* 5.5	Similar	NA	4 *vs* 4	NA	HALC is associated with shorter OT and greater lymph node harvest, but equal I.O blood loss, pedicle length and LOS

HALC: Hand-assisted laparoscopic colectomy; LAC: Laparoscopically assisted colectomy; OT: Operative time; LOS: Length of hospital stay; NA: Not available; MIS: Minimally invasive surgery; HALRPC: Hand-assisted laparoscopic restorative proctocolectomy; QOL: Quality of life; POD3: Postoperative day 3.

significant difference in bowel function recovery (2.5 d *vs* 2.8 d), length of hospital stay (5.2 d *vs* 5.0 d) or short-term complications such as anastomotic leak, ileus and wound infection (21% *vs* 23%) between the two groups. However, there was significant difference in the operating time (189 min *vs* 203 min) and conversion rate (0% *vs* 13%) in favor of the HALC group. The incision length was, however, significantly smaller (8.1 cm *vs* 6.2 cm) in the LAC group[25].

Another retrospective review of 40 patients (22 HALC and 18 LAC) comparing conventional laparoscopic and hand-assisted oncological segmental colonic resection was reported by Ringley *et al*[10]. HALC was found to be associated with a shorter operating time (120 min *vs* 156 min, $P < 0.05$) and greater lymph node harvest (16 *vs* 8, $P < 0.05$), but equal intraoperative blood loss, pedicle length and hospital stay (4 d)[10]. LAC was completed with smaller incision length to retrieve specimen (7 cm *vs* 5.5 cm, $P < 0.05$), but this 1.5 cm difference is of doubtful clinical significance[10]. Table 2 summarizes the above studies that compare HALC and LAC and their conclusions. Based on the reviewed literature, the following results were found between HALC and LAC: (1) HALC offers the same MIS benefits as LAC; (2) HALC has a shorter operative time and lower conversion rate; (3) They both have comparable complication rate and length of stay; (4) The incision length is bigger in HALC; (5) There an increased level of inflammatory markers in HALC; (6) There is an increased need for postoperative narcotics analgesia after HALC; (7) Bowel function recovery and passage of flatus are somewhat delayed in HALC, but this is of doubtful clinical significance; and (8) HALC is more suitable for the obese patients.

IMPACT OF HALC ON SURGICAL TRAINING

It has been postulated that "It takes 6-12 mo to teach fellows how to take down the splenic flexure independently using straight laparoscopic methods whereas most fellows become proficient at the same task about HAL method after performing 10-15 cases"[13] and it was also claimed that "a surgeon who uses either straight laparoscopic or HAL methods extremely will be handicapped"[13]. It was therefore advisable that trainees embrace and master both techniques. A recent comparative study measuring the percentage of left-sided HALC or straight LAC cases completed by a trainee surgical resident found that straight laparoscopy were more likely completed by the resident without the intervention of the attending physician than HALC (LAC, 88%; HALC, 72%; $P = 0.06$)[26]. Differences in the mean operating time favoring LAC were noted (HALC, 142 min *vs* LAC, 133 min; $P = 0.04$)[26]. However, the occurrence of complications was similar in the two groups (HALC, 19% *vs* LAC, 21%), so was the rate of conversions (HALC, 5.6% *vs* LAC, 4.5%). It was concluded that trainee surgical residents may be more successful in completing LAC than in adjusting to the novel HALC approach during training. This is somewhat surprising, but it may be explained by the hindrance of

the laparoscopic view by the intervening hand during HALC, especially in the early learning curve of the trainee surgeons.

A 25-question survey organized by The American Society of Colon and Rectal Surgeons about hands-on training cadaver courses, found that a laparoscopic colon resection was performed within 1 wk of the course by 52% of participants and within 1 mo by 90%[27]. Hand-assisted technologies have lowered the threshold for performing the first LAC in 62% of participants. Most participants (77%) declared that the most important factor in the course selection was a cadaver model. It was therefore concluded that cadaver courses enabled rapid integration of laparoscopic colon resection into clinical practice and that hand-assisted technologies promoted technique acquisition[27]. The author conducted HALC workshops on live animal (sheep) which made consultant surgeons with no experience in laparoscopic colectomy more confident in using the HALS technology they obtained in the animal workshop as a bridge towards totally laparoscopic procedures in humans[15].

COST ANALYSIS

A concern has been raised regarding the higher direct cost of HALC, however, the results are inconsistent. In a RCT that evaluated postoperative recovery after HAL *vs* open restorative proctocolectomy with ileal pouch anal anastomosis for ulcerative colitis and familial adenomatous polyposis[17], the HAL procedure was found more costly than the open procedure (the median overall cost was $16.728 for HAL procedure and $13.406 for the open procedure; $P = 0.095$)[17]. In a retrospective analysis of 73 patients undergoing LAC *vs* 101 undergoing HALC[28], it was found that the operative cost and cost of consumables were higher for HALC (US$4024.2 *vs* US$3568.1, $P = 0.01$ and US$1724.7 *vs* US$1302.7, $P < 0.001$, respectively). However, the total costs were not significantly different between the two procedures (HALC US$8999.8, LC US$7910.7, $P = 0.11$). In a more recent US study that looked at direct costs for the operating room, nursing care, intensive care, anesthesia, laboratory, pharmacy, radiology, emergency services and consultation, and professional and ancillary services related to the initial hospitalization and readmissions associated with 100 HALC *vs* 100 matched LAC cases which were performed concurrently[29], there were no differences in the operating time (168 and 163 min, respectively), length of hospital stay (4 d), readmission (6% and 11%, respectively), or reoperation rates (5% and 9%). The overall morbidity was 16% and 32% for HAL and LAC, respectively ($P = 0.009$). The major morbidities, including abscess, hemorrhage and anastomotic leak, were also similar in the two procedures. However, operating room costs were increased for HALC (US$3476 *vs* US$3167); the total costs were similar (US$8521 *vs* US$8373). Therefore, it can be concluded that the total costs for HALC and LAC are similar[29] and HALC reserves the benefits of LAC at no extra cost[30].

LONG-TERM COMPLICATIONS OF HALC

As HALS requires a larger incision that that used in totally laparoscopic procedures, it has been postulated that HALS may be associated with more long-term complications such as incisional hernias and adhesive small bowel obstruction. This has been addressed by Sonoda *et al*[31] who compared HALS ($n = 270$) and LAS ($n = 270$) over a median follow-up of 27 mo (1-72 mo). Despite the larger wound in the HALS group (median 75 mm *vs* 45 mm), the incidence of incisional hernia was similar in both groups and the rate of small bowel obstruction was also comparable (4.1% *vs* 7.4%, $P = 0.11$)[31]. Moreover, the incidence of wound infections was also comparable (HALS 6.8% *vs* LAS 4.8%, $P = 0.33$). Interestingly, the converted cases had a significantly higher incidence of incisional hernia than that of the non-converted patients (25% *vs* 5%), although the rate of small bowel obstruction was the same. It was therefore concluded that HALS does not lead to more long-term complications of incisional hernia and small bowel obstruction than totally laparoscopic procedures[31].

CONCLUSION

Based on the available evidence, hand-assisted laparoscopic colorectal resection offers similar short and long-term MIS benefits to that of totally laparoscopically assisted procedures. It combines the advantages of both laparoscopic (minimally invasive) and conventional open surgery. It is safe and feasible in benign as well as malignant colorectal tumors. Furthermore, it is easy to learn, easy to teach and most useful in complex colorectal procedures. Hence, hand-assisted colorectal surgery is advocated first as a 'bridge' and later as an adjunct to laparoscopically assisted colorectal procedures. Moreover, it can be used as an alternative to laparoscopic colectomy in the complex colorectal procedures.

Abstract

Barrett's esophagus is a well-known premalignant lesion of the lower esophagus that is characterized by intestinal metaplasia of the squamous epithelium. It is clinically important due to the increased risk (0.5% per annum) of progression to esophageal adenocarcinoma (EA), which has a poor outcome unless diagnosed early. The current clinical management of Barrett's esophagus is hampered by the lack of accurate predictors of progression. In addition, when patients develop EA, the current staging modalities are limited in stratifying patients into different prognostic groups in order to guide the optimal therapy for an individual patient. Biomarkers have the potential to improve radically the clinical management of patients with Barrett's esophagus and EA but have not yet entered mainstream clinical practice. This is in contrast to other cancers like breast and prostate for which biomarkers are utilized routinely to inform clinical decisions. This review aims to highlight the most promising predictive and prognostic biomarkers in Barrett's esophagus and EA and to discuss what is required to move the field forward towards clinical application.

Key words: Barrett's esophagus; Esophageal adenocarcinoma; Esophageal dysplasia; Prognosis

INTRODUCTION

Barrett's esophagus is defined as an esophagus in which the distal portion of the normal squamous lining has been replaced by a metaplastic columnar epithelium. In order to make a diagnosis of Barrett's esophagus, a segment of columnar metaplasia of any length must be visible endoscopically above the esophagogastric junction and be confirmed or corroborated histologically[1]. This condition usually develops in the context of longstanding, severe gastroesophageal reflux disease (GERD)[2], and is the only recognized precursor lesion for development of esophageal adenocarcinoma (EA). The incidence of EA arising from Barrett's esophagus is variable, depending on the grade of dysplasia associated with it. The risk of progression to cancer increases gradually from 0.5% per year for non-dysplastic Barrett's, to 13% in low-grade dysplasia (LGD) and 40% in high-grade dysplasia (HGD)[3,4].

In Barrett's esophagus, it is widely accepted that there are three main histological subtypes. They include epithelium that comprises mainly a gastric fundus subtype with parietal and chief cells; a junctional (cardia) subtype with mucus-secreting glands; and the distinctive metaplastic columnar epithelium with intestinal-type goblet cells[1,5]. These three histological subtypes occupy different zones in the esophagus. The intestinal-type metaplasia with goblet cells is found most proximally next to the squamous epithelium, followed by the junctional (cardia) subtype in the middle, and the gastric fundus subtype most distally. The relevance of this subgrouping of the histological subtypes of Barrett's esophagus lies in the potential to develop malignancy. The fundic subtype has a very low risk of developing EA malignant potential, whereas the metaplastic columnar epithelium with intestinal-type goblet cells and the junctional (cardia) type have a more significant risk of malignant transformation[6,7]. This concept is important as this together with the problem of defining Barrett's esophagus based on location and length of metaplastic epithelium has led to a detailed discussion in the American Gastroenterological Association Institute technical review on Barrett's esophagus. This meeting redefined Barrett's esophagus as "the condition in which any extent of metaplastic columnar epithelium that predisposes to cancer development replaces the stratified squamous epithelium that normally lines the distal esophagus"[8]. However, it is slowly becoming apparent that the risk for development of EA is not solely limited to the intestinal type and that better designed and powered studies are required to assess properly the true risk of progression in each subtype[9].

During the development of EA, the epithelium accumulates multiple molecular abnormalities and becomes increasingly dysplastic[10]. The diagnosis of dysplasia allows the progression from Barrett's esophagus to EA to be monitored by endoscopic surveillance biopsies with the aim of intervening prior to the development of invasive adenocarcinoma. Although randomized controlled evidence is lacking, EA detected *via* this strategy appears to confer a much better prognosis, as surveillance detected disease is often at an early stage prior to lymph node involvement[11,12].

There are a number of problems with this current clinical algorithm. First of all, a significant proportion of patients with Barrett's esophagus are undiagnosed[13-16], and therefore, will not benefit from any cancer prediction strategies. Second, surveillance is not proven to reduce population mortality and is based on the subjective assessment of dysplasia, which has inter and intra-observer error[17-19]. Lastly, because most patients with Barrett's esophagus are at extremely low risk of developing EA[20], the majority are having unnecessary surveillance, which is cumbersome both for the clinician and the patient, and poses a strain on the healthcare system. A recent review to assess the cost-effectiveness of surveillance of Barrett's esophagus based on a Markov model has revealed that surveillance of Barrett's esophagus for all grades of dysplasia does more harm than good when compared to no surveillance[21]. This report has suggested that surveillance does not produce more quality-adjusted life years than no surveillance, and that there is no apparent survival advantage of cancer detected by surveillance due to a high recurrence rate and increased mortality from surgical interventions. It is hoped that biomarkers assayed in readily obtainable biological samples, such as blood or endoscopic biopsies, can be identified to improve the clinical management at each stage in the disease. Screening biomarkers could enable unidentified cases of Barrett's esophagus to be diagnosed in the population (Figure 1, green arrow), whereas predictive biomarkers could be used as adjuncts or to replace the current surveillance program for the detection of dysplasia, as well as potentially being able to predict which patients are at high risk of developing cancer in the future (Figure 1, blue arrow). For patients presenting *de novo* with EA, prognostic biomarkers could be useful to determine the best therapeutic approach and prognosis (Figure 1, red arrow). In addition, biomarkers might have a role in determining response to treatment including chemopreventive agents, endoscopic treatments for patients with Barrett's, and the use of molecular targeted therapy for those with cancer.

CLINICAL BIOMARKERS

Clinical biomarkers can be defined as a characteristic that can be objectively measured or evaluated as an indicator of normal biological processes, pathological processes or a response to a therapeutic intervention[22]. Importantly, the quantification of biomarkers should aid, improve or alter clinical management. The criteria required for adoption of biomarkers into clinical use are not well defined. Therefore, the Early Detection Research Network (EDRN) has defined five stages for development of biomarkers for risk of progression[23] and similarly, McShane *et al*[24] have recently published recommendations for prognostic tumor marker development (Figure 2). Despite the recommendation of different robust algorithms for biomarker development, fewer than 12 biomarkers have been approved by the US Food and Drug Administration for monitoring response, surveillance and recurrence of cancer at the current time[25]. This is alarming as thousands of biomarkers have been declared to be useful for diagnosis, surveillance or therapeutic markers for diseases. Most of these biomarkers do not progress to clinical practice either due to problems developing accurate assays or because the biomarker lacks sufficient sensitivity and specificity in validation studies[26]. Clearly, a large concerted effort is needed to advance the field of biomarker discovery and clinical implementation.

Biomarkers in Barrett's esophagus and EA are mostly selected due to their role in carcinogenesis. It is clear that during the transition from metaplasia to carcinoma, many molecular alterations take place and they operate together to influence the pathogenesis of dysplasia and EA. Biomarkers can be identified and investigated for their clinical applicability using two different complementary

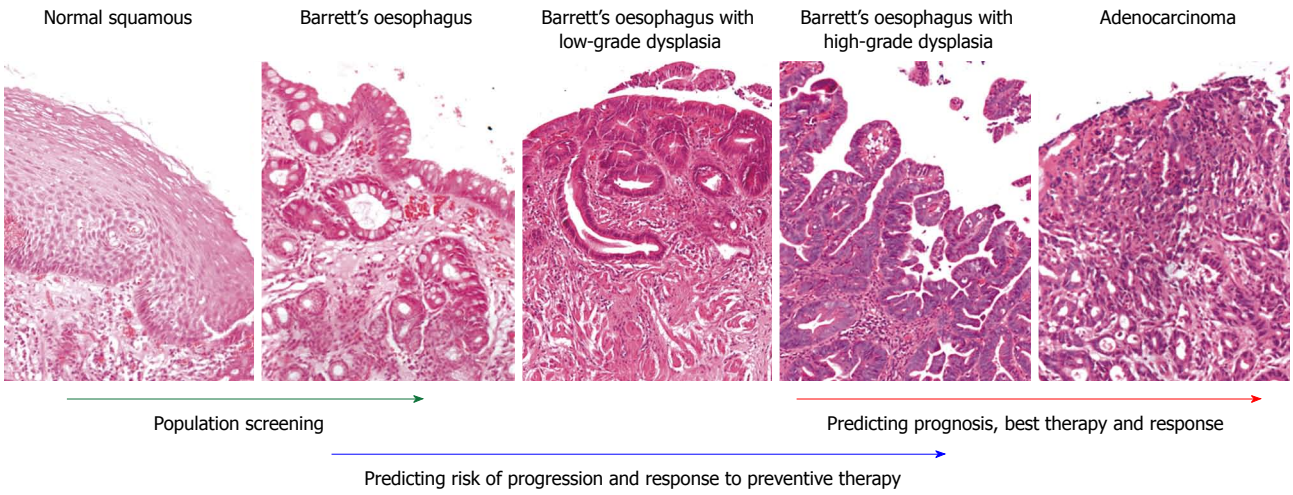

Figure 1 Transition of squamous epithelium to intestinal metaplasia, dysplasia and adenocarcinoma, with potential useful biomarkers at each stage of the disease. The left-most panel shows normal stratified squamous epithelium. The second panel shows Barrett's esophagus without dysplasia, with the presence of goblet cells. The third and fourth panels show Barrett's esophagus with low-grade dysplasia and high-grade dysplasia, whereas the last panel shows adenocarcinoma.

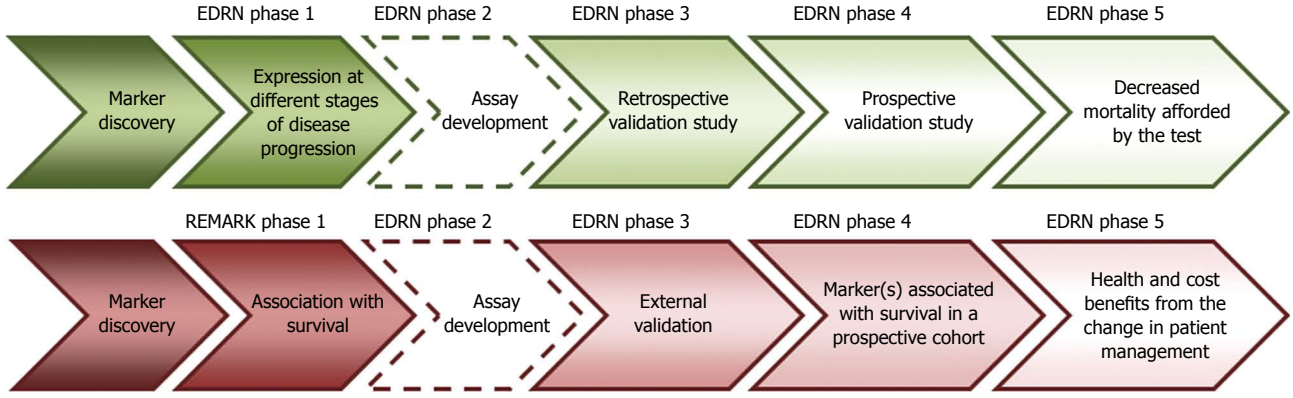

Figure 2 Phases of diagnostic and prognostic biomarker development proposed by the Early Detection Research Network and reporting recommendations for tumor marker prognostic studies before clinical implementation[23,24]. EDRN: Early Detection Research Network; REMARK: Reporting recommendations for tumor marker prognostic studies.

approaches[27]. The first approach is to identify candidate biomarkers from what is currently understood about the disease process. This is a comparatively inexpensive way to identify putative biomarkers and possibly allow for faster clinical implementation of the biomarker. The second method is to use a global screening approach without an *a priori* hypothesis. This has become possible due to the rapid expansion of "omics" technologies, including gene expression analysis, epigenetics, proteomics and single nucleotide polymorphism (SNP)-based platforms. The availability of microarray databases and other datasets on the internet also allows for the interrogation of multiple datasets to identify potential biomarkers. For example, Lao-Sirieix *et al*[28] have identified trefoil factor 3 (TFF3) as a promising biomarker to screen asymptomatic patients for Barrett's esophagus by comparing three publically available microarray databases. However, this approach requires an intensive validation process due to the potential for false discovery and can potentially be expensive and not reproducible between laboratories.

This review focuses on two main areas: (1) biomarkers predictive of progression in Barrett's esophagus, which it is hoped could transform the current surveillance program; and (2) prognostic biomarkers in EA.

PROMISING BIOMARKERS IN SURVEILLANCE OF BARRETT'S PATIENTS

Many biomarkers aimed at predicting progression in Barrett's patients have emerged over several years of research because it is appreciated that current clinical and endoscopic criteria are unable to predict which patients are likely to progress to EA. Biomarkers in Barrett's esophagus can be used for population screening and early detection of disease, confirmation of diagnosis of disease and prediction of risk of progression, which determine the prognosis of patients once adenocarcinoma develops and predict the effectiveness of therapy. Table 1 shows a summary of the biomarkers that have been most extensively investigated and their potential as clinical biomarkers. In studies evaluating the efficacy of the proposed biomarkers to determine the risk of progression from Barrett's

Table 1 Summary of the most promising biomarkers for identifying patients with Barrett's esophagus at high risk of developing esophageal adenocarcinoma

Surveillance biomarker	Highest EDRN stage	Study size (*n*)[1]	Findings	Statistical significance	Ref.
HGD	4	15	Progression to EA in 4 out of 15 patients with unifocal HGD	RR not available	[29]
		485	20 patients with HGD treated with omeprazole only developed EA	RR not available	[30]
		327	33 out of 76 patients with HGD developed EA	RR 28 (95% CI: 13-63)	[31]
		1099	12 out of 75 patients with HGD developed EA	RR 12.1 (95% CI: 5-29.4)	[32]
Aneuploidy and LOH (Reid Panel)	4	243	Panel of biomarkers (LOH of 17p and 9p and DNA abnormalities) can best predict progression to EA	RR 38.7 (95% CI: 10.8-138.5)	[33]
			LOH of 17p alone	RR 10.6 (95% CI: 5.2-21.3)	
			LOH of 9p alone	RR 2.6 (95% CI: 1.1- 6.0)	
			Aneuploidy alone	RR 8.5 (95% CI: 4.3-17.0)	
			Tetraploidy alone	RR 8.8 (95% CI: 4.3-17.7)	
p53 positivity by immunohistochemistry	3	164	Diffuse or intense TP53 staining elevated in patients who developed EA compared to controls	OR 11.7 (95% CI: 1.93-71.4)	[34]
		48	3 out of 5 patients with low grade dysplasia who progressed to high grade dysplasia had positive p53	RR not available	[35]
Mcm2	3	27	Ectopic luminal surface expression predictive of progression to HGD or EA	OR 136 (95% CI: 7.5-2464)	[36]
Cyclin A	3	48	Ectopic luminal surface expression predictive of progression to HGD or EA	OR 7.6 (95% CI: 1.6-37)	[37]
Methylation markers	3	53	Hypermethylation of *p16* (cyclin-dependent kinase inhibitor 2A), *RUNX3* (Runt-related transcription factor 3) and HPP1 (transmembrane protein with EGF-like and two follistatin-like domain 2) associated with an increased risk of progression to high grade dysplasia or EA	OR 1.74 (95% CI: 1.33-2.2), 1.80 (95% CI: 1.08-2.81) and 1.77 (95% CI: 1.06-2.81), respectively	[38]
		195	A 8 gene methylation panel in combination with age could predict half of progressors to HGD or EA who would not have been diagnosed without the use of the panel	RR not available	[39]

[1]Study size includes all patients in study and findings are extracted when relevant. Mcm2: Minichromosome maintenance protein 2; EA: Esophageal adenocarcinoma; HGD: High-grade dysplasia; LOH: Loss of heterozygosity; EDRN: Early Detection Research Network; RR: Relative risk; OR: Odds ratio; CI: Confidence interval.

esophagus to dysplasia and cancer, the odds ratio and relative risks are included whenever data were available in order to give a representation of the usefulness of the biomarkers.

DYSPLASIA

Dysplasia has been assessed as part of routine clinical practice for > 20 years. Although the assessment of dysplasia cannot be measured objectively, it is still considered a biomarker by most institutions, and is the current gold standard for determining the risk for cancer progression. The current dysplasia grading system is the Vienna classification, which divides patients into no dysplasia, LGD and HGD[40]. Due to its routine use, very few studies have been performed to document formally its predictive power. A recent meta-analysis has shown that the incidence of EA in patients undergoing surveillance for Barrett's esophagus rises in a stepwise manner using dysplasia as a biomarker. The incidence of EA was reported to be 5.98 per 1000 patient years, 16.98 per 1000 patient years and 65.8 per 1000 patient years in Barrett's patients without dysplasia, and with LGD and HGD, respectively[4]. However, histological differentiation of the different grades of dysplasia in Barrett's patients presents one of the most difficult tasks for the pathologist. In one study, 50% of Barrett's patients who were identified to have LGD by general pathologists were misdiagnosed. Forty-two percent of these misdiagnosed cases had only Barrett's esophagus without dysplasia, and 8% had HGD[41]. It is clear that histological differentiation between non-dysplastic Barrett's esophagus and LGD in particular is fraught with difficulties with poor intra- and inter-observer agreement.

HGD is known to be a surrogate marker for the high likelihood of progression to EA. Following diagnosis of HGD, endoscopic or surgical intervention is usually considered. Therefore, confirmation by two independent pathologists is a pre-requisite. As a result of the practice for intervention once HGD is detected, data on progression to EA have become much harder to obtain. Studies have shown that the risk of progression to EA ranges from 16% to 59%[31,32] and a proportion of patients in whom HGD is detected will already harbor invasive adenocarcinoma[29,32], although with intensive biopsy protocols and high definition endoscopes, this should no longer be so likely. A more ideal biomarker would be one that is less subjective and that appears earlier in the pathogenetic process, so that intervention could be considered for the highest risk patients earlier in the course of their disease. The evaluation of dysplasia is now well established and it has been suggested that other promising biomarkers are more likely to be used in conjunction with the current system than to replace the histopathological assessment of dysplasia[42].

DNA CONTENT ABNORMALITIES AND LOSS OF HETEROZYGOSITY

The use of DNA content abnormalities (aneuploidy and tetraploidy) and loss of heterozygosity (LOH) as biomarkers to predict progression of Barrett's esophagus to EA has been intensively studied by the Reid group. DNA content abnormalities are a well-known phenomenon in cancer biology. A normal cell contains 46 chromosomes, commonly referred to as 2N, and aneuploidy refers to the state in which cells have an abnormal number of chromosomes. Tetraploidy, on the other hand, specifically refers to cells that have double the number of chromosomes compared to normal cells (4N). In Barrett's esophagus, numerous studies have correlated aneuploidy and specific DNA abnormalities with the progression of Barrett's esophagus to EA[31,43-45], with Reid *et al*[31] producing the best results by combining DNA content abnormalities with LOH. Galipeau *et al*[44] have demonstrated that increased 4N (G2/tetraploid) cell populations predict progression to aneuploidy, and that the development of 4N abnormalities is interdependent with inactivation of the *p53* gene. Using flow cytometry and histology in a systematic endoscopic biopsy protocol, Reid *et al*[31] first described the use of aneuploidy and increased 4N fractions as biomarkers to identify subsets of patients with Barrett's esophagus at low and high risk of developing EA. Using a cut-off for 4N fractions of > 6% as abnormal, Reid has reported that the relative risk of cancer for these patients compared to those below this cut-off value was 7.5 (95% CI: 4-14). In addition, patients who had baseline aneuploidy had a relative risk of cancer of 5 (95% CI: 2.7-9.4) compared to patients who did not have baseline aneuploidy.

p16 and *p53* are two commonly studied tumor suppressor genes that reside on chromosome 9p and 17p, respectively. These two tumor suppressor genes can be silenced *via* LOH, mutations and DNA methylation. Silencing of the p16 allele is thought to be one of the earliest events in Barrett's esophagus, which results in clonal expansion[46]. However, a recent study by Leedham *et al*[47] has demonstrated that Barrett's esophagus can arise from multiple independent clones, which results in clonal heterogeneity. This study was performed by investigating individual crypts microdissected from esophagectomy specimens that contained adenocarcinoma and associated dysplasia, to detect clonal heterogeneity not detected by whole biopsy analysis. Overall, *p16* by itself is unlikely to be an ideal biomarker to predict progression because it appears too early in the pathogenesis, and it has been shown that there is no evidence of association between silencing of *p16* and grade of dysplasia[46]. *p53* LOH, on the other hand, provides one of the most promising biomarkers to predict progression of Barrett's esophagus, as part of the Reid panel. *p53* is a nuclear tumor suppressor protein that is responsible for the integrity of the genetic sequence. Any damage to DNA should result in increased expression of *p53*, which causes cells to arrest at the G1 phase to allow for DNA repair, and if this is not possible, then apoptosis ensues. Silencing of *p53* can occur *via* LOH or mutation of the genetic sequence, thus removing the self repair mechanism. Reid *et al*[48] have performed a prospective cohort study in 325 patients with Barrett's esophagus, and have demonstrated that LOH of chromosome 17p(p53) significantly increased the risk of progression to cancer (relative risk of 16, 95% CI: 6.2-39). In addition, Galipeau *et al*[33] have demonstrated that LOH of 17p can be combined with LOH at 9p, DNA content abnormalities and aneuploidy to form a panel of biomarkers to predict better progression of Barrett's esophagus. This panel of biomarkers provides the best predictor of progression to EA to date (relative risk of 38.7, 95% CI: 10.8-138.5). Each individual marker in the panel could in itself predict progression to EA with varying RR (Table 1), but when combined together in the Reid panel, they can most accurately predict progression to EA.

The panel of biomarkers that incorporate DNA abnormalities and LOH, which have been developed by the Reid group, are not easy to apply to the clinical setting. Efforts have therefore been made to develop alternatives. Fang *et al*[45] and Vogt *et al*[49] have tried to circumvent the problem of a high level technical expertise being required and the laboratory variability associated with flow cytometry, by using image cytometric DNA analysis in smaller studies. In these studies, they have concluded that image cytometry can provide a more sensitive marker than using HGD to identify groups of patients who are likely to progress to EA, and have highlighted that image cytometry has significant advantage over flow cytometry in terms of costs and practicality. These findings, while promising, still require validation with a much larger sample size. The development of high-fidelity DNA histograms generated by automated software to measure aneuploidy further strengthens the role of DNA abnormalities as a biomarker to predict progression in Barrett's patients[50,51]. Other interesting novel techniques to measure aneuploidy and other chromosomal aberrations have also been described in the literature. Li *et al*[52] have demonstrated that the number of SNPs was highly correlated with chromosomal abnormalities in Barrett's esophagus and EA, and have suggested that SNP-based genotyping could possibly be used to stratify the cancer risk in patients with Barrett's esophagus.

As mentioned previously, the use LOH as biomarkers is not without its own problems. The detection of LOH is complex and requires the collection of snap frozen samples, followed by extraction of DNA and an amplification step prior to polymerase chain reaction analysis[53]. This is in addition to the high costs needed to build and maintain facilities to enable the use of this panel of biomarkers in routine medical institutions. An alternative method would be to use fluorescence *in situ* hybridization (FISH) to detect LOH, but this method is limited by poor sensitivity (68.4%) when compared to genotyping[54].

Immunostaining for *p53* provides another alternative to genotyping of chromosome 17p to predict progression of Barrett's esophagus because the presence of *p53* mutations can often cause protein accumulation, which allows for detection by immunohistochemistry[34,35]. Although

the use of immunostaining of *p53* allows easy clinical implementation, its efficacy as a biomarker is limited, and positive staining was only seen in one third of patients in a nested case-control study to evaluate the efficacy of immunostaining for *p53* as a marker to predict progression[34]. This is because staining for *p53* does not always correlate with mutations. In instances in which mutations result in deletion or truncation of *p53*, it will not be detected by immunostaining.

In summary, the detection of aneuploidy and DNA content abnormalities in the Reid panel appears to be one of the most promising biomarker panels to detect the progression of Barrett's esophagus to EA. However, technical difficulties that have hindered the use of analysis of DNA content abnormalities in the Reid panel need to be addressed. SNP analysis or image cytometry are other alternative techniques used to measure aneuploidy and other chromosomal aberrations but remains to be validated in larger studies.

PROLIFERATION MARKERS

Dysplasia is typically described as being associated with abnormal cellular proliferation and differentiation[55,56]. Our laboratory and others have demonstrated abnormal surface staining of markers of proliferation [minichromosome maintenance protein (Mcm) 2, 5 and Ki67] in dysplastic Barrett's mucosa[36,55,56]. This finding has served as the basis for the use of aberrant surface expression of Mcm2, together with a brushing technique to predict progression in patients with Barrett's esophagus[36]. However, large prospective studies are needed before they can be used in routine clinical practice.

CELL CYCLE MARKERS

Members of the cyclin family such as cyclin A and D are also interesting biomarkers for Barrett's esophagus. Cyclin D is a proto-oncogene protein and overexpression in Barrett's esophagus results in inappropriate phosphorylation and inactivation of p105-Rb. Increased expression of cyclin D has been implicated in the predisposition to transform from metaplastic epithelium to cancer. and can possibly be a useful biomarker in identifying patients with Barrett's esophagus at high risk of developing EA[57,58]. Bani-Hani *et al*[58] have performed a case-control study and have shown that Barrett's patients who are positive for cyclin D detected *via* immunohistochemistry were more likely to develop EA (OR: 6.85, 95% CI: 1.57-29.91). These findings were however not replicated in a larger population-based case-control study performed by Murray *et al*[34]. In that study, only immunohistochemical detection of p53 has been shown to be a useful biomarker for malignant progression in Barrett's esophagus. Cyclin A is expressed just before the beginning of DNA synthesis and is an important check mechanism in the G1-S transition of the cell cycle. In a case-control study, surface expression of cyclin A in Barrett's esophagus samples has been shown to be correlated with the degree of dysplasia, and patients with biopsies that express cyclin A at the surface were more likely to progress to EA than those who did not (OR: 7.5, 95% CI: 1.8-30.7)[37]. Prospective studies are required to determine properly the usefulness of cyclins as predictive biomarkers.

EPIGENETIC CHANGES

Epigenetic changes (or non-DNA sequence changes) in the form of hypomethylation, hypermethylation and alteration to histone complexes have also been found to be implicated in the pathogenesis of Barrett's esophagus and EA[38,59]. Hypermethylation of promoter Cpg island is thought to be the cause of transcriptional silencing of tumor suppressor genes such as *CDKN2A* (*p16*), *APC*, *CDH1* (E-cadherin), and *ESR1* (*ER*, estrogen receptor α)[59]. Hypermethylation of these genes is usually found in a large contiguous field, which suggests possible clonal expansion of hypermethylated cells or hypermethylation of a field of metaplastic cells[59]. Further work on the methylation status of promoter regions of genes has revealed that methylation of *p16* (OR: 1.74, 95% CI: 1.33-2.20), *RUNX3* (OR: 1.80, 95% CI: 1.08-2.81) and *HPP1* (OR: 1.77, 95% CI: 1.06-2.81) in patients with non-dysplastic Barrett's esophagus and LGD were independent risk factors for progression to HGD and EA[38]. More recently, Jin *et al*[60] have demonstrated that a methylation biomarker panel that comprises eight genes could accurately determine the risk of progression in patients with Barrett's esophagus in a retrospective, multicenter validation study. In that study, promoter methylation levels of eight genes were quantified by methylation-specific PCR in patients who did not progress (n = 145) compared to those who did progress (n = 50) to HGD or EA. Receiver operating characteristics curves were constructed to evaluate the usefulness of the eight-gene methylation panel and the authors have concluded that, with specificity set at 0.9, the eight-gene methylation panel in combination with age predicted half the progressors who would not have been diagnosed without using these biomarkers. Similarly, a recent study by Wang *et al*[61] has shown that hypermethylation of p16 and APC was a good predictor of progression to HGD or EA [OR: 14.97, 95% CI (1.73, inf)]. The fact that methylation changes in DNA occur early in the progression from Barrett's esophagus to dysplasia suggest that they could potentially be used as biomarkers to predict which groups of patients are likely to progress to dysplasia and EA[59,62]. However, the main problem of the utility of hypermethylation as biomarkers lies in the fact that techniques that have been applied for detection of epigenetic changes require enzyme digestion, affinity enrichment or bisulfite treatment before probe hybridization or sequencing can be done to detect methylation in samples. These arrays of techniques are far too technically demanding and time consuming for routine utilization in the clinic[63-72].

PROGNOSTIC BIOMARKERS IN EA

The overall 5-year survival for EA remains < 14%[73].

The current staging of EA is the internationally recognized TNM system[74], which is based exclusively on the anatomical extent of the disease. This is assessed using a combination of tumor depth (T), number of lymph nodes involved (N), and presence or absence of metastasis (M). The TNM system remains useful for staging of esophageal tumors because patients with more advanced stage disease clearly do worse than those in the early stage of the disease. For patients deemed to have potentially curative disease (T3N1 or less), surgical treatment with or without chemotherapy provides the only chance of cure, but it is highly invasive and has a high morbidity rate. Biomarkers that can accurately predict the prognosis of patients with this disease could aid in the selection of patients most likely to benefit from surgery. In addition, it is also hoped that biomarkers can identify different subgroups of tumors that will benefit from specific treatment, including molecularly targeted treatments.

Prognostic biomarkers in patient with EA have commonly been studied to determine the association with the following outcome and tumor characteristics: (1) survival; (2) lymphovascular invasion and metastasis; and (3) response to chemotherapy and radiotherapy.

Traditional candidate approaches for analyzing gene and protein expression in cancer have identified a large number of biomarkers that have important prognostic value. These biomarkers can be considered in terms of the six classical hallmarks described by Hanahan *et al*[75], with inflammation added as the seventh hallmark recently. They include: (1) self sufficiency in growth signals; (2) insensitivity to growth inhibitory (antigrowth) signals; (3) evasion of programmed cell death (apoptosis); (4) limitless replicative potential; (5) sustained angiogenesis; (6) invasion and metastasis; and (7) cancer-related inflammation.

Table 2 gives an overview of the biomarkers in each category and their association with survival or surrogate measures of prognosis. This list is not exhaustive but it highlights the important biomarkers that have been investigated and reported to be prognostic. A recent review by Lagarde *et al*[76] has described in greater detail many of these biomarkers and their molecular basis. It is well known that many of these molecular alterations occur in tandem during the progression of Barrett's esophagus to EA and are present to varying degrees. These biomarkers have been shown to be associated with survival or tumor characteristics, but subsequent replication of findings, as required for the EDRN validation of biomarkers, is often lacking. It is highly unlikely that any of these markers by itself can predict survival accurately because several molecular alterations can operate together to influence the pathogenesis of EA. Again, generating panels of biomarkers to create a molecular signature in EA could be useful in determining the prognosis of patients with EA.

MOLECULAR SIGNATURE OF EA

Several studies have used microarray technologies to generate molecular signatures that correlate with overall survival, lymph node involvement or response to chemotherapy. The advantage of using these methods is that they allow the hypothesis-free interrogation of many targets simultaneously. Table 3 gives a summary of the molecular signatures discovered by microarray technology, including the methodology used. However, despite the number of studies, none of these molecular signatures or techniques to stratify patients with EA has yet reached clinical utility. This is in contrast to other cancers for which prognostic signatures are starting to be used in the clinical setting[101-103]. In EA, molecular signatures have usually been generated from underpowered cohorts and many studies have combined molecular profiling of both EA and squamous cell carcinoma of the esophagus in the same study. It is known that the molecular profile of squamous cell carcinoma and EA is different[104,105], and for accurate prognosis, studies should differentiate between these two types of tumors. An additional problem, which is not dissimilar to biomarkers discovered for the transition of Barrett's esophagus to EA, is that the technique used might not be applicable to routine laboratories and will therefore be expensive. It is therefore important that researchers also consider how best to apply molecular biomarkers to the clinic, and they should consider validation using methods such as immunohistochemistry. Whichever method is used, data reproducibility and validation in independent samples are perhaps the most important factors to determine whether molecular signatures are adopted for clinical application. This problem is becoming increasingly recognized, and many reviews have reiterated the need for validation of molecular signatures and the development of assays that have general clinical applicability[106-112].

CONCLUSION

The pathogenesis from Barrett's esophagus to EA is highly complex. Multiple molecular alterations occur during this process, which leads to a heterogenous tumor by the time that EA develops. Biomarkers can complement the current clinical management of Barrett's esophagus and its transition to EA in three main ways. They can be used to: identify patients not previously diagnosed with Barrett's esophagus *via* population screening; improve the surveillance of patients with Barrett's esophagus; and identify prognostic groups and best therapy once EA develops.

There has already been a tremendous amount of research done to create an ideal biomarker or panel of biomarkers to predict accurately progression of Barrett's esophagus to dysplasia or EA. This is in conjunction with large amounts of resources and money spent in laboratories and in clinical trials as the research is being conducted. Although no biomarkers have been able to replace the current gold standard of dysplasia as a biomarker in routine clinical practice, it is reassuring to know that certain biomarkers hold great promise to transit from the bench to the bedside. It is becoming increasingly clear that one biomarker by itself is highly unlikely to predict progression with high sensitivity and

Table 2 Summary of the biomarkers and the prognostic impact in esophageal adenocarcinoma

Category of cell alteration	Biomarker	Sample size (*n*)	Endpoint	Findings	Statistical significance	Ref.
Self sufficiency in growth signals	Cyclin D	124	Survival	2 of 3 genotypes confers a poorer overall survival	$P = 0.0003$	[77]
	EGFR	103	Survival	Expression showed a trend towards a correlation with poorer overall survival	$P = 0.07$	[78]
		75	Survival	Decreased expression correlated with poorer survival on univariate analysis only	$P = 0.034$	[79]
	Ki-67	59	Survival	Low levels (< 10%) of staining correlated with poorer survival	HR: 3.9, $P = 0.02$	[80]
	Her2/neu	63	Survival	Amplification detected by FISH correlated with poorer survival	$P = 0.03$	[81,82]
	TGF-α	61	Survival	Low levels significantly correlated with cancer specific death	$P = 0.03$	[83]
		87	Tumor progression, lymph node metastasis	High levels significantly correlated with:		
				Tumor progression	$P = 0.025$	[84]
				Lymph node metastasis	$P < 0.05$	
Insensitivity to growth inhibitory (antigrowth) signals	TGF-β1	123	Survival	Overexpression correlated with poorer survival on univariate analysis only	$P = 0.0255$	[85]
		57	Survival	High plasma levels correlated with poorer overall survival	$P = 0.0317$	[86]
	APC	52	Survival	High plasma levels of methylation of APC associated with poorer survival	$P = 0.016$	[87]
	P21	30	Survival	Alteration in expression after chemotherapy correlated with better survival	$P = 0.011$	[88,89]
Evasion of programmed cell death (apoptosis)	P53	30	Survival	Alteration in expression after chemotherapy correlated with better survival	$P = 0.011$	[88]
	Bcl-2	35	Survival	Expression correlated with poorer survival	$P = 0.03$	[90]
	COX-2	100	T-stage, N-stage, tumor recurrence and survival	Higher levels expression correlated with:		
				Higher T-stage,	$P = 0.008$	[91]
				Higher N-stage,	$P = 0.049$	
				Increased risk of tumor recurrence	$P = 0.01$	
				Poor survival	$P < 0.001$	
		20	Survival	Strong staining correlated with poorer survival	$P = 0.03$	[92]
		145	Distant metastasis, local recurrence and survival	Strong staining correlated with:		
				Distant metastasis	$P = 0.02$	[93]
				Local recurrence	$P = 0.05$	
				Poorer survival	$P = 0.002$	
	NF-κB	43	Survival	Activated NF-κB predictive of:		
				Poorer disease free survival	$P = 0.010$	[94]
				Poorer overall survival	$P = 0.015$	
Limitless replicative potential	Telomerase	46	Survival	Higher telomere-length ratio shown to be an independent poor prognostic factor	$P < 0.02$	[95]
Sustained angiogenesis	CD105	75	Survival, angiolymphatic invasion, lymph node metastasis and tumor stage and distant metastasis	Significant correlation between expression and:		
				Poorer survival	$P < 0.01$	[96]
				Presence of angiolymphatic invasion	$P < 0.05$	
				More lymph node metastasis	$P < 0.01$	
				Higher tumor stage	$P < 0.001$	
				More distant metastasis	$P < 0.01$	
	VEGF	75	Survival, angiolymphatic invasion, lymph node metastasis, stage of tumor and distant metastasis	Significant correlation between high expression and:		
				Poorer survival	$P < 0.01$	[96]
				Presence of angiolymphatic invasion	$P < 0.05$	
				More lymph node metastasis	$P < 0.01$	
				Higher stage of tumor	$P < 0.01$	
				More distant metastasis	$P < 0.01$	
Tissue invasion and metastasis	Cadherin	59	Survival	Reduced level correlated with poorer overall survival	HR: 3.3, $P = 0.05$	[80]
	uPA	54	Survival	High uPA correlated with poorer survival	$P = 0.0002$	[97]
	TIMP	24	Survival and disease stage	Reduction of expression correlated with poorer overall survival and higher disease stage	$P = 0.007$	[98]
					$P = 0.046$	
Others	Promoter hypermethylation	41	Survival and tumor recurrence	Earlier tumor recurrence and poorer overall survival if > 50% of gene profile methylated	$P = 0.05$	[99]
					$P = 0.04$	
		84	Differentiation	Hypermethylation of MGMT (Methylated-DNA-protein-cysteine methyltransferase) gene correlated with:	$P = 0.0079$	[100]
				Higher tumor differentiation		

EGFR: Epidermal growth factor receptor; Her2/neu: Human EGFR2; TGF: Transforming growth factor; APC: Adenomatosis polyposis coli; P21: Cyclin-dependent kinase inhibitor 1; Bcl-2: B-cell lymphoma 2; COX-2: Cyclooxygenase-2; NF-κB: Nuclear factor-κB; CD105: Endoglin; VEGF: Vascular endothelial growth factor; uPA: Urokinase-type plasminogen activator; TIMP: Tissue inhibitor of metalloproteinase.

specificity. Panels of biomarkers such as the eight-gene methylation panel or the Reid panel, which combine LOH at various loci and DNA content abnormalities to predict progression, seem to provide the most accurate predictor of progression based on statistics. Unfortunately, the common theme in these panels of markers is

Table 3 Summary of the molecular signatures discovered by microarray technology and latest methods used to correlate molecular alterations and prognosis in patients with esophageal adenocarcinoma

Method	Sample size (*n*)	Outcome	Findings	Statistical significance	External validation	Ref.
Oligonucleotide cRNA microarray	75	Survival	A 4-gene signature prognosticated patients	$P = 0.0001$	Yes	[113]
	77	Lymphatic spread	Created a gene signature predicting lymph node metastasis	Argininosuccinate synthetase expression (ASS) (P = 0.048)	No	[114]
	19	Chemotherapy response	Unsupervised hierarchical clustering divided patients into 2 groups, one of which responded to preoperative chemotherapy	Not statistically significant	No	[115,116]
	47	Chemotherapy response	86 genes dysregulated Ephrin B3 expression associated with chemotherapy response, tumor grading and stage	$P < 0.001$	No	[117]
Oligonucleotide cDNA microarray	46	Chemotherapy response	Gene signature not predictive in adenocarcinoma of esophagus	Not statistically significant	No	[118]
Proteomic analysis	34	Chemotherapy response	HSP27 expression associated with response to chemotherapy	$P < 0.05$	No	[119]
Single nucleotide polymorphism	210	Survival and recurrence	5 polymorphisms in 3 genes associated with longer recurrence free survival and reduced recurrence	$P = 0.004$	No	[120]
microRNAs analysis	96	Survival	Low miR-375 levels associated with worse survival	$P = 0.002$	No	[121]
Multiplex ligation-dependent probe amplification	33	Survival	Patients with more than 12 chromosomal aberrations had a poorer outcome than patients with < 12	$P = 0.014$	No	[122]

that they are far too expensive to be applied in routine clinical use, and technical expertise is not available in all centers to utilize these panels of biomarkers. The issue of costs and practicality of biomarkers should be one of the principle considerations before research and resources are channeled into it.

Although traditional methods of identifying biomarkers in Barrett's esophagus and its transition to dysplasia and EA have helped greatly in the understanding of the disease process, new technologies to create molecular signatures have also helped by identifying many important biomarkers not previously thought to be involved in its pathogenesis. A few biomarkers identified from both traditional methods and new technological platforms have shown great potential in predicting the progression from Barrett's esophagus to EA. However, a concerted effort is still needed to validate these biomarkers or molecular signatures in independent, large-scale prospective cohorts and to develop inexpensive, practical assays to allow for clinical applicability. Realistically, this can only be achieved by a multicenter collaboration to tackle the challenges of the large amount of resources, scientific and clinical input required to advance the field of biomarkers in Barrett's esophagus. There are a few major collaborations in the United Kingdom to date, and they include the Chemoprevention of Premalignant Intestinal neoplasia trial (CHOPIN) and Oesophageal Cancer Clinical and Molecular Stratification Study (OCCAMS). This is also mirrored in the international arena with Barrett's Esophagus and Adenocarcinoma Consortium (BEACON) and Asian Barrett's Consortium as two examples of collaborative work on Barrett's esophagus. These initiatives allow for the pooling of resources, expertise and knowledge between centers and allow for the recruitment of large numbers of patients that are necessary to advance the field of biomarkers in Barrett's esophagus and EA. Although each study has a slightly different focus, much could be gained these collaborative efforts if a proportion of the resources and patient samples could be used to validate biomarkers in Barrett's or tumor samples.

Lastly, biomarkers should be seen as adjuncts to aid clinical management of patients with Barrett's esophagus and EA rather than in isolation in predicting the risk of progression, prognosis or response to therapy. As such, clinical factors in conjunction with biomarkers should be incorporated into a model that can accurately determine the desired outcome. Such models have been used in other cancers and diseases such as the MELD score for liver disease or the Nottingham prognostic index for breast cancer. Upon generation and validation of the model, it should then be rigorously validated in an independent large cohort of patients in a prospective fashion. In future, patients can then be risk stratified based on a score to determine the treatment strategy, hence individualizing treatment to improve patient care and outcome.

ACKNOWLEDGMENTS

We would like to thank Dr. Elizabeth Bird-Lieberman for her kind contributions of the scanned histology slides for Figure 1.

REVIEW

Management of mucinous cystic neoplasms of the pancreas

Mario Testini, Angela Gurrado, Germana Lissidini, Pietro Venezia, Luigi Greco, Giuseppe Piccinni

Mario Testini, Angela Gurrado, Germana Lissidini, Pietro Venezia, Giuseppe Piccinni, Unit of Endocrine, Digestive and Emergency Surgery, Department of Biomedical Sciences and Human Oncology, Section of General and Oncologic Surgery, University Medical School of Bari, 70124 Bari, Italy
Luigi Greco, Department of Emergency and Organ Transplantation, University Medical School of Bari, 70124 Bari, Italy
Author contributions: Testini M and Gurrado A wrote the review; Lissidini G, Venezia P, Greco L and Piccinni G contributed to the literature search.

Abstract

The purpose of this study was to investigate the actual management of mucinous cystic neoplasm (MCN) of the pancreas. A systematic review was performed in December 2009 by consulting PubMed MEDLINE for publications and matching the key words "pancreatic mucinous cystic neoplasm", "pancreatic mucinous cystic tumour", "pancreatic mucinous cystic mass", "pancreatic cyst", and "pancreatic cystic neoplasm" to identify English language articles describing the diagnosis and treatment of the mucinous cystic neoplasm of the pancreas. In total, 16322 references ranging from January 1969 to December 2009 were analysed and 77 articles were identified. No articles published before 1996 were selected because MCNs were not previously considered to be a completely autonomous disease. Definition, epidemiology, anatomopathological findings, clinical presentation, preoperative evaluation, treatment and prognosis were reviewed. MCNs are pancreatic mucin-producing cysts with a distinctive ovarian-type stroma localized in the body-tail of the gland and occurring in middle-aged females. The majority of MCNs are slow growing and asymptomatic. The prevalence of invasive carcinoma varies between 6% and 55%. Preoperative diagnosis depends on a combination of clinical features, tumor markers, computed tomography (CT), magnetic resonance imaging, endoscopic ultrasound with cyst fluid analysis, and positron emission tomography-CT. Surgery is indicated for all MCNs.

Key words: Pancreatic cystic lesion; Pancreatic mucinous cystic neoplasm; Pancreatic mucin-producing cysts; Pancreatic cystic neoplasm; Pancreatic ovarian-type stroma

INTRODUCTION

Becourt first described cystic lesions of the pancreas in 1824[1]. In 1978, Compagno *et al*[2] first classified cystic tumors into serous cystic neoplasms (SCNs) and mucinous cystic neoplasms (MCNs) of the pancreas and identified MCN as a distinct disease occurring almost exclusively in the pancreas body and tail of middle-aged women[2,3]. Until 1996, when the World Health Organization distinguished between intraductal papillary mucinous neoplasms (IPMNs) and MCNs, emphasizing the presence of ovarian stroma in the latter, and until 1997 when the Armed Forces Institute of Pathology confirmed this distinction, MCN and IPMNs were frequently confused[3-7]. Nowadays, they represent two distinct neoplasms with different biologic behaviour, pathologic features, and prognosis[8-11].

Although until 1987, Warshaw *et al*[12] considered that pseudocysts account for the majority of pancreatic cys-

tic lesions, nowadays mucinous and serous cystic tumors represent 50%-60% of all cystic lesions[13]. Nevertheless pancreatic cystic neoplasms occur with less frequency than solid ones[4,14,15], but are now found with increasing frequency compared to the past due to the improvement and refining of modern imaging techniques like multidetector, three-dimensional computed tomography (CT) or magnetic resonance imaging (MRI), or endoscopic ultrasound (EUS)[16].

The aim of this study was to review the literature to clarify the management of cystic mucinous neoplasm of the pancreas.

LITERATURE SEARCH

A comprehensive literature review was performed in December 2009 by consulting PubMed MEDLINE for publications, matching the key words of "pancreatic mucinous cystic neoplasm", "pancreatic mucinous cystic tumor", "pancreatic mucinous cystic mass", "pancreatic cyst" and "pancreatic cystic neoplasm" to identify English language articles on MCNs.

Only studies including series with more than four patients affected by MCNs were included. Articles reporting reviews, case reports, abstracts and studies on only IPMNs, SCNs or pancreatic pseudocysts were excluded. Definition, epidemiology, anatomopathological findings, clinical presentation, preoperative evaluation, treatment and prognosis were analyzed.

A total of 16 322 references ranging from January 1969 to December 2009 were analyzed ("pancreatic mucinous cystic neoplasm", n = 930; "pancreatic mucinous cystic tumor", n = 924; "pancreatic mucinous cystic mass", n = 143; "pancreatic cyst", n = 6215; "pancreatic cystic neoplasm", n = 8110) and 77 articles were selected[10,14,17-89]. No articles before 1996 were usable because MCNs were not previously considered as a completely autonomous disease[9-11,17,77,86,89,90].

DEFINITION AND EPIDEMIOLOGY

MCNs are defined as mucin-producing and septated cyst-forming epithelial neoplasia of the pancreas with a distinctive ovarian-type stroma. Usually solitary, their size ranges between 5 and 35 cm with a thick fibrotic wall and without communication with the ductal system[11]. MCNs are rare and, in most series, less common than IPMNs and SCNs[73]. MCNs show a female to male ratio of 20 to 1 and a mean age at diagnosis of between 40 and 50 years (range 14-95 years)[6,7,10,11,91-93]. The site of the neoplasm is in the body and tail of the pancreas in 95%-98% of cases[3,7,9,34,35,89,94,95]. When localized in the pancreatic head, mucinous cystoadenocarcinoma is more prevalent[7,10].

Invasive carcinoma incidence in MCN varies between 6% and 36%[8-11,14,34,35,86]. The Ulm series reported on 39 patients with MCNs and a malignant histology in 51%, including carcinoma *in situ* and advanced cancer[11]. The explanation of this wide range may be the difficulty in interpreting the data on the prevalence of carcinoma because the majority of series have only indicated the advanced form.

ANATOMOPATHOLOGICAL FINDINGS

Macroscopically, MCNs usually appear as solitary, multilocular or unilocular lesions with a mean size of 7-8 cm (range 0.5-35 cm) with a thick fibrotic wall and containing mucin, even when hemorrhagic, watery or necrotic content is observed[8].

In 2004, the consensus conference of the International Association of Pancreatology in Sendai (Japan)[8,9] established that the histological presence of unique ovarian-type stroma was mandatory to diagnose MCN and that this was not found in other pancreatic neoplasms[10,73,93]. MCNs display no communication with the pancreatic ductal system, although some studies suggested that a small proportion of MCNs may show microscopic communication with the pancreatic ducts[68,96,97].

Under light microscopy, the cysts are lined by a columnar mucin-producing epithelium with different grade of dysplasia: mild (MCN adenoma), moderate (MCN borderline), and severe (MCN carcinoma *in situ*)[98]. The epithelial lining is positive for CKs (CK7, CK8, CK18, CK19), EMA and, less frequently, CK20, CEA, DUPAN-2 and CA 19-9[8,10,67]. An invasive adenocarcinoma of the tubular or ductal type is associated in about one-third of cases[6]. The immunophenotype of ovarian-type stroma is similar to the normal ovarian one with positivity for vimentin, calretinin, tyrosine hydroxylase, SMA, α-inhibin, Melan-A, CD99 and Bcl-2 and frequently for PR and ER. The origin of ovarian stroma of the pancreas is still being debated[99]. A stimulation of endodermal immature stroma by female hormones or primary yolk cell implantation in the pancreas has been suggested in literature[10] because buds of the genital tract and dorsal pancreas are adjacent to each other during embryogenesis. Moreover, dorsal pancreatic enlargement mainly gives rise to the pancreatic body and tail, and this could explain the predilection of MCNs for the distal pancreas[17].

Although the pathologic diagnosis of malignancy is based on invasion of the pancreatic parenchyma or metastases[5], MCNs that do not have conclusive evidence of carcinoma are considered premalignant[7].

A thickened wall with peripheral calcification and papillary proliferations, vascular involvement and hypervascular pattern should be considered as suggestive of MCN with malignant changes[68,95]. Although the invasive MCN (mucinouscystoadenocarcinoma or mucinous cystic neoplasm with associated invasive carcinoma) is generally a tubular/ductal carcinoma[8], rare histological variants are represented by undifferentiated carcinoma with osteoclast-like giant cells[100], adenosquamous or colloid cells[101], or sarcomatoid carcinoma[99], carcinosarcoma and choriocarcinoma[8,102].

The increasing degree of dysplasia and tendency for invasion have been correlated with activating point mutations in the *k-ras* gene and mutations in the *TP5* gene[8,103,104]; moreover, the discovery that the inactiva-

tion of SMAD4/DPC4 in the epithelium of the invasive MCNs, but not in the ovarian-like stroma, could suggest that the ovarian-type stroma is not neoplastic[105].

CLINICAL PRESENTATION

The majority of MCNs are slow growing and asymptomatic[95]. In a series of 212 consecutive patients with cystic pancreatic lesions, 36.7% were asymptomatic and among them 28% had MCNs; in the symptomatic group, 16% had MCN[106]. In spite of these lesions being occasionally discovered in patients scanned for other indications[16,35,107], the typical clinical appearance is characterized by epigastric heaviness and fullness (60%-90%) or by an abdominal mass (30%-60%)[7,10,12,35,89,106,108]. Nausea, vomiting (20%-30%) and back pain (7%-40%) can also be present.

No specific symptom was significantly associated with a likelihood of malignancy[35] although increasing anorexia and weight loss (10%-40%) may be associated with malignant changes[7,12,35,89,95,106,108,109].

PREOPERATIVE EVALUATION

MCNs main differential diagnosis includes other neoplastic cystic lesions (serous cystic neoplasm and the intraductal papillary mucinous neoplasms) and non-neoplastic cystic lesions (pancreatic pseudocysts). There is no single discriminating test, but preoperative diagnosis depends on a combination of modes, including clinical features, tumor markers, CT and MRI, EUS with cyst fluid analysis, and positron emission tomography (PET).

High values of CEA and CA 19-9 show a high positive predictive value for pancreatic malignancy or premalignancy in the preoperative assessment of pancreatic cystic mass (70%-100%)[9,95,110]. A CEA level of more than 400 ng/mL is a good predictor of malignancy in MCNs (sensitivity 45%-50%, specificity 95%-100%, accuracy 75%-80%)[107,111,112].

Trans-abdominal ultrasound examination has a low accuracy (50%) for cystic neoplasms of the pancreas[89].

EUS improves that accuracy and allows better evaluation of the wall as it may show separation or nodules within the cyst. Furthermore, EUS can be used to obtain aspiration of the cyst contents and to perform a biopsy of the wall. Cyst fluid amylase concentration of < 250 U/L has been considered capable of excluding pseudocysts of the pancreas (sensitivity 40%-45%, specificity 95%-100%, accuracy 60%-65%), while CEA < 5 ng/mL could suggest a benign etiology (sensitivity 45%-50%, specificity 95%-100%, accuracy 65%-70%)[31,111]. EUS-FNA cytology and cyst fluid CEA greater than 192 ng/mL show the highest accuracy (79%) for differentiating mucinous cystic from non-mucinous cystic neoplasms[113]. On the contrary EUS morphology alone cannot distinguish between the two groups[47,50,113].

In any case, the main differential diagnosis of MCNs is with SCNs which have a low CEA in the fluid and an equal distribution throughout the pancreas, with pancreatic pseudocysts (PC) that usually show necrotic debris within the cyst cavity, and with branch duct IPMNs communicating with the ductal pancreatic system and consequently showing elevated cystic fluid amylase[3].

Although pancreatitis may be present in the history of patients with pancreatic cystic neoplasms, when a cyst arises in a patient with chronic pancreatitis, the most frequent diagnosis is PC[109]. On the other hand, when pancreatitis is unexpected and occurs for the first time, the cyst could be a tumor, determining the development of pancreatitis due to compression of the pancreatic duct[13]. This is a crucial problem, because the risk of managing cystic mucinous neoplasms in patients with a prior history of pancreatitis, like pseudocysts by a pseudocyst-jejunal anastomosis or pseudocyst-gastrostomy, is higher than usual, with disastrous long-term prognosis[12,83]. Proper sampling of pseudocysts is essential and should consist of sampling of the cyst wall during surgery or analysis of cyst content during minimal access drainage procedures. Although the clinical context, radiological imaging and biochemical findings may help differentiate PC from cystic neoplasms, small lesions may be problematic.

The image based classification system proposed by Sahani *et al*[107], in which cystic pancreatic lesions are classified in four subtypes, is reported in Table 1.

The demonstration of a solid component, invasion outside the confines of the pancreas, or pancreatic duct obstruction through EUS is highly indicative of malignancy with sensitivity, specificity and accuracy of 70%, 100% and 60%, respectively[107]. However, in the absence of these findings the ability of EUS to diagnose malignancy is limited with an overall sensitivity, specificity and accuracy of 56%, 45% and 51%, respectively[113]. The added advantage of EUS in performing aspiration of cyst content and sampling of the cyst wall and septa or mural nodules is that it allows small lesions as well as suspicious areas to be analysed. Laparoscopic and intraoperative ultrasounds are highly operator dependent with an accuracy

Table 1 Imaging-based classification system of cystic pancreatic lesions

Type of lesions	Morphologic features	Pancreatic cystic lesions
Unilocular cyst	Without internal septation and solid component or wall calcification	Serous cystic neoplasm, intraductal papillary mucinous neoplasm[1], pancreatic pseudocyst
Microcystic lesion	Six or more cysts with diameter 0.2 mm-2 cm, external lobulation, fibrous central scar with or without stellate calcifications	Serous cystic neoplasm
Macrocystic lesions	Diameter > 2 cm, with internal septation and solid component or wall calcification	Intraductal papillary mucinous neoplasm[1], mucinous cystic neoplasm[2]
Cyst with a solid component	Unilocular or multilocular	Intraductal papillary mucinous neoplasm[1], mucinous cystic neoplasm[2]

[1]With or [2]without communication with main duct, respectively.

ranging from 40% to 90%[3,114-120].

Multidetector computed tomography and magnetic resonance cholangiopancreaticography (MRCP) play a critical role in assessment, defining size, septation, calcifications, nodules of the wall, and communication with the ductal system of the pancreatic cyst.

At cross-sectional imaging, the MCN appears as a unilocular or multilocular single macrocyst with a solid component, with no communication with the main duct[95,107,121]. The internal architecture of the cyst, including septa and internal wall, is best appreciated with MR imaging[122,123].

Recently, Kim *et al*[60] defined some significant CT features for differentiating MCNs from SCNs and IPMNs: the shape is smooth in MCNs, multicystic and lobulated in SCNs, and pleomorphic and clubbed finger-like in IPMNs; the main pancreatic duct is not dilated or proximally only in SCNs, and if dilated, whole in IPMN.

In spite of the improvement in pancreatic tumor visualization resulting from CT and MRI, the ability to perform diagnosis of these techniques individually - as well as EUS - remains poor (25%-30%)[6,124,125]. In a multivariate analysis by Visser *et al*[14] in 2008, the combination of CT and MRI data showed an accuracy ranging from 44% to 83%.

Cross-sectional imaging generally shows peripheral calcification, a thickened wall, papillary proliferations, vascular involvement and hypervascular pattern in the cases of malignant MCNs[36,95,126]. Although peripheral eggshell calcification is not easily detected by CT, this is a specific feature of the MCNs and is highly predictive of malignancy[126].

The clinical value of MRCP is similar to endoscopic retrograde cholangiopancreatography or percutaneous transhepatic cholangiography[127] but an MR multi-imaging protocol, which includes MR cross-sectional imaging, MRCP and dynamic contrast-enhanced MR angiography, integrates the advantages of multiple imaging techniques without morbidity[128-131].

The role of PET in managing pancreatic cystic lesions is currently limited but recent studies report detection of malignant pancreatic cysts with sensitivity and positive predictive values above 90%[132,133].

In spite of a complete diagnostic assessment, the surgeon's preoperative diagnosis is correct in one-third of cases, incorrect in another third, and non-specific in the remainder[6,14].

TREATMENT

Surgical excision is indicated for all MCNs considered premalignant. Factors influencing treatment include tumor histological features, the patient's age and surgical risk, and tumor size and location.

Left pancreatectomy

Because mucinous cystic adenoma of the pancreas are usually localized at the level of the body and tail of the pancreas, the most common operation performed to cure these neoplasms is distal pancreatectomy (Figure 1), which is a safe procedure in high volume centres (overall postoperative morbidity ranging from 5% to 50% and a mortality rate of 0%)[3,7,20,35,134,135]. The main complication, pancreatic fistula, occurs in 15%-20% of cases[136].

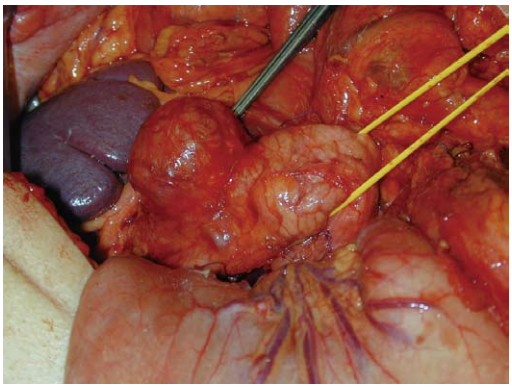

Figure 1 Distal pancreatectomy. Dissection of the pancreas in a patient with mucinous cystic neoplasm.

The distal pancreatectomy technique was first described in 1913 by Mayo[137] and the spleen-preserving distal pancreatectomy was outlined in 1943 by Mallet-Guy *et al*[138]. Preservation of the spleen can be performed with or without preservation of the splenic artery and vein. In 1988, Warshaw described a technique without the preservation of the splenic artery and vein, ligating the splenic vessels at the hilum[139]. Although this method appears technically less difficult and can be performed in a shorter operating time, it has been associated with a higher incidence of spleen vascular insufficiency[140]. However, this procedure should be considered in the event of an inflamed or fibrosed splenic artery and vein[139]. Spleen-preserving techniques must be avoided when in the presence of the largest tumors or risk factors for invasive malignancy, such as the size of the lesion, eggshell calcifications and mural nodules, in order to perform the complete oncological lymph node dissection[9,27,31]. However, these techniques are preferred in all other cases to avoid long term infectious and haematological complications[3,20,27,139].

Studies comparing patients undergoing distal pancreatectomy with or without splenectomy show no significant differences compared to perioperative complications, mean operating time, pancreatic fistula rate, length of hospital stay and mortality[20,108,135,141,142].

MCNs affecting the pancreatic neck or the proximal body could be managed either by an extended right or, more frequently, by an extended left pancreatectomy. These extended resections of normal pancreatic tissue may induce endocrine and exocrine insufficiency respectively in 30%-35% and 15%-20%, which in a benign or premalignant disease could be discussable[143-147].

Middle pancreatectomy

Middle pancreatectomy can be considered in the surgical management of MCNs located at the level of the pancreatic proximal body or neck, preserving endocrine and

exocrine function with respect to extended left pancreatectomy or pancreaticoduodenectomy, and also preserving the spleen.

The main pitfalls of this technique are the technical difficulty, the higher incidence of postoperative complications and the risk of recurrence from potentially residual neoplasm[9,146-153].

Different techniques have been proposed for gastrointestinal reconstruction, including jejunal anastomosis of the stump or the distal stump, with pancreaticoduodenal or pancreaticogastric anastomosis[143,148-156].

In the literature, mortality after middle pancreatectomy was none and the overall morbidity was 25%-35%[147-149,155-157]. The incidence of overall pancreatic fistula was 22%-45% and the type of reconstruction through Roux-en-Y pancreatojejunostomy or pancreaticogastrostomy did not affect the rate of any complication[147-149,155-157]. Moreover, the incidence of endocrine and exocrine insufficiency after middle pancreatectomy was 4%-7% and 5%-8%, respectively[147-149,155-157].

Enucleation

Because the probability of malignancy in patients with MCNs smaller than 2 cm without nodules is very low, enucleation could be performed to avoid post-operative pancreatic insufficiency[35]. This procedure is proposed for patients with MCNs smaller than 2 cm with benign features and superficially located[146,155,156]. Enucleation can be performed without risk of recurrence but has been associated with a higher incidence of pancreatic fistula (30%-50%)[158-160].

Whipple procedure

A major oncologic resection, applying a Kausch-Whipple or pylorus-preserving technique, is recommended for MCNs that are localized monocentrically in the head.

The operative mortality ranges from 0% to 5% and is generally related to pancreatic anastomosis complications[136,161]. The most common complications following the Whipple procedure are delayed gastric emptying and the pancreatic fistula occurring in 5%-10% and 6%-20% of operations, respectively[136,161-163].

When an enucleation is impossible or contraindicated, MCNs localized monocentrically in the pancreatic head that do not have an association with an invasive pancreatic cancer could be treated by duodenum-preserving total pancreatic head resection[34,94,164-167].

This procedure shows significant advantages when compared to Traverso-Longmire or Whipple pancreaticoduodenectomy, as regards the postoperative rate of morbidity and mortality, glucose metabolism, hospitalization and costs[11,168].

Lymphadenectomy

Pancreatectomy with lymph node dissection is necessary when an invasive carcinoma is suspected. Although the preoperative and intraoperative assessment of the grade of invasiveness is often difficult, whenever any doubt exists typical resection with lymph node dissection must be pursued[9]. There is no evidence in literature of invasive mucinous cystic adenocarcinoma with distant lymph node metastases, so only a loco-regional lymphadenectomy is justified[3,35]. Because the probability of malignancy is very low in the cases of small MCNs without nodules, lymphadenectomy can be avoided[3,146].

Laparoscopy

In the cases of benign-appearing and small malignant lesions (< 5 cm), a minimally invasive approach may be considered[35]. Recent experiences from high-volume centers demonstrate that the laparoscopic approach for distal pancreatectomy for MCNs of the body and tail of the pancreas is feasible and safe[169]. The complication rate of laparoscopic distal splenopancreatectomy (Lap SDP) ranges between 15% and 20%[30,46,170-173] with a mortality rate of 0%. In spleen-preserving laparoscopic pancreatic (Lap SPDP) resection, the overall morbidity ranges from 25% to 40% with a mortality rate of 0%[30,46,169-173]. The overall reported pancreatic fistula was 5%-8% and 10%-15% after Lap SPDP and Lap SDP, respectively[30,46,170-173]. This laparoscopic approach decreases the hospital stay and minimizes the cosmetic impact of the surgical wound[30,169,174,175].

Chemotherapy

Gemcitabine (GEM) is the standard therapy for advanced pancreatic cancer[176]. Its effectiveness against advanced MCNs has been reported[177,178].

Recently, some combinations have been reported to be superior to GEM alone[177,179-181]. GEM-oxaliplatin treatment has been proposed to be more effective in terms of clinical progression-free survival[177].

Discordant results on survival were reported by phase Ⅱ and Ⅲ trials combining GEM and inhibitors of epidermal growth factor receptor (cetuximab) and vascular endothelial growth factor (bevacizumab)[182-184].

Other modest but interesting advances have been provided by combinations such as GEM-capecitabine and GEM plus a platinum salt[185]. In spite of this, survival results remain disappointing.

Conservative treatment

A conservative management with regular follow-up has been proposed in the presence of asymptomatic cystic lesions of the pancreas smaller than 3 cm without mural nodules, because the reported risk of malignancy in these cysts was found to be 3%[11,35,63,186]. The suggested follow-up consisting of cross-sectional imaging and FNA cytology should be performed every 6 mo for a period of 2 years and yearly after that. This should be continued for at least 4 years and then the interval of follow-up can be lengthened after 6 years of no change[31,52,186]. When the cyst enlarges or when symptoms occur (in up to 20% of patients after follow-up), surgery is mandatory. The reported incidence of the subsequent resection due to change of the clinical, radiological and biochemical features of the lesions after initial conservative treatment was 4%-10% and malignancy rate in these cases was 3%[23,63].

PROGNOSIS

After resection, in the absence of invasive carcinoma, prognosis of MCNs is excellent, with an overall survival rate of 100%[5-7,10,35] and patients do not need follow-up, since several studies have shown that the risk of recurrence following resection is 0%[11,18]. Patients with invasive mucinous cystadenocarcinoma, show a 5-year survival rate of 20%-60%, which is much better than that for non-MCN-associated ductal adenocarcinoma[5-8,11,17,35,73,86]. When an anaplastic carcinoma of the pancreas associated with MCN is reported, the prognosis is obviously extremely poor, with a 3-year survival rate lower than 3%[5-8,11,17,35,73,86].

CONCLUSION

Although the histological distinction between MCNs and IPMNs, through the identification of ovarian stroma initially, is very important in clinical practice, the management of MCNs has not yet been standardized and continues to evolve.

The approach to patients with suspected MCN is based on EUS and cross-sectional imaging in association with FNA cytology, detecting an incidence of correct differentiation between mucinous cystic and non-mucinous cystic neoplasms of 75%.

Because at present we are unable to identify the benign MCNs that will progress into invasive carcinoma, all MCNs should be resected, regardless of size, in patients who are fit candidates for surgery, because surgery is routinely curative in the cases of non-invasive tumor. Moreover, the non-operative management based on periodic CT or MRI requires years of careful follow-up with a high cost of imaging and the enucleation technique carries the risk of non-oncological radicality. In patients with non-invasive MCN after complete anatomic resection, postoperative surveillance is unnecessary.

In order to obtain more benefit by applying adjuvant chemotherapy for the treatment of the advanced MCNs, further research focused on sequential cellular transformation from benign to malign tumor and on new combinations, incorporating the new targeted therapies and identifying potential predictive factors of response, is required to be able to offer effective tailored treatment to these patients.

Abstract

AIM: To investigate the benefits of insulin like growth factor-1 (IGF-1) supplementation to serum-free institut georges lopez-1 (IGL-1)® solution to protect fatty liver against cold ischemia reperfusion injury.

METHODS: Steatotic livers were preserved for 24 h in IGL-1® solution supplemented with or without IGF-1 and then perfused "*ex vivo*" for 2 h at 37℃. We examined the effects of IGF-1 on hepatic damage and function (transaminases, percentage of sulfobromophthalein clearance in bile and vascular resistance). We also studied other factors associated with the poor tolerance of fatty livers to cold ischemia reperfusion injury such as mitochondrial damage, oxidative stress, nitric oxide, tumor necrosis factor-α (TNF-α) and mitogen-activated protein kinases.

RESULTS: Steatotic livers preserved in IGL-1® solution supplemented with IGF-1 showed lower transaminase levels, increased bile clearance and a reduction in vascular resistance when compared to those preserved in IGL-1® solution alone. These benefits are mediated by activation of AKT and constitutive endothelial nitric oxide synthase (eNOS), as well as the inhibition of inflammatory cytokines such as TNF-α. Mitochondrial damage and oxidative stress were also prevented.

CONCLUSION: IGL-1® enrichment with IGF-1 increased fatty liver graft preservation through AKT and eNOS activation, and prevented TNF-α release during normothermic reperfusion.

Key words: AKT; Institut georges lopez-1® solution; Insulin like growth factor-1; Ischemia reperfusion injury; Nitric oxide; Oxidative stress; Steatotic graft preservation

INTRODUCTION

One of the major challenges in liver transplantation is to increase the use of marginal organs. Steatotic, or fatty, livers are increasingly transplanted, in spite of the associated risk of graft dysfunction or non-function as a result of cold ischemia reperfusion injury (IRI)[1,2]. Steatotic livers show poor tolerance to IRI due to severe mitochondrial damage, impaired energy metabolism[3], increased reactive oxygen species (ROS) and release of inflammatory cytokines such as tumour necrosis factor-α (TNF-α), which impairs microcirculation[4,5]. All these factors render steatotic livers more vulnerable to cold IRI.

Liver preservation is a crucial step in maintaining graft quality after prolonged ischemic periods, especially steatotic livers. University of Wisconsin (UW) is the most widely used serum-free preservation solution for transplantation but it does not fully protect liver grafts during prolonged storage[6-8]. Recently, the new institut georges lopez-1 (IGL-1)® solution has been proposed as an effective alternative to UW in clinical kidney transplantation[9,10], and in experimental orthotopic liver transplantation models[11,12]. IGL-1® solution is characterized by inversion of K^+ and Na^+ concentrations in the UW solution and contains polyethylene glycol as osmotic support instead of HES. In addition, we have previously demonstrated that IGL-1® is more suitable than UW solution for fatty liver preservation[13]. Its benefits are associated in part, with the prevention of oxidative stress and its capacity to generate nitric oxide (NO)[13]. NO is a vasodilator with anti-inflammatory properties that prevents microcirculatory alterations[5,13] and the release of pro-inflammatory cytokines, such as TNF-α, during IRI[14-16].

Insulin like growth factor-1 (IGF-1) is a vascular protective factor that is mainly synthesized and released by the liver[17,18]. We have recently reported impaired synthesis of IGF-1 in steatotic livers subjected to warm IRI, and that exogenous administration of recombinant IGF-1 reduced IRI in steatotic livers[18]. IGF-1 prevents oxidative stress[17] and induces NO generation by eNOS activation, as a consequence of AKT kinase phosphorylation[19,20].

Several trophic factors (TF), including IGF-1, have been added to UW solution in an attempt to improve the survival of pig orthotopic liver allografts after 18 h of cold storage[21]. In vascular endothelial cells, the benefits of TF supplementation are associated with limitation of mitogen-activated protein kinase (MAPK) activities after cold ischemia/rewarming injury[22].

Taking this into account, we explored the effects of the addition of IGF-1 to IGL-1® solution on fatty liver preservation during cold IRI. We examined the mechanisms responsible for such effects, including AKT phosphorylation and NO generation, and the prevention of ROS production and TNF-α release after reperfusion. These latter factors have been implicated in the poor tolerance of steatotic livers to cold IRI.

MATERIALS AND METHODS

Animals and liver procurement

Isolated perfused rat liver was used to evaluate hepatic function in isolation from the influence of other organ systems (undefined plasma constituents and neural/hormonal effects). Hepatic architecture, microcirculation and bile production were preserved in this experimental model, as previously reported[23]. Homozygous obese (Ob) Zucker rats, aged 16-18 wk were purchased from Iffa-Credo (L'Abresle, France) and were housed at 22℃[23]. All procedures were performed under isoflurane inhalation anaesthesia. Experiments were conducted according to European Union regulations for animal experiments (Directive 86/609 CEE).

Liver procurement and experimental groups

The surgical technique was performed as previously reported[23,24]. After cannulation of the common bile duct, the portal vein was isolated and the splenic and gastroduodenal veins were ligated. All animals were randomly distributed into groups as described below. The steatotic livers were flushed and preserved in cold IGL-1® solution for 24 h with or without the addition of IGF-1 (10 μg/L), as described elsewhere[21,22,25].

All animals were randomized according to the experimental protocols, as follows.

Cold storage: After 24 h of cold storage at 4℃, livers from 8 Zucker rats preserved in IGL-1 solution with (IGL-1 + IGF-1) or without IGF-1 were flushed with Ringer's lactate solution. Control livers (Cont 1) from 8 Zucker rats (Ob) were flushed with Ringer's lactate solution at room temperature immediately after laparotomy *via* the portal vein without cold storage. Aliquots of the effluent flush were sampled for measurements of cumulative AST and ALT after 24 h cold storage.

Cold storage and reperfusion: Briefly, after 24 h cold storage at 4℃, livers from 8 Zucker rats (Ob) preserved in IGL-1 and IGL-1 + IGF-1 solutions were subjected to 2 h reperfusion at 37℃, as previously reported[13,24]. Control livers (Cont 2) from 8 Zucker rats (Ob) were flushed with Ringer's lactate at room temperature and immediately perfused *ex vivo* without ischemic preservation.

Transaminase assay

Hepatic injury was assessed in terms of transaminase levels with commercial kits from RAL (Barcelona, Spain)[26].

Briefly, 200 μL of effluent perfusate were added to the substrate provided by the commercial kit and then alanine aminotransferase (ALT)/aspartate aminotransferase (AST) levels were determined at 365 nm with a UV spectrometer and calculated following the supplier's instructions.

Hepatic clearance

As with bile output, hepatic clearance was considered as another parameter of hepatic function. Thirty minutes after the onset of perfusion (t_{30}), 1 mg of sulfobromophthalein (BSP) (Sigma, Madrid, Spain) was added to the perfusate. The concentration of BSP in bile samples (t_{120}) was measured at 580 nm with a UV-visible spectrometer. Bile BSP excretion was expressed as a percentage of perfusate content (t_{120} bile/t_{30} perfusate*100)[23].

Vascular resistance

Liver circulation was assessed by measuring perfusion flow rate and vascular resistance. Perfusion flow rate was assessed continuously throughout the reperfusion period and expressed as mL/min per gram of liver. Vascular resistance was defined as the ratio of portal venous pressure to flow rate and expressed in mmHg/min per gram of liver/mL[26].

Glutamate dehydrogenase activity

Glutamate dehydrogenase (GLDH) was used as an indirect measure of mitochondrial damage. GLDH was measured in the perfusate as described elsewhere[26].

Lipid peroxidation assay

Lipid peroxidation in liver was used as an indirect measure of the oxidative injury induced by ROS. Lipid peroxidation was determined by measuring the formation of malondialdehyde (MDA) with the thiobarbiturate reaction[13].

Determination of nitrite and nitrate

NO production in liver was determined by tissue accumulation of nitrite and nitrate[13].

Western blotting analysis of eNOS, AKT, P38 and ERK 1/2

Liver tissue was homogenized as previously described and proteins were separated by SDS-PAGE and transferred to PVDF membranes[27-29]. Membranes were immunoblotted using the following antibodies: eNOS (Transduction Laboratories, Lexington, KY, USA), total and phosphorylated AKT, total and phosphorylated P38, and total and phosphorylated ERK 1/2 (Cell Signaling, Beverly, MA, USA) and β-actin (Sigma Chemical, St. Louis, MO, USA). Signals were detected by the enhanced chemiluminescence kit (Bio-Rad Laboratories, Hercules, CA, USA) and quantified by scanning densitometry as previously described[26,28].

TNF-α determination

Perfusate TNF-α levels were measured after 120 min of reperfusion using a commercial immunoassay kit for rat TNF-α from Biosource (Camarillo, CA, USA)[30,31].

Statistical analysis

Data are expressed as means ± SE, and were compared statistically by variance analysis, followed by the Student-Newman-Keuls test (Graph Pad Prism software). $P < 0.05$ was considered significant.

RESULTS

Protective effect of IGF-1 against liver injury and function

As shown in Figure 1A and B, the AST and ALT levels observed for steatotic livers preserved for 24 h at 4℃ in IGL-1® solution confirmed their poor tolerance to cold ischemia injury. IGF-1 addition prevented AST/ALT release from steatotic livers when compared with IGL-1 alone.

Similar AST/ALT profiles were obtained when fatty livers were subjected to normothermic reperfusion for 30 and 120 min, respectively. Reduced AST/ALT levels were observed when IGL-1 was enriched with IGF-1 (Figure 1C and D). Similar profiles were seen for 60 and 90 min of reperfusion (data not shown).

The mechanisms by which IGF-1 protects fatty livers against the harmful consequences of cold I/R damage were also investigated. For this reason, liver function was evaluated by the alterations in BSP clearance and vascular resistance, respectively. A reduction in BSP clearance was found in IGL-1 solution when compared to Cont 2. The highest BSP clearance in bile was observed after 2 h of normothermic reperfusion when IGF-1 was present (Figure 2A).

Vascular resistance was increased by IGL-1 solution (Figure 2B), but this was reversed by the addition of IGF-1. These alterations in vascular resistance were also seen in all groups at 30 and 120 min of reperfusion (Figure 2B).

Beneficial effects of IGF-1 on AKT and NO after reperfusion

In order to explore whether the beneficial effects of IGF-1 in IGL-1 solution are associated with other protective cell signalling involved in the protective mechanisms against IRI, we evaluated the changes in AKT and NO levels. As shown in Figure 3, IGF-1 increased AKT phosphorylation when compared to IGL-1 alone and Cont 2, respectively (Figure 3A). This was concomitant with a significant generation of NO, as revealed by the nitrites/nitrates levels, as well as eNOS activation (Figure 3B and C).

Role of IGF-1 on liver oxidative stress, mitochondrial damage and TNF-α release after reperfusion

In order to examine the relationship between the parameters studied and others associated with the poor tolerance of fatty livers to reperfusion injury, we evaluated lipid peroxidation (MDA) and mitochondrial damage (GLDH). Steatotic livers preserved in IGL-1 showed significant MDA augments when compared to Cont 2. These increases were significantly prevented by the addition of IGF-1 (Figure 4A). In accordance with this, IGF-1 also diminished liver mitochondrial damage, as shown by the reduction in GLDH (Figure 4B). These beneficial effects of IGF-1 were

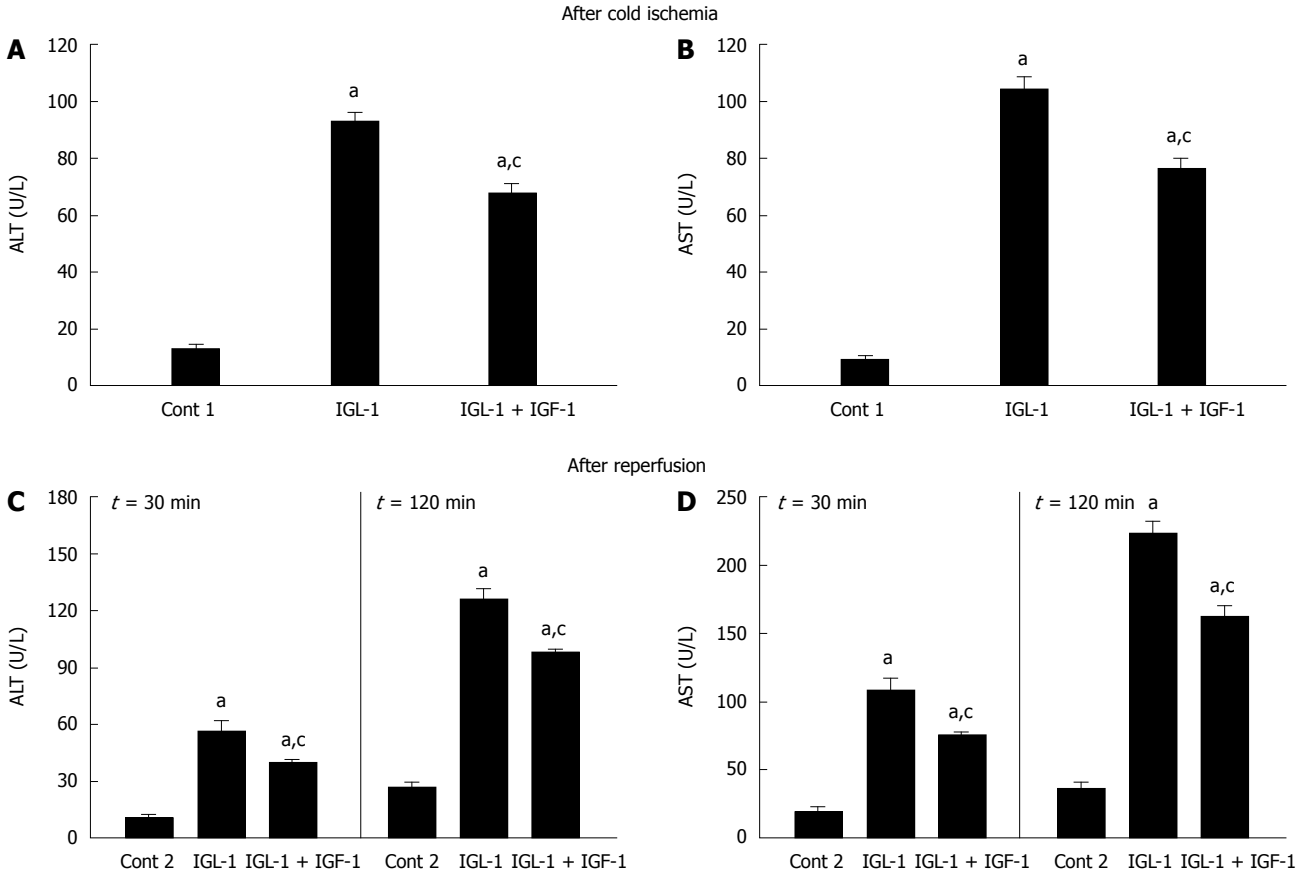

Figure 1 Alanine aminotransferase (A) and aspartate aminotransferase (B) levels in perfusate after 24 h cold storage, alanine aminotransferase (C) and aspartate aminotransferase (D) levels in perfusate after 30 and 120 min of normothermic reperfusion. Cont 2: Liver flushed and perfused *ex vivo* without cold preservation; IGL-1: Livers preserved in IGL-1 solution; IGL-1 + IGF-1: Livers preserved in IGL-1 with IGF-1. $^{a}P < 0.05$ *vs* Cont 2, $^{c}P < 0.05$ *vs* IGL-1. BSP: Sulfobromophthalein; IGF-1: Insulin like growth factor-1; IGL-1: Institut georges lopez-1.

also accompanied by a significant reduction in pro-inflammatory cytokine TNF-α level when compared to IGL-1 alone after 2 h normothermic reperfusion (Figure 4C).

Effects of IGF-1 on p-P38 and p-ERK MAPKs after reperfusion

Finally, we examined the effects of IGL-1 with and without IGF-1 on P38 and ERK 1/2 MAPKs, whose activation is closely related with hypothermic conditions. Figure 5 shows increased phosphorylation of ERK 1/2 and P38 MAPK in IGL-1 solution when compared to Cont 2, but again this increase was offset by the addition of IGF-1.

DISCUSSION

IGF-1 is a 70-amino-acid polypeptide, mainly synthesized by the liver, with protective effects against IRI in a variety of tissues[32-35], including the liver[18]. We recently reported

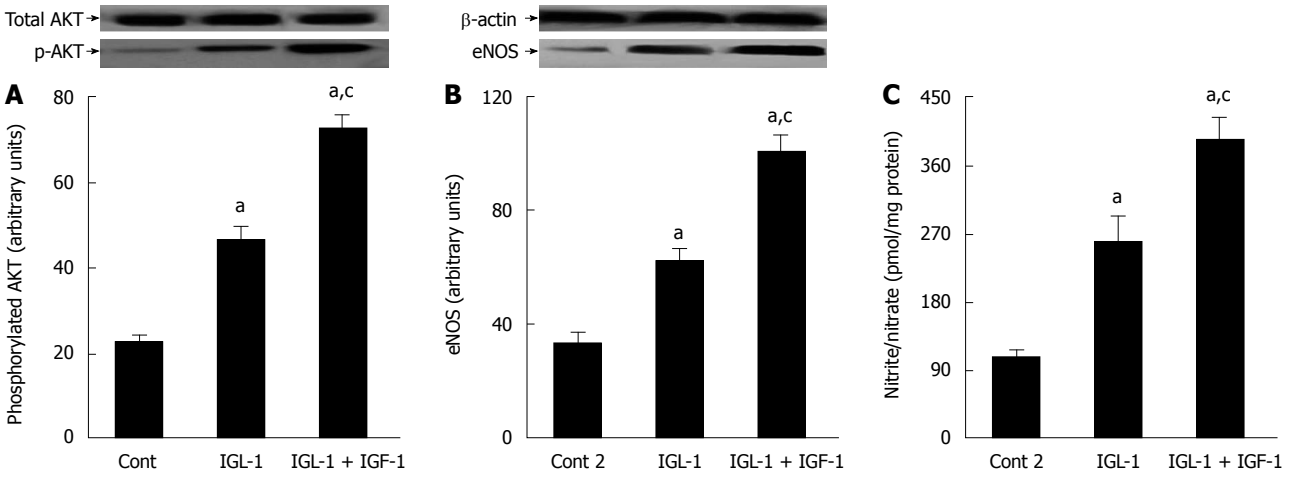

Figure 3 Beneficial effects of insulin like growth factor-1 on AKT and nitric oxide in steatotic liver graft preservation. that IGF-1 protects steatotic livers subjected to warm IRI, but its role in fatty liver preservation has been poorly investigated[18]. For this reason, we explored the effect of IGF-1 supplementation of serum free IGL-1® solution, which has been shown to protect fatty livers against cold IRI[13]. We used the concentration of IGF-I (10 μg/L) according to previous studies carried out in different experimental models. In these studies, IGF-I it was used to supplement UW solution in dog kidney transplantation, as well as, primary canine kidney tubule and human umbilical vein endothelial cell cultures[21,22,25,36]. The results reported here show that the addition of IGF-1 to IGL-1® solution significantly improved fatty liver preservation, as evidenced by the reduction in AST/ALT levels. These results are consistent with previous reports by other authors, who demonstrated that the addition of TF to UW solution improves the survival of orthotopic liver allografts[21].

BSP clearance in bile is a useful tool for assessing liver function after prolonged cold ischemia[23,24]. It is well established that complications in biliary structures appear in more than 25% of liver transplant recipients. The increases in BSP clearance observed in IGL-1 + IGF-1 solution revealed that IGF-1 supplementation enhances steatotic graft function.

Steatosis is the result of intracytoplasmic fat accumulation, which is associated with an increase in hepatocellular volume, induced distortion and narrowing of sinusoids with a reduction in the luminal diameter by up to 50% when compared to normal liver[5]. This provokes severe alterations in hepatic blood flow and microcirculation, and prevents appropriate revascularization of the graft. The benefits of the use of IGL-1® solution for fatty liver preservation are associated with its capacity to generate NO[13], a potent vasodilator involved in the regulation of hepatic microcirculation, through eNOS activation, as previously reported by us[24]. Moreover, it has been established that IGF-1 up-regulates eNOS activity by interacting with a tyrosine kinase membrane receptor which activates the AKT signalling pathway[19,37,38]. The results of the present study show that IGF-1 increases AKT phosphorylation and enhance eNOS activation induced by IGL-1® alone. This in turn induces NO generation, which reduces vascular resistance following reperfusion. This is in line with several reported studies demonstrating that a low concentration of eNOS-derived NO maximizes blood perfusion, promotes cell survival and protects the liver against IRI[39]. In contrast, the sustained presence of iNOS-derived NO might become detrimental by increasing toxic reactive oxygen species, thus leading to liver injury[39-41]. In our experimental model, the benefits of NO were not associated with iNOS activation (data not show). Moreover, other studies demonstrate that while increasing e-NOS, IGF-1 inhibits inducible NO[19,42].

It is clear that fatty accumulation resulting from steatosis induces ultra-structural and biochemical changes in liver mitochondria[43,44], which may render these organelles intrinsically more susceptible to IRI injury. Given that mitochondria are the main sites of ROS production in IRI, the increased oxidative stress observed in steatotic livers after cold IRI could be attributed to mitochondrial damage. It is well known that IGF-1 prevents mitochondrial damage and oxidative stress following IRI[17,33,34]. Our results indicate that the addition of IGF-1 to IGL-1® preservation solution increases liver mitochondria protection, and prevents ROS generation associated with reperfusion injury.

Vairetti *et al*[45] using the same "*ex vivo*" experimental model, have shown that TNF-α is released when fatty livers are subjected to cold ischemia reperfusion. In our conditions, TNF-α release was also evidenced in response to cold ischemia-reperfusion insult.

IGF-1 supplementation prevented the release of TNF-α[46], which has a pivotal role in the progression of liver reperfusion damage. This finding is consistent with the accumulating evidence of crosstalk between IGF-1 and TNF-α during ischemia reperfusion injury[47]. NO generated by IGF-1 could decrease TNF-α release, as occurs in liver ischemic preconditioning, in which the induced hepatoprotection is also mediated by the inhibitory action of NO on TNF-α release through eNOS activation[48].

In addition, several intracellular signalling pathways, including the extracellular signal-regulated kinases 1/2 and P38 mitogen-activated protein kinase, are activated during hypothermia[49-52], In these conditions, a mutual activation effect between TNF-α and MAPKs may also occur thus exacerbating the liver damage[53]. Our results indicate that cold storage in IGL-1® solution alone activates P38 and ERK 1/2, and that IGF-1 addition prevented this activation, which is consistent with a TNF-α reduction that leads to an improvement in liver injury and function. This is in line with previous reports that the addition of TF to UW improved endothelial cell preservation by reducing ERK 1/2 and P38 activation[22].

In conclusion, we have demonstrated that IGF-1 addition to IGL-1® solution protects fatty liver against cold IRI. The beneficial action of IGF-1 appears to be mediated by AKT activation and NO generation, with concomitant prevention of pro-inflammatory cytokines, such as TNF-α. However, further studies will be required to examine the underlying mechanisms. This may increase the use of steatotic livers, which partially compensates the shortage of organs for transplant.

COMMENTS

Background

Static preservation solution is crucial for graft viability; especially when steatosis is present. Serum-free preservation solutions deprive the donor organ of essential trophic factors such as insulin like growth factor-1 (IGF-1) which is associated with deleterious effects including cell cycle arrest and death. The addition of IGF-1 to University of Wisconsin (UW) solution improves the capacity of this preservation solution for protecting liver grafts subjected to a prolonged ischemic period. Serum-free institut georges lopez-1 (IGL-1) solution has been proposed as an effective alternative to UW for steatotic liver preservation.

Research frontiers

In this study, the authors focused on the importance of IGF-1 as a biological additive to IGL-1 preservation solution. The induction of nitric oxide (NO) synthesis by the modified IGL-1 solution improves microcirculatory disorders in fatty livers. IGL-1 supplementation with IGF-1 increases graft protection against ischemia reperfusion injury through the activation of protein kinase AKT and a concomitant reduction in tumour necrosis factor (TNF) release and P38/ERK 1/2 MAPKs activation which play an important cryoprotective role in liver graft preservation.

Innovations and breakthroughs

The enrichment of IGL-1 solution with IGF-1 increases NO generation through AKT activation and prevents pro-inflammatory cytokine release such as TNF-α during steatotic liver graft reperfusion.

Applications

The use of modified IGL-1 solutions should be a useful strategy for increasing steatotic liver graft preservation.

Peer review

This manuscript describes the beneficial effects of IGF-1 when added to IGL-1 solution in the preservation of (fatty) liver.

Abstract

AIM: To investigate the effects of dextrans of various molecular weights (Mw) during a 12 h cold storage time-course on energetics, histology and mucosal infiltration of fluorescein isothiocyanate (FITC)-dextran.

METHODS: Rodent intestines were isolated and received a standard University of Wisconsin vascular flush followed by intraluminal administration of a nutrient-rich preservation solution containing dextrans of varying Mw: Group D1, 73 kdal; Group D2, 276 kdal; Group D3, 534 kdal; Group D4, 1185 kdal; Group D5, 2400 kdal.

RESULTS: Using FITC-labeled dextrans, fluorescent micrographs demonstrated varying degrees of mucosal infiltration; lower Mw (groups D1-D3: 73-534 kdal) dextrans penetrated the mucosa as early as 2 h, whereas the largest dextran (D5: 2400 kdal) remained captive within the lumen and exhibited no permeability even after 12 h. After 12 h, median injury grades ranged from 6.5 to 7.5 in groups D1-D4 (73-1185 kdal) representing injury of the regenerative cryptal regions and submucosa; this was in contrast to group D5 (2400 kdal) which exhibited villus denudation (with intact crypts) corresponding to a median injury grade of 4 ($P < 0.05$). Analysis of tissue energetics reflected a strong positive correlation between Mw and adenosine triphosphate ($r^2 = 0.809$), total adenylates ($r^2 = 0.865$) and energy charge ($r^2 = 0.667$).

CONCLUSION: Our data indicate that dextrans of Mw > 2400 kdal act as true impermeant agents during 12 h ischemic storage when incorporated into an intraluminal preservation solution.

Key words: Intraluminal preservation solution; Intestinal-specific; Osmotic impermeant; Organ preservation; Cold storage

INTRODUCTION

Small bowel transplantation (SBT) has become an essential treatment for patients with irreversible intestinal failure who do not succeed on parenteral supplementation[1]. The global frequency and success rates of such procedures have seen steady increases over the last decade[1]. While only 11 intestinal transplants were performed in 1990, 140 cases were reported in 2003; currently approximate 200 are performed annually across the world[1]. For those individuals receiving antibody-based induction therapy and tacrolimus-based maintenance immunosuppression, one year post-transplant survival rates are comparable to those of liver (> 80%)[1]. The majority of individuals do not receive these therapies, hence 5-year graft survival rates for SBT remain low (31%-69%; 48% weighted average for 2005 data) compared to other commonly transplanted organs[2].

Among the obstacles to successful SBT is the extreme susceptibility of the mucosal epithelium to even brief periods of ischemia[3]. For this reason, the ability to successfully preserve graft viability during the period of ischemic cold storage is critical. Preventing hypothermia-induced cellular swelling is a basic principle of successful organ preservation[4]. One major advancement in preservation solution technology and design was the development of the "gold standard" preservation solution, the University of Wisconsin (UW) solution. Improvements in organ quality and safe cold ischemic times can be largely attributed to the control of cellular edema. This was accomplished by including cell-impermeant molecules lactobionate, raffinose, and hydroxyethylstarch (HES)[5]. With respect to the intestine, studies have shown that net fluid shifts contributing to mucosal injury can originate from the vasculature or lumen[6,7]. Since standard intestinal procurement involves a common intra-aortic flush of all abdominal organs, current preservation strategies do not address fluid shifts of a luminal origin.

Throughout the last several years, our laboratory has developed a novel nutrient-rich preservation solution (containing a large amino acid component) tailored to the specific metabolic requirements of the small intestine; termed AA solution. Numerous *in vitro* and *in vivo* models have documented superior maintenance of energetics, a reduction in oxidative stress, and a preservation of mucosal morphology and barrier function following intraluminal administration of the nutrient-rich solution[8-10]. We have demonstrated the benefits of using a high molecular weight (Mw) HES (2200 kdal) as an impermeant molecule in our novel solution[11,12], with no direct evidence that the starch molecule does not penetrate the mucosal barrier during ischemia. Recent data from our lab has demonstrated that dextran (Mw = 70 kdal) is not osmotically active when delivered as part of an intraluminal preservation solution; direct visualization of a fluorescently-labeled dextran-70 clearly showed the rapid migration of the dextran into the mucosa. This has raised the question as to the exact Mw characteristic of an effective impermeant agent in the realm of intestinal ischemia as it relates to a novel strategy of intraluminal preservation.

Although the UW solution contains HES on the basis of preventing interstitial edema incurred during cold ischemia[4], there exists controversy over its effectiveness for static organ storage. Some studies report that HES may be omitted from the UW solution without detrimental effects on overall graft quality[13-15], while others suggest a protective role of HES in stored tissues[16-20]. Because these previous studies deal solely with an intravascular delivery of UW solution, they do not provide information about the role of colloids in preservation solutions administered intraluminally for intestinal grafts. We suspect that during cold storage, alterations in the permeability characteristics of the mucosa will result in the infiltration of relatively large osmotic agents, thereby failing to effectively control tissue edema and mucosal viability. We hypothesized that there is a critical Mw for an effective osmotic agent to be used in an intraluminal preservation solution during cold ischemic storage.

MATERIALS AND METHODS

Summary of experimental design

Briefly, small intestines from rats were flushed intravascularly with UW solution, isolated and flushed intraluminally with a nutrient-rich preservation solution containing 5% dextran of varying Mw (73, 276, 534, 1185, 2200 kdal). Fluorescein isothiocyanate (FITC)-labeled dextrans to a final fluorescence of 10×10^6 fluorescence units/mL were incorporated into the solutions to aid in direct visualization of dextran infiltration. Intestines were stored at 4℃ and samples were taken over a 12 h time-course for subsequent analysis.

Surgical procedure and intestinal procurement

Male Sprague-Dawley rats (200-250 g) were obtained from the University of Alberta and used as organ donors. All experiments were conducted in accordance with Canadian Council on Animal Care policies. Animals were fasted overnight and provided water *ad libitum*. Rats were induced with pentobarbital (65 mg/250 g; IP), followed by inhalational isoflurane (0.5%-2%) to maintain anesthesia. Following a midline laparotomy, the aorta was exposed infrarenally and at the celiac trunk. The supraceliac aorta was clamped and 2-4 mL modified UW solution was administered *via* the infrarenal aorta. The vena cava was transected to facilitate the outflow of blood and perfusate. The entire jejunum and ileum was subsequently harvested. A nutrient-rich preservation solution (AA solution), developed in our lab, was used to flush and clear the lumen of its contents (40 mL; approximate 2.0 mL/g). Sixteen centimeter-long sections of ileum were measured out. The sections were filled at the proximal end with 4-5 mL nutrient-rich preservation solution containing 5% dextran of varying Mw (fluorescence was standardized to 10×10^6 fluorescence units/mL and each end ligated with 3-0 silk). The preservation solution contained (values in brackets are mmol/L): Glutamine (35), Lactobionate (20), Glutamate (20), Aspartate (20), Glucose (20), BES [N,N-Bis(2-hydroxyethyl)taurine] (15), Arginine (10), Glycine

(10), Asparagine (10), Threonine (10), Lysine (10), Valine (10), Serine (10), Methionine (5), Leucine (5), Isoleucine (5), Histidine (5), Ornithine (5), Proline (5), Adenosine (5), Cysteine (5), β-Hydroxybutyrate (3), Tyrosine (1), Tryptophan (1), Trolox (1), 3-Aminobenzamide (1), Allopurinol (1); plus the inclusion of 5% Dextran. The pH of each solution was adjusted to 7.40 with sodium hydroxide; measured osmolarity was 320 mOsm.

Group designations were as described in Table 1; briefly the dextran Mw for the 5 groups (D1-D5) were: 73 (D1); 276 (D2); 534 (D3); 1185 (D4); 2400 (D5) kdal.

Tissues were stored on ice at 4℃ in standard AA solution and sampled at 2, 4, and 12 h; at each time-point a 4 cm length of intestine was sampled; half was used for histology and half for metabolite analysis. To arrest metabolic activity, samples were snap frozen in liquid nitrogen, and stored at -65℃ until processed.

FITC-labeling of dextrans

Dextrans used in this study were obtained from American Polymer Standards Corporation, Ohio, US; these dextrans were of the highest purity available and characteristics are provided in Table 1. Briefly, peak average molecular weight (Mp), weight average molecular weight (Mw), number average molecular weight (Mn), and polydispersity index (PDI) describe molecular distribution curves. The key parameter defining dextran purity is the PDI with a value of 1.0 representing absolute purity. PDI values of less than 3 represent high purity fractions; hence values in the current study of 1.35 to 1.67 are of extremely pure dextran fractions. The procedure used to FITC-label the dextrans from the above solutions was based on the original procedure used by De Belder and Granath[21]. The dextran of interest together with fluorescein 5-isothiocyanate (FITC) were dissolved in dimethyl sulphoxide, pyridine and dibutyltin dilaurate and heated to 95℃ for 2 h. The mixture was then put on ice and the dextran was precipitated out with cold 100% ethanol, filtered and dried in an oven at 40℃. Labeling efficiency was 0.015-0.020; this corresponds to 1 fluorescein molecule per 50-67 glucose units. FITC-labeled dextran accounted for 8.5% ± 0.6% of total dextran in each solution; fluorescence was standardized. Fluorescence for FITC-dextrans was evaluated at an excitation wavelength = 485 nm/emission wavelength = 535 nm.

Stability of the FITC label

When labeling fluorescent moieties to target molecules, one of the key concerns that must be considered for subsequent experimentation to be valid is that the fluorescent label must remain bound to the target and does not spontaneously detach over time when in aqueous solution. In this study, a dilute solution (approximate 0.1%) of each dextran was incubated at 4℃ for 24 h. Following the incubation period, FITC-dextrans were precipitated with cold 100% ethanol, centrifuged, and the supernatant (containing free FITC) was assessed for fluorescence. When solutions were incubated at 4℃, there were no statistically significant decreases in FITC-bound dextrans; this indicated a stable conjugation for all high-purity dextrans used in this study.

Sample preparation and metabolite assay

Frozen small bowel samples were weighed and then extracted 1:5 weight/volume in perchloric acid containing 1 mmol/L ethylenediamine tetra-acetic acid. The precipitated protein was removed by centrifugation (20 min at 20000 × *g*). Acid extracts were neutralized by the addition of 3 mol/L KOH/0.4 mol/L Tris/0.3 mol/L KCl and then recentrifuged (20 min at 14000 × *g*). Aliquots of neutralized extracts were immediately processed *via* standard enzyme-linked metabolite assays[22]. Spectrophotometric analysis was then performed to measure the absorbance of NADH at 340 nm, providing quantification of adenosine triphosphate (ATP), total adenylates [ATP + adenosine diphosphate (ADP) + adenosine monophosphate (AMP)] and energy charge [(ATP + 0.5 ADP)/total adenylates] and malondialdehyde[22,23]. Values are reported as μmol per gram protein. Protein was measured according to the method of Lowry *et al*[24].

Histology

Bowel samples were fixed in alcohol formalin solution, processed to paraffin wax, embedded, and sections cut at 5 μm. Sections were dewaxed then mounted with Prolong Gold anti-fade reagent with 4',6-diamidino-2-phenylindole (DAPI; Invitrogen) and sealed with nail polish. Fluorescent microscopy was used to view FITC and DAPI fluorescence in tissues; wavelengths were Ex = 485/Em = 535 and Ex = 360/Em = 460, respectively. Fluorescent images were digitally captured using AxioVision software. All photos shown reflect representative findings. A second set of sections were stained with hematoxylin and eosin and graded according to a modified Park's classification for intestinal injury[25] as follows.

Grade 0: Normal mucosa; grade 1: Subepithelial space at villus tip; grade 2: Moderate subepithelial space; grade 3: Epithelial lifting along villus sides; grade 4: Denuded villi; grade 5: Loss of villus tissue; grade 6: Crypt layer injury; grade 7: Transmucosal injury; and grade 8: Transmural injury.

Statistical analysis

Metabolite data were reported as mean ± SE for each

Table 2 Intestinal morphology following cold ischemic storage

Time (h)	Group	Grade	Median	Significance	Event
2	D1	0, 2, 6, 7	4		Denuded villi
	D2	3, 4, 6, 6	5		Loss of villi
	D3	1, 2, 2, 3	2	D3, D4, D5 *vs* D1, D2, $P = 0.06$	Moderate clefting
	D4	1, 2, 3, 5	2.5		Moderate-extensive clefting
	D5	1, 2, 3, 4	2.5		Moderate-extensive clefting
12	D1	0, 6, 7, 8	6.5		Injury to crypts and submucosa
	D2	2, 6, 7, 7	6.5		Injury to crypts and submucosa
	D3	3, 7, 8, 8	7.5		Injury to crypts, submucosa and muscularis
	D4	3, 6, 8, 8	7		Injury to crypts and submucosa
	D5	0, 4, 4, 5	4	D5 *vs* D1-D4, $P < 0.05$	Clefting and denuded villi

A modified Park's classification for intestinal injury was used to assess mucosal morphology as follows: Grade 0: Normal mucosa; Grade 1: Subepithelial space at villus tip; Grade 2: Moderate subepithelial space; Grade 3: Epithelial lifting along villus sides; Grade 4: Denuded villi; Grade 5: Loss of villus tissue; Grade 6: Crypt layer injury; Grade 7: Transmucosal injury; Grade 8: Transmural injury.

group. Statistical differences between groups were determined using analysis of variance, followed by Student-Newman-Keuls'. Analysis of relationships between Mw and ATP, total adenylates, or energy charge was performed with a linear regression analysis for parametric data. Differences in histology grades were assessed by a non-parametric Kruskal-Wallis test.

RESULTS

Infiltration of FITC-labeled dextrans during cold ischemic storage

The lower Mw dextrans tested (D1, D2, D3) consistently demonstrated infiltration of the fluorescent label at all time-points. At the earlier time-points, 2 and 4 h, fluorescence intensity was greatest in the epithelium or in sloughed epithelial cells. After 12 h storage, there was significant infiltration into the cryptal regions, the lamina propria, as well as the vascular epithelium. Mucosal injury was greatest in these groups (D1, D2, D3), ranging from development of subepithelial clefts at 2 h to complete denudation at the later time-points, leaving the underlying tissue vulnerable to further dextran penetration.

Interestingly, the intermediate Mw dextran, D4, exhibited no extensive penetration of label into the epithelial layer and largely remained within the layer of mucous coating the surface of the villi. Several goblet cells and the apices of some villi did have a minor amount of fluorescence. However, by 4 h, there was considerable infiltration of the dextran label throughout the underlying tissue. Limited mucosal injury was apparent even after 12 h storage, at which time epithelial clefting had developed. Treatment with the highest Mw tested, D5, resulted in no observable infiltration into the epithelium or lamina propria; this was evident at all time-points (Figure 1).

Evidence of mucosal injury

Histologic injury was evident early on during cold storage, particularly for the lower Mw dextrans after only 2 h. Most notably, in groups D1 and D2, 50% of specimens exhibited a significant degree of crypt infarction, compared to no evidence of crypt infarction in groups D3, D4, and D5 ($P = 0.06$).

By 12 h, 75% (12/16) of specimens in groups D1-D4 had an injury grade of 6 or greater (damage to the crypts, mucosa, or transmural injury). Conversely, 75% of specimens in Group D5 exhibited clefting where the epithelium had lifted off the underlying lamina propria (grade 3) and at times had dissociated from the villus proper (grade 4) ($P < 0.05$). A summary of injury grading and median grades are presented in Table 2. Representative fields of injury are presented in Figure 2 micrographs.

ATP, total adenylate, energy charge levels

Following 12 h cold storage, ATP levels ranged from 5.3 to 9.6 μmol/g, with D1 and D2 having the lowest levels (5.3-5.6 μmol/g). Intermediate Mw groups, D3 and D4, exhibited intermediate ATP levels, both significantly different from D1 and D2 ($P < 0.05$). ATP progressively increased to a maximum of 9.6 μmol/g in D5; this group had significantly greater levels than all other groups ($P < 0.05$). Levels of total adenylates (ATP + ADP + AMP) closely resembled those of ATP. Levels in groups D2 and D3 were significantly higher than in D1 and D2, $P < 0.05$. Similarly, D5 level was significantly greater than all groups, $P < 0.05$. Atkinson described another useful measure of tissue energetics, "energy charge" as: EC = (ATP + ADP/2)/total adenylates[26]. In illustrating the significance of this measurement, Pegg used the analogy of a battery in describing the energy charge as being a measure of the "charged up" state of the adenylate pool[27]. As ATP levels decline relative to ADP and AMP levels, energy charge also drops, indicating that less of the total adenylate pool exists in a form that is immediately available for cellular work. Energy charge ratios showed similar trends to those of ATP and total adenylates. Values increased as Mw of the dextran increased, starting at 0.45 in D1 and reaching 0.62 in D5; D5 value was significantly different than all values in groups D1-D4 ($P < 0.05$) (Figure 3).

Correlation between energetics and dextran Mw

With respect to dextran Mw, there was a strong positive and statistically significant correlation with ATP ($r^2 = 0.809$); total adenylates ($r^2 = 0.865$); and energy charge

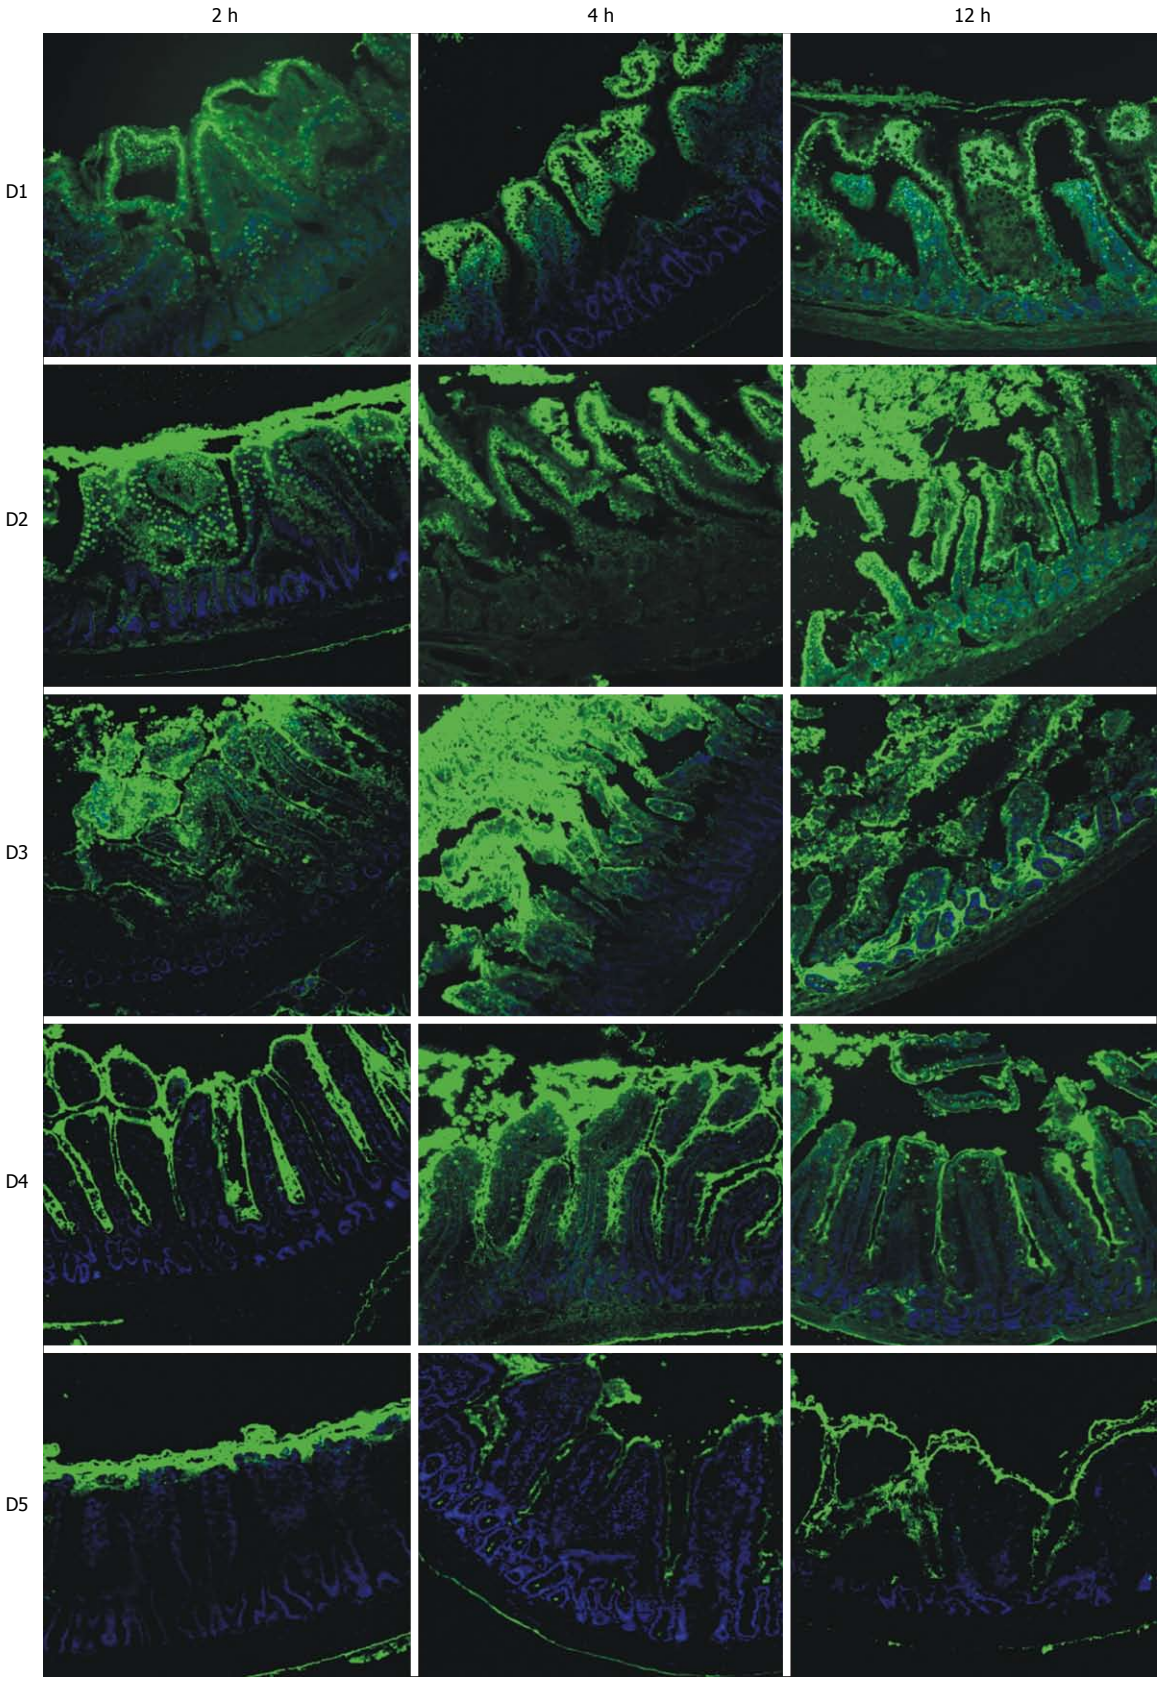

Figure 1 Infiltration of fluorescein isothiocyanate-labeled dextrans during cold ischemic storage. All magnifications (× 10 objective) are of representative fluorescent intensities and mucosal injury. All photos have a standardized exposure time of 250 ms for the fluorescein isothiocyanate channel; exposure times for 4',6-diamidino-2-phenylindole, a common nuclear stain, are 2-20 ms and are included for contrast.

(r^2 = 0.667). Overall, group D5 was the most effective in preserving the three parameters of tissue energetics over the 12 h period of cold ischemic storage, while lower Mw groups exhibited poor conservation of energetics. Supe-

rior maintenance of energetic parameters supported the preservation of mucosal viability as determined by direct histologic observation of mucosal morphology as well as penetration of the FITC-labeled dextrans (Figure 4).

Oxidative stress

No significant differences were detected among groups D1-D5 with respect to the parameter of oxidative stress (malondialdehyde) after 12 h storage; values varied between 236 and 274 nmol/g protein in all 5 experimental groups (data not shown).

DISCUSSION

The major clinical application of dextrans, in addition to other starches and albumin, has been for their plasma volume expansion properties. These molecules exert their osmotic effects by binding water within the vasculature and creating an osmotic force to extract water from edematous tissues. The Mw of a molecule required to remain captive within the vasculature is very low as demonstrated by the effectiveness of an intravascular flush during organ procurement with the UW solution (osmotic agents, lactobionate and raffinose; Mw = 358 and 504, respectively). With respect to osmotic support and the application of an intraluminal preservation solution, the Mw permeability limit of the epithelial barrier during ischemic storage has not been clearly defined.

In the realm of organ preservation, osmotic agents are required to counteract the metabolic events that result in the influx of water into the cells/tissue. Under normal circumstances, cells have an extracellular environment rich in Na^+ and low in K^+[5]. The Na^+/K^+ transporter maintains the respective gradients of these ions, relying on the use of ATP as its energy source. Essentially, this pump makes Na^+ an impermeant outside of the cell, creating an osmotic force that counteracts the osmotic pressure exerted by proteins and impermeable anions in the cell interior. Together, these intracellular proteins and impermeable ions require an osmotic force of 110-140 mOsm/kg to

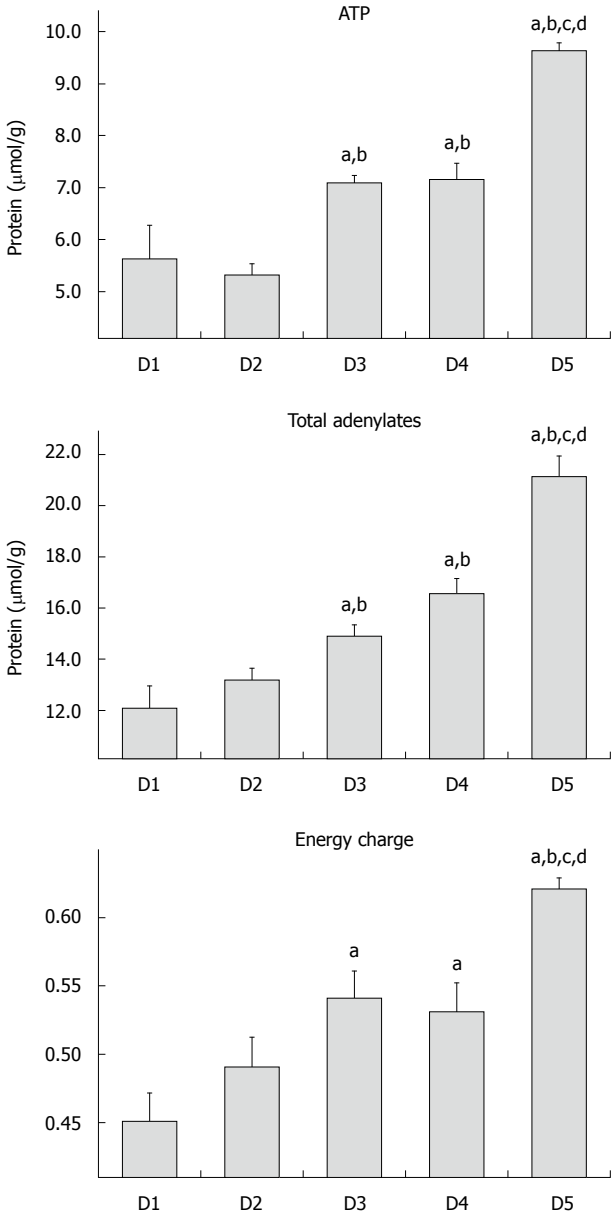

Figure 3 Parameters of energy metabolism during cold ischemic storage. Adenosine triphosphate (ATP), total adenylates and energy charge levels are presented. $^{a,b,c,d}P < 0.05$, significantly different *vs* D1, D2, D3, D4, respectively.

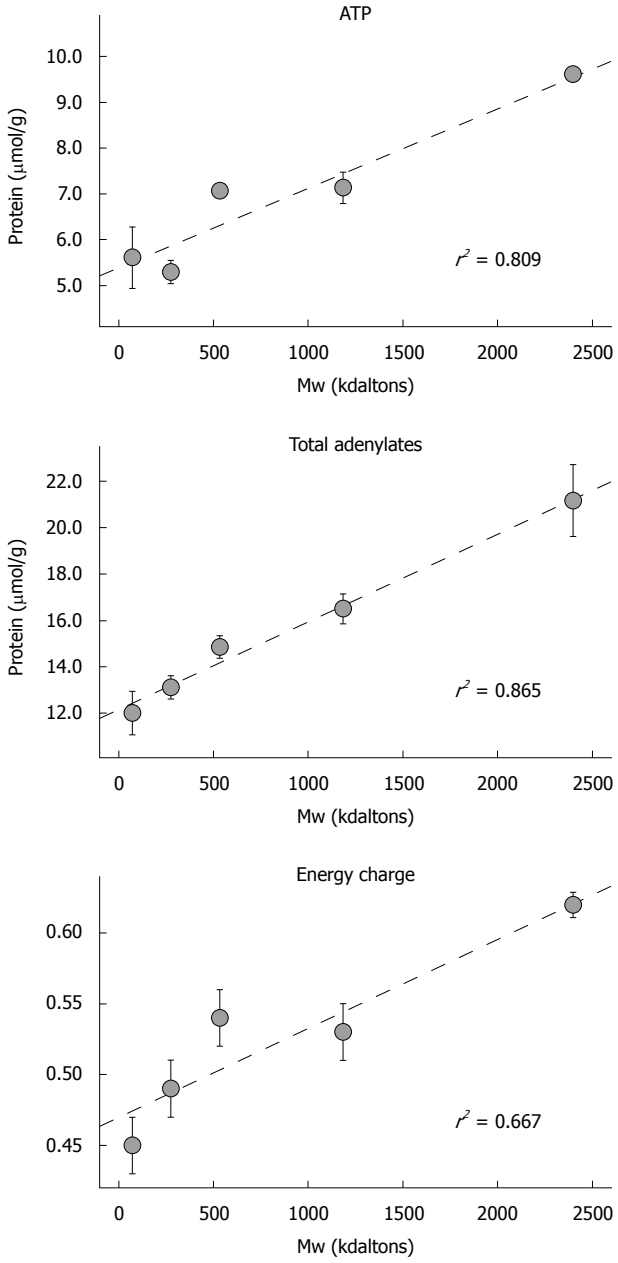

Figure 4 Correlation between dextran size and energy metabolism. Linear regression analysis was performed; correlation coeffients (r^2) are presented. ATP: Adenosine triphosphate; Mw: Molecular weight.

offset fluid flow into the cell[5]. In ischemic tissue under cold storage, the above situation is quite different. Hypothermic conditions coupled with aerobic metabolism collectively work to inhibit Na^+/K^+ ATPase activity, decreasing the cell membrane potential. As a result, Na^+ and Cl^- flow down their concentration gradients into the cell, and water follows, causing the cell to swell; cells eventually become damaged and may lyse[5,19]. Cell impermeant molecules are critically important in regulating fluid movement into the cell; there is a fundamental requirement of 110-140 mmol/L of osmotic agents in order to counteract cell swelling[5].

When utilizing an intraluminal preservation solution, inadequate osmotic support will culminate in direct injury to the epithelium. This leads to the compromise of cellular integrity and consumption of essential energy reserves in an attempt to repair damaged tissue. Depletion of cellular energy reserves (ATP and total adenylates) results in an inability of the mucosal epithelium to preserve its barrier function, compromising epithelial integrity during organ storage[20,28]. The barrier consists of numerous tight junctions located toward the apical surface of intestinal epithelial cells[8]. A number of proteins form the tight junctions, which are active, energy-consuming structures[8]. The transepithelial flow of both macromolecules and enteric bacteria are thought to be caused by tight junction dilation[3], and the consequences are twofold: (1) an increased likelihood of sepsis and (2) a need to consider the permeability of molecules used for osmotic support during preservation. Sepsis may occur due to bacterial translocation[29,30], and continues to account for the majority

of deaths after intestinal transplantation (46.0% between April 1985 and May 2003)[1]. Increased permeability of the intestine during ischemic conditions should influence the critical Mw limit for molecules added to the intraluminal preservation solution for impermeant support. Inclusion of the appropriate agent capable of acting as a true osmotic will improve the quality of the intestinal graft and ultimately influence success of the transplant.

Hydrostatic and impermeant forces regulate the movement of fluids between intracellular and extracellular compartments. Hydrostatic forces have a predominant role in continuous perfusion methods; whereas, impermeant forces are the sole contributors governing net fluid flux in the setting of static cold storage, the current standard for most intra-abdominal organs. Shifts in net fluid flow during cold storage are proposed to originate from the intestinal vasculature and/or lumen[6,7]. In the current study, fluid shifts of vascular origin were controlled by delivering a standard intra-aortic vascular flush with UW solution to all treatment groups, as would happen in the clinical situation. Keeping such fluid shifts constant was essential, allowing us to attribute any inter-group differences of luminal permeability to the specific dextran size of interest. Based on the data presented in the current communication, there was a definitive inverse relationship between dextran Mw and its ability to cross the epithelial barrier during cold storage. Several relatively large Mw dextrans (73-534 kdal) exhibited a definitive pattern of penetration of the mucosal layer within 2 h cold storage, eventually infiltrating the submucosa and muscularis propria after 12 h. The only effective dextran fraction tested that exhibited impermeant characteristics by remaining captive within the lumen even after 12 h cold ischemia was one of Mw = 2400 kdal. This study is the first to establish the critical permeability limit of the mucosal layer during intestinal preservation and to delineate the requisite Mw of a true osmotic impermeant in the lumen.

The relationship between Mw (size) and permeability determined in this study was somewhat expected based on the results from various animal and human intestinal permeability studies[15,17,18]. An inverse relationship between Mw and mucosal-to-serosal permeability has been established previously for rodents[17]. In a comprehensive report addressing comparative intestinal permeability in pig, rat, and human models, Nejdfors *et al*[15] found an inverse relationship between the Mw of marker molecules and their mucosal permeability across all species, irrespective of location in the gastrointestinal tract. The power of such a study comes from the fact that identical standardized methods of evaluating molecular permeability and a wide range of Mw were used for each species; this included ^{14}C-mannitol, FITC-dextrans 4.4/70 kdal and several proteinaceous macromolecules (α-lactalbumin, 65 kdal and ovalbumin, 45 kdal).

In an animal study assessing the uptake of FITC-dextran (Mw 70 kdal) by the small intestinal epithelium, Ekström *et al*[29] found that during neonatal development (< 30-d old) there were negligible amounts of FITC-dextran in the serum with no enterocyte infiltration. One should note that this experiment was conducted in healthy fully oxygenated tissues without any prior ischemic insult. Based on such reports, our nutrient-rich solution has in the past contained a dextran fraction with similar Mw for impermeant support[8,30,31]. There is no reason to suspect that a macromolecule which is impermeant in the lumen of a healthy bowel will do so during ischemic conditions, even at reduced temperatures. As the number of tight junctions and the magnitude of the dilatations increase, the potential for infiltration and translocation of large macromolecules and eventually bacteria also increases. As a consequence of these impermeant characteristics, the lack of osmotic support contributes directly to tissue edema and its negative sequelae. In tissues lacking sufficient impermeant support during hypothermic storage, edema becomes a major concern.

In the current study, parameters of cellular energetics (ATP, total adenylates and energy charge) consistently reflected strong and significant positive correlations with respect to dextran Mw. Although the value of ATP to the cell is obvious, higher Total Adenylate levels reflect reduced rates of purine catabolism, potentially leading to the accumulation of hypoxanthine and the production of uric acid and superoxide (a highly reactive oxygen free radical)[32]. A second consequence is that greater amounts of purines are available for ATP regeneration (once carbon exits the total adenylate pool, reconversion is not enzymatically possible in this pathway). These biochemical parameters of tissue integrity all indicate that the 2400 kdal dextran was maximally effective in protecting the mucosa from ischemic insult during cold storage.

In conclusion, the permeability characteristics of the rat small bowel during cold ischemia are very different than those of intestinal tissue that is not limited with respect to oxygen and nutrients. In order for a molecule to behave as a true osmotic impermeant, the Mw must be much greater than that established for intravascular preservation solutions. From the data presented in this study, the size of dextran showing the lowest degree of epithelial or mucosal infiltration, superior morphology and minimal disruption to cellular energetics was 2400 kdal. These findings clearly delineate the critical Mw limit that must be addressed in the development of an effective intraluminal preservation solution.

COMMENTS

Background

An effective osmotic agent is one of the fundamental requirements of organ preservation for transplantation. Commonly used preservation solutions that are typically administered *via* an intravascular route utilize low molecular weight (Mw) impermeant compounds to maintain tissue water balance. Our laboratory has developed a novel strategy for intestinal preservation involving the intraluminal delivery of a nutrient-rich preservation solution; however, an appropriate impermeant molecule has not been clearly defined.

Research frontiers

Although organ preservation methods have existed for decades, luminal administration of a preservation solution tailored to the metabolic requirements of the small bowel is a novel concept.

Innovations and breakthroughs

This study reveals for the first time that a large Mw impermeant molecule is a fundamental requirement of an intraluminal preservation solution during cold, static storage of the small intestine. Interestingly, only the highest Mw dextran (2400 kdal) remained within the intestinal lumen throughout the entire 12 h period of cold storage, resulting in superior graft energy status and tissue morphology.

Applications

The current study focused on defining a suitable osmotic agent for use in our intraluminal preservation solution, a key factor affecting intestinal viability during organ storage. As a back-table luminal flush that does not interfere with the clinical vascular preservation method, our AA solution has the potential to revolutionize intestinal preservation, and therefore improve patient outcomes following transplantation.

Peer review

The manuscript submitted by Schlachter *et al* represents a methodical and well written study investigating the protective effects of different Mw dextrans in a novel intestinal preservation solution. The findings of the study are potentially important and widely applicable to the intestinal transplantation field.

Abstract

AIM: To examine the accuracy of the aspartate aminotransferase (AST)/Platelet Ratio Index (APRI) and FIB-4, in predicting longitudinal changes in liver histology in hepatitis C virus (HCV) patients.

METHODS: Patients that underwent repeat liver biopsies at least 1 year apart from 1999 to 2007 were identified. Liver fibrosis was staged on needle core biopsies evaluated by a single expert liver pathologist. Only laboratory values within 3 mo of the liver biopsies were used.

RESULTS: Thirty-six patients met the inclusion criteria with 50% stage 1 on initial biopsy, 25% stage 2, and 22% stage 3. Nineteen of 36 (53%) had progression of fibrosis on repeat biopsies, while 16 (44%) showed no change in stage, and one (3%) showed improvement. Patients that showed progression of fibrosis had significantly higher alanine aminotransferase and aspartate aminotransferase levels than the group that did not show progression. A significant correlation was seen between change in stage of fibrosis and change in APRI (r^2 = 0.39, P = 0.00001) and a change in FIB-4 (r^2 = 0.31, P = 0.00004). A change in APRI (ΔAPRI) of 0.18 had 80% positive predictive value (PPV) and 67% negative predictive value (NPV) for progression of fibrosis. A change in FIB-4 (ΔFIB-4) of 0.39 had 75% PPV and 75% NPV for predicting progression of fibrosis.

CONCLUSION: ΔAPRI and ΔFIB-4 parallel changes in fibrosis progression, and could be useful tools for clinicians in following patients with active chronic HCV infection.

Key words: Hepatitis C; Liver fibrosis; Liver biopsy; Biomarkers

INTRODUCTION

Hepatitis C virus (HCV) infection is one of the most common causes of chronic liver disease, and affects ap-

proximately 3% of the world's population[1]. Current treatment decisions in chronic HCV are guided by the histopathological findings on liver biopsy. Although it is still considered the gold standard for assessment of fibrosis in chronic hepatitis C, liver biopsy has limitations. It is an expensive and invasive procedure with complications that range from pain (0.06%-22%) to death (0.0088%-0.3%)[2]. Liver biopsy is also limited by both inter-observer and sampling variability. Although inter-observer variability has been improved by standardized scoring systems for fibrosis and inflammation, discordance rates for the stage of fibrosis of approximately 33% have been reported[3,4]. The frequency of sampling errors is not surprising given the fact that a standard percutaneous liver biopsy specimen has been calculated to sample only 1/50 000 part of the liver[5]. Considering the expense and limitations of liver biopsy, there is great interest in the use of non-invasive markers of liver fibrosis that can replace liver biopsy both as a guide to therapy and as a prognostic indicator. Current studies have shown that non-invasive markers can predict the absence of significant disease or the presence of advanced disease at the time of liver biopsy, but it is not clear that they can predict step-wise progression of fibrosis[6]. It is also not clear if they have prognostic value regarding long-term clinical outcomes. If they can be proven to be useful longitudinally, this would be of great benefit to clinicians and their patients.

Non-invasive markers can be broadly divided into two major groups: radiological and serum-based markers. Transient elastography using ultrasound waves to measure stiffness of liver is an example of a radiological method but is limited in terms of cost, technical complexity and availability. It currently is not approved for clinical use in the United States by the Food and Drug Administration. Serum biomarkers have been proposed as an inexpensive and effective alternative to replace liver biopsy and can be subdivide into two categories: (1) indirect markers that are composed of simple routine biochemical and/or hematological tests; and (2) markers composed of substances that are part of the extracellular matrix (ECM). Although simple markers are inexpensive and available universally, the markers of ECM are expensive and available only in reference or research laboratories. Two indirect marker panels, aspartate aminotransferase (AST)/Platelet Ratio Index (APRI) and FIB-4, are composed of panels that are routinely preformed in patients with liver disease, and therefore, could be a practical and convenient way to follow patients[7,8].

Most studies of biomarkers in fibrosis have compared their diagnostic accuracy in predicting the presence of mild *vs* significant fibrosis, mild/moderate *vs* advanced fibrosis, or cirrhosis, using a liver biopsy obtained at the same time as the gold standard[6]. This approach has limitations because liver biopsy is a less than ideal reference standard and it is not clear if these biomarkers are useful in identifying patients in whom fibrosis is likely to progress. It is important to develop a non-invasive tool for predicting progression of fibrosis, because these patients are the ones who might benefit from clinical interventions like antiviral therapy and/or more frequent and intense monitoring.

In this study, we examined APRI and FIB-4 in a group of patients with paired liver biopsies to determine if longitudinal changes in the markers correlated with changes in the histological stage of fibrosis, and also examined whether the initial or follow-up APRI and FIB-4 was useful in predicting those patients who showed an increase in stage of fibrosis on liver biopsy.

MATERIALS AND METHODS

Patients studied

Following approval by the Institutional Review Board, we searched a database available in the Department of Pathology for all patients who had undergone at least two liver biopsies for staging fibrosis in mono-infected HCV-positive patients between 1999 and 2007. Patients were selected for inclusion if the liver biopsies were at least 1 year apart. Patients were excluded if they had cirrhosis, were co-infected with hepatitis B virus (HBV) or human immunodeficiency virus, had an organ transplant, daily alcohol intake of > 30 g/d, hepatocellular carcinoma or primary metabolic or autoimmune liver disease. The laboratory values used for the calculations of the APRI and FIB-4 were those that were closest to the liver biopsy date. Our hepatology service has had an ongoing prospective study of hepatic fibrosis markers since 2003, and 20 of the patients were enrolled in that study for one or both of their liver biopsies. Those patients had their blood drawn on the day of the liver biopsy. All other patients had blood work within 3 mo of the biopsy, or they were excluded from the study.

Laboratory studies

The platelets were measured using the Sysmex SE 9500 (Sysmex, Mundelein, IL, USA) and the AST and the alanine aminotransferase (ALT) were measured using either the Vitros 950 or 5,1 FS (Ortho Clinical diagnostics, Raitan, NJ, USA).

Biomarker panels

The APRI is a numerical value that is calculated using the following formula: APRI = [AST (U/L)/upper limit of normal (U/L)] × 100/platelets (10^9/L)[7]. The FIB-4 index is also a numerical value that is calculated using the following formula FIB 4 = Age × AST (U/L)/[platelets (10^9/L) × $ALT^{1/2}$ (U/L)][8].

Liver histology

All liver biopsies were read by a single pathologist (S.X.), without prior knowledge of the study status or the value of laboratory parameters being tested. Fibrosis was staged as described below. The fibrosis score is based on a five-point scale: stage 0 = no fibrosis; 1 = either mild pericellular fibrosis in the lobules, or mild portal fibrosis; 2 = periportal fibrosis, or portal fibrosis plus lobular pericellular fibrosis; 3 = septal or bridging fibrosis without evident parenchymal remodeling; and 4 = cirrhosis (with architectural remodeling and nodular formation). The rationales of including lobular pericellular fibrosis in our staging system are: (1) that this type of fibrosis is frequently observed among pa-

tients with chronic HCV infection; and (2) that zone 3 (or centrilobular) hepatic stellate cell activation is common in hepatitis C liver biopsies without other co-morbidity[9].

Statistical analysis

In the initial analysis the median AST, ALT, platelets, APRI and FIB-4 scores were compared between patients who had an increase in at least one stage on liver biopsies (progressors) and those who did not progress (non-progressors) using a non-parametric test (Mann-Whitney *U* test). Logistic regression was used to calculate the accuracy of the ALT, AST, platelets, APRI and FIB-4 in predicting progression of fibrosis. Receiver operating characteristic (ROC) curves were calculated for the biomarkers at the time of initial and repeat biopsies. Area under the ROC curve (AUROC), sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were calculated. Non-parametric tests were performed using Stats Direct statistical software (Sale, Cheshire, UK) and ROC curves were constructed using MedCalc statistical software (Marialterke, Belgium).

Calculation of sample size

Assuming that the AUROC for APRI and FIB-4 would be 0.8 if the null hypothesis is rejected and 0.5 if the null hypothesis is valid, a sample size of 29 is needed to detect the difference at an α value of 0.05 and β value of 0.8.

RESULTS

Patient characteristics

A total of 36 patients met the inclusion criteria. The baseline characteristics of the subjects are described in Table 1. The median age at the time of initial biopsies was 47 years (range: 25-68 years). Seventy-five percent (27/36) of patients were male, with 50% (18/36) Caucasians, 31% (11/36) African Americans and 19% (7/36) Hispanics. The majority (50%) of the patients were stage 1 on biopsy followed by stage 2 (25%) and stage 3 (22%). One patient had stage 0 fibrosis on biopsy, and there were no patients with cirrhosis because they were excluded from the study. The median duration between biopsies was 4 years (range: 2-9 years).

Duration between biopsies (yr)	4	4	0.200

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; APRI: AST/Platelet Ratio Index; NS: Not significant.

Relationship of baseline parameters and progression

Out of a total of 36 patients, 19 (53%) had progression of fibrosis on repeat biopsies, 16 patients (44%) showed no change in stage, and one (3%) showed improvement in fibrosis on repeat biopsy. Among the patient factors examined (Table 2), the group that showed progression had significantly higher ALT and AST at baseline when compared to the group that did not show progression ($P = 0.003$ and 0.0001, respectively). There was no statistically significant difference between baseline APRI, FIB-4 index, stage at initial biopsy, age, or duration between biopsies between progressors and non-progressors.

Parameters at time of repeat biopsy

Progressors *vs* non-progressors: Differences in parameters were explored between the two groups at the time of repeat biopsies. ALT, AST, APRI and FIB-4 were significantly higher in patients who showed progression of fibrosis (Table 3). The APRI and FIB-4 at the time of the second biopsy had excellent predictive value for progression in fibrosis with an APRI $\geqslant$ 0.69 having a 79% PPV and a 78% NPV for progression of at least one stage of fibrosis. A FIB-4 $\geqslant$ 1.65 had an 81% PPV and 70% NPV for prediction of fibrosis by at least one stage. A one-stage change in fibrosis on repeat biopsies might reflect sampling variability, therefore, we examined the predictive value of the APRI and FIB-4 for a change of two stages of fibrosis. We found that the APRI and FIB-4 had excellent predictive values for a two-stage progression of fibrosis with an APRI $\geqslant$ 1.94 and FIB-4 $\geqslant$ 3.01 having a 100% PPV and NPV and 62% PPV and 100% NPV, respectively. In addition the APRI had an AUROC of 1.0 [95% confidence interval (CI): 0.85-1.00] and FIB-4 had an AUROC of 0.911 (95% CI: 0.717-0.986, $P = 0.0001$) for those who

Table 3 Differences between progressors and non-progressors on repeat biopsies

	Progressors	Non-progressors	*P* value
APRI	1.293	0.413	0.0006
FIB-4	2.816	1.36	0.0038
ALT (IU/mL)	92	47	0.0030
AST (IU/mL)	100	38	0.0001
Platelets (× 10^9/L)	184	221	0.1160

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; APRI: AST/Platelet Ratio Index.

had a two-stage change in fibrosis. The number of patients who progressed by two stages was low ($n = 5$), and caution should be exercised in interpreting this particular subset of the results.

Change in APRI and FIB-4 and progression *vs* non-progression: Changes in APRI and FIB-4 were correlated with change in stage of fibrosis. There was a significant correlation between change in stage and change in APRI ($r^2 = 0.39$, $P = 0.00001$) (Figure 1A) with the regression equation for a change in stage = 0.50 × (ΔAPRI) + 0.44. AUROCs were constructed for predictive value of change in APRI for change in stage with a ΔAPRI of 0.18 having an 80% PPV and 67% NPV in predicting progression of fibrosis. Similarly, the correlation between change in stage and ΔFIB-4 was also significant ($r^2 = 0.31$, $P = 0.00004$) (Figure 1B). The regression equation for a change in stage = 0.34 × (ΔFIB-4) + 0.32. An analysis of ROC curve revealed that a ΔFIB-4 of 0.39 had 75% PPV and NPV for predicting progression of fibrosis.

Accuracy of individual tests: AST proved to be the most useful of the tests. There was a significant correlation between change in stage of fibrosis and change in AST ($r^2 = 0.33$, $P = 0.002$). There was a less but still significant correlation of ALT between change in fibrosis and change in ALT ($r^2 = 0.21$, $P = 0.0048$). Changes in the platelets alone did not correlate well with changes in fibrosis ($r^2 = 0.07$).

DISCUSSION

Liver biopsy is the gold standard for estimating severity of fibrosis in patients with liver disease and is used as a guide for therapy of HCV infection. However, because antiviral therapy with pegylated interferon and ribavirin carries significant toxicity, and fibrosis progresses in only 20%-30% of patients with chronic HCV infection[10], therapy is ideally offered to patients whose risk of progressive liver damage is high. Current strategy involves using the stage of fibrosis on initial liver biopsy to determine the risk of progressive liver damage. However, the stage at the time of the biopsy might not predict the risk of progression, especially in a younger patient and/or someone with a shorter duration of infection.

Apart from the complications associated with the invasive nature of liver biopsy, issues like sampling variability, inter-observer variability, and expense limit its utility and diagnostic accuracy[9,11]. Factors that determine the varying rates of fibrosis progression are poorly understood, partially because of the logistical difficulties for studies in performing serial liver biopsies. Non-invasive biomarkers that reflect hepatic fibrosis have been proposed to overcome these limitations with the ideal biomarker of hepatic fibrosis being inexpensive, easily available, and accurately reflecting changes in fibrosis. The APRI and FIB-4 are two biomarker panels that incorporate readily available and routinely performed tests for all patients with liver disease. Both have been confirmed to be accurate in predicting fibrosis stage on liver biopsies[1,7,8,12-23]. However, few studies have examined the longitudinal behavior of fibrosis biomarkers. Patel *et al*[24] have evaluated a single direct hepatic fibrosis marker, hyaluronic acid (HA), in patients undergoing liver biopsies before, and 6 mo following antiviral therapy for chronic HCV. Although HA has some association with the stage of fibrosis, it does not predict histological changes over the treatment period. Our study addressed the longitudinal behavior of these markers in individuals who underwent serial biopsies, and examined the role of these biomarkers in predicting progression.

There is accumulating evidence that hepatic fibrosis markers can be used for prognosis. Following 6 mo of interferon-based therapy, an APRI > 1.5 has been shown to be associated with significant short-term mortality and risk of hepatocellular carcinoma in patients with chronic

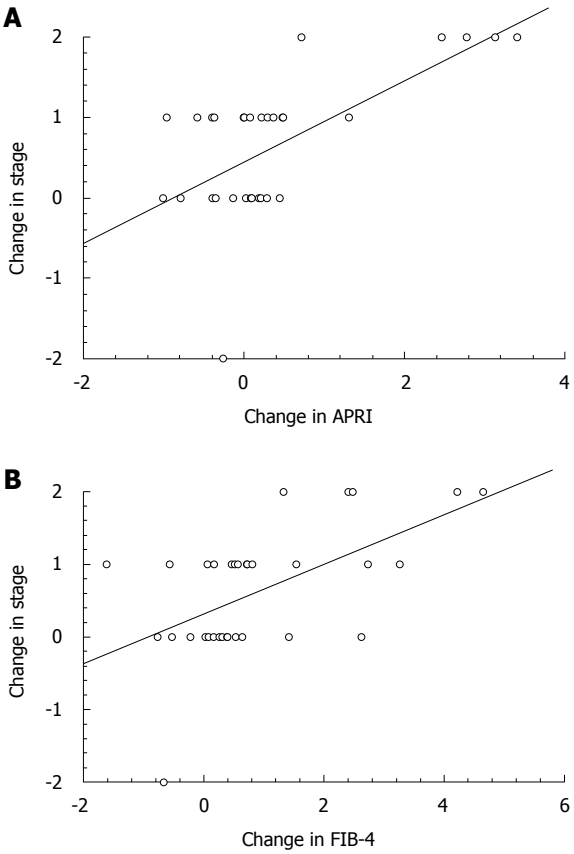

Figure 1 Linear regression plot. A: Correlation between changes in stage of fibrosis *vs* change in aspartate aminotransferase/Platelet Ratio Index (APRI); B: Correlation between stages of fibrosis *vs* FIB-4.

HCV[21]. A commercially available test, FibroTest, has been found at baseline to predict outcomes in chronic HCV[25]. In addition, two other commercially available tests, Fibrometer and Hepascore, have been shown to be as good as liver biopsy in the prediction of survival in alcoholic liver disease[26]. Recently, the European Liver Fibrosis Test has been shown to be superior to several other parameters in the prediction of outcomes of primary biliary cirrhosis[27].

One finding of our study that is potentially useful for clinicians is that serial changes in APRI and FIB-4, which are easily calculated using routine laboratory tests, correlated well with changes in fibrosis staging. There was a significant correlation between change in stage and change in APRI and FIB-4 of 0.627 ($r^2 = 0.39$, $P = 0.00001$) and 0.56 ($r^2 = 0.31$, $P = 0.00004$), respectively. A ΔAPRI of 0.18 had 80% PPV and 67% NPV in predicting progression of fibrosis, whereas a ΔFIB-4 of 0.39 had 75% PPV and NPV for predicting progression of fibrosis. These results are significant as they suggest that longitudinal changes of APRI and FIB-4 markers can be useful in predicting progression of fibrosis, which could lead to changes in clinical management.

The baseline characteristics of the study population did not differ between progressors and non-progressors, except for aminotransferases, which were significantly higher in the group that later showed progression of fibrosis, which has been shown previously[28]. This was independent of the initial stage of fibrosis and did not differ significantly between groups. It seems likely that, even with the same stage of fibrosis, higher enzyme levels are a marker for subsequent progression. The effect of timing between the biopsies is unlikely to have an impact on the conclusions because there was no significant difference between duration of biopsies between the progressor and non-progressor groups. As expected, the APRI and FIB-4 were significantly higher at the time of the second liver biopsy in the patients with progression of fibrosis, which reflected the accuracy of these tests at a single point in time. Therefore, not unexpectedly, the APRI and FIB-4 were predictive of progression at the time of the second biopsy. Although the number of patients was small, both tests were able to predict a two-stage change in fibrosis at the second biopsy.

This study had several limitations, mainly due to the largely retrospective nature of the study. Previously, we have found that the APRI was less accurate retrospectively than prospectively[16]. This might have been because the retrospective patient group was more heterogenous, as well as the fact that laboratory values were not always performed close to the time of the biopsy. In addition, concurrent illnesses that could influence aminotransferases and platelets could not be easily determined in some of the patients. Another significant limitation was the relatively small sample size. A larger and well-designed prospective trial that could confirm the role of biomarkers, including those from the ECM, in predicting fibrosis progression would be very useful.

In summary, the APRI and FIB-4 at initial liver biopsy were not useful in predicting patients whose fibrosis would be progressive. However, as previously reported[28], patients with higher aminotransferases appear to have an increased risk of progression of fibrosis. Importantly, the longitudinal use of the APRI and FIB-4 is accurate in predicting progression of fibrosis, and could be useful to clinicians that follow patients with chronic HCV. Based on our data, a ΔAPRI of 0.18 or a ΔFIB-4 of 0.39 in a patient with chronic HCV suggests progression in fibrosis of at least one stage, and could be used to trigger a reconsideration of antiviral therapy and/or liver biopsy. Larger, prospective studies are needed to validate the findings of our study.

COMMENTS

Background

The complications of chronic liver disease are largely related to the development of fibrosis. Medical treatments are aimed at prevention of progression of cirrhosis. A liver biopsy has been the usual way to estimate fibrosis. However, it is invasive and expensive, and can be inaccurate because of variability in the degree of fibrosis in parts of the liver that can be sampled. The use of certain serum biomarkers to estimate fibrosis has been found to useful, especially in chronic hepatitis C. These biomarkers can be composed of a combination of simple tests that are used to assess liver function, as well as more complex indices that measure substances in the blood that can originate in the extracellular matrix of the liver itself.

Research frontiers

Although several simple and complex biomarkers have been found to be accurate at differentiating mild from significant fibrosis, there has been little evaluation of them in a longitudinal manner. In other words, it is not clear whether changes over time in the value of the markers reflect actual changes in the degree of fibrosis. If these markers can accurately predict changes in fibrosis, then this would be useful to clinicians. Not only could this lead to fewer liver biopsies, but it could lead to changes or initiation of treatment. This study evaluated two simple biomarkers, the aspartate aminotransferase (AST)/Platelet Ratio Index (APRI) and the FIB4, longitudinally in a group of patients with chronic hepatitis who had two liver biopsies that were at least 1 year apart. It found that both biomarkers could accurately predict changes in the stage of fibrosis.

Innovations and breakthroughs

The APRI utilizes AST and platelets, which are simple tests obtained in all liver patients. It was originally described by Wai *et al* in 2003 (*Hepatology* 38: 518-526). Its usefulness has been confirmed in multiple studies including that of Snyder *et al* (*J Clin* Gastroenterol 2006; 40: 535-542). The FIB4 utilizes AST, platelets, alanine aminotransferase (ALT), and age. It was originally described by Sterling *et al* in 2006 (*Hepatology* 43: 1317-1325). A high APRI score at 6 mo following treatment has been shown to correlate with poor survival, as well as the development of hepatocellular carcinoma.

Applications

This article shows that physicians can accurately follow patients with chronic hepatic C that have failed previous antiviral therapy or that have not been treated. Treatment decisions can be based on changes in these indices. These findings should be confirmed in larger studies from other institutions. Also, further research should be done with the longitudinal use of the more complex biomarkers, as well as the longitudinal use of simple and complex biomarkers in diseases other than chronic hepatitis C.

Terminology

Liver fibrosis refers to the amount of scar tissue in the liver. This impairs blood flow and eventually can lead to cirrhosis. AST is an enzyme that is in liver cells and is released when there is active liver damage. ALT is an enzyme specific to liver cells, which is released when there is liver damage. The platelets are a component of the blood that helps with clotting. Platelets decrease with advancing liver disease and fibrosis because some of them are sequestered in the spleen, which enlarges with liver disease, and also a hormone called thrombopoeitin that stimulates platelets production is released in smaller quantities with advancing disease. Biomarkers are substances that can be objectively measured that are used as an indicator of a biological state. They are being increasingly used in medicine as non-invasive ways to screen for and evaluate various diseases including cancer.

Peer review

The authors show that evolutionary changes in simple scores (APRI and FIB-4) based on routine biochemical parameters can be of value in predicting the evolution of liver fibrosis in chronic hepatitis C. The data provided in this study have important clinical implications that pertain to the management of patients with chronic hepatitis C.

Abstract

AIM: To investigate morphological changes of the enteric nervous system (ENS) and the interstitial cells of Cajal (ICCs) in small bowel atresia.

METHODS: Resected small bowel specimens from affected patients (n = 7) were divided into three parts (proximal, atretic, distal). Standard histology and enzyme immunohistochemistry anti-S100, anti-protein gene product (PGP) 9.5, anti-neurofilament (NF), anti-c-kit-receptor (CD117) was carried out on conventional paraffin sections of the proximal and distal part.

RESULTS: The neuronal and glial markers (PGP 9.5, NF, S-100) were expressed in hypertrophied ganglia and nerve fibres within the myenteric and submucosal plexuses. Furthermore, the submucous plexus contained typical giant ganglia. The innervation pattern of the proximal bowel resembled intestinal neuronal dysplasia. The density of myenteric ICCs was clearly reduced in the proximal bowel, whereas a moderate number of muscular ICCs were found. The anti-CD117 immunoreaction revealed additional numerous mast cells. The distal bowel demonstrated normal morphology and density of the ENS, the ICCs and the mast cells.

CONCLUSION: The proximal and distal bowel in small bowel atresia revealed clear changes in morphology and density of the ENS and ICCs.

Key words: Small bowel atresia; Enteric nervous system; Gastrointestinal motility; Interstitial cells of Cajal

INTRODUCTION

Small bowel atresia is a congenital disorder that carries a substantial morbidity[1,2]. The etiology of bowel atresia remains unclear. One of two accepted theories of its pathogenesis is the concept of a lack of recanalization of the solid organ cord during the late stage of intestinal development[3]. Another concept is the occurrence of a late intrauterine mesenteric vascular accident[4]. The lack of revacuolization is the probable cause for most cases of duodenal atresia. Further studies have demonstrated that

jejunoileal atresias occur as a result of intestinal volvulus, intussusception, internal hernia, or strangulation in a tight gastroschisis or omphalocele defect[5-11].

Newborns with small bowel atresia are operated on soon after birth. Owing to the severity of the dilatation of the proximal bowel and the hypoplasia of the distal bowel, various postoperative gastrointestinal motility problems may occur; such problems include prolonged adynamic ileus (11%) and the need for total parenteral nutrition (30%-70%)[12]. The underlying cause of this postoperative intestinal motility disorder is still unclear.

Basically, normal gastrointestinal motility depends on the coordinated function of the enteric nervous system (ENS), the intestinal smooth muscle and the interstitial cells of Cajal (ICCs). Previous studies revealed histological changes within the wall of the atretic and adjacent bowel in small bowel atresia. Hypertrophy of the bowel muscle proximal to the atresia was found in clinical and experimental studies on small bowel atresia. Various changes have been reported within the ENS in small bowel atresia[13]. Nevertheless, the relationship between the macroscopic and histological changes of the affected bowel and the postoperative motility disorder are still under investigation. Furthermore, the role of the ICCs in small bowel atresia needs to be elucidated further.

ICCs play a major role in gastrointestinal motility. ICCs express the tyrosine kinase receptor c-kit. Therefore specifically designed c-kit antibodies have been developed which stain ICCs but also other cell groups such as stem cells and mast cells. However, c-kit positive ICCs can be identified by clear morphological features.

The aim of this study was to investigate the morphology of the ENS and the ICCs in resection specimens of small bowel atresia.

MATERIALS AND METHODS

Patients and tissues

Resected small bowel specimens (ileum) from affected newborn patients (n = 7) were included in the investigation after parental consent. The resected ileal specimens were divided into three parts (proximal, atretic, distal).

Tissue processing

The specimens were fixed in 4% paraformaldehyde and processed into paraffin blocks. Paraffin-embedded tissues were sectioned at 2-4 μm (Leica SM 2000 R) followed by drying at 37℃ in an incubator overnight. Before immunohistochemical staining, the paraffin sections were dewaxed for 10 min in xylene, followed by 10 min in acetone and 10 min in acetone/Tris-buffered saline (TBS; 1:1). After this treatment, the slides were washed in TBS.

Antigen demasking

If heat antigen retrieval was required, dewaxed paraffin sections were placed in microwave-proof tubes containing target retrieval solution (Dako). The slides were treated in the tubes for 5 min at 600 W in a microwave (SS 566H; Bosch, Munich, Germany). The evaporated volume was replaced by distilled water, and the procedure was repeated twice. After microwave treatment, the slides were left to cool down, then were washed in TBS.

Table 1 Primary antibodies

Antibody	Clone	Company	Dilution
S-100	Polyclonal (Z0311)	Dako, Glostrup, Denmark	1:500
PGP-9.5	Polyclonal (Z5116)	Dako, Glostrup, Denmark	1:25
Neurofilament	2F11 (M0762)	Dako, Glostrup, Denmark	1:50
c-kit	Polyclonal (A4502)	Dako, Glostrup, Denmark	1:50

PGP: Protein gene product.

Histochemistry and immunohistochemistry

Standard histology [hematoxylin/eosin (HE)] was performed on the sections. For immunohistochemistry, an alkaline phosphatase-anti-alkaline phosphatase (APAAP) staining kit (Dako Real™ Detection System, APAAP, Mouse) using anti-S100, anti- protein gene product (PGP) 9.5, anti-neurofilament (NF) and anti-c-kit-receptor (CD117) antibodies was employed. A non-sense mAb (clone: MR 12/53) served as negative control by omitting the primary antibody. The final concentrations are given in Table 1.

Evaluation

The evaluation of the immunohistochemical staining results was focused on the proximal and distal parts of the resected ileum.

The sections were evaluated by two independent investigators using light microscopy (magnification, × 40). HE staining was used to determine the overall histology of the investigated specimen. The distribution and density of immunoreactive ganglion cells, glial cells, nerve fibers and c-kit positive cells (ICCs, mast cells) were studied in each part of the resected bowel (proximal, atretic, distal). Since quantitative analysis of immunohistochemical staining is not possible, semi-quantitative scoring was performed as follows; - no expression (no staining), + low expression (few neuronal fibers and cells/few ICCs), ++ moderate expression (numerous neuronal fibers and cells/numerous ICCs), +++ high expression (dense networks of neuronal fibers and cells/dense network of ICCs).

RESULTS

Patients

The study included resected ileal segments from seven newborn patients (gestational age 38-40 wk). Six patients presented with type Ⅲa ileal atresia and one patient presented with multiple ileal atresia.

Neuronal markers (PGP 9.5, NF)

The neuronal markers PGP 9.5 and NF were strongly expressed within the ganglion cells and nerve fibers of the myenteric plexus (and submucosal plexus in the proxi-

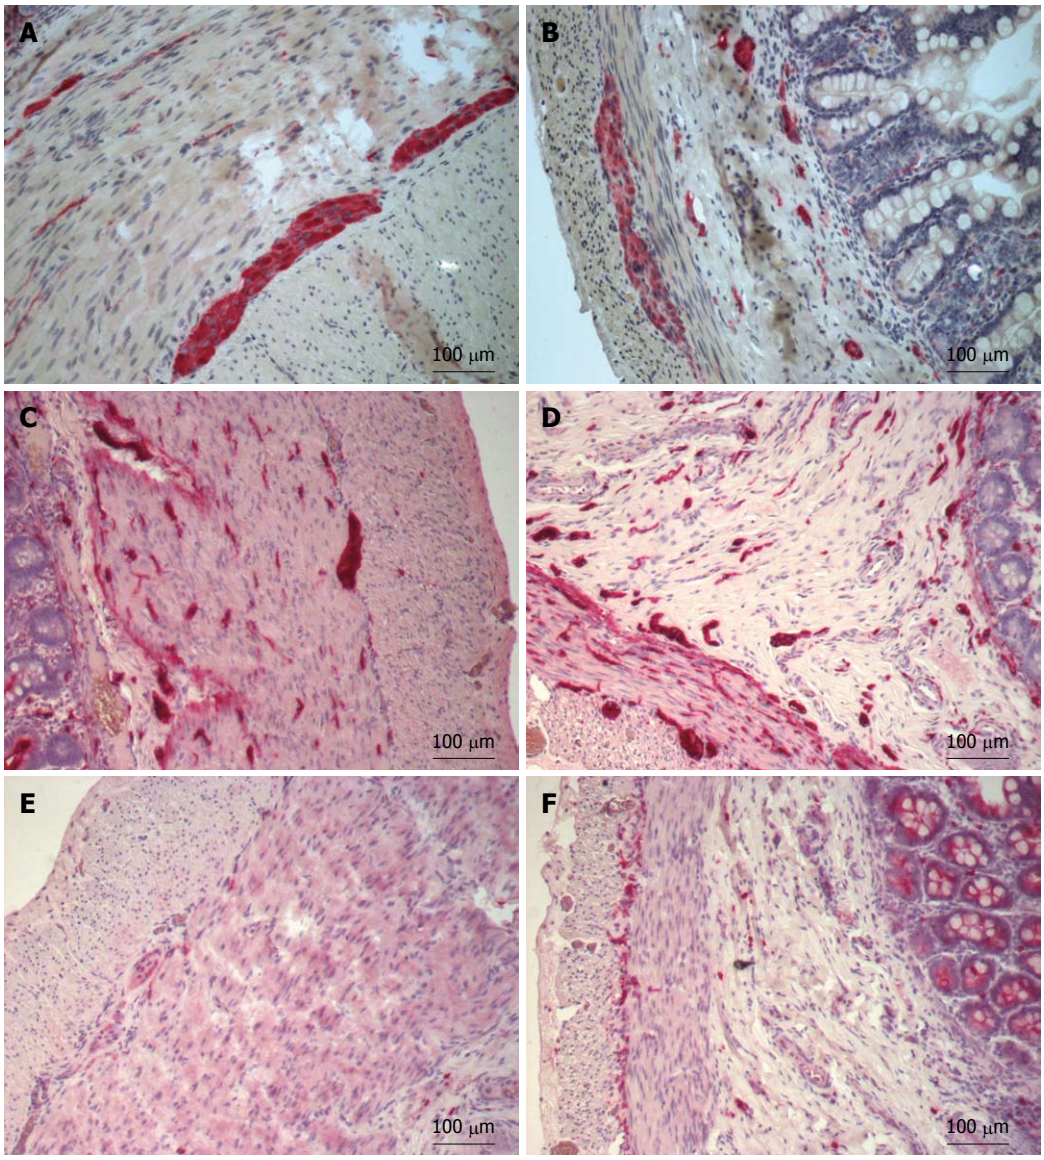

Figure 1 Immunohistochemistry of a full-thickness section of the ileum. A: Protein gene product (PGP) 9.5 in the ileum proximal to the atresia shows a dense innervation within the submucosal and myenteric plexus; B: PGP 9.5 in the ileum distal to the atresia shows a normal innervation pattern of the submucosal and myenteric plexuses; C: S-100 in the ileum proximal to the atresia shows numerous fibers and large ganglia (> 20 μm) within the submucosal plexus and normal innervation within the myenteric plexus; D: S-100 in the ileum distal to the atresia shows a normal innervation pattern within the submucosal and myenteric plexuses; E: c-kit in the ileum proximal to the atresia shows that myenteric and muscular interstitial cells of Cajal (ICCs) are almost absent; F: c-kit in the ileum distal to the atresia shows normal distribution of myenteric and muscular ICCs.

Table 2 Distribution and density of immunostaining (proximal *vs* distal)

	Proximal				Distal			
	SP	CM	MP	LM	SP	CM	MP	LM
PGP 9.5	++	+	++	+	++	+	++	+
S-100	+++	+	+++	+	++	+	++	+
NF	++	+	++	+	++	+	++	+
c-Kit (ICCs)	-	-/+	+/-	-	-	+	++	+

PGP: Protein gene product; ICCs: Interstitial cells of Cajal; SP: Submucosal plexus; CM: Circular muscle; MP: Myenteric plexus; LM: Longitudinal muscle; NF: Neurofilament; -: No expression (no staining); +: Low expression (few neuronal fibers and cells/few ICCs); ++: Moderate expression (numerous neuronal fibers and cells/numerous ICCs); +++: High expression (dense networks of neuronal fibers and cells/dense ICCs networks).

mal ileum (Figure 1A). The submucosal plexus contained some giant ganglia (n > 10 ganglion cells) and numerous thick nerve fibers. The overall numbers of ganglia were not increased within the myenteric and submucosal plexuses (Table 2). The immunohistochemical staining revealed features of intestinal neuronal dysplasia (giant ganglia, hypertrophied nerve fibers).

The distal bowel had a normally expressed ENS within the submucosal and myenteric plexuses (Figure 1B).

Glial marker (S-100)

Numerous S-100 immunoreactive glial cells were found in the two plexuses of the proximal ileum (Figure 1C). The expression of glial cells was increased within the proximal dilated bowel compared to the atretic and distal bowel

(Table 2). Additional giant ganglia (> 10 ganglion cells/ganglion) were stained by S-100 within the submucosal plexus of the proximal bowel. Regular distribution and morphology of S-100 immunoreactive cells and fibers was found within the myenteric and submucosal plexuses of the distal ileum (Figure 1D).

c-kit (CD-117) staining (ICCs, mast cells)

The density of ICCs within the myenteric plexus was clearly reduced in the proximal bowel (Figure 1E), whereas some ICCs were found in the circular and longitudinal muscle layer (Table 2). The anti-CD117 immunoreaction revealed numerous mast cells within the proximal bowel. The distal bowel had a normal distribution of ICCs within the myenteric plexus and muscular layers and a normal number of mast cells (Figure 1F).

DISCUSSION

This study revealed distinct changes in the morphology of the ENS and ICCs in parts of the resected bowel proximal to small bowel atresia. In general, our findings are not unique since previous studies described changes within the ENS in small bowel atresia. Ozguner *et al*[14] reported that the proximal segment of the atretic intestine showed structural deficits. Abnormal ganglia cells and defects in the intestinal musculature were prominent, but the intestinal mucosa remained intact. They found abnormalities in both the antimesenteric side and mesenteric side. Their interpretation supported a vascular accident as a causative factor.

Di Nardo *et al*[15] presented an interesting case report of small bowel atresia that was initially diagnosed as hyper-ganglionosis and later changed to an enteric degenerative neuropathy. Watanabe *et al*[16] contributed an elegant study investigating the myenteric plexus in small bowel atresia using whole-mount preparations. This study showed mild hypoplasia of the ENS plexuses in the proximal segments[16].

In our study the expression of nerve fibers and glial cells appeared to be slightly increased, and some submucosal giant ganglia were found, which resembled intestinal neuronal dysplasia within the proximal dilated bowel. The expression of c-kit positive ICCs was clearly decreased in the dilated proximal bowel. The reduction of ICCs within the proximal dilated bowel has also been described before. In contrast to our study, some previous investigators have shown a reduction of the innervation density within the proximal bowel segments[13]. The innervation pattern and the expression of ICCs within the distal small bowel were normal in our study, similar to comparable investigations[13].

The crucial problem of investigating the developing ENS or pathological changes within the ENS in order to define hyper-ganglionosis or hypoganglionosis is the uncertainty in the normal numbers and distribution of enteric ganglia. The normal neuron density of the human myenteric plexus was investigated in several studies and resulted in a huge variation of more than 200-fold[17-20]. Schuffler *et al*[17] found 27.8 nerve cells per 100 mm of smooth muscle, Ikeda *et al*[19] described more than 30 nerve cells per 10 mm of smooth muscle as normal, whereas Smith[18] estimated 7 nerve cells per mm of smooth muscle. Finally Meier-Ruge *et al*[20] found 756 ganglion cells per 10 mm of smooth muscle. All these investigations were performed on conventional paraffin sections[17-20], which usually display only a two-dimensional image of the investigated structures. Since these profound differences have already been found within normal bowel specimens, conflicting results on numerical changes of ganglia and nerve fibers within the changed ENS in bowel atresia must be expected. Another major aspect is the widely accepted concept of ongoing postnatal plasticity of the ENS, which has to be taken into consideration.

A previous animal study which created a partial obstruction in dog ileum revealed that the ganglion cells increased in size and the smooth muscle of the dilated bowel became thicker[21]. The number of ganglion cells related to the muscle mass was decreased above the constriction. Although some ganglion cells increased in size, there was no evidence of any increase in number. Experimentally, a similar increase in ganglion size was observed proximal to a stenosis in another study[22]. In a chicken embryonic model of bowel obstruction, a marked reduction of the submucous plexus ganglia with intact muscular plexus ganglia was noted in the dilatated gut[23].

Our study also showed an increase in size of ganglia (hypertrophy). These hypertrophic myenteric and submucosal ganglia in the proximal resected bowel could be considered the result of adaptive phenomena to the long-lasting prenatal bowel obstruction. Several experimental models have been instrumental in supporting the concept that adaptive changes to the ENS occur proximal to the obstructed gut[24-31]. These studies revealed an increased density and size in both myenteric[26,28,29,31] and submucosal neurons[29-31], along with neurochemical[28,30] and cytoskeletal abnormalities of the myenteric neurons[31].

Ekblad *et al*[28] showed that, in the hypertrophic ileum, several neuronal populations showed changes in the expression of neuro-messengers. Myenteric neurons expressing vasoactive intestinal peptide (VIP), pituitary adenylate cyclase activating peptide, and galanin were notably increased in number. In submucosal ganglia, the number of VIP-immunoreactive neurons decreased, while those expressing VIP mRNA increased. NADPH diaphorase-positive submucosal neurons increased dramatically, while the number of neuronal-type nitric oxide synthase expressing neurons was unchanged. The number of ICCs decreased markedly in the hypertrophic ileum.

Another observation is the delayed maturation of ENS within the distal bowel during fetal development in cases with small bowel atresia[32]. Distortion of the polygonal architecture of the myenteric plexus has been shown postnatally in atretic parts of ileal type IIIa atresia[33]. It could only be speculated that after the restoration of bowel continuity does maturation of the ENS occur.

A previous animal study using a partial small obstruc-

tion model in mice revealed that 2 wk following the onset of a partial obstruction, the bowel increased in diameter, and hypertrophy of the tunica muscularis was observed oral to the obstruction site[27]. Networks of ICCs were disrupted oral to the obstruction, and this disruption was accompanied by the loss of electrical slow waves and responses to enteric nerve stimulation. These defects were not observed aboral to the obstruction. Furthermore, it was shown that removal of the obstruction led to the redevelopment of ICC networks and the recovery of slow wave activity within 30 d. Neural responses were partially restored in 30 d[27]. Similar repair mechanisms may occur after surgical correction of small bowel atresia. It seems obvious that decreases in ICCs in small bowel atresia and their restoration after removal of the obstruction contributes to the regulation of gastrointestinal motility.

Masumoto *et al*[34] showed muscular alterations in both segments of IA cases, which further contributes to the postoperative motility disorder. Another case report recently revealed long lasting chronological changes within the ENS, muscle components and ICCs in small bowel atresia[35].

The ENS and ICCs are altered in the proximal and dilated bowel in small bowel atresia. The innervation pattern of the proximal bowel resembles intestinal neuronal dysplasia. These changes might be the result of long-lasting bowel obstruction and stasis of bowel contents. The presented histological features do not contribute to the search for the pathogenesis of small bowel atresia. Nevertheless, the confirmed innervation abnormalities and defective expression of CD117-positive cells of the proximal bowel may have an influence on the postoperative gastrointestinal motility of the affected patients.

COMMENTS

Background

Small bowel atresia is a congenital anomaly of unknown cause. Despite early corrective surgery, patients carry a substantial morbidity because of postoperative gastrointestinal motility problems. Normal gastrointestinal motility is generated by the complex interaction of the enteric nervous system (ENS), the intestinal smooth muscle and the interstitial cells of Cajal (ICCs). Alterations in the ENS and ICCs may contribute to the motility problems in patients with small bowel atresia after surgery.

Research frontiers

Previous studies revealed histological changes within the wall of the atretic and adjacent bowel in small bowel atresia. Nevertheless the relationship between the macroscopic and histological changes of the affected bowel and the postoperative motility disorder are still under investigation. Furthermore, the role of the ICCs in small bowel atresia needs to be elucidated further.

Innovations and breakthroughs

This study showed that the ENS and ICCs are altered in the proximal and dilated bowel in small bowel atresia. The innervation pattern of the proximal bowel resembles intestinal neuronal dysplasia.

Applications

The changes within the ENS and the ICCs may be the result of a long-lasting bowel obstruction and stasis of bowel contents. The presented histological features do not contribute to the search for the pathogenesis of small bowel atresia. However, the confirmed innervation abnormalities and defective expression of CD117-positive cells of the proximal bowel may have an influence on postoperative gastrointestinal motility in the affected patients.

Terminology

Bowel atresia is a congenital defect in the continuity of the bowel. The incidence of small bowel atresia is higher than that of large bowel atresia and varies between 1:300 to 1:3000.

Peer review

The authors studied the ileum of seven patients with ileal atresia. They reported that the proximal dilated intestine had an increased expression of nerve fibers and glial cells, with a decrease in ICCs, and an increase in ganglia size, whereas the distal intestine displayed normal features. They conclude that these alterations may influence on postoperative intestinal motility. The authors performed a well designed study in a very uncommon congenital disease, which is very interesting for the readers.

Abstract

AIM: To present a new technique of cervical esophagogastric anastomosis to reduce the frequency of fistula formation.

METHODS: A group of 31 patients with thoracic and abdominal esophageal cancer underwent cervical esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach tube. In the region elected for anastomosis, a transverse myotomy of the esophagus was carried out around the entire circumference of the esophagus. Afterwards, a 4-cm long segment of esophagus was invaginated into the stomach and anastomosed to the anterior and the posterior walls.

RESULTS: Postoperative minor complications occurred in 22 (70.9%) patients. Four (12.9%) patients had serious complications that led to death. The discharge of saliva was at a lower region, while attempting to leave the anastomosis site out of the alimentary transit. Three (9.7%) patients had fistula at the esophagogastric anastomosis, with minimal leakage of air or saliva and with mild clinical repercussions. No patients had esophagogastric fistula with intense saliva leakage from either the cervical incision or the thoracic drain. Fibrotic stenosis of anastomoses occurred in seven (22.6%) patients. All these patients obtained relief from their dysphagia with endoscopic dilatation of the anastomosis.

CONCLUSION: Cervical esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach tube presented a low rate of esophagogastric fistula with mild clinical repercussions.

Key words: Esophageal cancer; Esophagectomy; Constriction; Pathologic; Fistula; Gastroplasty

INTRODUCTION

Definitive curative treatment for cancer of the esophagus remains a challenge for surgeons[1-8]. The approach involves major surgery that has high morbidity and mortality rates, mainly due to pulmonary complications,

cervical fistulas, stenosis of anastomosis, necrosis of the tubularized stomach, and mediastinitis[5,9-12].

Among these possible complications, fistula of the esophagogastric anastomosis represents one of the principal problems of esophagectomy. In several studies, the incidence has ranged from 0% to 50%, with most authors reporting a high incidence of this complication[4,6,13-18].

Although these fistulas usually have a favorable course, about 2% of cases can have a catastrophic outcome[5,16]. In cases in which the fistula does not lead directly to death, it can compromise quality of life, interfere with resumption of feeding, require laborious local care, and prolong hospital stay. Additionally, 30%-50% of those patients who present with fistula go on to develop stenosis[15,19-22].

Given this scenario and personal experience of a high incidence of cervical esophagogastric fistula in treatment of carcinoma of the esophagus[23], we decided to perform cervical esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach tube, and to analyze the incidence of fistula and stenosis formation following this procedure.

MATERIALS AND METHODS

This study conformed to the regulations of The Human Ethics Research Committee at our Institution and with the Helsinki Declaration, revised in 1983.

Our study group consisted of 31 patients with thoracic or abdominal carcinoma of the esophagus, who underwent open access with subtotal esophagectomy and esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach tube. The study group included 27 (87.1%) men and four (12.9%) women, with a mean age of 60.2 ± 8.5 years (range: 44-74 years). Lesions were located in the medial third of the esophagus in 15 cases (48.3%) and the inferior third in 16 (51.6%).

The inclusion criteria for operation were: esophagogram with no abnormal axis deviation, lesions up to 5.0 cm long, absence of signs of invasion of the respiratory tree on bronchoscopy, and absence of signs of irresectability of the esophageal lesion or neoplastic dissemination on thoracic and abdominal helicoidal tomography. Cases in which an anesthetic or surgical procedure was contraindicated due to compromised clinical state and/or concurrent serious systemic disease were excluded from the study. The diagnosis was confirmed by upper esophageal endoscopy and biopsy: 25 (80.6%) patients had squamous cell carcinoma and the remaining six (19.3%) had adenocarcinoma.

All patients underwent preoperative clinical evaluation. Thirteen (41.9%) had serious clinical malnutrition as shown by weight loss of greater than 20% of normal weight. Tumor staging was performed using physical examination, thoracic radiography, barium esophography, thoracic and abdominal tomography, and bronchoscopy in patients whose lesions were situated in the medial third of the esophagus. Clinicopathological staging using the TNM classification by the UICC[24] was: stage I in two (6.4%) patients; stage ⅡA in five (16.1%); stage ⅡB in four (12.9%); stage Ⅲ in 16 (51.6%); and stage ⅣA in four (12.9%).

Surgical technique

In the absence of contraindications, a transhiatal esophagectomy followed by a cervical esophagogastroplasty was performed. All surgeries were carried out in parallel during the same operating period by two teams, with one team operating in the abdominal region and the other in the cervical region. Lymph node resection was done in both the abdominal and inferior mediastinal fields. In all cases, the tubularized stomach was placed into the cervical region by the posterior mediastinum.

The esophagus was dissected and separated from its neighboring structures in the cervical, thoracic and abdominal areas. In distally located tumors, the esophagus was sectioned in the cervical region, with care taken to preserve enough of the proximal end to allow 4.0 cm of esophagus to be inserted into the stomach, with a safe margin ⩾ 5.0 cm. The esophagus was then pulled to the abdominal region, and the stomach sectioned with a linear stapler that released the surgical specimen.

To guarantee a sufficient margin for lesions that involved the middle third, the stomach was initially sectioned and tubularized, and the piece pulled up to the cervical region, where it was very carefully examined, and the surgical section site was chosen with a safe margin. If the margin was judged to be inadequate, end-to-end anastomosis was performed instead of invagination, and that patient was excluded from the study.

In the region that was selected for anastomosis, a transverse myotomy was carried out around the entire circumference of the esophagus (Figure 1A). The proximal border of the myotomy was anastomosed, with the tip of the tubularized stomach placed in the cervical region. The anastomosis of the posterior wall was performed first using interrupted sutures of 4-0 polydioxanone (Figure 1B). Subsequently, the 4-cm segment of esophagus was introduced or invaginated into the stomach and sutured to the anterior wall as per the posterior wall (Figure 1C). In all patients, extra-mucosal pyloroplasty was carried out, a nasogastric tube was also inserted, and the cervical region was drained by a laminar drain.

Oral feeding was typically started on the postoperative day 10, in the absence of signs of esophagogastric fistula. If a fistula was present, the affected site was treated, to maintain feeding by nasogastric tube. In this case, oral diet was begun following closure of the fistula.

RESULTS

No patients died intraoperatively. Postoperative minor complications occurred in 22 (70.9%) patients. Four (12.9%) patients had serious complications that led to death: two (6.4%) as a result of bronchopneumonia, one due to multiple organ failure after acute cholecystitis, and the other from sepsis following ischemic necrosis of the stomach; all of them with no relationship to the esophagogastric anastomosis.

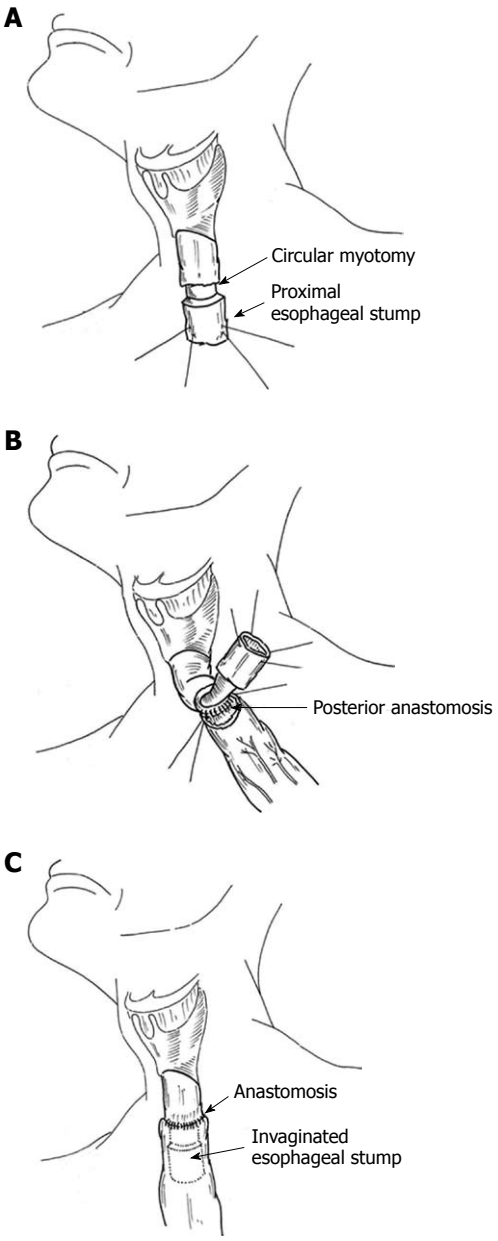

Figure 1 Esophagogastric anastomosis with stomach invagination. A: Diagram showing the circular myotomy (long arrow) in the section of the proximal esophageal stump (short arrow), which created a 4.0 cm segment of extension to be invaginated into the stomach (the illustration of the trachea was omitted); B: Diagram showing the anastomosis of the posterior wall of the esophagus performed first using interrupted sutures (the illustration of the trachea was omitted); C: Diagram showing the sectioned esophagus protruding into the stomach (the illustration of the trachea was omitted).

Three (9.7%) patients had fistula at the esophagogastric anastomosis with minimal leakage of air or saliva; all of them with mild clinical repercussions. Two of these had a fistula on postoperative days 7 and 10, with the leak of a small quantity of air or saliva from the cervical incision and consequent formation of a bubble during swallowing. In these two patients, spontaneous closure occurred after 10 and 5 d, respectively. The third case had a seropurulent pleural effusion on postoperative day 13, which was later drained. There was a negligible quantity of secretion from the pleural drain, which indicated a mild

Table 1 Postoperative complications in 31 patients with thoracic and abdominal esophagus cancer, who underwent cervical esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach tube

Complication	*n* (%)
Dysphonia	15 (48.4)
Anastomosis stricture	7 (22.6)
Bronchopneumonia	6 (19.3)
Anastomosis fistula	3 (9.7)
Atelectasis	2 (6.4)
Renal failure	2 (6.4)
Gastric ischemic necrosis	1 (3.2)
Acute cholecystitis	1 (3.2)
Wound infection	1 (3.2)

blocked esophago-pleurocutaneous fistula. This patient had no adverse effects from this and was discharged from hospital on postoperative day 23. No patients had esophagogastric fistula with intense saliva leakage from either the cervical incision or the thoracic drain.

Postoperative stricture of the anastomosis occurred in seven (22.6%) patients; in six of these, this appeared within 16-60 d, and the last appeared at 12 mo after surgery. All of these patients obtained relief from their dysphagia with endoscopic dilatation of the anastomosis, with the number of sessions required ranging from one to seven (mean = 3). One (3.2%) patient with a lesion located in the inferior third of the esophagus had recurrence of the cancer in the area of the anastomosis and required a nasogastric tube. The other complications were successfully treated: dysphonia in 15 (48.4%), bronchopneumonia in four (12.9%), atelectasis in two (6.4%), renal failure in two (6.4%), and wound infection in one (3.2%). Dysphonia was temporary and resolved after a few weeks in all cases. Patients with pre-renal renal failure responded well to expansion with fluids. Atelectasis was reversed with respiratory physiotherapy. The mean length of hospital stay was 15.2 d, with a range of 13-35 d (Table 1).

DISCUSSION

Esophagogastric anastomosis with invagination is a modification of a technique that is performed to reduce fistula formation at the anastomosis site[22]. Szücs *et al*[22] have reported 108 patients that underwent esophagectomy with esophagogastric anastomosis and telescoping of a 10-15-mm length of the esophageal end into the stomach. Twelve (11.1%) of these patients developed fistula at the anastomotic site. We chose to invaginate a 4.0-cm segment made up of all the layers of the esophagus wall, a much longer segment than that suggested by Szücs *et al*[22] and we added a transverse myotomy around the circumference of the esophagus. Our intention was not only to cover the entire site of the anastomosis, but also to encourage the discharge of saliva at a lower region, while attempting to leave the anastomosis site out of alimentary transit. To this end, it was necessary to invaginate a longer segment that consisted of all the layers of the wall of the esopha-

gus, such that the inserted portion remained in the shape of a tube in the interior of the stomach.

To execute the anastomosis, we elected a region at the proximal esophagus where the suture would be placed, and preserved 4.0 cm of esophagus to be invaginated into the stomach. At this point, a transverse myotomy was done around the circumference of the esophagus. We sutured the proximal border of the myotomy together with the seromuscular layer of the stomach. The purpose of the myotomy was to create a border with viability in the muscular layer of the esophagus, to be sutured with the seromuscular layer of the stomach, and also to elongate the esophageal tube to be inserted into the stomach.

The point of esophageal section must be chosen to allow for a safe margin, because carcinoma of the esophagus can disseminate within the wall to sites distal from the principal lesion[8,25-28]. To perform an esophagogastric anastomosis with invagination, it is necessary to save 4.0 cm more of proximal esophagus than for anastomosis without invagination. If it is not possible to achieve an adequate margin, the invagination procedure should be abandoned.

In our view, the fact that this technique conserves 4.0 cm more of the esophagus does not detract from the radical nature of the operation. Upon constructing a cervical esophagogastric anastomosis with invagination, the amount of remaining esophagus is no greater than that usually left when anastomosis is done in the thoracic apex. Walther *et al*[6], in a prospective randomized study, have compared cervical with intrathoracic esophagogastric anastomosis. They have concluded that the withdrawal of an extra 5.0 cm of esophagus to perform anastomosis in the neck does not affect the 5-year survival rate. Consequently, we believe that following all the recommendations and leaving a secure margin, esophagogastric anastomosis with invagination does not breach any radical oncological principles.

The diagnosis of fistula of the esophagogastric anastomosis was made based exclusively on clinical criteria, given that a radiological study with water-soluble contrast medium has low sensitivity and a high incidence of false-negative results[29]. None of our cases operated upon by esophagectomy with esophagogastric anastomosis and invagination developed fistula with heavy egress of saliva from the cervical incision. Compared with results from the literature[4,6,13-18,30] which show an incidence of fistulas of 0%-50%, cervical esophagogastric anastomosis with invagination had a low incidence of fistula formation, with only one case (3.4%) having clinical repercussions.

It is possible that esophagogastric anastomosis with invagination did not influence the factors responsible for the formation of the fistula. Moreover, it is likely that points of dehiscence could occur along the suture line similarly when we perform the end-to-end technique. However, as the saliva flows to an area below the anastomosis, these points of dehiscence probably can undergo rapid regeneration. On the other hand, in cases without invagination, the saliva discharges directly into the area of the suture with dehiscence, which provokes local inflammation and infection, thereby delaying the healing process of the suture line and enlarging this area.

In view of this mechanism, we believe that the three cases observed of fistula formation in esophagogastric anastomosis presented with mild clinical repercussions, even when the fistula was directed toward the pleural space. We also believe that, despite fistula with minimal clinical repercussions, the technique of esophagogastric anastomosis with invagination can still prove advantageous over the method without invagination.

In the present study, seven (24.1%) cases developed postoperative strictures of anastomosis; this rate lies within the 5%-45% limit described by other authors[15,19,20]. We believe that this result could have been due to the fact that anastomosis with invagination did not influence the factors that might predispose the formation of fistulas, such as ischemia in the proximal portion of the gastroplasty. In this situation, the points of dehiscence would have occurred along the suture line at a similar rate to anastomosis without invagination. However, the presence of a fistula was not always identified using clinical criteria, possibly due to the fact that saliva discharges below the point of the dehiscence. These events could possibly trigger a fibrotic reaction and scarring, with subsequent stenosis formation in the anastomosis.

We conclude that performing cervical esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach in subtotal esophagogastrectomy with gastroplasty in patients with carcinoma of the thoracic and abdominal regions of the esophagus represents a potential real advantage of this technique over other conventional techniques without invagination.

However, prospective, randomized, and controlled studies that involve esophagogastric anastomosis with invagination of the proximal esophageal stump into the tip of the stomach placed to the cervical region are needed to confirm the initials results obtained in this study.

COMMENTS

Background

Definitive curative treatment for cancer of the esophagus remains a challenge for surgeons. The approach involves major surgery that has a high morbidity and mortality rate, mainly due to pulmonary complications, cervical fistulas, stenosis of anastomosis, necrosis of the tubularized stomach, and mediastinitis. Among these possible complications, fistula of the esophagogastric anastomosis represents one of the principal problems of esophagectomy. Incidence in several studies has ranged from 0% to 50%, with most authors reporting a high incidence of this complication.

Research frontiers

In view of the high incidence of esophagogastric fistulas associated with significant levels of mortality and morbidity, several surgical techniques have been tried to reduce the frequency of fistula formation. These approaches include protection of the anastomosis with fibrin glue, anastomosis in two stages, gastric fundus rotation, microsurgical revascularization of the transposed viscera, mechanical anastomosis, laparoscopic construction of the gastric tube 5 d before esophagectomy, preservation of the vascular arcade of the splenic hilum, administration of prostaglandin E1, and anastomosis with invagination.

Innovations and breakthroughs

Esophagogastric anastomosis with invagination is a modification of a technique that is performed to reduce fistula formation at the anastomosis site. We chose to invaginate a 4.0-cm segment made up of all the layers of the esophagus wall, a much longer segment than that suggested by other authors, and we added transverse myotomy around the circumference of the esophagus. Our intention was not only to cover the entire site of the anastomosis, but also to

encourage the discharge of saliva at a lower region, while attempting to leave the anastomosis site without contact with saliva. To this end, it was necessary to invaginate a longer segment that consisted of all the layers of the wall of the esophagus, such that the inserted portion remained in the shape of a tube in the interior of the stomach.

Applications

Cervical esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach in subtotal esophagogastrectomy with gastroplasty in patients with carcinoma of the thoracic and abdominal regions of the esophagus is associated with a low incidence of esophagogastric fistula, while having similar stenosis rates to anastomosis without invagination.

Terminology

Cervical esophagogastric anastomosis with invagination of the proximal esophageal stump into the stomach tube is a new technique of cervical esophagogastric anastomosis to reduce the frequency of fistula formation.

Peer review

This is an interesting report on a novel technique for cervical esophagogastric anastomosis after esophagectomy and gastric replacement.

Abstract

AIM: To test for association of *SLC11A1* with inflammatory bowel disease (IBD) and *Mycobacterium avium* subspecies *paratuberculosis* (MAP) status in a Caucasian cohort.

METHODS: Five hundred and seven Crohn's disease (CD) patients, 474 ulcerative colitis (UC) patients, and 569 healthy controls were genotyped for *SLC11A1 1730G>A* and *SLC11A1 469+14G>C* using pre-designed TaqMan® SNP assays. χ^2 tests were applied to test for association of single nucleotide polymorphisms (SNPs) with disease, and the presence of MAP DNA.

RESULTS: *SLC11A1 1730G>A* and *SLC11A 1469+14G>C* were not associated with CD, UC, or IBD. The *SLC11A1 1730A* minor allele was over-represented in patients who did not require immunomodulator therapy (P = 0.002, OR: 0.29, 95% CI: 0.13-0.66). The frequency of the *SLC11A1 469+14C* allele was higher in the subset of study participants who tested positive for MAP DNA (P = 0.02, OR: 1.56, 95% CI: 1.06-2.29). No association of *SLC11A1 1730G>A* with MAP was observed.

CONCLUSION: Although *SLC11A1* was not associated with IBD, association with MAP suggests that *SLC11A1* is important in determining susceptibility to bacteria implicated in the etiology of CD.

Key words: *NRAMP1*; Crohn's disease; Ulcerative colitis; IS900 polymerase chain reaction

INTRODUCTION

The solute carrier family 11 (*SLC11A1*) gene (also known

as *natural resistance associated macrophage protein 1*, *NRAMP1*)[1] has been associated with susceptibility to intracellular pathogens since its initial identification in mice[2]. *SLC11A1* encodes a divalent cation transporter that is located in endosome and phagosome membranes[3] of macrophages and monocytes within the liver, spleen and lungs[2,4]. This transporter plays a key role in mounting an effective immune response against intracellular pathogens[1,5] through its involvement in the acidification of the phagosomes[6], as well as the regulation of nitric oxide, interleukin-10[7] and vacuolar iron concentrations[8].

Given the pivotal roles that *SLC11A1* plays in innate immunity, it is not surprising that the relationship between polymorphisms in *SLC11A1* and a number of autoimmune and mycobacterial diseases has been explored. Associations have been found with leprosy[9], tuberculosis[10], rheumatoid arthritis[11], visceral leishmaniasis[12], multiple sclerosis[13], type 1 diabetes mellitus[14], and inflammatory bowel disease (IBD)[15-18]. Most of these disease associations have been with a promoter dinucleotide microsatellite (GT_n) that is known to affect *SLC11A1* expression levels[19]. However, *SLC11A1* also contains a number of single nucleotide polymorphisms (SNPs), including *SLC11A1 1730G>A* (*rs17235409*; D543N) and *SLC11A1 469+14G>C* (*rs3731865*; INT4G>C). The non-synonymous SNP 1730G>A is thought to alter the protein function[18], whereas the intronic SNP 469+14G>C has no known functional effect, but has been suggested to be in linkage disequilibrium with functional promoter polymorphisms[12].

SLC11A1 1730G>A and *SLC11A1 469+14G>C* have been tested for association with Crohn's disease (CD) in two European cohorts. Although the smaller of the two studies found no association with CD, Gazouli *et al*[18] have reported a significant association of both SNPs with disease (*SLC11A1 1730G>A* $P_{genotypic}$ = 0.0001, OR: 3.43, 95% CI: 1.95-5.93, *SLC11A1 469+14G>C* $P_{genotypic}$ = 0.006, OR: 15.91, 95% CI: 0.92-273.46). The involvement of SLC11A1 in the handling and elimination of intracellular pathogens, as well as its association with mycobacterial diseases makes it a biologically plausible candidate risk gene for CD. The results of recent genome-wide association studies strongly suggest defects in genes involved in bacterial detection, handling, and elimination are central to CD pathogenesis. Furthermore the assertion, albeit controversial, that *Mycobacterium avium* subspecies *paratuberculosis* (MAP) is an initial trigger for CD provides an additional rationale to investigate *SLC11A1* as a candidate risk gene for IBD. As a result, this study had two aims. The first was to attempt the first independent replication of the association of *SLC11A1 1730G>A* and *SLC11A1 469+14G>C* with IBD. The second aim was to use previously collected MAP IS900 data[20] to test for association of *SLC11A1* genotypes with occurrence of MAP DNA in peripheral blood.

MATERIALS AND METHODS

Study participants

Patients were selected from a New Zealand Caucasian IBD cohort that had been recruited to investigate genetic and environmental factors that contribute to CD and UC etiology[20-24]. Detailed phenotypic data were available for members of this cohort including ancestry, location of disease, family history of IBD, age of onset, presence of extra-intestinal manifestations, and requirement for surgery. The MAP status of the CD patients in this cohort had been determined previously using IS900 polymerase chain reaction[20]. Randomly selected blood donors (n = 501) from Christchurch (New Zealand), including 180 who had been previously tested for MAP status[20] served as controls.

Genotyping

Genotyping of *SLC11A1 1730G>A* (*rs17235409*) and *SLC11A1 469+14G>C* (*rs3731865*) was performed in 384-well plates using the pre-designed Taqman® SNP genotyping assays C_256352269_10 and C_1659793_10 (Applied Biosystems, Foster City, CA, USA) in a LightCycler® 480 Ⅱ (Hoffmann La Roche, Basel, Switzerland). Cycling conditions for *rs17235409* were 10 min at 95℃, 40 cycles of 15 s at 92℃ and 1 min at 60℃, and 30 s of cooling at 40℃. Conditions were the same for *rs3731865*, but annealing was at 66℃ rather than 60℃. Results were analyzed using Lightcycler® 480 software version 1.5.0. The accuracy of the genotyping assays was confirmed by repeat analysis of 13% of samples. Concordance between original and repeat genotype calls was 99%.

Statistical analysis

A web-based calculator (http://ihg2.helmholtz-muenchen.de/cgi-bin/hw/hwa1.pl) was used to test for deviations from Hardy-Weinberg Equilibrium (HWE). The χ^2 and OR analyses were performed using SPSS for Windows, version 13.0 (SPSS Inc., Chicago, IL, USA). Associations were considered significant if P was < 0.05. *Post hoc* power analysis demonstrated that our cohort had 90% power to detect a relative risk of 2.15 for *SLC11A1 1730G>A* ($MAF_{controls}$ = 0.02, α = 0.05) and 99.8% power to detect a relative risk of 1.5 for *SLC11A1 469+14G>C* ($MAF_{controls}$ = 0.30, α = 0.05).

Ethical considerations

All study participants provided written informed consent to be involved in ongoing IBD research, and ethical approval for this study was given by the Upper South Regional Ethics Committee (Canterbury, New Zealand).

RESULTS

Genotyping for *SLC11A1 1730A>G* and *469+14G>C* was successful in 1468 (94.7%) and 1432 (92.4%) of study participants, respectively. No deviations from HWE were detected in cases or controls for either SNP (P > 0.05). The percentage minor allele frequency (MAF) of *SLC11A1 1730G>A* and *SLC11A1 469+14G>C* in our controls was 2% and 30%, respectively. We found no evidence of association of either *SLC11A1* SNP with overall CD, UC or IBD susceptibility (Table 1). Similarly, the minor allele and genotype frequencies of *SLC11A1*

[1]Tested by IS900 polymerase chain reaction to detect the presence of *Mycobacterium avium* subspecies *paratuberculosis* (MAP) DNA in peripheral blood[20]. OR: Odds ratio; CI: Confidence interval.

1730G>A and *469+14G>C* did not associate with age of disease onset, disease behavior, disease location, or requirement for resectional surgery (all *P* values > 0.1, data not shown). A significantly higher frequency of the *SLC11A1 1730A* allele was seen in IBD patients who did not require immunomodulator therapy, compared to those who did require this treatment approach (P_{IBD} = 0.002, OR: 0.29, 95% CI: 0.13-0.66, P_{CD} = 0.03, OR: 0.38, 95% CI: 0.15-0.95, P_{UC} = 0.01, OR: 0.75, 95% CI: 0.71-0.79) (Table 2). There was no significant association of *SLC11A1 1730G>A* with MAP status, whereas the *SLC11A1 469+14C* allele was associated with increased incidence of MAP DNA in peripheral blood (*P* = 0.02, OR: 1.56, 95% CI: 1.06-2.23) in our cohort (Table 3).

DISCUSSION

Previous association of *SLC11A1 1730G>A* and *469+14G>C* with mycobacterial infections and preliminary evidence of association with CD[10-12,25] suggest that *SLC11A1* alters susceptibility to IBD. The primary aim of our study was to conduct the first independent replication of the association of *SLC11A1* with CD. In contrast to the original study of Gazouli *et al*[18], we found no evidence of *SLC11A1 1730G>A* or 469+14G>C as risk factors for IBD, CD or UC (all *P* values > 0.8) (Table 1). Comparison of the MAFs for the two *SLC11A1* SNPs revealed the existence of significant heterogeneity between Gazouli *et al*[18] and other studies for *SLC11A1 1730A*, and between populations of Northern versus Southern European ancestry for *SLC11A1 469+14C*. Our cohort and the cohort of Liu *et al*[26], which were composed primarily of individuals of Northern European ancestry, had *SLC11A1 469+14C* frequencies of 30% and 27% respectively. In contrast, the cohorts drawn from Southern European populations (Italian, Greek, and Turkish) exhibited significantly lower MAFs for this SNP. These differences in MAF distribution hint at the existence of a North-South gradient for *SLC11A1*, which could in turn explain the discordance between our study and that of Gazouli *et al*[18]. The occurrence of such gradients is not without precedence. The frequency of the CD-associated SNPs, *R702W*, *G908R* and *1007fs*, within the nucleotide oligomerization binding domain 2 gene (*NOD2*, also known as *CARD15*) exhibits a strong North-South gradient within Europe. A recent meta-analysis of *NOD2* association studies performed on European IBD cohorts has found that the MAFs and thus the contribution of these SNPs to CD risk increased significantly with decreasing latitude[27].

The minor allele of *SLC11A1 1730G>A* was found to be significantly over-represented in the subset of our IBD patients who had never used immunomodulators, and by inference had less severe disease (Table 2). However, we saw no association with other markers of disease severity in our cohort. Due to the very low minor allele frequency (no minor allele homozygotes were observed), this result requires replication in other large cohorts to rule out a type 1 error.

The second aim of this study was to test for association of *SLC11A1* with MAP. The MAP status of 321 CD patients and 180 controls has been determined previously[20]. Combining these patients and controls, we found no association between MAP status and *SLC11A1 1730G>A*, but did find an association with *SLC11A1 469+14G>C* (P = 0.02, OR: 1.56, 95% CI: 1.06-2.29) (Table 3). Earlier studies[14,16] on smaller CD cohorts (n = 37 or 59) did not find any evidence of association of MAP status with *SLC1A11 469+14G>C*. However, this polymorphism has been associated with susceptibility to *Mycobacterium tuberculosis*[10], and additional variation within *SLC11A1* has been associated with susceptibility to other mycobacterial diseases such as leprosy[9]. Our results provide preliminary evidence of an association of the *SLC11A1 469+14C* allele with susceptibility to MAP.

We conclude that although *SLC11A1* could be a risk factor for IBD in some Southern European populations, we did not find an association of *SLC11A1 469+14G>C* or *SLC11A1 1730G>A* with IBD in our cohort that comprised primarily patients of Northern European ancestry. However, the significantly higher incidence of MAP DNA in the peripheral blood of *SLC11A1 469+14C* heterozygotes and homozygotes compared to *SLC11A1 469+14G* within our cohort suggests that this *SLC11A1* SNP, although not directly influencing disease risk, might modify susceptibility to potential CD-causing bacteria.

ACKNOWLEDGMENTS

We thank the people who generously gave of their time to take participate in the study. We also thank Rhondda Brown and Judy Hoar for their assistance in coordinating the recruitment of patients; Pip Shirley, Megan Reilly, David Tan, Ramez Ailabouni and Charlotte Duncan for entering patient details into the clinical IBD database.

COMMENTS

Background

The involvement of *SLC11A1* in the handling and elimination of intracellular pathogens, as well as its association with mycobacterial diseases makes it a biologically plausible candidate risk gene for Crohn's disease (CD). The suggestion that *Mycobacterium avium* subspecies *paratuberculosis* (MAP) is an initial trigger for CD provides an additional rationale to investigate *SLC11A1* as a candidate risk gene for inflammatory bowel disease (IBD).

Research frontiers

A previous genetic association study has indicated that SLC11A1 is a susceptibility gene for IBD. The authors performed an independent replication of this study in a large population-based cohort of Northern European origin. They also tested for the association of these polymorphisms with MAP status.

Innovations and breakthroughs

This is believed to be the first study to examine the association of SLC11A1 polymorphisms in a well-powered cohort of Northern European origin. These findings indicate that *SLC11A1* polymorphisms do not modify disease risk for IBD, but might influence disease behavior (through indirect markers of severity) and susceptibility to MAP, a putative pathogen in CD. The authors also note the disparity of allele frequency between populations of Northern and Southern European origin.

Applications

By understanding how *SLC11A1* genotype influences the risk of colonization/infection with MAP, the authors might gain some insight into the contribution of this bacterium to IBD, and how defective clearance of MAP and other intracellular bacteria might be associated with modified disease risk.

Terminology

SLC11A1, solute carrier family 11 gene (also known as Natural Resistance Associated Macrophage Protein 1, *NRAMP1*) plays a key role in an effective innate immune response against intracellular pathogens. MAP is an intracellular bacterium that has been cited in several studies as a putative causal agent of CD.

Peer review

This paper provides interesting new results regarding the possible relationship between SLC11A1 polymorphisms and IBD risk. The study has been done carefully and thoroughly, and the paper is very well written. The lack of association of SLC11A1 and IBD risk in the study population (New Zealand Caucasians primarily of Northern European descent) is an important finding. The positive result that shows an association of an SLC11A1 allele and MAP status is novel and interesting.

Abstract

AIM: To identify the role of anti-pancreatic antibody (PAB) in the diagnosis of inflammatory bowel diseases (IBD) among Turkish patients, and its frequency in first-degree relatives.

METHODS: PAB and anti-Saccharomyces *cerevisiae* (ASCA) were examined in serum samples of 214 subjects including patients with Crohn's disease (CD, n = 64), ulcerative colitis (UC, n = 63), first-degree relatives of patients with CD (n = 25), first-degree relatives of patients with UC (n = 28),and a control group with gastrointestinal symptoms other than (IBD) (n = 34) by indirect immunofluorescence Positivity of PAB and ASCA was compared in terms of Vienna classification, disease activity and medications used.

RESULTS: In terms of PAB positivity, no difference was found between patients with CD (14.1%) and UC (7.9%) however, significant difference was observed between patients with CD and subjects in the control group (P < 0.05). No difference was found between patients with CD and their relatives in terms of ASCA positivity, whereas a significant difference was found between other groups (P < 0.001). Compared to ASCA, the sensitivity of the PAB was 19% (7/37), its specificity was 93% (25/27), positive predictive value was 77% (7/9) and negative predictive value was 45% (25/55). ASCA was found with significantly higher prevalence in patients with CD activity index > 150 (P < 0.05).

CONCLUSION: PAB is valuable in the diagnosis of IBD rather than CD, but cannot be used alone for diagnostic purposes. PAB is not superior to ASCA in CD diagnosis and in detecting CD among relatives of patients with CD.

INTRODUCTION

The incidence of Crohn's disease (CD) and ulcerative colitis (UC) is gradually increasing. Despite clinical, endoscopic, radiological andhistopathological findings, about 10% of patients with CD and UC are misclassified[1]. Moreover, 10% of the cases are not classified and referred to as indeterminate colitis. New treatment options for inflammatory bowel disease (IBD) are available today. Medical treatment and surgical operations to be implemented vary depending on the type of the disease.

Several serological indicators can be used for differential diagnosis[2]. The most commonly used two indicators are anti-Saccharomyces *cerevisiae* (ASCA) and perinuclear anti-neutrophil cytoplasmic antibodies (pANCA)[3]. Anti-pancreatic antibody (PAB) is another indicator that is currently under investigation in this regard. Serological indicators are not sensitive enough in IBD screening. Therefore, depending on merely serological indicators, diagnosis and treatmentof IBD are not possible. Several studies that areexamining the serological indicators in diagnosis and treatment are underway.

The familial occurrence of IBD is well known. Around 5.5%-22.5% of patients with IBD have another family member also affected with the disease[1-3]. In fact, the most important risk factor for IBD is having a family member with the disease. The relative risk for a sibling of a CD patient to also become affected is 13-36, and for a sibling of a UC patient this risk is 7-17[4], therefore first-degree relatives with no complaints are at risk of developing the disease. Early diagnosis is considered to decrease the disease complications, as well as possible surgical treatment in the long term. Although the search for predictive markers that could identify family members at risk for IBD has been intensive, no such markers have been identified to date. Studies with auto antibodies are being carried out, as these are non-invasive assays. Positive serum antibody findings in first-degree relatives of patients with IBD will, in most cases, indicate potential disease.

To the best of our knowledge, there are no studies that are investigating PAB in CD in Turkey. In our study, PAB was compared with ASCA, which is the most commonly used serological indicator in CD. The five groups included in the study were: patients with CD, patients with UC, first-degree relatives of patients with CD, first-degree relatives of patients with UC, and control subjects. The study aimed to: identify whether PAB plays a role in the differential diagnosis of CD; compare PAB with ASCA; determine the frequency of PAB in first-degree relatives of CD patients who carry potential risk for the disease; and determine whether PAB can contribute to early diagnosis in first-degree relatives.

MATERIALS AND METHODS

Patient enrollment

Among outpatients and inpatients who presented to Sisli Etfal Education and Research Hospital Department of Gastroenterology; we enrolled 64 patients with CD, 63 with UC, 25 first-degree relatives of patients with CD, 28 first-degree relatives of patients with UC, and 34 control patients with gastrointestinal symptoms other than IBD. Diagnosis of CD and UC was established by means of clinical, endoscopic and histopathological examinations. Exclusion criteria were; infective enterocolitis (excluded *via* feces microscopy, culture, serological examination for bacterial and ameba infection, staining of the biopsy with acid-resistant dye and bacterial culture), Behcet's disease, microscopic colitis and indeterminate colitis. Patients with a diagnosis of IBD for > 6 mo were enrolled. Enrolled patients were categorized according to age, sex, disease type, disease activation, clinical picture and involvement site of the disease.

Patients with UC were classified with proctitis, distal involved colitis, left colon involved colitis, diffuse colitis, and pancolitis. First-degree relatives involved either the siblings or the parents of the patients with IBD. First-degree relatives who had suspected complaints and histories of IBD were excluded. The control group consisted of patients from outpatient clinics who presented with gastrointestinal symptoms other than IBD, and who had no first-degree relative with IBD. Table 1 summarizes the demographical characteristics, disease duration, disease type and sites involvement, and medication being taken for all the enrolled groups.

For the activity of the diseases, CD activity index (CDAI) for CD and Trulove and Witts clinical activity index for UC were used. Medication was classified into seven groups: no medication; 5-aminosalicylic acid (ASA); azathioprine (AZA); 5-ASA + corticosteroid (CS); 5-ASA + AZA; 5-ASA + antibiotics and 5-ASA + CS + AZA.

Conduction of antibody testing

All tests were conducted by product specialists from Euroimmun AG, Turkey, who were trained at Euroimmun Laboratories in Germany, and were confirmed by a second specialist. Both specialists were blinded to the diagnoses. After being collected from patients, relatives and control group, venous blood samples were centrifuged within 3 h, and serum was separated and were maintained at 80℃ until the time of testing. Serum samples to be studied were transported to laboratories in ice boxes.

Determination of PAB

The presence of PAB was determined by indirect immunofluorescence staining in primate pancreas tissue (Figure 1). Kits prepared by Euroimmun AG were used. Substrates that were developed from pancreatic tissue from primates were divided into thin sections (biochips), transferred to slides, and utilized in the kit. The materials in the kits were kept under suitable conditions (4-8℃) until use For dilution and washing steps, we used a solution that was prepared from 10.2 g phosphate buffer, pH 7.2 and 2 mL Tween 20 (organic detergent). Antibodies tend to precipitate after the serum is dissolved, therefore serum samples of each patient were subjected to a string step (vortexing) to ensure homogeneous dispersion in the serum. Dilutions of 1/10 with PBS were prepared for

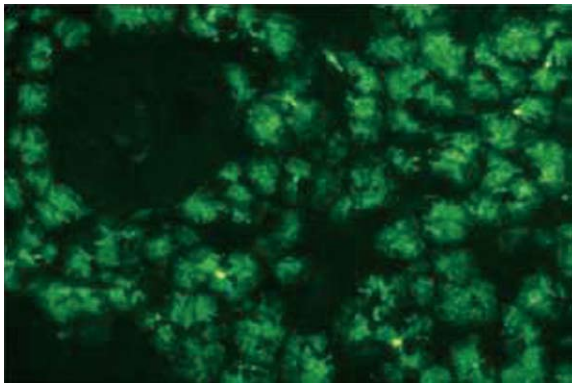

Figure 1 Pancreatic antibodys were determined by indirect immunofluorescence staining in primate pancreas tissue.

each patient. Prepared dilutions were incubated at room temperature (18-25℃) for 30 min, followed by 5 min washing with PBS. Later, incubation with fluorescence-marked anti-human globulin IgA and IgG conjugates was performed for each patient. After being washed with PBS for 5 min, the slides were prepared for examinations by specialists by adding glycerol, pH 8.4, included in the kit and closing with lamella.

Determination of ASCA

Kits prepared by Euroimmun AG that contained antibodies against S. *cerevisiae* were used. Storage conditions of this kit were the same as for the PAB kit. The same solutions were used for dilutions and washing steps. However, we used 1/100 dilutions for ASCA rather than 1/10 as in the previous preparation. Dilutions were incubated at room temperature (18-25℃) for 30 min, followed by 5 min washing with PBS. Later, incubation with fluorescence-marked anti-human globulin IgA and IgG conjugates was performed for each patient. After washing with PBS for 5 min, the slides were prepared for examination by specialists by adding glycerol, pH 8.4, included in the kit, and closing with lamella.

Statistical analysis

Data were evaluated using (SPSS) for Windows, version 9.05 statistical software. Research findings were converted into numeric and percentage distributions and Fischer's exact χ^2 test (used when the number of the object was < 20, or between 20 and 40 but if the least expectant value was < 5) and Pearson's χ^2 test were used to determine the level of significance of correlations between dependent (PAB and ASCA), independent (disease duration, disease onset age, disease type, site of involvement, medication) variables. $P < 0.05$ was considered statistically significant.

RESULTS

Demographic features of the involved patients are summarized in Table 1.

PAB was found to be positive in nine patients with CD (9/64; 14.06%) and five with UC (5/63; 7.93%) (Table 2, Figure 2), but the difference was not statistically significant.

ASCA was found to be positive in 57.80% (37/64) of patients with CD, and 20.60% (13/63) of patients with UC, 36% (9/25) of CD relatives, 17.90% (5/28) of UC

A1: Disease onset age < 40 yr; A2: Disease onset age ≥ 40 yr; B1: Inflammatory type; B2: Stricturizing type; B3: Fistulizing type; L1: Ileal involvement; L2: Colonic involvement; L3: Ileocolonic involvement. PAB: Pancreatic antibody.

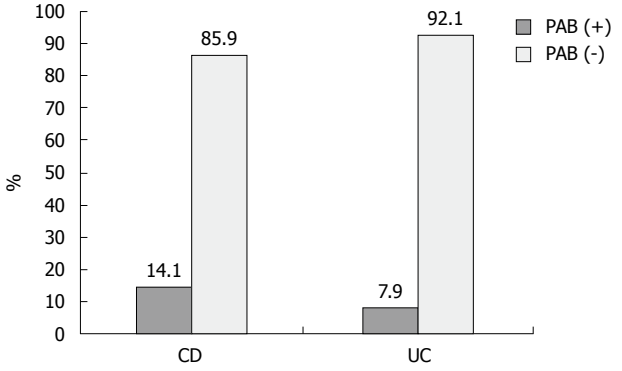

Figure 2 Pancreatic antibody frequency in Crohn's disease and ulcerative colitis patients. CD: Crohn's disease; UC: Ulcerative colitis; PAB: Pancreatic antibody.

relatives, and 17.60% (6/34) of the control subjects. A statistically significant difference was found between the patients with CD and UC and between the relatives of patients with UC and the control group ($P < 0.001$ for both), but there was no significant difference between the patients with CD and their relatives.

Sensitivity and specificity of PAB was 19% (7/37) and 93% (25/27), respectively. Positive predictive value was 77% (7/9) and negative predictive value was 45% (25/55). The likelihood ratio was 2.7 (0.19/10.93) and coherence was 0.50 (7+25/64).

Although frequencies of PAB and ASCA were found to be higher among the patients aged < 0 years than in the older group (Tables 3 and 4), the differences were not statistically significant for PAB or ASCA. The positivity ratios of ASCA and PAB were not significantly different between the patients with UC and CD.

When CD activity was classified as mild and severe, no difference was found in PAB positivity (Table 5). The same assessment performed for ASCA yielded no statistically significant difference.

CD patients were grouped according to medication and classified according to PAB and ASCA positivity. No significant difference was found in patients using corticosteroids or immunosuppressive drugs in terms of PAB and ASCA levels.

DISCUSSION

Tissue damage in IBD is caused by multiple mechanisms that are mediated by the immune system. Although several studies have supported the argument that autoimmune mechanisms are the primary responsible mechanism, the consensus is that autoimmune stimulation does not have direct significance. Therefore, IBD is not actually an autoimmune disease. However, because the pathogenesis is mediated by the immune system, determination of autoantibodies and other immunological indicators is of clinical importance and warrants further research[5].

PAB frequency in patients with CD was found as 14.06% (9/64) and as 7.93% (5/63) for UC patients in the present study. No PAB positivity was noted in the relatives of both CD and UC patients. Although PAB was more positive in CD patients, the difference was not statistically significant. Related studies in the literature have reported PAB frequencies of 15%-40% in CD, 1%-4% in UC, and 1%-4% in control subjects[6-15]. The results of the present study can be considered consistent with those of Greek

and Belgian studies that have demonstrated that PAB is present not only in patients with CD, but also in those with UC. Frequency of antibody in patients with UC was reported to be 23.3% in a Belgian study and 24.7% in a Greek study[11-14]. As PAB positivity is also seen in patients with UC, and because the frequency in patients with UC is not significantly different from that in CD patients, PAB seems to be a more suitable indicator for IBD rather than CD. In the light of these findings, PAB cannot be regarded as a screening test for IBD. Nishimori *et al*[13], Desplat-Jégo *et al*[15] and Koutroubakis *et al*[11] have arrived at the same conclusion.

Several serological indicators that are useful in differential diagnosis of UC and CD have been studied recently, and utilization of multiple indicators has been shown to improve differential diagnosis in cases of indeterminate colitis. Some of these indicators are pANCA, ASCA, PAB, OmpC antibody and I-2 and anaerobic coccoid rods antibodies[8-19]. This is why ASCA, together with PAB, was examined in the present study. As shown in Table 2, ASCA positivity was 57.8% (37/64) in CD patients, 20.6% (13/63) in UC patients, 36% (9/25) in the first-degree relatives of patients with CD, 17.9% (5/28) in the first-degree relatives of patients with UC, and 17.6% (6/34) in the control group. These values are much higher than the PAB positivity rates. In terms of these positivity rates, a statistically significant difference was identified between CD and UC, and relatives of UC patients and control subjects ($P < 0.001$); however, no significant difference was noted between CD patients and their relatives between UC patients and their relatives,or between UC patients and the control group. PAB seems to be a less desirable serological indicator compared to pANCA and ASCA in patients with IBD, as our findings indicate a lower prevalence. However, it can improve diagnosis and the predictive value when used in combination with common indicators.

ASCA, which is found with higher rates of positivity in patients with CD, is reported to be positive also in spondyloarthropathy associated with HLA-B27, which is its disadvantage[8]. In contrast, studies of PAB, have emphasized that it has a high specificity for CD and is positive only in patients with CD[8,17,18].

In a study by Stöcker *et al*[9], higher rates of PAB positivity were noted in patients with disease duration > 2.5 years compared to those with duration < 2.5 years. Similarly, Klebl *et al*[16] have also identified a significant relationship between PAB positivity and disease duration ($P = 0.04$). Koutroubakis *et al*[11] have compared patients with disease duration less and more than 2 years, and have noted a tendency towards increased PAB positivity in the latter; however, the result was not statistically significant. When PAB frequency was assessed in terms of disease duration in our study, positive findings were identified for 14.3% (5/35) of the patients with disease duration < 3 years compared to 13.8% (4/29) in those with disease duration > 3 years. The results are very close to each other and no difference was detected with the statistical methods used in this study (Fisher's exact χ^2 test).

Another research topic in studies with PAB is the relationship of PAB with disease activity. Most of the earlier studies[7,11,19,20] have failed to identify a correlation between PAB positivity and disease activity, and a parallel was found only by Goischke *et al*[12]. There were no significant relationships between disease activity and PAB positivity in our study (Fisher's exact χ^2 test).

According to the disease type of CD, PAB was positive in 13.72% of patients with inflammatory type, in 14.28% of patients with stricturing type, and in 16.66% of patients with fistulizing type disease. The differences between the groups mentioned above were not found to be statistically significant, although a higher frequency was noted for the fistulizing type. Antibody frequency has been shown to be higher in fistulizing and stricturing type diseases[11,16]. Klebl *et al*[16] have found that PAB frequency was 31.5% in stricturing and non-penetrating type, 41.7% in stricturing type, and 31.5% in penetrating type disease. Koutroubakis *et al*[11], on the other hand, have reported the frequency as 60% in stenotic type, 28.6% in inflammatory type, and 41.2% in fistulizing type disease, with a statistically significant result for stenotic type compared to the other types.

The most problematic cases in differential diagnosis are CD patients with isolated colon involvement, as the sites of involvement are the same as with UC. Sites of involvement in CD patients in this study were ileum for 26, ileocolon for 36 and colon for two patients. There were very few subjects with colon involvement, therefore, it was not possible to perform a comparison with subjects with ileum involvement. PAB positivity of patients with ileocolon involvement was higher than for other groups, but without statistical significance. There were also no significant differences in ASCA results according to site of involvement. These results were in accordance with several other relevant studies. In their studies from 1991 and 1996, Seibold *et al* did not find a relationship between PAB and site of bowel involvement[7-21]. Klebl *et al*[16] noted no relationship between PAB positivity and L category by the Vienna classification system. Koutroubakis *et al*[11] did not detect a significant relationship between disease localization and PAB positivity, but found less frequent PAB positivity in CD with colon involvement as compared to ileum or ileocolon involvement ($P = 0.1$). Similarly, no relation between PAB and disease localization was identified by Lawrance *et al*[22].

Another issue investigated in PAB studies is the relationship between PAB and concomitant drugs. Despite the studies by Stöcker *et al*[9] and Folwaczny *et al*[10] that have reported a high antibody frequency in patients not using glucocorticosteroids, Seibold *et al*[7,21], Goischke *et al*[12] and Klebl *et al*[16] did not detect any relationship between PAB frequency and drug use, including glucocorticosteroids. In our study, PAB positivity rates showed no difference between CD patients who were and were not taking glucocorticosteroids. Similarly, no statistically significant difference was noted in patients who were and were not using AZA.

Of the patients with IBD in the present study, 5%-10% had a positive familial history. Farmer *et al*[23] observed that one third of IBD patients had family histories positive for IBD. It is known that the incidence of CD is 14-times higher in complaint-free first-degree relatives of CD patients compared to the general population, and that these individuals are at risk of developing the disease[24] whereas Monsén *et al*[25] found that the prevalence of CD among first degree relatives 21 times higher than among non-relatives. Some studies have indicated that PAB positivity has a low frequency in the first-degree relatives of patients with CD. Seibold *et al*[21] have investigated 606 patients and arrived at the conclusion that PAB was a specific indicator for CD, and that PAB was rarely positive in family members of CD patients (2.5%). They concluded that most of the PAB-positive family members were CD patients[5,19]. Folwaczny *et al*[10] have calculated PAB positivity in first-degree relatives of CD patients as 4%. The same study has reported that there were no significant differences between the incidence of PAB-positivity in the relatives of CD and patients and healthy controls[6]. On the other hand, the findings of Joossens *et al*[14] are inconsistent with those reported in the above studies; they have found PAB prevalence of 32% in CD, 23.3% in UC and 22.2% in family members of patients with IBD. One of the purposes of the present study was to investigate PAB and ASCA positivity in first-degree relatives of patients with IBD, and to determine whether these indicators would contribute to early detection of the disease in these risk groups. However, PAB was detected in none of the first-degree relatives of IBD patients, nor in any subjects in the control group. ASCA results for the relatives of patients with CD, relatives of UC patients and the control group did not differ significantly, either. Shanahan *et al*[19] had summarized that autoantibodies were unlikely to have a direct, primary pathogenic role in CD and viewed that autoantibodies as important bridge between clinical and basic science. Müller-Ladner *et al*[20] had also found a link between pancreatic antibodies and Crohn's disease. Therefore, we believe it would not be appropriate to use PAB or ASCA alone for determining the potential of CD patients' relatives to develop CD.

In conclusion, in our study based on the absence of a significant difference between positivity in CD and UC, PAB has a diagnostic value for detecting patients with IBD rather than CD, and it should not be used alone for diagnosis. Also, we can say that investigating PAB and ASCA in first-degree relatives of IBD patients does not offer much benefit in early detection of the disease, and there is no superiority of PAB over ASCA in clinical practice in terms of CD diagnosis and early detection of the disease in patients'relatives. Further studies with novel indicators are still needed in the diagnosis of CD, and early diagnosis in relatives of CD patients.

COMMENTS

Background

Several antibodies have been associated with inflammatory bowel disease (IBD), with one of the most comprehensively studied being antibodies against

anti-Saccharomyces *cerevisiae* (ASCA). Pancreatic antibodies (PABs) are also newly studied antibodies that are specific for Crohn's disease (CD) and ulcerative colitis (UC), but their sensitivity alone is low.

Research frontiers

PAB in combination with ASCA might increase the sensitivity for detecting CD, especially isolated colonic CD. This study focused on the value of PAB alone or in combination with ASCA for diagnosing IBD, and differentiating CD from UC.

Innovations and breakthroughs

Several serological indicators can be used for differential diagnosis of IBD. PAB is another indicator that is currently under investigation in this regard. Serological indicators are not sensitive enough for IBD screening. Therefore, depending on serological indicators alone, diagnosis and treatment of IBD will not be possible. Several studies that are examining serological indicators for diagnosis and treatment are underway. There are no studies that are investigating PAB in CD in Turkey. The present study aimed to: identify whether PAB plays a role in the diagnosis and differential diagnosis of CD; compare it with ASCA; determine its frequency in first-degree relatives of CD patients who carry a potential risk for the disease; and determine whether it can contribute to early diagnosis.

Applications

This study suggest that PAB is a novel indicator that is still needed in the diagnosis of CD, and early diagnosis in relatives of CD patients.

Peer review

This study aimed to identify the role of PAB in the diagnosis of CD, and determine its frequency in first-degree relatives. The main focus of this work was to measure the frequency of PAB and ASCA in Turkish IBD patients.

Abstract

AIM: To evaluate the efficacy of self expandable metallic stents (SEMS) in patients with malignant esophageal obstruction and fistulas.

METHODS: SEMS were implanted in the presence of fluoroscopic guidance in patients suffering from advanced and non-resectable esophageal, cardiac and invasive lung cancer between 2002 and 2009. All procedures were performed under conscious sedation. All patients had esophagus obstruction and/or fistula. In all patients who required reintervention, recurrence of dysphagia, hemorrhage, and fistula formation were indications for further endoscopy. Patients' files were scanned retrospectively and the obtained data were analyzed using SPSS 13.0 for Windows. The χ^2 test was used for categorical data and was analysis of variance for non-categorical data. Patients' long-term survival was assessed using the Kaplan-Meier method.

RESULTS: Stents were successfully implanted in 90 patients using fluoroscopic guidance. Reasons for stent implantation in these patients were esophageal stricture (77/90, 85.5%), external pressure (8/90, 8.8%) and tracheo-esophageal fistula (5/90, 5.5%). Dysphagia scores (mean ± SD) were 3.37 ± 0.52 before and 0.90 ± 0.43 after stent implantation (P = 0.002). Intermittent, non-massive hemorrhage due to the erosion caused by the distal end of the stent in the stomach occurred in only one patient who received implementation at cardio-esophageal junction. Mean survival following stenting was 134.14 d (95% confidence interval: 94.06-174.21).

CONCLUSION: SEMS placement is safe and effective in the palliation of dysphagia in selected patients with malignant esophageal strictures.

Key words: Esophagus cancer; Stenosis; Stents; Complication; Dysphagia

INTRODUCTION

Patients with esophageal cancer and cancer of the gastro-esophageal junction commonly present with an advanced disease mainly because the esophagus is quite distendable and patients may not experience dysphagia until almost half of the luminal diameter is compromised[1]. At the time of diagnosis, a high percentage of patients with esophageal cancer have an advanced stage of disease and when the tumor is not operable, only palliative treatment is applicable, primarily to manage dysphagia[2]. Dysphagia is the most devastating symptom in malign stricture of the

esophagus. Aspiration is another frequent symptom requiring palliative therapy. This is either aspiration of saliva or food as a result of complete dysphagia or a tracheo-esophageal fistula. Similar problems may occur due to local pressure, particularly in patients with advanced lung cancer or mediastinal tumors. Early palliation of dysphagia and other symptoms is important in terms of nutritional status and a good quality of life. Among palliative treatments, radiotherapy, laser therapy and conventional plastic endoprostheses have a limited effect in preventing rapid weight loss due to malnutrition[3].

Several self expandable metallic stents (SEMS) are now available and have been used widely to provide immediate symptomatic relief of malignant dysphagia. They are useful for patients with poor functional status who cannot tolerate radiotherapy or chemotherapy, who have advanced metastatic disease, or in whom previous therapy has failed[3]. The aim of this report was to summarize our experience with expandable metal stents for palliation of malignant dysphagia in our 90 patients.

MATERIALS AND METHODS

From September 2002 to December 2009, 90 patients (65 men, 25 women; mean age 61.57 years, range 38-85 years) with malignant inoperable esophageal obstruction and high grade dysphagia or fistula were treated using flexible self-expanding metallic stents. Surgery was considered to be contraindicated in all patients due to the patients' poor general condition, the advanced stage of tumors, untreatable tumor recurrence or distant metastases. The ability to swallow was expressed as a dysphagia score. The scoring system was modified from that reported by Mellow and Pinkas; a score of 0 denoted the ability to eat a normal diet; 1, the ability to eat some solid food; 2, the ability to eat semisolid only; 3, the ability to swallow liquids only; and 4, complete dysphagia[4]. The data were compared with that published in the literature. All patients gave their informed consent for the procedure.

Stent material

We employed self-expendable covered metallic esophageal stents from different companies (Boston Scientific, Watertown, MA, USA and Micro-Tech, Nanjing, China) in 76 patients. A covered self expanding stent was used in 5 patients with esophagotracheal fistulas. Diameters and length of covered stents varied between 18 and 20 mm, and 6 and 15 cm, respectively. Uncovered metallic stents (Ultraflex Boston Scientific, Watertown, MA, USA) were used in 14 patients. Diameters and length of uncovered stents varied between 18 and 23 mm, and 10 and 15 cm, respectively.

Implantation procedure

Before stent implantation, patients were prepared by administering conscious sedation analgesia (2.5-5 mg midazolam and 25-50 mg meperidine iv) The entire length of tumor stenosis and the location of the esophagotracheal fistula, if available, were precisely determined by an endoscope with an 11 mm diameter. High-grade strictures that could not pass an endoscope were opened prior to stenting to a diameter of at least 8-10 mm using a balloon dilator. After the preparatory treatment, the upper gastrointestinal tract was inspected endoscopically and the tumor margins on both sides were marked on the patients' skin with metallic markers. After the placement of a guidewire into the stomach and the removal of the endoscope, the stent introducer was inserted over the guidewire into the esophagus under fluoroscopic guidance. The stent was positioned under fluoroscopic control with guidance of radio-opaque skin markers and then released from the delivery system. The stents expanded by themselves within 10-60 s. After another minute, the delivery system and the guidewire were carefully removed. After retraction of the delivery system, an immediate endoscopic check was made (Figure 1). A plain chest radiograph and a contrast study using swallowed water-soluble contrast medium were performed to ensure the correct positioning and expansion of the stent and to exclude perforation. In cases of esophago-tracheal fistula, a radiographic control using a water-soluble contrast medium was carried out (Figure 2). These patients were advised to consume only liquids until the stent position was checked. Then they had semisolid or solid food, as individually tolerated. Most patients were discharged on an outpatient basis and were instructed to

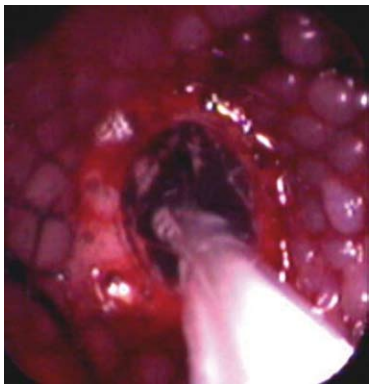

Figure 3 In some cases with insufficient stent expansion due to tight stricture, endoscopic balloon dilatation was performed through the opened stent.

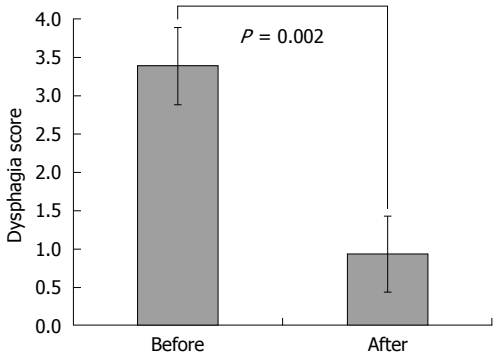

Figure 4 Comparison of oral alimentation status before and after placement of self expandable metallic stents. Figure shows the change in dysphagia score on day 3 after stenting. For the scoring system, see Materials and Methods section.

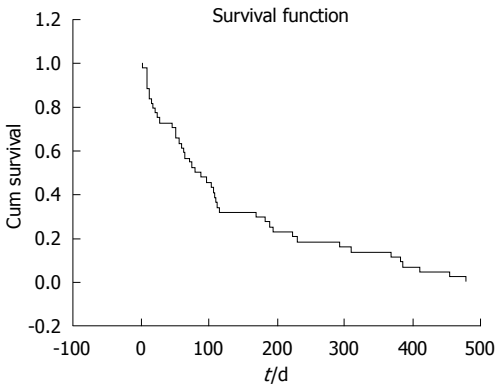

Figure 5 Kaplan-Meier survival curve of 90 patients following stenting.

start oral ingestion the same day. Anti reflux measures (proton pomp inhibitors and/or prokinetic agents) were administered to patients whose prosthesis extended beyond the gastroesophageal junction. We did not use anti-reflux stents.

In some cases, because of the kinking of the esophageal lumen due to malign stricture, insertion of the stent introducer was difficult. In such cases, an endoscope was inserted after the introducer to help push it through the narrowed malign segment. In 3 cases with distal esophageal polypoid tumors, debulking was performed with a polypectomy snare because of extensive vegetation in the lumen preventing stent positioning and expansion. In 17 cases with insufficient stent expansion due to tight stricture, an endoscopic balloon dilatation through the opened stent was performed immediately after stenting to obtain an appropriate passageway (Figure 3).

An exploratory analysis was performed by using SPSS 13.0. Analysis of variance was used for non-categorical (continuous) data and the χ^2 test was used for categorical data. Survival data were assessed by the Kaplan-Meier method.

RESULTS

A total of 100 expandable metal stents were placed in 90 patients for malignant dysphagia caused by esophageal cancer or extrinsic compression. Fifteen uncovered SEMS were placed in 14 patients and 85 covered stents were placed in 76 patients. Our series consisted of 25 women and 65 men with a mean ± SD age of 61.57 ± 12.05 years (range, 38-85 years). The mean size of the strictured segment of the esophagus where the stent was implanted was 7.14 ± 2.67 cm. The primary reason for stenting was esophageal stenosis alone in 77 patients (85.5%), followed by esophageal extrinsic compression in 8 patients (8.8%) and trachea-esophageal fistula in 5 patients (5.5%). In one patient stenting was performed in both his esophagus and the bronchus. In 4 cases, when the stent was opened in an inappropriate position, the stent was removed by pulling the attached string and a new stent was reinserted. Endoscopic balloon dilatation was performed before stenting in 27 patients (30%). Almost all patients improved in terms of oral intake. After the procedure, 84.4% of the patients (76/90) did not report any dysphagia during follow-up. Before stent placement, mean dysphagia score was 3.37 ± 0.52; after stent placement, mean dysphagia score was 0.90 ± 0.43 ($P = 0.002$) (Figure 4). There were no clinically significant complications during the insertion of stents. With respect to complications associated with stents, migration was noted in 4 patients (5%). Intermittent, non-massive hemorrhage due to the erosion caused by the distal end of the stent in the proximal stomach occurred in one patient who had received stent implantation in the cardio-esophageal junction. Migration was noted after 140 d on average (after 419 d in the first patient, after 69 d in the second patient, after 45 d in the third patient and after 27 d in the fourth patient). Migrations occurred following chemotherapy in 3 of the patients. Proximal tumor overgrowth was observed after 165 d on average following stenting in 6 patients (8.1%). Tumor overgrowth was observed within the first month following stenting only in one patient (at day 13). A second extendable stent was implanted in all of these patients. Minimal tissue ingrowth was detected in 3 patients (3.3%) treated with the uncovered stent and none had overt dysphagia.

Mean survival following stenting was 134.14 d [95% confidence interval: 20.45 (94.06-174.21)] (Figure 5). Restenting was needed in 10 patients (Table 1). No patient

Table 1 Characteristics of restented patients

Table 2 Patient demographics

	n (%)
Total No. of patients	90
Mean age (yr, range)	61.57 (38-85)
Male/female	65/25 (72.2/27.8)
Present illness	
Esophagus carcinoma	54 (60.0)
Squamous cell carcinoma	47 (52.2)
Adenocarcinoma	7 (7.7)
Gastric carcinoma (and cardiac)	20 (22.2)
Lung carcinoma	16 (17.7)
Location of obstruction	
Proximal	5 (5.6)
Middle	31 (34.4)
Distal	54 (60.0)
Restenting	10 (11.1)

had esophageal perforation or procedure-related death. Dilatation was performed in 27 patients pre-operatively *via* a 12-16 mm balloon dilator for high grade strictures. Argon plasma coagulation was performed for one patient because of proximal tumor overgrowth.

Table 2 illustrates the localizations of the stents, the reasons for stenting and the patients' demographic data.

DISCUSSION

Our results suggest that SEMS provide a rapid and effective palliation for dysphagia in malignant stenosis, and low morbidity is associated with the procedure. In our study, all patients had significant relief of dysphagia. The frequency of the common conditions associated with stenting as identified in our study are presented in Table 3, in comparison with data reported from other studies[5-15].

Palliation is often difficult to achieve in patients with esophageal obstruction as a result of cancer. Among many endoscopic and nonendoscopic treatment alternatives for palliation of cancer-related dysphagia, stenting with SEMS is one of the main options. It is useful for patients with poor functional status who cannot tolerate radiation or chemotherapy, who have advanced metastatic disease, or in whom previous therapy has failed[16]. It can be concluded that stents provide better oral intake and quality of life compared to surgical palliation techniques. Despite the substantially higher cost of expandable metal stents as compared to traditional rigid plastic esophageal stents, there are substantial overall cost savings resulting from the reduction in the number of days of hospitalization for surgery and possible complications[7]. The majority of our subjects were patients who were referred to our clinic for dysphagia palliation from different centers and none were hospitalized after stenting. Our experience supported that SEMS could be inserted in outpatients, reducing the cost of treatment.

It has been shown that dysphagia was relieved in approximately 90% of patients who received an expendable metal stent[7,12,17]. Compared to other palliative methods, the most significant and fastest improvement in swallowing is achieved in patients undergoing implantation of SEMS[6,14,18,19]. Improvements in dysphagia were achieved in almost all of our patients following stenting. While the mean dysphagia score was 3.37 before stenting, the score was 0.90 following SEMS (P = 0.002). This decrease in dysphagia score is consistent with the literature. Recurrent dysphagia due to device migration and proximal overgrowth occurred in 10/90 (11.1%) of those who received SEMS. No significant difference was found between mean decreases in dysphagia scores in patients who were implanted with covered and uncovered stents (mean decreases in dysphagia scores in the 2 groups were 2.48 ± 0.53, 2.42 ± 0.51, respectively; P = 0.487). Covered and uncovered stents are equally good for dysphagia palliation[20].

Esophageal expandable metal stents are also used to treat tracheo-esophageal fistulas due to cancer. Tracheo-esophageal fistulas develop in patients with advanced esophageal and lung cancer and lead to devastating symptoms as a result of continuous aspiration of saliva and food. Survival over 30 d is rare in these patients, unless they undergo an occluding procedure using an endoprosthesis[18,21-25]. Noncovered stents are not suitable for the treatment of fistulas, because the esophageal contents can pass easily through the mesh and into the esophageal defect. The covered types of metal stents are considered as the primary choice of treatment since treatment of fistula with SEMS improves survival[18,26,27]. In our study group, fistulas were successfully closed with covered stents in all patients with a fistula. All 5 of these patients had primary lung tumors.

Table 3 Outcome of published series of self-expandable metallic stent insertion: with or without fluoroscopy for self-expandable metallic stent insertion

Series	*n*	Dilation rate (%)	Stents uncovered	Perforation rate (%)	Migration rate (%)	Overgrowth rate (%)	Ingrowth rate (%)	Reintervention rate (%)	Median survival (d)

[1]Stent was placed under direct visualization in the study; [2]Study of self-expandable metallic stent (SEMS) *vs* plastic esophageal prostheses treatment, but only data from SEMS arm was included; [3]Only esophacoil stents were used.

Stents were implanted in 5 of our patients because of proximal constriction within 4 cm. The Ultraflex type of covered stent was implanted in all these patients. Stent intolerability due to foreign body sensation, aspiration, perforation, proximal migration or pain was not observed in any of these patients. Verschuur *et al*[28] reported 44 patients had a malignant stricture within 4 cm of the upper esophageal sphincter. In this study, dysphagia improved in most patients, and the occurrence of complications and recurrent dysphagia was comparable to that in patients who underwent stent placement in the mid and distal esophagus. It has been reported that 5%-15% of patients had a foreign body sensation; however, in none of the patients was stent removal indicated[29]. There is a continuing debate about the advisability of SEMS placement for proximal esophageal cancer. If placed, it is frequently recommended that a distance of 2 cm below the upper esophageal sphincter should be maintained while placing a stent.

Intraprocedural complications of endoscopic stenting include those associated with sedation, aspiration, malpositioning of the stent, and esophageal perforation. Immediate postprocedural complications may include chest pain, bleeding, and tracheal compression, with resultant airway compromise and respiratory arrest. Late complications include distal or proximal stent migration, formation of an esophageal fistula, bleeding, perforation, and stent occlusion. Approximately 0.5%-2% of patients who undergo the procedure die as a direct result of placement of an expandable metal stent[30]. No patients died during the procedure in our patient group. Perforation of the esophageal wall is potentially related to the device itself and prior chemoradiotherapy[31]. This complication is presumably due to stent-induced pressure necrosis within devitalized esophageal tissue. The majority of stenting complications are reported in the literature to occur with plastic endoprostheses. In a study by Knyrim *et al*[7], 42 patients with metallic stent and plastic endoprosthesis were compared and the frequency of complications was reported to be less in patients who were implanted with metallic stents (0 and 9 patients, respectively). Two prospective, randomized, controlled trials have shown a significantly lower rate of procedural complications using expanding metal stents[7,12]. Perforation as a direct complication of stent placement was not seen in our patients. This result of perforation compares favorably with other studies[18,32-37]. In contrast to placement of conventional esophageal stents, placement of expendable metal stents do not require a large-bore bougienage, thereby minimizing the risk of perforation and facilitating the insertion procedure. However, in our series balloon dilatation was performed in 27 patients before stenting. The frequency of dilatation has been reported to be in the range of 0%-100% in the literature[7,12,13].

A tracheoesophageal (TE) fistula is one of the late complications that may occur after SEMS. The incidence of fistulas following stenting has been reported as 0%-10% in the literature. The type of the implanted stent was found to have no role in fistula development[6,18,38,39]. Fistulas should be treated with placement of additional, overlapping covered metallic stents. Retrospective analysis of our patients did not reveal any patient developing fistulas after stenting. Kozarek *et al*[13] did not find an association between perforation, bleeding or TE fistula development in patients who had received previous chemotherapy/irradiation. Consistent with the findings reported by Kozarek *et al*[13], TE fistulas did not develop in any of our patients who were receiving treatment.

Stent migration may be a bothersome problem in SEMS. Studies have reported the incidence of late migration from 0% to 58% for different types of covered stents. A higher incidence of late migration of all types of covered stents was observed compared to the uncovered types[6,18,21,40]. Stent migration was noted in 4 (4.4%) of our patients; 3 of these patients had covered and one had an uncovered type of stent.

Another ongoing issue with stents is the occurrence of recurrent dysphagia because of stent migration, tumoral or nontumoral tissue growth and food impaction. Frequencies of recurrent dysphagia associated with overgrowth, ingrowth and obstruction due to food impaction

reported in the literature varies between 17% and 33%, somewhat higher than those observed in our study[2,7]. As the malignant tumor continues to grow after stent implantation, the growth of tumor tissue through the stent lumen (ingrowth) and extension over the stent borders (overgrowth) are 2 major late complications[10,41,42]. The disadvantages of uncovered stents are tumor ingrowth and recurrent obstruction. Covered stents have been designed to prevent ingrowth. Ingrowth in uncovered stents has been reported in literature to be in the range of 0%-100%[6,10,11,38,39]. Authors who used partially covered stents reported the incidence of growth in the uncovered ends of stents between 2% and 25% in different series[10,41,42]. The frequency in covered stents has been reported as 0%-53%[2,6]. In our study, tumor ingrowth was found in 3 patients (3.3%) treated with uncovered stents.

Overgrowth is the result of progression of malignancy rather than a failure or a complication of the stent. It is usually seen in 2.3%-30% of patients after a mean period of 2-4 mo after stent replacement[2,6,9,39,43]. Overgrowth may not always be due to the tumor but may also result from benign epithelial hyperplasia or granulation tissue. The most frequent symptom in cases of overgrowth was dysphagia in our group. Following stenting, 6 patients (6.6%) were restented due to restenosis associated with proximal overgrowth. Restenosis associated with early proximal overgrowth occurred in only one of our patients (at day 13). Stent migration may facilitate development of overgrowth formation though it may not be possible to confirm this complication endoscopically. The use of covered stents may help decrease tumor ingrowth, although it will not affect tumor overgrowth. The most frequently used method for the treatment of tumor overgrowth is the placement of a second stent. Argon plasma coagulation was performed additionally in one of our patients with proximal tumor overgrowth. Stent obstruction was observed in 4 of our patients as a result of food impaction, and stents were cleaned endoscopically in all patients.

Hematemesis is also a possible complication after SEMS insertion, and the incidence in our study was 1.1% (1/90). This complication could have been the result of pressure necrosis, the natural progress of the disease, or esophageal or gastric trauma from the sharp end of the stent.

Mean survival after stenting, reported in the literature, varies between 53 and 198 d[6,7,12]. In our study mean survival after stenting was 134 d. Overall survival time in our study was not significantly different from others in the literature. It has been shown that survival is influenced by the type and stage of the underlying disease.

It has been reported that SEMS are being implanted in the absence of fluoroscopic guidance in some centers and that this is a safe approach[5,6,15]. We believe that esophageal stenting under fluoroscopic guidance with endoscopic control is safer.

In summary, in our retrospective screening, we noted that all of our patients had been stented with covered or uncovered metallic stents and that the use of these stents was safe and effective in rapid alleviation of dysphagia. The placement of a self-expandable metallic stent can improve the oral alimentation status. Esophageal fistulas can be completely and rapidly closed with placement of covered metallic endoprostheses. Esophageal stents are a means to an end: in the setting of malignant disease, they occlude TE fistulae or alleviate dysphagia, but do not affect the natural course of the disease process except by virtue of inadequate palliation or subsequent stent-related complications.

COMMENTS

Background

Self expandable metallic stents (SEMS) introduction plays an important role in the management of esophageal obstruction and fistula secondary to malignancy. Early palliation of dysphagia is important for the maintaining of nutritional status and life quality. SEMS provides a considerable palliation with low mortality and morbidity especially in patients with advanced disease.

Research frontiers

This research is regarding to the efficacy and safety of SEMS in patients with esophageal obstruction or fistula due to advanced cancer.

Innovations and breakthroughs

The authors found that the covered and uncovered SEMS are equally effective for dysphagia palliation in malignant esophageal obstruction. This study is the most comprehensive retrospective review from Turkey about the palliation of malignant esophageal obstruction and fistula with SEMS. Also this study showed that it is possible to minimize the complications which may arise from SEMS placement.

Applications

The advantages of SEMS over the other palliative methods are rapidly improving of dysphagia, nutritional status and life quality. Stenting with covered SEMS is the most effective method in patients with malignant esophageal fistula.

Peer review

Palliation of malign obstruction of esophagus *via* SEMS is a rapid and effective treatment. The authors summarized their own experience retrospectively and the manuscript is generally well written.

Abstract

AIM: To improve our understanding of Iranian regional variation in *Helicobacter pylori* (*H. pylori*) antibiotic resistance rates to find the best antibiotic therapy for eradication of *H. pylori* infections.

METHODS: A total of 266 patients undergoing endoscopy in Shiraz, Southern Iran, were included in this study. *H. pylori* strains were isolated from antral biopsies by culture and confirmed by the rapid urease-test and gram staining. Antibiotic susceptibility of *H. pylori* isolates was determined by E-test.

RESULTS: A total of 121 *H. pylori* strains were isolated, 50 from male and 71 from female patients. Data showed that 44% (n = 53), 20% (n = 24), 5% (n = 6), and 3% (n = 4) of all strains were resistant to the antibiotics metronidazole, amoxicillin, clarithromycin, and tetracycline, respectively. When the antibiotics were considered together we found 11 sensitivity patterns for the strains. Resistance to metronidazole was significantly higher in female than in male patients ($P < 0.05$). In about 71% of the metronidazole-resistant isolates, the minimum inhibitory concentrations (MICs) exceeded 256 μg/mL.

CONCLUSION: We found a moderate rate of primary resistance to metronidazole. However, a high MIC (> 256 mg/L) which was found in 71% of the isolates is considerable. In the case of amoxicillin, an increased resistance rate of 20% is worrying. Resistance to clarithromycin and tetracycline is also emerging among the *H. pylori* strains in our region.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is involved in the pathogenesis

of a number of gastrointestinal diseases, including acute and chronic gastritis, peptic ulceration, gastric carcinoma and gastric lymphoma[1]. Eradication treatment of *H. pylori* infection usually consists of various combinations of drugs. Most commonly, an acid suppressor (usually a proton pump inhibitor) or an H_2-receptor antagonist (e.g. ranitidine) is prescribed in combination with two antibiotics usually amoxicillin, metronidazole or clarithromycin[1]. The combination of two antibiotics can increase the success of eradication therapy and decrease the possibility of secondary antibiotic resistance[2]. Antibiotic resistance in *H. pylori* is the major cause of eradication failure. Growing resistance often parallels the patterns of antibiotic consumption, and may vary within patient groups according to the geographic region, patient age and sex, type of disease, birthplace, other infections and other factors. The geographic map and the process of primary *H. pylori* resistance are clinically important, and should be considered when choosing eradication regimens, as is constant monitoring at both national and global level in an attempt to reach the recently recommended goal of eradicating more than 95% of resistant cases[3]. The prevalence of clarithromycin, metronidazole and amoxicillin resistance varies between countries and is highest for metronidazole[4,5]. Resistance to tetracycline and ciprofloxacin has been reported but appears uncommon[6-8].

There are several problems with antimicrobial susceptibility testing of *H. pylori*[9,10]. Agar or broth dilution methods are difficult to perform routinely[11], thus, disk-diffusion testing is often used because it is simple, easy to perform, and economical[12]. However, the E-test has proved to be an accurate method for assaying the susceptibility of fastidious organisms, including *H. pylori*, to antibiotics. The E-test has a more stable pattern of antibiotic release and has been found to tolerate prolonged incubation[13]. This is the main reason why the E-test rather than the disk diffusion method, has been recommended for *H. pylori*.

Pre-treatment resistance rates in *H. pylori* vary markedly between countries and regions. In Europe, mean resistance rates of 27% for metronidazole and 10% for clarithromycin are typical[14,15]. There is no systematic surveillance of primary antibiotic resistance rates in Shiraz, and widely divergent rates have been reported in Iran, depending on the local population.

The present study aimed to improve our understanding of the Iranian regional variation in *H. pylori* antibiotic resistance rates in relation to gender, and to find the best antibiotic therapy for the eradication of *H. pylori* infections.

MATERIALS AND METHODS

The patient groups and sample collection

In this study, 266 patients attending the endoscopy ward of Motahhary Clinic of Shiraz University of Medical Sciences during the period between October 2008 and October 2009 were enrolled. Exclusion criteria for patient recruitment to the study were: previous attempts to eradicate *H. pylori*, use of antibiotics or proton pump inhibitors within the last 2 wk prior to endoscopy, and previous gastric surgery. The diagnosis of *H. pylori* infection and confirmation of gastric disease by histology were established by a central study pathologist. Antral biopsies taken from each patient were transferred to the lab in an appropriate transfer medium (brain heart infusion broth, supplemented with 20% glucose) for *H. pylori* isolation and identification.

Isolation and identification of H. pylori

Biopsy samples were gently homogenized and cultured on rapid urease-test media and colombia agar base (Merck, Germany), supplemented with 10% lysed horse blood and 7% fetal calf serum and the antibiotics amphotericin B (5 μg/L), trimethoprim (5 μg/L) and vancomycin (10 μg/L). The cultures were kept in a microaerophilic atmosphere (7% O_2, 7.1% CO_2, 7.1% H_2, 79.8% N_2), provided by Anoxomate (Mark Ⅱ, Mart Microbiology BV, Netherlands) at 37℃ for 2-4 d. The isolates were then confirmed as *H. pylori* by positive oxides, catalase and rapid urease-tests. The samples were also evaluated for the presence of *H. pylori* by the modified gram staining and rapid urease-tests. If any of the two tests were positive simultaneously, the sample was considered *H. pylori* positive.

Antibiotic susceptibility test

For *in vitro* susceptibility testing of the *H. pylori* strains, a suspension equal to the McFarland tube no. 3 was prepared for each isolate. We used only one colony from each patient for the analysis. Brain heart infusion broth (Merck, Germany) plates, supplemented with fetal calf serum (Gibco, USA) were inoculated by confluent swabbing of the surface with the adjusted inoculum suspensions. The E-test strips (Biomerieux, France) for the antibiotics amoxicillin, metronidazole, tetracycline, and clarithromycin, were aseptically placed onto the dried surface of inoculated agar plates. The plates were then incubated at 37℃ under microaerophilic conditions. The minimum inhibitory concentrations (MICs) were read after 48-72 h of incubation on the basis of the intersection of the elliptical zone of growth inhibition using the MIC scale on the E-test strip, as per the manufacturer's instructions[16]. Susceptibility results were recorded as resistant according to the following interpretive criteria; for metronidazole, clarithromycin, tetracycline and amoxicillin, MIC breakpoints of $\geqslant$ 8 mg/L, $\geqslant$ 1 mg/L, $\geqslant$ 4 mg/L and $\geqslant$ 0.5 mg/L, respectively[17-19].

Statistical analysis

Fisher's exact test and *P* values were determined. A *P* value of < 0.05 was considered significant.

RESULTS

A total of 121 *H. pylori* strains were isolated from the patients under study, 50 from males and 71 from females. The antimicrobial susceptibility results of the *H. pylori* strains are presented in Table 1. According to the data, 44% (n = 53), 20% (n = 24), 5% (n = 6), and 3% (n = 4) of the strains were resistant to metronidazole, amoxicillin, clarithromycin, and tetracycline, respectively. Fifty isolates were

Table 1 Rates of antibiotic resistance in *Helicobacter pylori* isolates in relation to patient gender

Sex No.	No. of isolates (% of resistance)			
	MTZ	AMX	CLA	TET
Male (n = 50)	17 (34)	9 (18)	1 (2)	1 (2)
Female (n = 71)	36 (50)	15 (21)	5 (7)	3 (4)
Total (n = 121)	53 (43)	24 (19)	6 (5)	4 (3)

MTZ: Metronidazole; AMX: Amoxicillin; CLA: Clarithromycin; TET: Tetracycline.

Table 2 Antibiotic resistance patterns of the *Helicobacter pylori* strains

Antibiotic resistance patterns	*n*	Male	Female
MTZ	44	15	29
AMX	14	7	7
CLA	1	0	1
TET	1	1	0
MTZ-AMX	3	1	2
MTZ-TET	1	0	1
AMX-TET	1	0	1
AMX-CLA	1	0	1
MTZ-AMX-TET	1	0	1
MTZ-AMX-CLA	4	1	3
Sensitive	50	25	25
Total	121	50	71

MTZ: Metronidazole; AMX: Amoxicillin; CLA: Clarithromycin; TET: Tetracycline.

sensitive to all the tested antibiotics. When the antibiotics were considered together, we found 11 sensitivity patterns for drug sensitivity among the strains (Table 2). When the data were analyzed on the basis of patient gender (Table 1), 32% (n = 16), and 51% (n = 36) of the strains isolated from males and females, respectively, were resistant to metronidazole. Statistical analysis showed that resistance to metronidazole was significantly higher in female than in male patients ($P < 0.05$). With regard to clarithromycin and amoxicillin, the percentage of resistance in female patients was 7% and 20%, respectively and in male patients was 2% and 20%, respectively. The differences in resistance to these two antibiotics among the strains isolated from both genders were not significant ($P > 0.05$). We found that 3 (4%) and 1 (2%) strains isolated from female and male patients were resistant to tetracycline, respectively.

In about 71% of the metronidazole-resistant isolates, the MICs exceeded 256 μg/mL. The MIC ranges for the antibiotics tested in both genders are shown in Table 3.

Table 3 Range of minimum inhibitory concentrations for antibiotics tested against *Helicobacter pylori* strains in relation to patient gender

Sex	Range of MICs for antibiotics (mg/L)			
	MTZ	AMX	CLA	TET
Male	0.064 to > 256	< 0.016 to > 256	< 0.016 to 64	0.016 to 8
Female	0.047 to > 256	< 0.016 to > 256	< 0.016 to > 256	0.016 to 8

MIC: Minimum inhibitory concentration; MTZ: Metronidazole; AMX: Amoxicillin; CLA: Clarithromycin; TET: Tetracycline.

DISCUSSION

Resistance to antimicrobials is of particular concern to practitioners in this field, and is a major cause of the failure to eradicate *H. pylori* infections[20,21]. It has also been shown that resistance to different antibiotics develops in *H. pylori* strains by acquiring chromosomal mutations at the site where the drug acts[22]. However, many reports have indicated that the prevalence of resistance varies geographically and that there is a broad range of resistance variability depending on the drug used[23]. The special nutritional and atmospheric conditions required by these organisms make susceptibility testing relatively difficult; however, the E-test technique developed to determine the minimum inhibitory concentration (MIC) has remained valid[24]. Accordingly, in the present study we evaluated the sensitivity of *H. pylori* strains isolated from patients with gastric disorders to 4 antibiotics using the E-test to find the resistance pattern in these strains in our region.

It was observed that 44% of the isolates in this study were resistant to metronidazole with a MIC range of 0.064 to > 256 μg/mL. This resistance rate was consistent with reports from some developed countries, where it has been reported that 15.8%-40% of *H. pylori* strains were resistant to metronidazole[25-27]. However, most reports from developing countries describe a high level of resistance to metronidazole, which varies from 66.2% to 100%[28,29]. Resistance rates to metronidazole may also vary within a country. For example, in India, the resistance rate to metronidazole was high in Lucknow, Chennai and Hyderabad (68%, 88.2% and 100%, respectively), whereas a moderate rate was observed in Delhi (37.5%) and Chandigarh (38.2%)[30]. Similarly, the resistance rate was high (78%) in Tehran, Iran in one study carried out by Falsafi *et al*, while in another study it was reported to be 34%[31,32]. In Europe, according to studies conducted between 1989-2001 and 1990-2002, respectively, the resistance rate varied between 16.0% and 43% in pediatric patients and between 14.9% and 40.3% in adult patients[22]. It seems that primary resistance to nitro-imidazole has been attributed to frequent use of the drug, which is commonly prescribed for other diseases, especially parasitic conditions, and periodontal or gynecological infections. The higher resistance rate to metronidazole in females reported in this and other studies could be due to the treatment of gynecological infections using this drug which is also used in the treatment of bacterial vaginosis. Moreover, the use or abuse of this inexpensive drug may contribute to the increased metronidazole resistance seen in developing countries[33]. For this reason, metronidazole has been excluded from first-line empirical therapy plans in some countries[23]. However, it has been reported that the results of *in vitro* resistance to this drug are also poorly correlated with the outcome of therapy, and consequently, susceptibility testing is not rou-

tinely indicated[34]. Therefore, assessment of the drug concentration in blood samples could be recommended to assess the correlation with *in vitro* results. Another important finding from the present study was that in about 71% of the metronidazole-resistant isolates, the MICs exceeded 256 μg/mL, which has rarely been reported[17].

In contrast to most studies, we found a high resistance (20%) to amoxicillin among *H. pylori* isolates. Most studies have shown that *H. pylori* resistance to this drug is either very rare or non-existent[25,33,35]. Usually, the MIC of amoxicillin for *H. pylori* is very low (0.03 μg/mL); nevertheless, in our study, we found a few sensitive isolates with reduced susceptibility (MICs: < 0.016 μg/mL)[33]. However, high resistance rates have been reported in some studies from other parts of the world: 18.5% in South Korea[36], 19.4% in Indonesia[37], 32.8% in India[38], and 38% in Brazilia[39]. In a study conducted in Ile-Ife, southwest of Nigeria, 100% of the 32 isolates were resistant[28]. It has been shown that resistance to amoxicillin could have emerged by genomic mutation in the pbp1A gene[39]. When comparing different sets of data, it is important to note that variations in rates may arise due to the effects of inter-laboratory reproducibility, caused by the lack of standardized testing protocols or regional prescribing practice. This may be the reason why the resistance rates for amoxicillin in *H. pylori* isolates have been reported to be 1.6% and 27% in different studies conducted in Iran[31,32]. Moreover, high resistance to amoxicillin observed in the present study reflects the importance of its use in our country.

Clarithromycin is a macrolide used frequently in combination with other antimicrobial agents for the treatment of *H pylori* infection[40]. However, resistance to clarithromycin has become one of the major reasons for treatment failure[41]. The prevalence of *H. pylori* resistance to clarithromycin varies in different countries, and was 12% in Japan, 1.7%-23.4% in Europe and 10.6%-25% in North America[22]. Resistance in 5% of our isolates resembles data from the Northern regions of Europe[27]. In contrast, two other studies from Tehran, Iran reported a high rate of resistance to clarithromycin ranging from 16.7% to 21%[31,32]. Since clarithromycin is not currently used in Iran, emerging resistance to this antibiotic is unexpected. On the other hand, it has been shown that there is cross-reactivity between clarithromycin and other macrolides such as erythromycin, which implies that resistance to one macrolide could cause the emergence of resistance to other macrolides[42]. Genetic studies have revealed that clarithromycin resistance is often associated with point mutation of the 23S rRNA[2].

We observed a low resistance (3%) to tetracycline among the isolates, which is consistent with most studies which have reported no resistance or low resistance to this antibiotic in *H. pylori* strains[2,31,35,43]. In contrast, a high resistance rate (20%) to tetracycline was reported by Falsafi *et al*[32]. Similarly, these variations could be due to the effects of inter-laboratory reproducibility caused by the lack of standardized testing protocols or regional prescribing practice. However, resistance to tetracycline, mainly caused by mutations in the 16S rRNA gene, is emerging and can impair the efficacy of such second-line regimens[44]. Thus, it seems that molecular methods can help verify the exact rate of resistance to this antibiotic. Recently a novel real-time PCR has been described which is able to detect the strains carrying the mutant genes for tetracycline resistance[44].

In conclusion, this study showed a moderate rate of primary resistance to metronidazole which is included in the guidelines for the empirical therapy of *H. pylori* infections. However, a high MIC (> 256 mg/L) observed in about 71% of the isolates is considerable. On the other hand, in the case of amoxicillin, there was an increased resistance which is worrying. In particular, it is important to determine whether the increased resistance to amoxicillin is a result of its increased use or due to the ethnic differences of the populations described herein. The data also indicate that resistance to clarithromycin and tetracycline is emerging among the *H. pylori* strains in our region. Therefore, considering the increasing resistance rate in many countries, monitoring of susceptibility of *H. pylori* to these antibiotics appears to be necessary in order to choose effective therapy to eradicate *H. pylori* infections and to optimize the regimen in case of treatment failure. Finally, taking into account the present findings along with other reported findings, continued surveillance of the resistance profiles and the resistance mechanisms present in *H. pylori* strains isolated in Iran is essential, if therapeutic plans are to satisfy the country's needs.

COMMENTS

Background

Antibiotic resistance in *Helicobacter pylori* (*H. pylori*) is the major cause of eradication failure. Growing resistance often parallels the patterns of antibiotic consumption, and may vary within patient groups according to the geographic region, patient age and sex, type of disease, birthplace, other infections and other factors.

Research frontiers

Geographic mapping and the process of primary *H. pylori* resistance are clinically important, and should be considered when choosing eradication regimens. These should also be constantly monitored both at national and global level in an attempt to reach the recently recommended goal of eradicating the highest rate of resistance. The present study aimed to improve our understanding of Iranian regional variation in *H. pylori* antibiotic resistance rates in relation to gender and to find the best antibiotic therapy for the eradication of *H. pylori* infections.

Innovations and breakthroughs

The E-test has proven to be an accurate method of assaying the susceptibility of fastidious organisms, including *H. pylori*, to antibiotics. Using this method and improved culture conditions, we found a moderate rate of primary resistance to metronidazole which is included in the guidelines for the empirical therapy of *H. pylori* infections. However, a high minimum inhibitory concentration (MIC) (> 256 mg/L) observed in 71% of the isolates is considerable. On the other hand, in the case of amoxicillin, there was an increased resistance (20%) which is worrying. The data also indicate that resistance to clarithromycin and tetracycline is emerging among the *H. pylori* strains in our region.

Applications

Considering the increasing rate of resistance in many countries and based on the varied results from different studies, even in the same regions, the results of this study can improve the monitoring of *H. pylori* susceptibility to antibiotics, which is necessary in order to choose effective therapy to eradicate *H. pylori* infections and to optimize the regimen in case of treatment failure in our region.

Terminology

MIC is minimum inhibitory concentration. E test is the epsilometry test, a test to determine the MIC of antimicrobial agents using strips with epsilometric concentrations of antimicrobials.

Peer review

It is an interesting publication showing the prevalence of antibiotic resistance of *H. pylori* in southern part of Iran (Shiraz).

Abstract

AIM: To identify a method for efficient large-scale purification of functional hepatitis B virus polymerase (HBV-Pol) without addition of cellular factors.

METHODS: Full-length HBV-Pol (843 amino acids) tagged with 5′ end Polyhistidine was expressed at a high level in an *Escherichia coli* (*E. coli*) system. Sodium dodecyl sulfate lysis buffer was utilized to dissolve insoluble HBV-Pol, and Ni-NTA resin affinity chromatography was utilized for HBV-Pol purification. Most recombinant HBV-Pol was eluted with 100 mmol/L imidazole in the presence of NP-40, a weak detergent that keeps HBV-Pol in solution. A reducing agent was utilized throughout the purification steps to keep soluble HBV-Pol from redundant disulfide bond formation.

RESULTS: The large-scale production of functional intact human HBV-Pol was achieved in an *E. coli* expression system. Purified HBV-Pol showed stable reverse transcriptase activity and DNA polymerase activity. The purified protein was of high purity and had stable reverse transcriptase activity.

CONCLUSION: Large-scale production of HBV-Pol in pure form should facilitate crystallization and detailed analysis of the structure and mechanism of HBV-Pol. Ability of this purification approach to obtain human HBV-Pol in an enzymatically active form should be helpful for development of drugs for treatment of chronic hepatitis B.

Key words: Hepatitis B Virus; Virus polymerase; Reverse transcriptase; Detergent

INTRODUCTION

Hepatitis B virus (HBV) infection is a global public health problem. It is estimated that between 350 and 400 million people worldwide are chronically infected, and a significant proportion of chronic infection patients ultimately develop life-threatening liver disease such as cirrhosis, hepatocellular carcinoma (HCC) and other complications[1]. HBV replicates *via* a reverse transcription step, using the polymerase (HBV-Pol) that is encoded by its own genome. HBV-Pol is a multifunctional protein, with protein-priming activity[2-4],

DNA polymerase, reverse transcriptase[2,5] and RNase H activity, but it is short of proofreading activity[6]. Most approved medications for chronic hepatitis B (CHB) infection are nucleotide reverse transcriptase inhibitors (NRTIs) that target HBV-Pol[7]. Although NRTIs have been used in CHB infection for several decades, their therapeutic efficacy has been limited by high frequency appearance of mutants during treatment[8]. Therefore, a quick and easy way to obtain a large quantity of functionally intact human HBV-Pol is required for selection of sensitive CHB medications, mutated HBV strains research, and mass high-throughput screening.

It is known that expression of an enzymatically active HBV-Pol in heterologous systems, or purification of useful quantities of human HBV-Pol from virions is difficult to achieve. Due to these problems, drug development for HBV infection has not progressed satisfactorily, and biological studies of hepadnaviral polymerase have been conducted by using duck HBV[9]. Several groups have succeeded in achieving heterologous *in vitro* expression of full-length polymerase proteins of duck HBV that exhibit DNA-dependent DNA polymerase (DDDP) activity and RNA-dependent DNA polymerase (RDDP) activity. However human HBV-Pol is expressed by *in vitro* translation with a rabbit reticulocyte lysate system[10], and *in-vitro*-translated human HBV-Pol shows only DDDP activity and fails to show RDDP activity. RDDP activity of human HBV-Pol has been observed in *Escherichia coli* (*E. coli*) as a fusion protein in frame with maltose-binding protein[11]. The enzymatically active HBV-Pol has also been obtained in *E. coli* by co-expression of the polymerase with the chaperone GRP94[12]. However, the stable and large-scale heterologous expression of intact human HBV-Pol without co-expression of molecular chaperon in common hosts such as *E. coli* or yeast has not been reported.

In this study, a full-length HBV-Pol with a 6 × His tag was expressed in *E. coli*. HBV-Pol is a large molecule with approximately 2.5% cysteine residues[2], therefore, the protein is expected to be present as inclusion bodies. For this reason, the total lysate was dissolved by applying high concentration of sodium dodecyl sulfate (SDS) and reducing agents to dissolve inclusion bodies, and then SDS was replaced by weak detergent for renaturation during washing. Finally, the target protein was purified with nickel-based chromatography. Purified HBV-Pol showed RDDP and DDDP activity. This is believed to be the first time that functional intact human HBV-Pol has been expressed in *E. coli* without co-expression molecules or in the presence of certain helper chaperons. The functional HBV-Pol might be helpful for development of potential pharmaceutical agents for CHB treatment.

MATERIALS AND METHODS

Plasmid construction

Liver tissues were obtained from a chronic hepatitis B surface antigen carrier who developed HCC and underwent surgical resection. The tumor tissues were dissected and immediately cut into small pieces and stored into liquid nitrogen until use. The cellular DNA was isolated from tissues by SDS-protease K digestion and phenol-chloroform extraction as described previously[13]. HBV-Pol sequence [spanning 2307 to 1623 bp, 843 amino acids] were amplified with PrimeSTAR™ high fidelity polymerase using CPNotIF01: GTTGCGGCCGCATA-ATGGCCCTATCTTATC and CPBstBIR01: ATTTTC-GAATTCTCACGGTGGTTTCCA for complete P gene. The vectors were designed as follows (Figure 1).

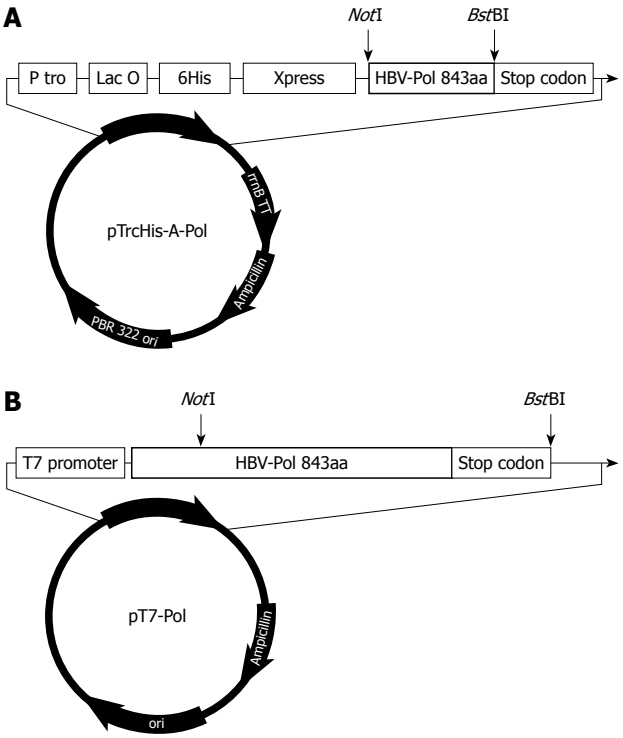

Figure 1 Organization of pTrcHis-A-Pol and pT7-Pol recombinant plasmids. A: Structural arrangement of pTrcHis-A-Pol. A full-length hepatitis B virus polymerase (HBV-Pol) sequence was fused into pTrcHis-A between *Not*I and *Bst*BI sites under the control of Trc promoter and Lac operator. This polyhistidine tag plays a role in rapid purification using a nickel-based resin. To determine the expression level under different conditions, an Xpress antigen was fused to the 5'-end of the HBV-Pol sequence; B: Structure of pT7-Pol. A full-length HBV-Pol sequence was fused to P-T7 between *Not*I and *Bst*BI sites. Full-length HBV-Pol sequence was under the control of the T7 promoter for expression in the TNT T7 transcription–translation-coupled rabbit reticulocyte lysate expression system.

The pTrcHis-A-Pol and pT7-Pol were constructed by the following procedure. HBV-Pol full-length sequence was cloned into *Not*I and *Bst*BI sites of the two expression vector pTrcHis-A (Invitrogen, Carlsbad, CA, USA) and pT7 vector (Promega, Madison, WI, USA). For expression of HBV-Pol in *E. coli*, the plasmid pTrcHis-A-Pol was constructed as showed in Figure 1A. The HBV-Pol frame was under the control of the Trc promoter and Lac operator. His-tag and Xpress antigen were fused at the 5' end of the HBV-Pol sequence. For expression of HBV-Pol in the rabbit reticulocyte lysate system, the plasmid pT7-Pol was constructed as showed in Figure 1B. The HBV-Pol frame was driven by T7-promoter.

E. coli transformation

Plasmid pTrcHis-A-Pol was chemically transformed in competent DH5α (*F-,φ80dlacZ⊿M15,⊿(lacZYA-*

*argF)U169,deo*R,*recA1,endA1,hsdR17(rk-,mk+),phoA, supE44,λ-,thi-1,gyrA96,relA1*) cells following the manual supplied by Real Biotech Corporation (Taipei, Taiwan, China). Isopropylthiogalactopyranoside (IPTG, Sigma, St Louis, MO, USA) was added into 5 mL overnight-cultured *E. coli*, to a final concentration of 1 mmol/L, and incubated for 4, 8, 12 and 16 h, respectively, at 18℃, 24℃, 30℃, 37℃ and 42℃, as indicated. Cells were harvested by centrifugation and disrupted with lysis-buffer (50 mmol/L phosphate buffer, pH 8.0; 0.5 mmol/L NaCl; 1% SDS; 10 mmol/L imidazole; 0.1 mg/mL lysozyme; 20 mmol/L 2-mercaptoethanol; 1 × Roche protein inhibitor cocktail). Protein expression level was determined with dot blot using anti-Xpress antibody (Invitrogen).

Expression and purification of histidine-tagged HBV-Pol

Transformed cells were grown in 100 mL LB broth until the culture reached OD_{600} 0.6-0.8. IPTG was added to a final concentration of 1 mmol/L and incubated for 8-10 h at 18℃ with shaking. Induced cells were harvested by centrifugation at 2000 *g* for 20 min at 4℃. The ratio of lysis-buffer volume and wet weight of cell pellet was about 4 to 1. The lysate was incubated at room temperature for 30 min and sonicated for 10 × 10 s. The samples were cooled on ice for 5-10 s between each sonication. The suspension was centrifuged at 20000 *g* for 30 min at room temperature. The supernatant was transferred to an Ni-NTA resin (Invitrogen) column (bed volume: 2 mL), which had been equilibrated with 16 mL equilibration buffer (same components of previous lysis buffer without lysozyme). Resin and lysate supernatant were mixed thoroughly but gently for 45-60 min at room temperature. The resin was washed with 8 ml washing buffer (50 mmol/L phosphate buffer, pH 8.0, 0.5 mmol/L NaCl, 1% NP-40, 10 mmol/L imidazole, 20 mmol/L 2-mercaptoethanol, and 1 × Roche protein inhibitor cocktail) for 6-8 times. The HBV-Pol fractions were eluted with 6 mL E-50, E-75, and E-100 Elution buffer (50 mmol/L phosphate buffer, pH 8.0, 0.5 mmol/L NaCl, 1% NP-40, 1 × Roche protein inhibitor cocktail), and dithiothreitol (DTT) was added to the harvest tube to achieve a final concentration of 5 mmol/L. The concentration of imidazole in E-50, E-75, and E-100 buffer was 50 mmol/L, 75 mmol/L and100 mmol/L, respectively. HBV-Pol elution fractions were harvested and stored at -70℃. The concentration of purified protein samples was determined using a BCA assay with bovine serum albumin as a standard.

Anti-reverse transcriptase polyclonal antibody preparation

Anti-reverse transcriptase (RT) polyclonal antibody was prepared before full-length polymerase purification (data not shown). A recombinant RT domain (spanning 304-693 amino acids) was purified from *E. coli*. Fifty micrograms purified RT and Freund's complete adjuvant were injected subcutaneously into C57BL/6 mice (Macrogen, Seoul, South Korea). Another 50 μg purified RT and Freund's incomplete adjuvant were injected 2 wk after the first injection. The mice were sacrificed 2 wk after the second injection for serum extraction of anti-RT polyclonal antibody. The antibody titers against the RT peptides, monitored with ELISA (Sigma), were > 1:32000.

SDS-PAGE, dot blot and Western blotting analysis

Total lysate and other washing/elution fractions were heated at 95℃ for 5 min for denaturation. Proteins were separated by SDS-PAGE. Gels were stained with Coomassie Blue. For dot blot analysis, 1 μL of each sample was dropped on nitrocellulose membranes (Amersham, Bucks, UK), and the membranes were treated first with a 1/4000 dilution of anti-Xpress antibody and then goat-anti-mouse conjugated alkaline phosphatase (AP; Invitrogen). For Western blotting analysis, proteins were electrophoretically transferred to a polyvinylidene difluoride blotting membrane (Amersham, Piscataway, NY, USA), and membranes were treated first with a 1/4000 dilution of anti-RT antibody and then goat-anti-mouse conjugated AP.

Expression of HBV-Pol in in vitro transcription and translation system

The recombinant plasmid pT7-Pol was purified with Qiagen Midiprep DNA purification kit. *In vitro* transcription and translation reactions were performed using the TNT T7 coupled reticulocyte lysate system (Promega). Two micrograms of the plasmid DNA template was transcribed and the protein was translated in each 50-mL reaction in the presence or absence of 40 mCi of [^{35}-S]-methionine (1000 Ci/mmol) (Amersham) at 30℃ for 75 min[10]. The *in vitro* translation reaction was stopped by the addition of 0.1 mg/mL cycloheximide for the polymerase activity assay, or SDS sample buffer for checking the efficiency of translation. The *in vitro* translated proteins were separated by 4%-12% SDS-PAGE and dried prior to autoradiography.

DNA polymerase activity and RT activity assays

DDDP and RT/RDDP were monitored by synthesis of DNA using poly (dA) • oligo $(dT)_{12-18}$ and poly (rA) • oligo $(dT)_{12-18}$ as template primer (Amersham Biosciences), respectively. The standard enzyme reaction (50 mL) contained 50 mmol/L Tris-HCl pH 7.4, 50 mmol/L KCl, 10 mmol/L $MgCl_2$, 1 mmol/L DTT, 0.01% Nonidet P-40, 50 ng homopolymer template [poly(dA) • oligo $(dT)_{12-18}$ for DDDP activity assay and poly(rA) • oligo $(dT)_{12-18}$ for RDDP activity assay], and 2 mCi of [α-^{32}P]dTTP (3000 Ci/mmol), (PerkinElmer, USA). For RDDP activity assay, RNase inhibitor and RNase-free water were employed in the reaction[10,11]. Reactions were started by the addition of 0.5 mg of the purified HBV-Pol or 5 μL products from the TNT-T7 coupled reticulocyte lysate system into the reaction buffer. The endogenous DNA polymerase activity from the reticulocyte lysate was suppressed by the addition of 60 mmol/L aphidicolin and 1 mmol/L NEM. After incubation at 37℃ for 75 min, reactions were stopped by the addition of 0.2 mg/mL protease K in the presence of 0.5% SDS. Incubation was continued for another 20 min, followed by spotting on Whatman DE81 filter paper. Filters were washed three times with 0.5 mol/L Na_2HPO_4, and once with distilled

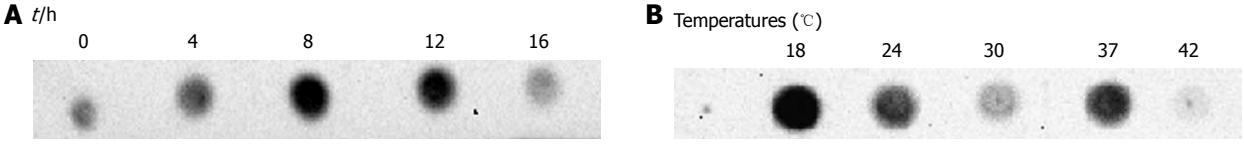

Figure 2 Induction optimization of hepatitis B virus polymerase expressed in *Escherichia coli*. Total lysate samples of *Escherichia coli* transformants after different induction times were blotted on to nitrocellulose membranes. Hepatitis B virus polymerase (HBV-Pol) expression level was determined by anti-Xpress antibody. A: 8-h induction sample showed the strongest signal; B: HBV-Pol expression level at different temperatures was determined by anti-Xpress. Sample from 18℃ showed the highest expression level. Preliminary expression data showed that no obvious signal was detected in samples induced at temperatures < 18℃, therefore, previous values for duration and temperature for induction were selected for this study.

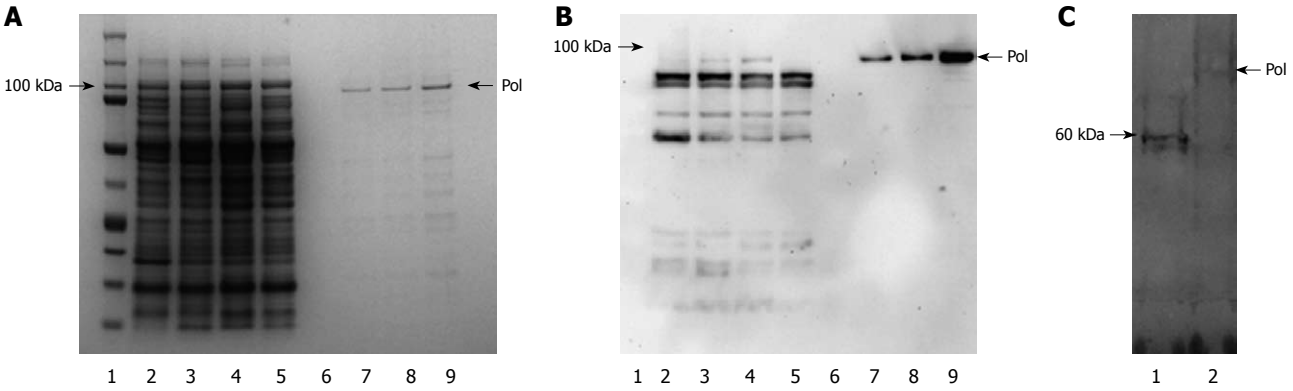

Figure 3 Expression and purification of hepatitis B virus polymerase. Recombinant human hepatitis B virus polymerase (HBV-Pol) was produced in *Escherichia coli* (*E. coli*) cells transformed by pTrcHis-A-Pol and purified with nickel-based resin. Protein samples were analyzed by 4%-12% sodium dodecyl sulfate (SDS)-PAGE, and gels were stained with Coomassie Blue (A). HBV-Pol bands were located at the expected molecular mass, approximate 98 kDa (lane 1). Although HBV-Pol bands were also detected in 50 mmol/L (lane 7) and 75 mmol/L (lane 8) imidazole washing fractions, most HBV-Pol was eluted by 100 mmol/L imidazole (lane 9). Purified recombinant human HBV-Pol was also analyzed by immunoblotting with an anti-reverse transcriptase (RT) antibody (B). HBV-Pol bands were detected in total lysate of uninduced transformant (lane 3) and total lysate of induced transformant (lane 4), but not in untransformed *E. coli* (lane 2), unbound fraction (lane 5) and fifth washing fraction with 10 mmol/L imidazole (lane 6). Some positive small bands were also detected in lanes 2-5, which was mainly because some components from total lysate of E. coli were recognized by anti-RT polyclonal antibody. Expression of human HBV-Pol in TNT T7 transcription-translation-coupled rabbit reticulocyte lysate expression system is shown in C. PT7-pol and pT7-luciferase (1650 bp, ORF size approximate 61 kDa) were added to *in vitro* transcription-translation reactions for 75 min at 30℃ in the presence of [^{35}S]-methionine. Five microliters of each sample was incubated in SDS sample buffer at 95℃ for 3 min, and electrophoresed through 4%-12% SDS-PAGE. A band of pT7-luciferase (lane 1) and pT7-pol (lane 2) were detected by autoradiography.

H_2O[11]. Incorporation of radioactivity was determined by liquid scintillation counting in a Packard Tri-Carb Series 2300 liquid scintillation counter.

RESULTS

Expression, induction optimization and purification of HBV-Pol in E. coli

A high expression level of target protein is crucial to obtain an ideal elution result in affinity chromatography. To achieve the highest expression level, expression level was examined at various conditions. Recombinant HBV-Pol is a large molecule of 95 kDa full-length HBV-Pol plus a 5-kDa fused tag, and a low induction temperature and short or long induction time were considered for expression. It is known that heterologous protein was stabilized at low temperature[14] and formation of inclusion bodies was restrained[15]. Decreasing the temperature of induction medium should lower the rate of association of folding intermediates, which allows unfolded proteins and partially folded proteins to have more time to refold into native, soluble tertiary structures. Appropriate induction time is another important factor to obtain sufficient recombinant polymerase. The quantity of expressed protein varies with different induction times.

HBV-Pol level was monitored in the total lysate of *E. coli* transformed with HBV-Pol recombinant plasmid, pTrcHis-A-Pol (Figure 2). HBV-Pol expression level was the highest at 8 h induction compared to shorter or longer incubation (Figure 2A). In terms of temperature, the lowest temperature tested, 18℃, showed the highest level of expression compared to other samples expressed at higher temperatures (Figure 2B). Based on these data, incubation of HBV-Pol expression was carried out under these conditions throughout the experiment. For HBV-Pol purification, a denaturing-renaturing purification protocol was applied. According to previous lysis data under native conditions, inclusion bodies do not dissolve in the presence of weak detergent at 4℃, which decreased the quantity of target protein in the binding step. A strong detergent (SDS) was employed in the lysis step to dissolve overexpressed HBV-Pol in inclusion bodies, and to denature some protease present in the total lysate.

HBV-Pol fractions were eluted with elution buffers (50, 75, 100 mmol/mL imidazole). Figure 3A shows that a prominent HBV-Pol band was detected with SDS-PAGE, and analysis by Western blotting confirmed the purification results (Figure 3B). DTT, a stronger reducing agent

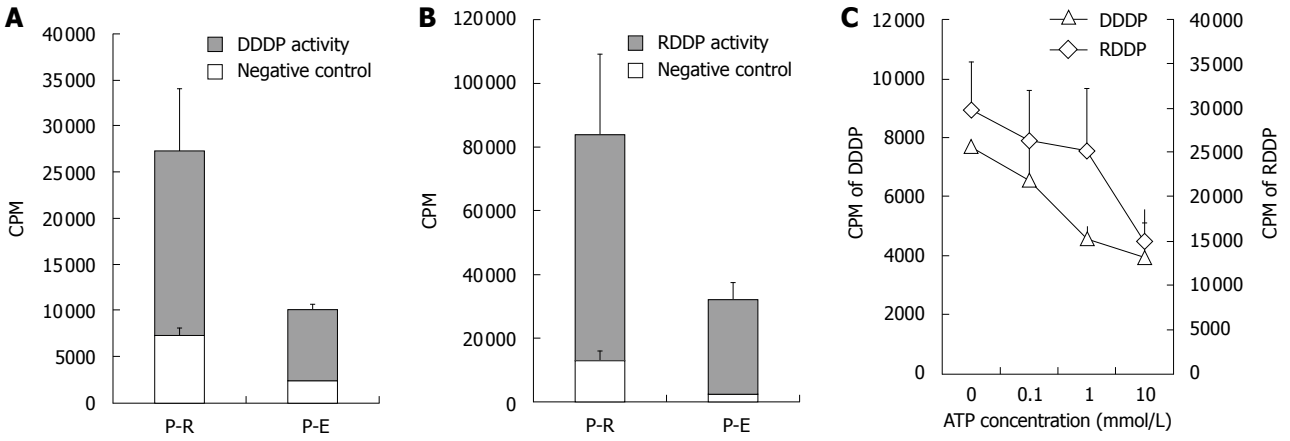

Figure 4 Enzyme activity assay of recombinant hepatitis B virus polymerase. Comparison of enzyme activities between hepatitis B virus polymerase (HBV-Pol) from *Escherichia coli* expression system (P-E) and *in vitro* expression system (P-R). DNA-dependent DNA polymerase (DDDP) activity and RNA-dependent DNA polymerase (RDDP) activity of the P-E and P-R were monitored under standard conditions. All endogenous DDDP activities were suppressed by 60 mmol/L aphidicolin and 1 mmol/L NEM (A and B). The effects of increasing concentrations of adenosine triphosphate (ATP) are shown in C. DDDP activity using poly (dA) • oligo $(dT)_{12-18}$ and RDDP activity using poly (rA) • oligo $(dT)_{12-18}$ were used as the substrate for DDDP activity and RDDP activity assays, respectively. CPM: Counts per minute.

than 2-mercaptoethanol, is suitable for long-term protein storage and is used in many experiments for HBV-Pol purification at a high concentration[2,5,6,16]. Although nickel resin is easily reduced by strong detergent, in the present study, 2-mercaptoethanol was employed in all steps except elution. DTT was finally added into HBV-Pol fractions for long-term storage. SDS-PAGE and Western blotting clearly showed high efficiency of purification. Involvement of the denaturing-renaturing purification process also suggested that purified recombinant HBV-Pol is a stable, single-component product. HBV-Pol was purified up to 5 mg/mL.

There have been many reports about purified or partially purified active HBV-Pol in eukaryotic systems. In the present study, recombinant HBV-Pol was also expressed in a reticulocyte lysate system as a positive control in the activity assay. The protein products from *in vitro* expression labeled with [^{35}S]-methionine are shown in Figure 3C. Approximately 95-kDa HBV-Pol protein was detected as predicted from the nucleotide sequence of the HBV-Pol-ORF.

Characterization of the purified HBV-Pol

To measure the enzymatic activity of purified HBV-Pol, the enzymatic activity assays for DDDP and RDDP were performed by using purified HBV-Pol (expressed in recombinant *E. coli*, named P-E) and HBV-Pol (expressed in reticulocyte system, named P-R). pT7 plasmid was expressed in the reticulocyte lysate system as a negative control for P-R enzyme activity assays. The solvent of P-E was regarded as a negative control for P-E enzyme activity assays. Enzyme activities of P-R and P-E were compared (Figure 4A-C). P-R showed medium DDDP activity and much higher RDDP activity under these reaction conditions. Homopolymer primer-template has been used for many groups[10,11] in HBV-Pol activity assays. Activity assay results showed that P-E and P-R have high RDDP activity and relatively weak DDDP activity compared to the negative controls. This pattern had been observed previously with partially purified HBV-Pol[9].

DDDP and RDDP activities affected with adenosine triphosphate

It has been shown that adenosine triphosphate (ATP) participates in HBV-Pol activation during duck HBV replication[17]. To study the effect of ATP on purified HBV-Pol, different concentrations of ATP were added to the enzyme activity assays. As shown in Figure 4B, RDDP and DDDP activities of P-R were affected by ATP concentration. In the presence of ATP (0.1, 1 and 10 mmol/L), RDDP and DDDP activities of P-R showed a declining trend in a dose-dependent manner.

DISCUSSION

Human HBV-Pol is crucial for HBV genome DNA replication. It shows RDDP activity in minus strand DNA synthesis and DDDP activity in plus strand synthesis. Among six medications approved by the United States Food and Drug Administration for the treatment of CHB, lamivudine, adefovir dipivoxil, entecavir and telbivudine are HBV-Pol inhibitors[7]. Blocking HBV DNA replication is still the main target for CHB therapy. However, stable and large-scale heterologous expression of intact human HBV-Pol in common hosts such as *E. coli* or yeast has not been successfully achieved[9]. Although recombinant HBV-Pol has been expressed in different systems and purified in various ways, obtaining high-purity functional HBV-Pol without coexpression of a chaperon is still problematic[2,5,9,12]. Therefore, we developed a reliable purification method for further investigation of HBV-Pol activities.

The major obstacle for a large multi-functional protein such as HBV-Pol is its instability in heterologous expression systems and during purification[9]. It is known that inclusion bodies are formed during expression of human HBV-Pol, not only in *E. coli* expression systems, but also in eukaryotic expression systems[2]. In accordance with this, the target protein was present in total lysate and pellet rather than supernatant in detergent-free lysis buffer. Our preliminary study showed that expressed human HBV-Pol was degraded easily

under native purification conditions, even with the presence of protease inhibitor. Choi *et al*[9] also have observed this phenomenon in a yeast expression system. Therefore, the key points of successful large-scale purification of human HBV-Pol are the solubilization and stabilization of the target protein. So far, nobody has reported a high level of expression and purification of HBV-Pol by using an *E. coli* expression system, in which we purified the protein up to 5 mg/mL. This is far higher than the earlier studies done by Choi *et al*[9], who used a *Pichia methanolica* expression system and Qadri *et al*[5] who used *Saccharomyces cerevisiae*.

In this study, we tried to achieve a high level of recombinant HBV-Pol with application of the following strategies. First, an amino-terminal 6 × His tag was used to facilitate rapid purification. Also, a sequence that encoded the Xpress epitope was fused to the N terminus of HBV-Pol so that it could be recognized rapidly by anti-Xpress primary antibody. Second, induction temperatures were lowered to maximize target protein expression. Third, for cell lysate purification, strong detergent lysis was followed by weak detergent washing and elution. Fourth, a high-concentration reducing agent was present during all the purification steps to keep HBV-Pol in soluble form by inhibiting disulfide bond formation, because approximately 2.5% of amino acid residues of HBV-Pol are cysteine.

It has been reported that structural and biochemical investigations of HBV-Pol have been complicated by the requirement of cellular factors such as HSP90[18], HSP60[3] and other cofactors[19] during purification. However, we developed a new method for large-scale purification of fully active HBV-Pol without addition of cellular factors by adjustment of salts during the purification steps. A binding step under denaturation conditions was used to isolate target protein from total lysate. With the presence of 1% SDS in the lysate, insoluble human HBV-Pol was dissolved rapidly. Proteases released from *E. coli* were also inactive in this SDS denaturing step. Soluble HBV-Pol was washed and eluted from nickel resin using the buffer in the presence of weak detergent and reducing agent. SDS was replaced by NP-40 during washing and elution. To prevent target protein from oxidization and to keep cysteine residues in a reduced state, a high concentration of reducing agents was employed throughout the purification steps.

The large-scale production of functionally intact human HBV-Pol was achieved in the *E. coli* expression system in this study. The availability of this recombinant protein in pure form should facilitate the crystallization and detailed analysis of the structure and mechanism of HBV-Pol. The availability of a large quantity of functional human HBV-Pol will help in high-throughput screening assays for development of potential pharmaceutical agents for CHB treatment.

COMMENTS

Background

Hepatitis B virus polymerase (HBV-Pol) is a multifunctional protein, which has intrinsic RNA-dependent reverse transcriptase (RT), DNA-dependent DNA polymerase, and RNase H activity. HBV-Pol is limited by difficulties in expressing and purifying the proteins in a heterologous system. This is believed to be the first time that functionally intact human HBV-Pol was expressed in *Escherichia coli* (*E. coli*) without co-expression of other molecules or in the presence of certain helper chaperons. Purified HBV-Pol showed stable RT activity and DNA polymerase activity. Functional HBV-Pol might be helpful for development of potential pharmaceutical agents for chronic hepatitis B (CHB) treatment.

Research frontiers

HBV is a small DNA virus that replicates by reverse transcription of pre-genomic RNA, and is a major threat to human health. Most approved medications for CHB infection are nucleotide reverse transcriptase inhibitors that target HBV-Pol. Analysis of HBV-Pol has been hampered by the inability to express the functional enzyme in a recombinant system. For this reason, we applied various strategies to the production of functionally intact human HBV-Pol on a large scale by using an *E. coli* expression system.

Innovations and breakthroughs

This is believed to be the first time that functionally intact human HBV-Pol has been expressed in *E. coli* without co-expression of other molecules or in the presence of certain helper chaperons. To achieve high levels of recombinant HBV-Pol, an N-terminal 6×His tag and Xpress epitope were fused to the N terminus of HBV-Pol. Second, the induction temperature was lowered to maximize target protein expression, and a high concentration of reducing agent was present during all the purification steps to keep HBV-Pol in a soluble form. The availability of this recombinant protein in pure form should facilitate the crystallization and detailed analysis of the structure and mechanism of HBV-Pol.

Applications

The availability of a large quantity of functional human HBV-Pol can be helpful in high-throughput screening assay for potential pharmaceutical agents for CHB treatment.

Peer review

This is a well-written paper and documents the expression and purification of full-length HBV-Pol in an *E. coli* system with promising results that could be the basis of forthcoming research on potential pharmaceutical agents for CHB treatment.

Abstract

AIM: To investigate the effects of *Lactobacillus plantarum* (*L. plantarum*) in the intestinal permeability and expression of tight junction (TJ) using the normal human colon cell line NCM460.

METHODS: Paracellular permeability of NCM460 monolayers was determined by transepithelial electrical resistance and dextran permeability. Expression of TJ proteins in NCM460 cell monolayers was detected by Western blotting and quantitative real-time polymerase chain reaction.

RESULTS: *L. plantarum* played an important role in increasing transepithelial electrical resistance and decreasing the permeability to macromolecules of NCM460 monolayers against the disruption caused by enteropathogenic *Escherichia coli* (*E. coli*) or enteroinvasive *E. coli*. *L. plantarum* also prevented the decrease in the expression of TJ proteins and F-actin in NCM460 cells.

CONCLUSION: *L. plantarum* can protect against dysfunction of NCM460 intestinal epithelial barrier caused by enteropathogenic *E. coli* or enteroinvasive *E. coli*, and thus can be a potential candidate of therapeutic agents for the treatment of intestinal diseases.

Key words: *Lactobacillus plantarum*; NCM460; Tight junction; Intestinal barrier

INTRODUCTION

The human intestinal system included a group of viable microorganisms, which exceed the total number of somatic and germ cells[1-3]. Therefore, the human colon is confronted with the highest bacterial load in the digestive tract with enormous bacteria per gram of feces. Growing evidence showed that bacteria closely adherent to the mucosa are more relevant to human body, compared with those evacuated in the feces[4,5]. There is a homeostasis between probiotics and pathogens in the intestinal

systems of healthy individuals[6,7], which, if broken, may lead to an imbalanced ecological microenvironment and subsequent intestinal barrier dysfunction[8,9]. Thereafter, the accumulation of pathogens and secretory products, such as the exotoxins and secretory antigens, can also directly or indirectly initiate and amplify the local and systemic inflammatory responses[10,11]. Probiotics of the genus lactobacillus that reside in the human intestine play an important part in maintaining the homeostasis of gut flora by adhering and colonizing to the intestinal mucosa and competing with pathogenic bacteria, such as pathogenic *Escherichia coli* (*E. coli*)[12,13]. Enteric diseases with flora disequilibrium have been treated with lactobacillus over the past decades[14-16]. There is evidence indicating that the modulation of the gut flora by lactobacillus can improve the intestinal epithelial barrier function[17].

Adhesion of lactobacillus to the intestinal epithelium initially involves the activation of specific binding between bacterial ligands and their corresponding surface receptors on the intestinal cells of the host, following the non-specific physical interactions[18,19]. Generally, these ligands are adhesive molecules either existing on the surface layer of the bacteria or secreting from the mycelium of the bacteria. Furthermore, these ligands could interact with the corresponding receptors on the surface of the intestinal epithelial cells. Thereafter, these adhesins activate specific signal transduction pathways in both the bacteria and host cells. The interaction between lactobacillus and the intestinal epithelial cells can also block the adhesion of other pathogenic bacteria to the receptors of the intestinal epithelial cells, such as enteropathogenic *E. coli* (EPEC) and enteroinvasive *E. coli* (EIEC). As a widespread member of the genus lactobacillus, *Lactobacillus plantarum* (*L. plantarum*) is commonly found in many fermented food and anaerobic plant products. Our previous studies demonstrated that *L. plantarum* was able to prevent colonic damage caused by EIEC or inflammation *in vitro*, *in vivo* and in patients with acute pancreatitis[20-24]. The normal human colon cell line NCM460, which is derived from the normal human colon mucosal epithelium and expresses colonic epithelial cell-associated antigens such as cytokeratins and villin, has been applied exclusively in various intestinal research areas, including the infectious diseases[25-27].

Our previous studies indicated that *L. plantarum* exerted its therapeutic effects by adhering to the intestinal epithelial cells, restoring tight junction (TJ) structure and function, and reducing paracellular permeability. However, studies about the interaction between lactobacillus and the human intestine were limited in the cancer cell line and the animal models, and further researches based on the normal human intestinal cells are still needed. Therefore, our study aims to investigate the protective effects of *L. plantarum* against epithelial barrier dysfunction of the normal human colon cell line NCM460 caused by EIEC and EPEC.

MATERIALS AND METHODS

Bacterial strains and culture conditions

L. plantarum CGMCC 1258 (generously provided by Dr. Xiao-Min Hang, the Onlly Institute of Life Science, Shanghai Jiao Tong University, Shanghai, China) was inoculated in 5% fresh De Man, Rogosa and Sharpe broth at 37℃ for 24 h, harvested by centrifugation (3500 × *g*) at 4℃ for 20 min, and washed with 50 mL 0.01 mol/L phosphate buffered saline (PBS) (pH 7.4). The EIEC strain ATCC 43893 (O124:NM) and EPEC strain ATCC 43887 (O111:NM) (both from Shanghai Municipal Center for Disease Control and Prevention, Shanghai, China) were grown in static Dulbecco's modified eagle media (DMEM) at 37℃ for 24 h. Quantification of bacterial density was measured at 600 nm (Beckman DU-50 spectrophotometer) with the colony forming units.

NCM460 cells were purchased from INCELL Corporation (San Antonio, TX, USA) and cultured in M3 media supplemented with 10% FBS, 100 U/mL penicillin and 100 g/mL streptomycin at 37℃ in a 95% humidified atmosphere with 5% CO_2, as previously described[25].

Measurement of transepithelial electrical resistance in NCM460 cell monolayers

NCM460 cells were grown on filters (Millicell culture plate inserts; 0.4 μm pore size; 0.6 cm^2 surface area) at 37℃ in a 95% humidified atmosphere, with 5% CO_2. At full confluence (10-14 d) (i.e. a monolayer was formed), a transepithelial electrical resistance (TER) of > 450 Ω.cm^2 monolayer was achieved as measured using a voltmeter (Millicell-ERS; Millipore, MA, USA). The intestinal epithelial monolayers were treated with EIEC or EPEC in the presence or absence of *L. plantarum*. In infection groups, 100 μL EIEC ATCC43893 (O124:NM) and EPEC ATCC43887 (O111:NM) at 1.0 × 10^8/mL were, respectively, added to the apical side of the cell culture insert for rapid infection of the monolayer, with an inoculation ratio of EIEC/EPEC to NCM460 cells of 100:1, and the insert was placed in a 50-mL tube and centrifuged at 200 × *g* for 4 min. In *L. plantarum* groups, *L. plantarum* (100 μL of 1.0 × 10^8/mL) was added onto the monolayer of NCM460 cells simultaneously with the EIEC/EPEC infection. NCM460 cells cultured under the same conditions but without the infection of EIEC/EPEC, and addition of *L. plantarum* served as the control group. Two experiments were performed separately for EIEC and EPEC.

The integrity of the confluent polarized monolayers was verified by measuring TER at different time intervals. TER (Ω.cm^2 monolayer) = (Total resistance - Blank resistance) (Ω) × Area (cm^2 monolayer). Because TER values often vary among individual NCM460 cultures, the electrical resistance value was recorded for each monolayer before and after the treatment, and the percentage in the decrease of TER from the baseline (%TER) was calculated.

Determination of dextran permeability in NCM460 monolayers

DMEM (0.2 mL) containing conjugated dextran was added to the apical compartment of Transwells (Corning Costar Co., MA, USA), and 0.4 mL DMEM alone added to the basolateral compartment. After treatment as described above, samples (0.5 mL) collected from the basolateral

Table 1 Primers used for real-time polymerase chain reaction amplification for genes encoding tight junction proteins in NCM460 cells

Gene	Upstream primer	Downstream primer
Occluding	GCAGCTACTGGACTCTACG	ATGGGACTGTCAACTCTTTC
Claudin-1	GTGCCTTGATGGTGGTTG	TGTTGGGTAAGAGGTTGT
JAM-1	GATGTGCCTGTGGTGCTG	GCTCTGCCTTGAGATAAGAA

compartment were placed into a 96-well plate (Corning Costar Co., MA, USA) and analyzed to determine their fluorescent intensity using the Odyssey infrared imaging system (LI-COR Biosciences, NE, USA) at a wavelength of 700 nm. Relative intensity (RI; the integrated intensities of treated samples relative to the integrated intensity of untreated samples) was calculated to indicate the effect of the treatment.

Western blotting for determining the distribution and expression of TJ proteins in NCM460 cell monolayers

For Western blotting, NCM460 cells were cultured and the monolayers were treated as described above, and the protein samples from NCM460 cells was prepared for sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) according to the previous studies[20]. SDS-PAGE was performed using the standard laboratory techniques with a discontinuous gradient, 5% (w/v) stacking gel and a 10% (w/v) separating gel, in a Mini-PROTEAN Ⅱ (Bio-Rad Laboratories, CA, USA). Briefly, samples were mixed with loading buffer containing SDS and mercaptoethanol, boiled for 3 min, centrifuged, and loaded onto the SDS-PAGE gel for separation. Molecular weights of samples were determined by comparing mobility with known marker proteins. Gel was then transferred to PVDF membrane (Millipore, MA, USA) in a semidry electroblotter (Bio-Rad Laboratories) for 120 min at 100 V. The membrane was washed three times (20 min each) with PBS containing 0.1% Tween-20 (PBS-T buffer). After blocking overnight in Tris-buffered saline containing 0.05% Tween-20 (TBS-T) and 5% dry powdered milk, membranes were washed three times for 5 min each with TBS-T and incubated with corresponding primary antibodies against TJ proteins (claudin-1, occludin, JAM-1, and ZO-1) and a cell cytoskeleton element F-actin (all from Abcam, MA, USA) for 2 h at room temperature. After three washes with TBS-T, the membranes were incubated for 1 h with corresponding HRP-conjugated secondary antibodies. The membrane was washed three times (60 min each) with PBS-T buffer. The TJ proteins were tested using enhanced chemiluminescence (ECL kit; Pierce, IL, USA) according to the manufacturer's instructions.

Quantitative real-time polymerase chain reaction for detecting the mRNA expression of TJ proteins in NCM460 cells

mRNA expression of TJ proteins, including claudin-1, occludin, JAM-1, and ZO-1, was determined by quantitative real-time polymerase chain reaction (RT-PCR). After the treatment as described above, total RNA was isolated from NCM460 cells using the Trizol reagent (Gibco Brl, USA)[28], followed by DNase I treatment. The quantity and quality of RNA were verified with the ratio of absorbance values at 260 and 280 nm, and by visualization of the bands on agarose gels. For each sample, 600 ng mRNA was used in reverse transcription reaction (iScript kit from BioRad Laboratories) according to the manufacturer's specifications. Further analysis of mRNA levels of each group was performed by RT-PCR with a light-cycling system (LightCycler; Roche Diagnostics GmbH, Mannheim, Germany). Sequences of the primers used are listed in Table 1. The mRNA expression level was described as the ratio of the mean reading of the experimental group over that of the control group for NCM460 cells.

RESULTS

L. plantarum prevented EIEC/EPEC-induced decrease of TER in NCM460 cells

TER in the NCM460 cell monolayers was decreased significantly in response to infection with EIEC/EPEC compared with uninfected control cells. However, decrease of TER induced by EIEC/EPEC was prevented by the simultaneous treatment of *L. plantarum* (Figure 1A and B).

L. plantarum inhibited increased macromolecular permeability of NCM460 cell monolayers in response to EIEC/EPEC

EIEC/EPEC had an obvious enhancing effect on permeability of NCM460 cell monolayers, as compared with the uninfected control cells. However, this effect was inhibited by the co-treatment of *L. plantarum* (Figure 2A and B).

L. plantarum prevented the decreased expression of TJ proteins and a cell cytoskeleton element F-actin detected by Western blotting

The expression of TJ proteins, including claudin-1, occludin, JAM-1 and ZO-1, and the cytoskeleton element F-actin, was decreased in NCM460 cells infected with EIEC or EPEC (Figure 3A and B) compared with the control cells, as detected by Western blotting of epithelial whole cell protein extracts of NCM460 cells ($P < 0.001$). However, after the pre-treatment of *L. plantarum*, the expression of TJ proteins and F-actin remained at similar levels to the control cells.

sion levels similar to those in the uninfected control cells (Figure 4A and B).

DISCUSSION

It has been reported that probiotics, such as *L. plantarum*, have beneficial effects on the human intestinal barrier function in patients with intestinal diseases[29]. Our previous studies also found that *L. plantarum* adhered to the intestinal epithelial cells, restored TJ structure and function, reduced paracellular permeability, and then showed the therapeutic effects[20,23]. However, the studies about the interaction between lactobacillus and the human intestine were only limited in the cancer cell line and the animal models. The present study investigated the protective effects of *L. plantarum* against epithelial barrier dysfunction of the normal human colon cell line NCM460.

L. plantarum played an important role in increasing TER and decreasing the permeability to macromolecules of NCM460 monolayers against the disruption caused by EIEC or EPEC. EIEC and EPEC had the ability to decrease TER and increase the permeability to macromolecules[20]. In the present study, we further observed that *L. plantarum* protected the epithelial barrier of NCM460 monolayers against the disruption caused by EIEC or EPEC. In other words, *L. plantarum* is able to attenuate the pathogen-induced decrease in TER, and inhibit the increase in the macromolecular permeability of dextran. Similar results were also found in other studies. Johnson-Henry reported that probiotics attenuated enterohemorrhagic *E. coli* O157:H7-induced drop in electrical resistance, and increased the corresponding intestinal barrier permeability[30].

Furthermore, we found that *L. plantarum* prevented the decrease in the expression of TJ proteins and F-actin in NCM460 cells. The expression of TJ proteins, including claudin-1, occludin, JAM-1 and ZO-1, and the cytoskeleton element F-actin were decreased in NCM460 cells infected with EIEC or EPEC compared with the control cells, as detected by Western blotting of epithelial whole cell protein extracts of NCM460 cells. However, after the pretreatment of *L. plantarum*, the expression of TJ proteins and F-actin remained at similar levels to the control cells. Other studies also found that *Lactobacillus rhamnosus* GG protected epithelial monolayers against EHEC-induced redistribution of the claudin-1 and ZO-1 TJ proteins. Resta-Lenert suggested that probiotics and/or commensals also reversed the epithelial damage produced by cytokines, and prevented the deleterious effects of tumor necrosis factor-α and interferon-γ in epithelial function[31].

Lactobacillus is reported to exert its beneficial effects by either producing bacteriostatic or bactericidal agents[32,33], competitively excluding pathogenic bacteria[34], or regulating immunomodulatory effects[13,31]. Furthermore, special signal transduction pathway is involved in the protective effects of *L. plantarum* on the intestinal epithelial barrier. Janus kinase inhibitor synergistically potentiated the effects of lactobacillus acidophilus on TER and permeability, while p38, ERK1, 2, or PI3K had no effects. After treated by lactobacillus, epithelial cells exposed to cytokines reduced the activation of SOCS3 and STAT1, 3.

We believe that our study broadens our knowledge of effects of *L. plantarum* in intestinal epithelial function and its therapeutic effects in the cellular and molecular mechanisms of intestinal barrier dysfunction and intestinal inflammation and justifies the use in inflammatory disorders, which is significant to both biotechnical and clinical fields. *L. plantarum* can protect against intestinal epithelial barrier dysfunction of NCM460 caused by EIEC or EPEC. However, the bacterial protein and its exact mechanisms of action remain unknown. We are conducting a study in an attempt to identify the protein and the smallest active domain within the protein from *L. plantarum* strain CGMCC1258 that is responsible for the adhesion of the bacterium to the intestinal epithelium. And further functional characterization by determining the effects of smallest active domain on the intestinal barrier function and immune responses is also in progress.

ACKNOWLEDGMENTS

The authors thank Dr. Xiao-Min Hang (Onlly Institute of Life Science, Shanghai Jiao Tong University, Shanghai, China) for the generous gift of *L. plantarum* CGMCC 1258, and colleagues from Shanghai Jiao Tong University Affiliated Sixth People's Hospital for their technical assistance.

COMMENTS

Background

Lactobacillus plantarum (*L. plantarum*) that resides in the human intestine plays an important part in maintaining the homeostasis of gut flora by adhering and colonizing to the intestinal mucosa and competing with pathogenic bacteria, which contributes to the protection of the human intestinal barrier function.

Research frontiers

Although *L. plantarum* exerted its therapeutic effects by adhering to the intestinal epithelial cells, restoring tight junction structure and function, and reducing paracellular permeability, the studies about interaction between lactobacillus and the human intestine were just limited in the cancer cell line and the animal models, and further studies based on the normal human intestinal cell had been unavailable.

Innovations and breakthroughs

Using the normal human colon cell line NCM460, this study investigated the protective effects of *L. plantarum* against epithelial barrier dysfunction caused by enteropathogenic *Escherichia coli* (*E. coli*) or enteroinvasive *E. coli*.

Applications

L. plantarum can be a potential candidate of therapeutic agents for the treatment of intestinal diseases.

Terminology

NCM460 cell line is a normal human colon cell line, which is derived from the normal human colon mucosal epithelium and expresses colonic epithelial cell-associated antigens such as cytokeratins and villin.

Peer review

This is a straightforward study extending previous work of the authors showing that *L. plantarum* maintains a high resistance to permeability to enteropathogenic and enteroinvasive *E. coli*. The work is extended to NCM460 colon cell cells in culture. Transepithelial electrical resistance was maintained high, dextran permeability was low and TJ protein expression was normal.

Abstract

AIM: To determine the safety and effectiveness of transarterial embolization ablation (TEA) of hepatocellular carcinoma (HCC) with a lipiodol-ethanol mixture.

METHODS: Between January 1 and December 31, 2009, 15 patients with HCC (13 men/two women, aged 38-75 years) accepted TEA treatment and were enrolled in this study, including five newly diagnosed patients and 10 with refractory disease. Two months after TEA, angiography and contrast computed tomography (CT) were performed, and responses were assessed using a modified version of Response Evaluation Criteria in Solid Tumors (RECIST version 1.1). The follow-up period was to June 30, 2010.

RESULTS: Every new case was treated once. Angiography was performed immediately after TEA, and showed that the tumor-feeding vessels were completely embolized and that lipiodol was densely deposited inside tumors. Two months after treatment, contrast CT showed no enhanced lesions. Alpha fetoprotein levels returned to normal in four patients and markedly decreased in another. mean ± SD survival after treatment was 10.8 ± 4.5 mo. All five patients survived during the follow-up period. Ten patients with refractory disease were treated a total of 14 times. Angiography immediately after TEA showed that blood flow to the tumors was obviously decreased in all cases, and contrast CT showed obvious depositions of lipiodol. Two months after treatment, the tumors had shrunk (6/10) or were stable (3/10). One had progressed after 2 mo and died of tumor rupture 3 mo after TEA. mean ± SD survival after treatment was 8.6 ± 4.3 mo; two patients survived during the follow-up period. Adverse effects included reversible hepatic decompensation, upper abdominal pain, and fever.

CONCLUSION: TEA is an effective therapy for patients with HCC and might be more effective than transcather arterial chemoembolization for treating refractory disease.

Key words: Transarterial embolization ablation; Lipiodol-ethanol mixture; Hepatocellular carcinoma

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common tumor worldwide and the third most common cause of tumor-related death[1-3]. HCC is not sensitive to radiotherapy or chemotherapy, therefore, surgery is still the treatment of choice. Unfortunately, < 30% of patients with HCC benefit from surgical resection because of unfavorable tumor location, stage or extent of disease, limited liver functional reserve, or high operative risk[4,5].

Minimal invasive ablation, a new treatment for HCC, achieves complete responses in > 80% of tumors < 3 cm in diameter. However, in tumors of 3-5 cm in diameter, the complete response rate is only 50%[6]. Therefore, ablation is not recommended for tumors > 5 cm. HCC is a hypervascular tumor that receives mostly hepatic arterial blood[7]. Since its introduction by Yamada *et al*[8,9] in the 1980s, transcatheter arterial chemoembolization (TACE) has been widely used to treat patients with inoperable liver tumors. The theoretical basis of TACE for treating HCC is that chemotherapeutic agents mixed with embolic material and injected into the hepatic artery will embolize the arteries that supply the tumor and kill the tumor cells[8,9]. However, Liu *et al*[7] also have reported that many HCC tumors, especially those > 5 cm in diameter, receive blood from both the hepatic artery and the portal vein. Therefore, TACE must be administered more than once, and tumor necrosis might still be incomplete[10-12].

Ethanol can kill tumor cells, and percutaneous ethanol injections have been used to treat unresectable small HCC tumors[13]. Ethanol can also produce permanent microcirculatory embolization that inhibits tumor growth by denaturing protein, coagulating platelets, and dehydrating vascular endothelial cells in tumors[14,15].

Transarterial embolization ablation (TEA) has been used to treat HCC with lipiodol-ethanol mixture (LEM)[16-18]. Compared with TACE, TEA has the following potential advantages: (1) LEM can permanently embolize tumor-feeding vessels that come from the hepatic artery and portal vein[15,17,19]; therefore, TEA might have a stronger antitumor effect than TACE; (2) after TACE, tumor and peritumoral normal tissues are ischemic, hypoxic, and secrete angiogenic substances that provide new conditions for tumor proliferation and recurrence[20,21], whereas TEA leads to infarction of the entire tumor and of the peritumoral normal liver tissue without collateral circulation; and (3) embolization of tumor vessels by LEM helps ethanol diffuse into the tumor[18,22-26]. It has been reported that the mean ± SD lipiodol retention rate (89.5% ± 10.7%) after TEA was significantly higher than after TACE (47.5% ± 21.2%) in liver lesions, and 1- and 2-year survival after TEA (93.3% and 80.0%, respectively) was also significantly higher than that after TACE (73.3% and 43.3%, respectively). Furthermore, the 1- and 2-year incidence of extrahepatic metastasis after TEA (both 0%) was substantially lower than it was after TACE (35.5% and 39.2%, respectively)[18].

In the present small pilot study, we sought to determine further the safety and effectiveness of TEA in treating patients with newly diagnosed and refractory HCC tumors.

MATERIALS AND METHODS

Patient recruitment

The protocol was approved by the Institutional Review Board of the Department of Medical Imaging and Interventional Radiology, Cancer Center, Sun Yat-sen University, Guangzhou, Guangdong, China. A total of 15 HCC patients who provided written informed consent before being enrolled in the study were treated with TEA from January 1 to December 31, 2009. Inclusion criteria included accurate proof of HCC, refusal of or contraindication to surgical resection (five cases), refractory disease (10 cases, progressed after TACE), Eastern Cooperative Oncology Group performance status not greater than 2. Exclusion criteria included total serum bilirubin ⩾ 50 μmol/L, serum albumin level < 28 g/L, and evidence of extrahepatic disease at presentation.

The demographic data of these patients are shown in Table 1. There were 13 men and two women with an average age of 55.7 ± 10.3 years (range: 38-75 years). All 15 patients were positive for hepatitis B and had concomitant cirrhosis. With regard to liver function status, 13 had Child-Pugh classification grade A and two had grade B. Of the 15, five had been recently diagnosed with single-nodule HCC (patients with new tumors and tumor diameter ⩽ 5 cm) and 10 patients with refractory tumors, including five with huge lesions (> 5 cm) and five with diffuse lesions. The five patients recently diagnosed with single-nodule HCC were all α fetoprotein (AFP)-positive and the lesion diameters ranged from 2.6 to 4.8 cm (mean ± SD, 3.7 ± 1.0 cm). The lesions were in the right lobule in two patients and in the left in three patients. Three of the five patients with huge HCC were AFP-positive, and all lesions were in the right lobule and the lesion diameters ranged from 8 to 15 cm (10.8 ± 3.1 cm). The five patients with diffuse lesions were all AFP-positive.

Treatment protocol

After puncturing the right femoral artery with the Seldinger technique, a Yashiro (5F, Terumo Heart, Inc., Japan) or R-H (5F, Terumo Heart) catheter was inserted into the common hepatic or superior mesenteric artery through a 5-F catheter sheath. Angiography was then performed to evaluate tumor blood supply and the surrounding vascular anatomy. Next, a 3F microcatheter (Terumo Heart) was inserted into the catheter (which remained in the proximal hepatic artery) and was advanced into the tumor-feeding arteries. For diffuse tumors, the microcatheter was inserted into segmental or subsegmental liver arteries to avoid the gastroduodenal and cystic arteries.

One percent lidocaine (from 2% lidocaine with saline, 1:1 by volume), 5-10 mL, was injected through a 2.5-mL syringe and followed by injection of a mixture of lipiodol (Guerbert S.A., Villepinte, France) and absolute ethanol (Department of Pharmacy, General Hospital of Guangzhou Military Command, China), 1:1 by volume. The in-

jection of LEM was stopped when the tumor-feeding arteries were occluded, or when injection reflux was noted, or when the amount injected reached 60 mL.

Follow-up was to June 30, 2010 and measurements consisted of the degree of tumor embolization as determined visually immediately after TEA by angiography, judged by two skilled radiologists, liver function [alanine aminotransferase (ALT) and aspartate aminotransferase (AST)] for 1-7 d after TEA, and AFP levels, computed tomography (CT) or magnetic resonance imaging, and changes of postoperative symptoms and signs up to 8 wk after treatment. Responses were assessed using a modified version of Response Evaluation Criteria in Solid Tumors (RECIST version 1.1)[27].

RESULTS

Every newly diagnosed patient was treated once. The maximum total dose of LEM was 54 mL (10.8 ± 5.4 mL). Angiography immediately after TEA showed that all tumor-feeding arteries were completely embolized and that lipiodol had been densely deposited inside tumors. CT images 2 mo after treatment showed lesions with non-enhancement that had been replaced by deposition of lipiodol (Figure 1). AFP levels returned to normal in four patients (before TEA: 2947.6 ± 3724.5 μg/mL; post-TEA: 13.7 ± 8.2 μg/mL; $P = 0.04$) and decreased substantially in another patient (from 37 625 μg/mL to 26 376 μg/mL). Mean survival after treatment was 10.8 ± 4.5 mo. All five patients survived during the follow-up period (Table 2).

All refractory patients were treated a total of 14 times. The total dose of LEM was 256 mL (mean: 18.3 ± 13.5 mL). Angiography immediately after TEA showed that blood flow to the tumors was obviously decreased. Two months after treatment, CT showed that lipiodol was deposited more obviously than before and the tumors were smaller

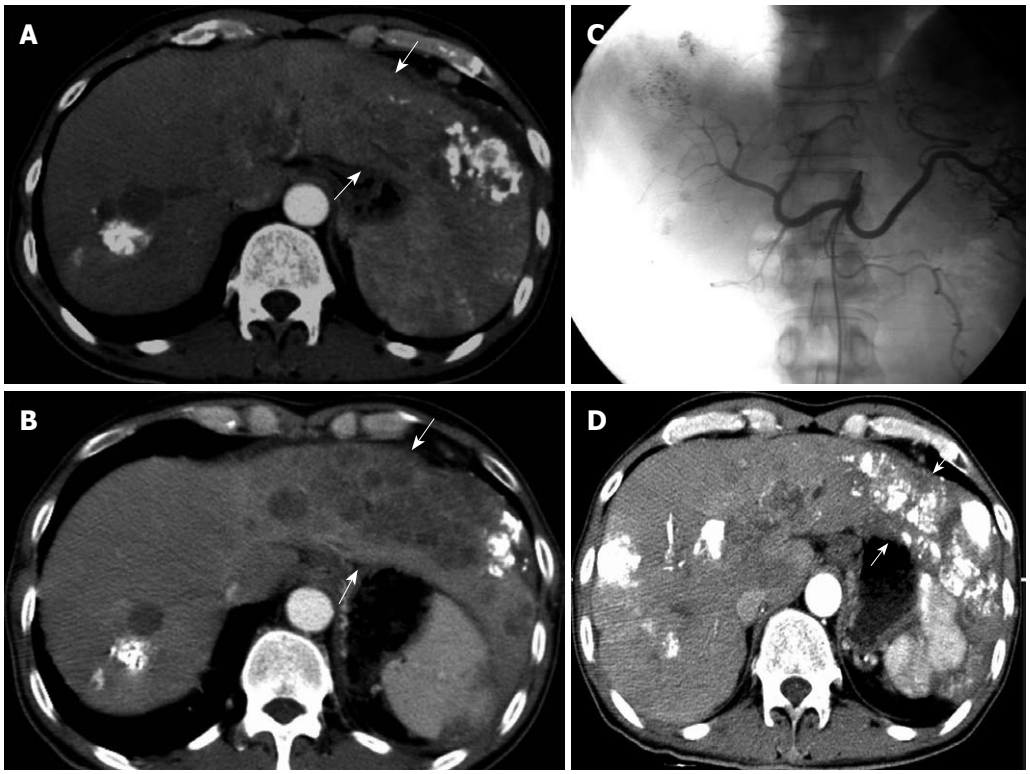

Figure 2 A patient with refractory tumors treated by transarterial embolization ablation. A: Limited lipiodol accumulation in a patient with a diffuse hepatocellular carcinoma tumor after transcatheter arterial chemoembolization (TACE) (arrows); B: After a second treatment with TACE, the tumor had progressed and showed less lipiodol accumulation (arrows); C: Hepatic artery angiography showed that tumor staining was not obvious. According to computed tomography images before transarterial embolization ablation (TEA), lipiodol-ethanol mixture was injected through the left and right hepatic arteries; D: Two months after TEA, the tumor had shrunk and lipiodol accumulation had increased (arrows).

Table 2 Clinical efficiency of newly diagnosed case

Newly diagnosed cases	Tumor response evaluation[1]		Follow-up period (mo)	Survival[2]
	Target lesion 2 mo post-TEA	Time to progress (mo)		
1	CR	9.9	16.8	Yes
2	CR	6.1	14.1	Yes
3	PR	6.3	9.5	Yes
4	PR	5.1	7.5	Yes
5	PR	0	6.3	Yes

(6/10) or stable (3/10) in nine patients (Figure 2). For eight AFP-positive patients, AFP levels returned to normal in one patient, were decreased in six after a mean 2.5 ± 1.1 mo, and continued to rise in one. The mean survival was 8.6 ± 4.3 mo after treatment. Two patients survived during the follow-up period (Table 3).

Adverse events

Adverse events post-TEA are listed in Table 4. Of the 15 patients, 10 had transient elevations in transaminase after TEA, all of whom returned to normal after drug treatment to protect liver function. All patients had intraoperative or postoperative upper abdominal pain, which was relieved or eliminated after symptomatic treatment. Eleven patients had fever at 2-7 d after TEA but recovered with the administration of antipyretic drugs or dexamethasone (5-10 mg). There were no other serious adverse effects.

Table 3 Clinical efficiency of refractory cases

Refractory cases	Tumor response evaluation[1]		Follow-up period (mo)	Survival[2]
	Target lesion[4] 2 mo post-TEA	Time to progress (mo)

DISCUSSION

Currently, TACE has become an important palliative treatment for patients with inoperable HCC[5,11,12,28-30]. Embolization of tumor-feeding arteries also prolongs the exposure and concentration of tumor drugs and chemo-

Table 4 Adverse events

therapeutic agents in the tumor microvascular bed, rather than allowing the drugs to reach the systemic circulation, which would reduce their effectiveness[5,8,9]. However, HCC tumors are occasionally partially supplied by the portal vein, especially when capsule formation around the tumor is incomplete[7,17,31]. After TACE, tumor blood supply from the portal vein increases, which makes achieving complete tumor necrosis difficult. In addition, embolization after TACE creates ischemia and hypoxia in the tumor and surrounding normal tissue, which leads tumor cells and peritumoral normal liver cells to secrete angiogenic factors, such as vascular endothelial growth factor and fibroblast growth factors, which promote collateral circulation and restoration of the tumor blood supply, which leads to tumor proliferation and recurrence[20,21]. To achieve complete tumor necrosis, the blood supply to the tumor from the liver artery and portal vein and fistula between them needs to be stopped, and the formation of collateral circulation needs to be prevented[32,33].

In animal experiments, Kan *et al*[15] have proved that transarterial injection of LEM achieves lobar ablation effects because it simultaneously embolizes the hepatic artery and portal vein. Ethanol is a strong protein coagulant that can inactivate tumor cells directly *in situ* and cause vascular endothelial injury and platelet cohesion, which results in permanent occlusion of tumor-feeding vessels and tumor infarction without causing collateral circulation[14,15].

In 1993, Matsui *et al*[17] described transarterial ethanol embolization of HCC. However, ethanol is not radiopaque, and its flow and speed are difficult to visualize when it is administered. In contrast, LEM traces not only the ethanol, which is necessary to avoid regurgitation and ectopic embolization, but also enhances the effects of embolization. Therefore, we call the transarterial injection of LEM TEA to distinguish it from TACE by injection of gelatin sponge or other embolic materials.

Optimal lipiodol:ethanol ratios

We treated 15 HCC patients with a mixture of equal volumes of lipiodol and ethanol. The results showed that TEA could completely embolize tumor-feeding vessels, reduce the size of single-nodule HCC tumors, and decrease levels of AFP. Enhanced CT examinations of the liver showed no enhancement of lesions. For refractory HCC, TEA can also shrink tumors and decrease AFP levels.

Reports were varied about the effectiveness of different ratios of lipiodol to ethanol. Matsui *et al*[17] have treated 100 patients with 124 HCC tumors < 4 cm with equal volumes of lipiodol and ethanol through hepatic artery injection. Survival rates for 82 patients with Child class A or B disease at 1 and 4 years were 100% and 67%, respectively. Kan *et al*[15] have reported that embolic effects were better when the lipiodol:ethanol ratio was 5:1, 4:1, or 3:1 than if the ratio was 1:1. However, several studies have reported good results in treating HCC with transarterial injections with lipiodol:ethanol ratios between 3:1 and about 1:3[16,17,19,34-36].

We think that the lipiodol:ethanol ratio can be adjusted according to the type of HCC. For single-nodule HCC, a relatively high lipiodol ratio (such as 2-3:1) is appropriate because the tumors are relatively small, have a complete capsule, and have a blood supply that comes mainly from the hepatic artery, with few fistulae between the hepatic artery and the portal vein. The injury to small arteries is relatively slight because of the lower percentage of ethanol in the mixture, and accordingly, more LEM is deposited inside the tumor. Meanwhile, the uptake of lipiodol by liver cancer cells means that the mixture is retained longer in tumor cells and has more time to produce antitumor effects[15,37].

For refractory HCC, a relatively high ethanol ratio is appropriate to inhibit the double blood supply from the hepatic artery and the portal vein with fistulae between them. Ethanol can permanently embolize tumor-feeding vessels and block the fistulae, as well as reducing the loss of lipiodol and extending the exposure time in the tumor cells, which achieves a better therapeutic effect. However, further research is needed to determine the optimal lipiodol:ethanol ratios for different types of HCC.

Treating adverse events

The most common adverse events after TEA were liver dysfunction, fever, and upper abdominal pain. In this study, 10 of 15 patients experienced liver dysfunction, and mean levels of ALT and AST rose to 600-1200 U/L in serious cases; therefore, liver function needs to be monitored closely and protected after TEA. We usually review patient's liver function the day after TEA and then every 2-3 d until it returns to normal or nearly normal. Antipyretic drugs or dexamethasone are usually effective in treating fever. Damage to the vascular wall caused by ethanol results in upper abdominal pain in all patients. We administer intramuscular injections of 10 mg diazepam at 10-30 min before treatment and 10 mg intramuscular morphine after catheterization of tumor-feeding arteries. We also inject 5-10 mL 1% lidocaine into the arteries before LEM. Patients generally tolerate TEA given this preparation. We stop injection of LEM for 1-2 min if patients feel pain and resume injection when the pain is relieved after injection of lidocaine through the catheter. For those who still feel pain after TEA, a fentanyl patch (4.2 mg from beginning) can be applied.

Potential problems and study limitations

Ethanol is a strong protein coagulant and a permanent embolic material, but it can also injure normal liver tissue and vessels[4,16,27,35,36,38]. Therefore, tumor blood vessels must be selected and treated carefully to avoid severe liver damage,

and even failure, and other serious complications caused by shallow intubation. On the other hand, excessively deep intubation can lead to incomplete embolization.

In addition, the speed of injection can also affect the efficacy of TEA. Blood dilutes ethanol and therefore will weaken the effect of ethanol on tumor cells if it is injected slowly, yet rapid injection might destroy blood vessel walls and form a vessel-casting mold. Injection of too much mixture can lead to reflux into normal liver tissues or to the blood vessels that supply the gastrointestinal tract. Therefore, research is needed into the effect of injection speed and on the dose of LEM.

Our study had some limitations. The sample size was small, but it was large enough to prove the concept. The follow-up after TEA was also short, and long-term efficacy needs to be studied further. In addition, some huge tumors had some necrosis before TEA, and the degree of tumor shrinkage was difficult to determine. Finally, we determined efficacy only on the basis of angiographic and CT imaging, without a postoperative pathological examination. These limitations can easily be avoided in larger, longer, and better-funded studies.

On the basis of our findings, we conclude that TEA is effective therapy for patients with HCC and might be better than TACE for treating refractory disease. Further studies, including randomized controlled trials, are warranted to confirm its role.

COMMENTS

Background

Transarterial embolization ablation (TEA) is a new treatment strategy for hepatocellular carcinoma (HCC). Some researchers have reported its effectiveness in HCC, especially in single-nodule HCC. However, its clinical effect for refractory HCC [not suitable for surgery and local ablation and with disease progression after transcatheter arterial chemoemblization (TACE)] remains unknown.

Research frontiers

TACE is accepted widely in treating advanced HCC because of its confirmed clinical effect. Advanced HCC tumors often receive blood from the hepatic artery and portal vein. Therefore, TACE must be administered more than once, and tumor necrosis can still be incomplete. In the present study, the authors demonstrated that TEA with lipiodol-ethanol mixture was an effective therapy for patients with HCC and might be more effective than TACE for treating refractory disease.

Innovations and breakthroughs

TACE with a mixture of lipiodol and ethanol has been shown to be an effective treatment for intrahepatic lesions of HCC, although it has not been widely used or described. Recent reports have highlighted the importance of this new method for its good results in nodular or capsulated HCC. Furthermore, this study suggests that this new method can also be applied in advanced refractory HCC.

Applications

Due to the exciting results and acceptable adverse events, TEA could represent a future treatment strategy for advanced HCC.

Terminology

Lipiodol is a very important embolization agent in TACE of HCC. Ethanol can kill tumor cells, and percutaneous ethanol injections have been used to treat unresectable small HCC tumors (chemical ablation). Ethanol can also produce permanent microcirculatory embolization that inhibits tumor growth by denaturing proteins, coagulating platelets, and dehydrating vascular endothelial cells in tumors. Transarterial lipiodol-ethanol mixture injection is called TEA.

Peer review

The authors report on the prospective follow-up of 15 patients treated with lipiodol-ethanol injection. The results are interesting. They reveal that TEA is a effective and safe treatment for advanced HCC. A further comparative study with TACE is needed to re-evaluate this new method.

Abstract

AIM: To detect the expression of mitochondrial uncoupling protein 2 (UCP2) in colon cancer and analyze the relation between UCP2 expression and clinical pathological features of colon cancer.

METHODS: Fifteen colon tissue samples and 15 its adjacent tissue samples were obtained from colon cancer patients during surgical interventions. UCP2 expression was detected with immunohistochemical method in 10 normal controls, 10 hyperplastic polyp patients, 20 tubular adenoma patients and 78 colon cancer patients. Patients with rectal cancer were excluded. Quantitative reverse transcription polymerase chain reaction and Western blotting were used to detect UCP2 expressions in colon cancer tissue samples and its adjacent tissue samples. Relation between UCP2 expression and clinical pathological features of colon cancer was also analyzed.

RESULTS: The UCP2 mRNA expression level was four-fold higher in colon cancer tissue samples than in its adjacent tissue samples. The UCP2 protein expression level was three-fold higher in colon cancer tissue samples than in its adjacent normal tissue samples. The UCP2 was mainly expressed in cytoplasm. The UCP2 was not expressed in normal colon mucosa. Strong positive staining for UCP2 with a diffuse distribution pattern was identified throughout the mucosa in colon cancer tissue samples with a positive expression rate of 85.9%. The UCP2 expression level was higher in colon cancer tissue samples at clinical stages Ⅲ and Ⅳ than in those at stage Ⅰ + Ⅱ. Univariate analysis showed that the high UCP2 expression level was significantly correlated to colon cancer metastasis (hazard ratio = 4.321, confidence interval = 0.035-0.682, P = 0.046).

CONCLUSION: UCP2 is highly expressed in human colon cancer tissue and may be involved in colon cancer metastasis.

INTRODUCTION

Colon cancer is one of the malignant tumors threatening to human health, and the mortality of colon cancer patients ranks second among all malignant tumors in developed countries. In recent years, its incidence has been increas-

ing in China, particularly in the economically developed coastal cities[1,2]. Its etiology and pathogenesis remain unclear. Great achievements have been made in studies on changes in tumor suppressor gene or proto-oncogene, but some problems cannot be explained. Recent studies showed that mitochondrial dysfunction is involved in the occurrence and development of tumor[3-5]. Uncoupling protein-2 (UCP2) is a mitochondrial membrane protein, which negatively regulates the production of reactive oxygen species (ROS)[6-8]. Adaptive mechanisms of cancer cells include resistance to tumor growth inhibition and evasion of apoptosis, and cellular events that are appreciably affected by oxidative stress[9,10]. The UCP2 expression level is significantly higher in colon cancer tissue than in its adjacent tissue and UCP2 may play a role in intestinal epithelial cells from benign to malignant transformation[11]. However, the role of UCP2 in development of colon cancer is unclear. In this study, the expression of UCP2 in normal human colon tissue and colon cancer tissue was detected, and the relation between UCP2 expression in colon cancer tissue and clinical pathological features of colon cancer was also analyzed.

MATERIALS AND METHODS

Patients and tissue samples

Fifteen colon caner tissue samples and 15 its adjacent tissue samples were obtained from the First Affiliated Hospital of Nanjing Medical University, snap-frozen and stored at -70℃. UCP2 expression was detected with immunohistochemical method in 10 normal controls, 10 hyperplastic polyp patients, 20 tubular adenoma patients, and 78 patients (45 males and 33 females) with colon cancer at different stages. Rectal cancer patients were excluded. Clinical pathological characteristics of the 78 colon cancer patients are listed in Table 1.

Immunohistochemistry

Tissue sections were stained with rabbit polyclonal antibody against human UCP2 (LS-C41270, LifeSpan BioSciences, Seattle, WA, USA), horseradish peroxidase (HRP)-labeled goat anti-rabbit secondary antibodies (Santa Cruz Biotechnology, Inc, USA) and visualized using peroxidase. Negative control sections were treated in PBS instead of primary antibodies. Intensity of UCP2 staining was scored as negative (0), weak (+1), moderate (+2), and strong (+3).

Quantitative reverse transcription polymerase chain reaction

After extraction of total RNA from snap-frozen colonic surgical samples with TRIzol reagent (Invitrogen, Carlsbad, CA) and removal of contaminating genomic DNA with DNase I and RNasefree (Roche Diagnostics Corp., Indianapolis, IN), reverse transcription polymerase chain reaction (RT-PCR) was performed using a first-strand cDNA synthesis kit (Roche Diagnostics Corp, Indianapolis, IN) following its manufacturer's instructions. Quantitative RT-PCR was performed using an ABI Prism 7300 real-time PCR detection system (Bio-Rad, Hercules, CA) following its manufacturer's instructions. The sequences of UCP2 and internal control GAPDH primers used in this study are as follows: Ucp2 gene: R: 5'-TCAGAATGGTGCCCATCACA-3', F: 5'-CCGGTTACAGATCCAAGGAGAA-3', GAPDH: R: 5'-ACCCTGTTGCTGTAGCCA-3', F: 5'-CCACTCCTCCACCTTTGAC-3'. The PCR amplification conditions were 95℃ for 5 min, followed by 40 cycles at 95℃ for 30 s, at 60℃ for 1 min, and a final extension at 72℃ for 3 min. The relative amount of gene expression = 2 Δct × 100 (Δct = ct target gene-ct internal reference).

Western blotting for UCP2

Sample was prepared for Western blotting using a mitochondria isolation kit following its manufacturer's instructions (AR0156, Wuhan Boster Biological Technology, LTD, Wuhan, China). An equal amount of protein was size-fractionated with 12.5% SDS-PAGE and transferred to a polyvinylidene difluoride membrane (Perkin-Elmer Life Sciences, Boston, MA). Immunoblots were developed using anti-UCP2 antibody (C-20; Santa Cruz Biotechnology, Inc, USA). Mitochondrial protein obtained from wild-type mouse spleen was used as a positive control. An equal loading was confirmed using cytochrome C (sc-13561, Santa Cruz Biotechnology, Inc, USA). Membranes were incubated with secondary antibody conjugated with horseradish peroxidase (Santa Cruz Biotechnology, Inc, USA), detected with enhanced chemiluminescence (ECL detection system, NEN, Boston, MA, USA), and used for visualization.

Statistical analysis

Data are expressed as mean ± SE. Correlation between categorical groups was evaluated by χ^2 test or Fisher's exact test, when appropriate. Univariate analysis of hazard model was employed to detect independent predictors of colon cancer metastasis. When appropriate, linear regression and Pearson r correlation were calculated. Two-tailed *P* value of ⩽ 0.05 was considered statistically significant.

UCP2: Uncoupling protein 2; T: Tumour; P: Peritumoral.

RESULTS

Expression of UCP2 mRNA in colon cancer and its adjacent tissue samples

The expression of UCP2 mRNA in 15 colon cancer tissue samples and 15 its adjacent tissue samples was detected by quantitative RT-PCR. The expression level of UCP2 mRNA was about four-fold higher in colon cancer tissue samples than in its adjacent tissue samples (Table 2).

Expressions of UCP2 protein in colon cancer and its adjacent tissue samples

The expression of UCP2 protein in 15 colon cancer tissue samples and 15 its adjacent tissue samples was detected by Western blotting. The expression level of UCP2 protein was three-fold higher in colon cancer tissue samples than in its adjacent tissue samples (Figure 1, Table 3).

Correlation between UCP2 protein and mRNA expressions in human colon cancer tissue samples

The correlation between UCP2 protein and UCP2 mRNA expressions in human colon cancer tissue samples was observed. A strong linear correlation was found between the T/P ratio of UCP2 mRNA and protein expression ($r = 0.7442$, $P < 0.05$), suggesting that increased UCP2 expression in colon cancer tissue is largely determined at the transcriptional level (Figure 2).

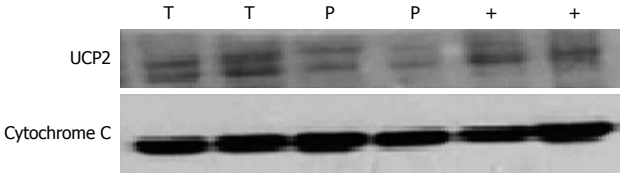

Figure 1 Western blotting analysis showing uncoupling protein 2 expression in human colon cancer tissue samples. T: Colon cancer tissue sample, P: Peritumor tissue sample; +: Positive control, spleen from wild type mouse. Cytochrome C was used as a loading control. UCP2: Uncoupling protein 2.

UCP2 expression in colon tissue samples detected by immunohistochemistry

The expression of UCP2 was detected by immunohistochemistry in colon tissue samples from 78 colon cancer patients, 20 adenoma patients, 10 hyperplastic polyp patients and 10 normal controls. UCP2 was mainly expressed in cytoplasm but not expressed in epithelium of normal colon. In contrast, strongly positive staining for UCP2 with a diffuse distribution pattern was identified throughout the mucosa in most tubular adenomas and adenocarcinomas. The positive staining rate was 85.9% and 55% for

Table 4 Uncoupling protein 2 expression in different diseases detected by immunohistochemistry

Tissue	*n*	Negative	Mild	Moderate	Strong	Rate of positive (%)
Normal colon	10	10	0	0	0	0
Hyperplastic polyps	10	9	2	0	0	20
adenoma	20	9	3	6	2	55
Colon cancer	78	10	15	30	22	85.9

Positive cells < 15% in negative control and ⩾ 15% positive cells were counted as positive. Staining intensity was classified as negative (0), mildly positive (+1), moderately positive (+2), and strongly positive (+3).

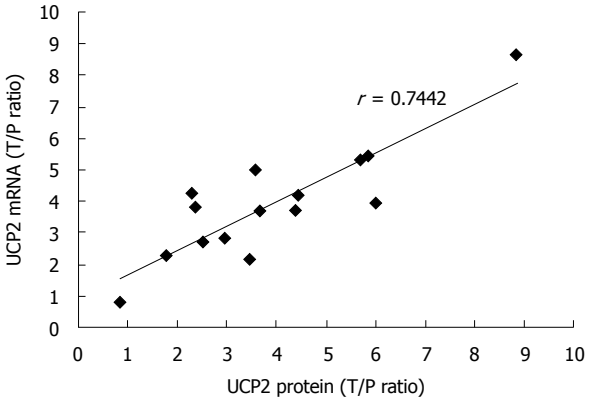

Figure 2 Correlation between uncoupling protein 2 and uncoupling protein 2 mRNA expressions in human colon cancer. UCP2: Uncoupling protein 2; T: Tumour; P: Peritumoral.

colon cancer tissue and colon adenoma tissue, respectively (Figure 3, Table 4).

Correlation between UCP2 expression and clinical pathological features of colon cancer

The correlation between UCP2 expression and clinical pathological features of colon cancer (including tumor stage and cell differentiation) was analyzed. The expression level of UCP2 was significantly higher in patients with colon cancer at clinical stages Ⅲ and Ⅳ than in those at stage Ⅰ + Ⅱ. However, the UCP2 expression seemed to be irrelevant to cell differentiation status, indicating that further study is needed (Table 5).

Analysis of colon cancer metastasis- related factors

The relation of colon cancer metastasis with sex and age of patients, tumor location, UCP2 expression and other features was assessed by univariate analysis, showing that cell differentiation and UCP2 expression were involved in colon cancer metastasis. However, colon cancer metastasis seemed to be irrelevant to age and sex of patients and tumor location (Table 6).

DISCUSSION

In this study, different UCP2 expressions in colon cancer tissue and normal peritumoral tissue samples were observed. The expression of UCP2 mRNA in colonic mucosa samples from patients undergoing colon cancer resection was detected by quantitative PCR. As shown in Table 2, the UCP2 mRNA expression level was 4-fold higher in colon cancer mucosal tissue samples than in grossly normal peritumoral colonic mucosal

Table 5 Relation between uncoupling protein 2 expression and clinical pathological features of colon cancer

Tumor differentiation/ clinical stage	Positive staining rate of UCP2 (%)	*P*
Tumor differentiation		
Well differentiation	72.8	0.072
Poor differentiation	91.4	
Clinical stage		
Stage Ⅰ + Ⅱ	65.1	0.032[1], 0.0248[2]
Stage Ⅲ	80.4	0.248[3]
Stage Ⅳ	92.6	

[1]*P* = 0.032, uncoupling protein 2 (UCP2) expression in colon tissue from patients with clinical stage Ⅲ *vs* that in colon tissue from patients with clinical stage Ⅰ + Ⅱ; [2]*P* = 0.0248, UCP2 expression in colon tissue from patients with clinical stage Ⅳ *vs* that in colon tissue from patients with clinical stage Ⅰ + Ⅱ; [3]*P* = 0.248, UCP2 expression in patients with clinical stage Ⅳ *vs* that in colon tissue from patients with stage Ⅲ.

Table 6 Univariate Cox proportional hazards analysis of metastasis variables in colon cancer patients

Variable	Hazard ratio	95% CI	*P*-value
Age (⩾ 60 yr)	0.098	0.081-33.058	0.915
Gender	0.895	0.078-41.221	0.389
Primary site	2.135	0.610-18.281	0.078
Tumor differentiation	1.270	0.031-1.672	0.049
UCP2 high expression	4.321	0.035-0.682	0.046

UCP2: Uncoupling protein 2; CI: Confidence interval.

tissue samples (3.92 ± 0.84, n = 15). The expression level of UCP2 protein in colon cancer tissue samples was measured by Western blotting and densitometry, respectively (3.27 ± 0.78, n = 15). A strong linear correlation was found between the T/P ratio of UCP2 mRNA and protein expressions (r = 0.744, P < 0.05), suggesting that increased UCP2 expression in colon cancer tissue is largely determined at the transcriptional level, which is consistent with the reported findings[11].

To characterize the UCP2 protein expression in different human colonic lesions, immunohistochemistry staining was performed for colon tissue sections (including normal colon tissue, non-neoplastic hyperplastic polyp tissue, tubular adenoma tissue, and colon cancer tissue). UCP2 in epithelium of normal colon was not stained. In contrast, strongly positive staining for UCP2 with a diffuse distribution pattern was identified throughout the mucosa from most tubular adenomas and adenocarcinomas. These findings indicate that colonic epithelium is the primary source of increased UCP2

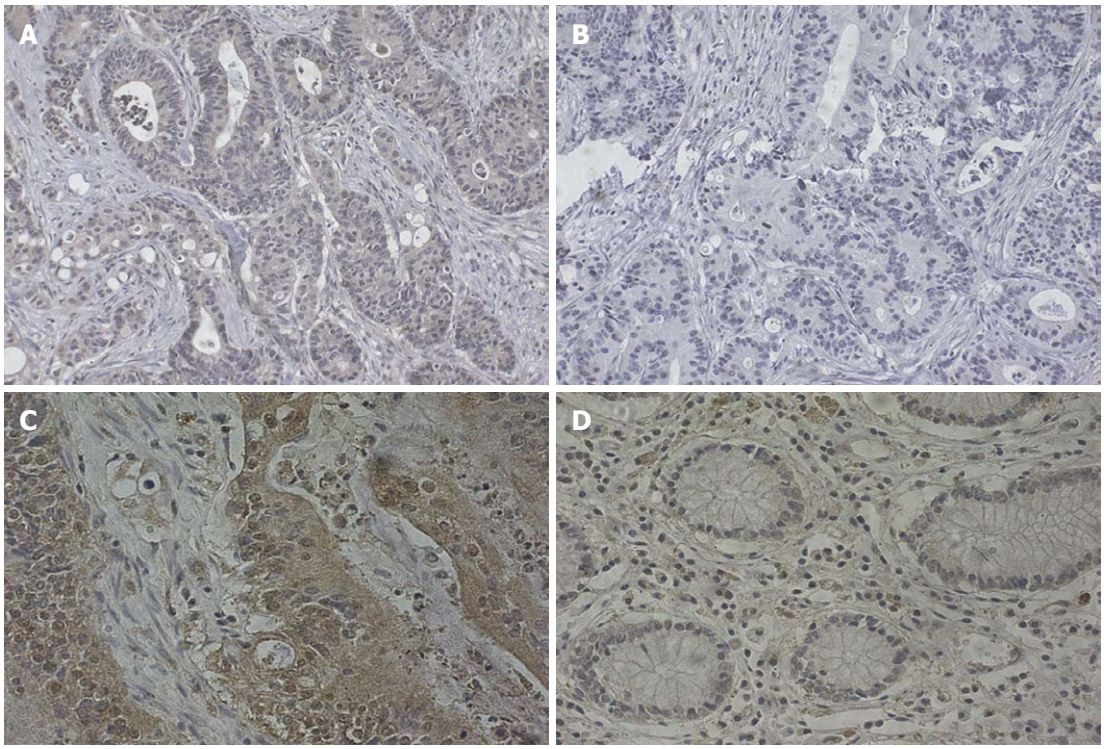

Figure 3 Immunohistological analysis showing uncoupling protein 2 expression in positively stained colon cancer tissue sample (A, C), negative control sample (B), and normal colonic tissue sample (D). Magnification: × 200 (A and B), × 400 (C and D).

expression in colon cancer. The positive UCP2 expression rate was 20% in hyperplastic polyp tissue samples, and over 50% in tubular adenoma samples, and 85.9% in colon cancer tissue samples, respectively, suggesting that UCP2 expression may intensify along the adenoma-carcinoma sequence.

The relation between UCP2 expression and clinical pathological features of colon cancer was analyzed. The expression level of UCP2 was significantly higher in patients with colon cancer at clinical stages Ⅲ and Ⅳ than in those at stage Ⅰ + Ⅱ. However, the UCP2 expression seemed to be irrelevant to cell differentiation status, indicating that further study is needed (Table 5). Furthermore, the relation of colon cancer metastasis with sex and age of patients, tumor location, UCP2 expression and other features was also assessed by univariate analysis, showing that highly expressed UCP2 was significantly correlated to colon cancer metastasis (hazard ratio = 4.321, confidence interval = 0.035-0.682, $P = 0.046$).

Very few studies have reported the potential role of UCP2 in carcinogenesis[12]. Limited literature showed that experimental data are somewhat controversial[13,14]. It has been shown that the UCP2 expression level is moderately higher in human colon cancer cells (LoVo) treated with ionized radiation than in controls not treated with ionized radiation[12,15], and the amount of UCP2 transcripts is greater in apoptosis-sensitive lymphoma cell line after radiation than in apoptosis-resistant cell line[16], suggesting that the decreased mitochondrial membrane potential mediated by UCP2 may activate the cell death pathways[17,18]. Recent reports from multiple laboratories offer a different conclusion[14]. It was reported that drug-resistant tumor cell sub-lines increase the UCP2 expression with a lower mitochondrial membrane potential and a diminished susceptibility to oxidative stress[19-21], indicating that tumor cells may use UCP2 in their metabolic adaptation to avoid ROS-mediated apoptosis.

Over-expression of UCP2 reduces neuronal cell death in transgenic mice and in cell culture exposed to hypoxia and glucose deprivation, coinciding with a decrease in mitochondrial ROS formation[21], and over-expression of UCP2 in cultured cardiomyocytes limits mitochondrial ROS production and suppresses loss of mitochondrial membrane potential elicited by H_2O_2 treatment[22], suggesting that UCP2 over-expression may protect different normal cells against apoptosis, and the cyto-protective role of UCP2 is likely involved in reduction of mitochondrial ROS production.

It has been shown that glycolysis is the preferred energy-producing pathway in rapidly growing cancer cells, while their mitochondrial respiration is diminished[23]. Changes in cancer cell bioenergetics are often associated with more aggressive tumor growth and drug resistance, resulting in worse prognosis[24]. This metabolic switch in cancer cells is to steer away reducing equivalents from the mitochondria to limit ROS generation.

In conclusion, UCP2 is over-expressed in human colon cancer *in vivo*. Increased UCP2 expression in colon cancer is largely determined at the transcriptional level. Highly expressed UCP2 is associated with colon cancer metastasis. Over-expression of UCP2 may be involved in tumor aggressiveness and UCP2 may be a novel target therapy for colon cancer.

COMMENTS

Background

Colon cancer is one of the malignant tumors threatening to human health, and

the mortality of colon cancer patients ranks second among all malignant tumors in developed countries. Its etiology and pathogenesis remains unclear. Adaptive mechanisms in cancer cells include resistance to tumor growth inhibition and evasion of apoptosis, cellular events that are appreciably affected by oxidative stress. Uncoupling protein-2 (UCP2) negatively regulates the production of reactive oxygen species (ROS).

Research frontiers

The etiology and pathogenesis of colon cancer remain unclear. Recent studies showed that mitochondrial dysfunction is involved in the occurrence and development of tumor. UCP2 is a mitochondrial membrane protein, which negatively regulates the production of ROS. The role of UCP2 in development of colon cancer is unclear. In this study, the expression of UCP2 in normal human colon tissue samples and colon cancer tissue samples was detected and the relation between UCP2 expression and clinic-pathological features of colon cancer was analyzed.

Innovations and breakthroughs

Recent studies showed that mitochondrial dysfunction is involved in the occurrence and development of tumor. UCP2 is a member of the inner mitochondrial membrane anion-carrier protein super family and negatively regulates the production of ROS. This is the first study to report the relation between high expression of UCP2 and clinical pathological features of colon cancer.

Applications

By understanding how the expression of UCP2 in colon cancer and analyzing the relation between UCP2 expression and clinical pathological features of colon cancer, we showed that UCP2 might be a novel target therapy for colon cancer.

Terminology

UCP2 is a member of the inner mitochondrial membrane anion-carrier protein super family and negatively regulates the production of ROS. Cancer cells acquire drug resistance as a result of selection pressure dictated by unfavorable microenvironments. This survival process is facilitated through efficient control of oxidative stress originating from mitochondria that typically initiates programmed cell death. This critical adaptive response in cancer cells is linked to UCP2, a mitochondrial suppressor of reactive oxygen species.

Peer review

The authors detected the expression of UCP2 and the relation between UCP2 expression and clinical pathological features of colon cancer. The authors showed that UCP2 expression was increased in colon cancer, and UCP2 might be involved in colon cancer metastasis.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Advances in molecular research in cancer have brought new therapeutic strategies into clinical usage. One new group of targets is tyrosine kinase receptors, which can be treated by several strategies, including small molecule tyrosine kinase inhibitors (TKIs) and monoclonal antibodies (mAbs). Aberrant activation of growth factors/receptors and their signal pathways are required for malignant transformation and progression in gastrointestinal (GI) carcinomas. The concept of targeting specific carcinogenic receptors has been validated by successful clinical application of many new drugs. Type I insulin-like growth factor (IGF) receptor (IGF-IR) signaling potently stimulates tumor progression and cellular differentiation, and is a promising new molecular target in human malignancies. In this review, we focus on this promising therapeutic target, IGF-IR. The IGF/IGF-IR axis is an important modifier of tumor cell proliferation, survival, growth, and treatment sensitivity in many malignant diseases, including human GI cancers. Preclinical studies demonstrated that downregulation of IGF-IR signals reversed the neoplastic phenotype and sensitized cells to anticancer treatments. These results were mainly obtained through our strategy of adenoviruses expressing dominant negative IGF-IR (IGF-IR/dn) against gastrointestinal cancers, including esophagus, stomach, colon, and pancreas. We also summarize a variety of strategies to interrupt the IGFs/IGF-IR axis and their preclinical experiences. Several mAbs and TKIs targeting IGF-IR have entered clinical trials, and early results have suggested that these agents have generally acceptable safety profiles as single agents. We summarize the advantages and disadvantages of each strategy and discuss the merits/demerits of dual targeting of IGF-IR and other growth factor receptors, including Her2 and the insulin receptor, as well as other alternatives and possible drug combinations. Thus, IGF-IR might be a candidate for a molecular therapeutic target in human GI carcinomas.

Key words: Dominant negative; Gastrointestinal cancer; Insulin like growth factor-I receptor; Monoclonal antibody; Tyrosine kinase inhibitor

INTRODUCTION

Signals from a variety of growth factors and their receptors are required for tumorigenesis, cancer development, and maintenance of the malignant phenotype[1]. Those signals alter regulation of the cell cycle, induction of apoptosis, and interactions of tumor cells with their environment, which affect the continuous growth potential of gastrointestinal (GI) cancer cells[1].

Recently, advances in molecular cancer research have brought new therapeutic arms from the bench into clinical usage. One group of new targets is the receptor tyrosine kinases (RTKs), including epidermal growth factor receptor (EGFR, erbB1), Her2/neu (c-erbB2), c-Kit (stem cell factor receptor), and vascular endothelial growth factor receptor (VEGFR). RTKs can be blocked by small molecule tyrosine kinase inhibitors (TKIs), for example gefitinib[2] and imatinib[3], targeting EGFR and c-kit, respectively. Multikinase inhibitors are also available for several tumors, including sorafenib (targeting Raf, VEGFR, PDGFR, c-kit, Flt-3, and RET)[4] and sunitinib (targeting for Flt-3, c-kit, VEGFR, and PDGFR)[5]. RTK signals can be inhibited by human or humanized monoclonal antibodies (mAb), e.g. trastuzumab[6] and cetuximab[7], targeting Her2 and EGFR, respectively. Bevacizumab is a mAb against VEGF-A, which is a ligand for VEGFRs, and is also in clinical use for patients with colorectal cancer[8]. Insulin-like growth factor (IGF) receptor-I (IGF-IR) could be the next molecular target in RTKs of human neoplasms[9].

INSULIN-LIKE GROWTH FACTOR/IGF-I RECEPTOR AXIS

IGF-IR is synthesized as a single precursor peptide of 1367 amino acid residues, which is then cleaved at residue 706, into the α-chain (containing the extracellular domain) and the β-chain (having the transmembrane and tyrosine kinase domains) (Figure 1)[10]. IGF-IR is transported to the membrane fully assembled in the dimeric form with two α-chains and two β-subunits. IGF-I and IGF-II are the ligands of IGF-IR and are produced by the liver and by many extrahepatic sites, including tumor cells and stromal fibroblasts. After the ligands bind to IGF-IR, which is autophosphorylated to stimulate tyrosine kinase activity, IGF-IR subsequently phosphorylates intracellular substrates, including insulin receptor substrates-1 to -4 (IRS-1~4) and Shc. These early events activate multiple signaling pathways, including the mitogen-activated protein kinase [MAPK, extracellular signal-regulated kinase (ERK)] and phosphatidylinositide 3-kinase (PI3-K)/Akt-1 (protein kinase B) pathways[11,12]. Those pathways then switch on several cellular functions, including anti-apoptosis, transcription, metabolism, proliferation, growth, and translation.

In normal cells, the IGF/IGF-IR system is controlled by multiple steps (Figure 2)[13]. Growth hormone-releasing hormone (GHRH) stimulates the expression of growth hormone (GH), which is produced in the pituitary gland. GH then stimulates the secretion of IGFs and IGF binding proteins (IGFBPs) from hepatocytes. Activation of IGF-IR is tightly regulated by the amount of the free forms of the ligands, which is controlled by the action of IGFBP and the non-stimulatory receptor type 2 IGF receptor (IGF-IIR, also known as mannose 6-phosphate receptor)[14,15]. IGFBP-1 to -6 circulate and modulate IGF activity by reducing IGFs bioavailability to bind to the IGF-IR. The complex balance between IGFs and IGFBPs is modulated by specific IGFBP proteases, such as matrix metalloproteinase (MMP)[16]. IGFBPs have IGF-independent actions, but their role in cancer is not yet clear. IGF-IIR is also a negative regulator of IGF signaling, and works by as a decoy by binding IGFs.

THE ROLES OF IGF-IR SIGNALS IN HUMAN NEOPLASMS, ESPECIALLY GASTOROINTESTINAL CANCERS

Dysregulation of the IGFs/IGF-IR system has been implicated in the proliferation of numerous tumors[17]. IGF-IR appears to be essential for malignant transformation in certain systems, for example, fetal fibroblasts with a disruption of the IGF-IR gene, while viable, cannot be transformed by the potent oncogene, SV40 T antigen[11,18]. Elevation of serum IGF-I increases the risk of developing several cancers, e.g. colon, prostate, and breast[14,19,20]. In addition, low serum concentration of IGFBP3 increases the risk of cancer[14]. Increased IGF-II expression has been implicated as a biomarker of colorectal cancer risk[21]. Overexpression of IGFs and the receptor, either by gene amplification, loss of imprinting, or overexpression of convertases or transcription factors, have been observed, as well as posttranslational modifications of the IGF-IR by glycosylation. IGF-IR is also important for the maintenance, as well as the initiation, of malignancy[11]. Moreover, reduction of IGF-IR has been shown to induce apoptosis in tumor cells, but produces only growth arrest in untransformed cells[1], implying that receptor blockade might have a greater therapeutic index than strategies targeting fundamental cell mechanisms, such as DNA synthesis or the cell cycle. In support of this, IGF-IR knockout mice are viable (though physically smaller than normal and ultimately die of respiratory failure), indicating that relatively normal tissue development and differentiation can occur in its absence[22].

Exogenous IGFs stimulate the proliferation of colon, gastric, esophageal, hepatocellular, and pancreatic cancer cells, whereas blocking IGF-IR inhibits tumor progression[23-29]. Intestinal fibroblast-derived IGF-II has been shown to stimulate proliferation of intestinal epithelial cells in a paracrine manner[30]. Both IGF-II and IGF-IR expressions are increased in gastrointestinal cancers[23,28,29,31-33]. Soluble IGF-IIR rescues Apc(Min/+) intestinal adenoma progression induced by loss of IGF-II imprinting[15]. Previously, we reported that detection of IGF-II/IGF-IR might be useful for the prediction of recurrence and poor prognosis of ESCC and for selecting patients for IGF-IR targeting therapy[33]. IGF-I has also

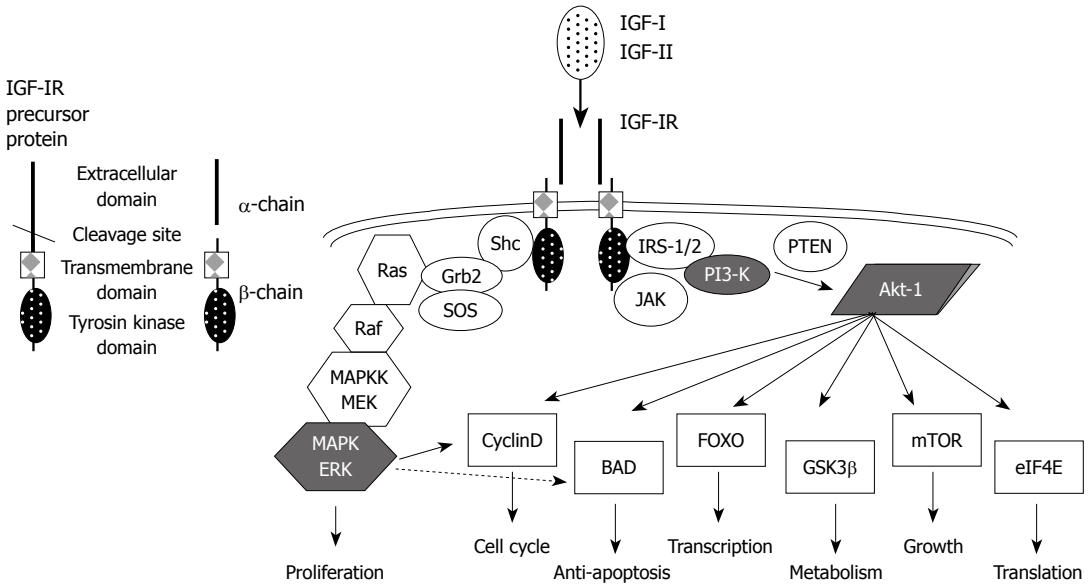

Figure 1 The structure, signal transductions, and effects of the type I insulin-like growth factor receptor system. Type I insulin-like growth factor receptor (IGF-IR) is synthesized as a single precursor peptide and then is cleaved into the α-subunit (extracellular domain) and the β-subunit (transmembrane and tyrosine kinase domains). After binding to the ligands (IGF-I and IGF-II), IGF-IR, which is constructed with two α- and two β-chains, turns on its signal transductions *via* two major pathways, such as mitogen-activated protein kinase (MAPK) and phosphatidylinositide 3-kinase (PI3-K)/Akt, results in survival and mitogenesis. IRS: Insulin receptor substrate; Shc: Src homology and collagen-containing protein; Grb2: Growth factor receptor-bound protein 2; PTEN: Phosphatase and tensin homolog; JAK: Janus kinase; MAPKK: MAPK kinase; MEK: MAPK/ERK kinase; ERK: Extracellular signal-regulated kinase; BAD: Bcl-2-associated death promoter; FOXO: Forkhead box O; GSK3β: Glycogen synthase kinase 3 beta; eIF4E: Eukaryotic translation initiation factor 4E.

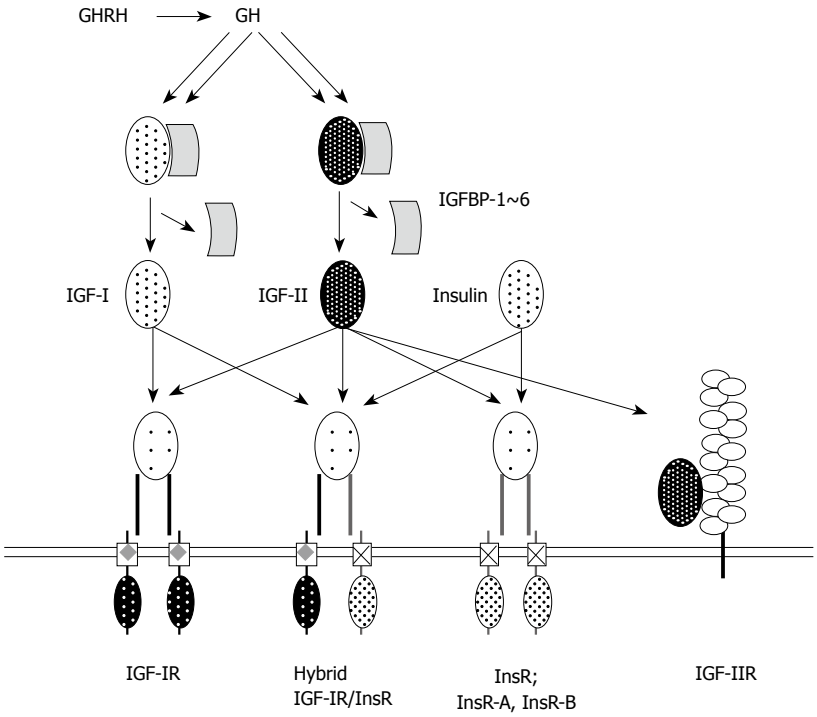

Figure 2 Insulin-like growth factor/type I insulin-like growth factor receptor and insulin/insulin receptor systems. Growth hormone-releasing hormone (GHRH) can stimulate secretion of growth hormone (GH), which upregulates insulin-like growth factors (IGFs) expression. IGF-I and IGF-II, which have about 40% sequence similarity to pro-insulin, predominantly activate type I IGF receptor (IGF-IR), which is a similar structure to insulin receptor (InsR) (59% sequence similarity). IGF-II is able to bind IR and both IGFs can bind hybrid IGF-IR/IR receptors. Ligand supply of both IGFs is regulated by two components. One is IGF binding proteins, which comprise at least six proteins [IGF binding protein (IGFBP)-1~6]. Another is IGF-IIR (lacks tyrosine kinase activity), which internalizes IGF-II for degradation in the pre-lysosomal compartment. Insulin can activate both IR and hybrid IGF-IR/InsR. Two isoforms of InsR exist, the A-isoform (InsR-A) and the B-isoform (InsR-B).

been shown to antagonize the antiproliferative effects of cyclooxygenase-2 inhibitors on pancreatic cancer cells[34]. Thus, overexpressed IGF-IR signals are also important in tumor dissemination through the control of adhesion, migration, and metastasis.

IGF-II, in conjunction with IGF-IR, IGF-I, COX-2, and MMP-7, seems to play a key role in the early stage of colorectal carcinogenesis[35,36]. Matrilysin (MMP-7) can cleave all six IGFBPs and can thus cause increased IGF-mediated IGF-IR phosphorylation[37]. Moreover, matrilysin is also able to generate bioactive IGF-II by degrading the IGF-II/IGFBP-2 complex binding to heparan sulfate proteoglycan in the ECM of HT29[16]. We have previously reported a positive feedback loop between the IGF/IGF-IR axis and matrilysin in the progression and invasiveness of GI cancers[38] (Figure 3).

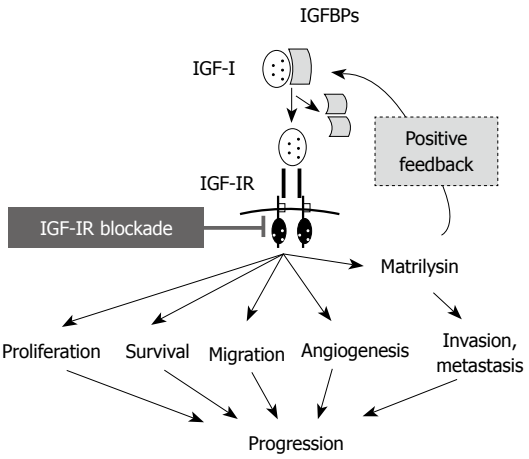

Figure 3 Blockades of type I insulin-like growth factor receptor reduce tumor progression through several interruptions of type I insulin-like growth factor receptor-mediated functions, including type I insulin-like growth factor receptor/matrilysin positive feedback system. IGF-IR: Type I insulin-like growth factor receptor; IGFBPs: IGF binding proteins.

These findings suggest a potential basis for tumor selectivity in therapeutic applications in GI cancers.

INSULIN AND INSULIN RECEPTOR AXIS

The insulin receptor (InsR) is also a key component of the IGF signaling pathway (Figure 2). IGF-IR shares a high degree of sequence similarity to InsR. The ATP binding sites of these two receptors display 100% sequence identity, whereas the entire kinase domains share 84% sequence identity, both with each other and across species[39]. InsR activation leads to cell proliferation in addition to glucose metabolism. In addition to insulin, InsR can also bind IGF-II and initiate mitogenic signaling[40]. In cells that express both receptors, IGF-IR/InsR hybrids form by random association. The hybrid receptors bind both IGF-I and IGF-II at physiological concentrations.

Epidemiological studies linked long standing type 2 diabetes, obesity, and metabolic syndrome with increased risk for developing cancer, including pancreatic and colon cancer[41]. High levels of both insulin and IGF-I are risks for breast cancer in postmenopausal women[12,42]. Phosphorylated IGF-IR/InsR is present in all breast cancer subtypes, and is related to poor survival[43]. InsR and IGF-IR/InsR hybrid receptors might also be involved in cancer biology, as both insulin and IGF-I contribute to the development and progression of adenomatous polyps[44].

Two isoforms of InsR are generated by alternative splicing of exon 11[45]. The A-isoform (InsR-A) is a fetal type and does not contain exon 11, and the B-isoform (InsR-B) is a classic form and contains exon 11[45]. InsR-A can bind IGF-II in addition to insulin and initiates mitogenic signaling[40]. InsR-B is able to bind IGF-I in addition to insulin. Cancers are now known to express InsRs, particularly the fetal variant InsR-A that mediates proliferation and apoptosis protection in response to IGF-II.

THE EFFECTS OF DOMINANT NEGATIVE IGF-IR IN COLORECTAL, GASTRIC, PANCREATIC, AND ESOPHAGEAL CANCER CELLS

Of the many potent strategies targeting the IGF/IGF-IR axis in GI cancer, we will first discuss data generate by our own group[33,38,46-48]. We constructed dominant negative (dn) versions IGF-IR, which can inhibit the function rather than the expression of the naturally expressed receptor[46,49]. We generated two different truncated IGF-IR constructs (950 and 482 amino acid residue IGF-IRs, IGF-IR/950st and IGF-IR/482st, respectively). The former lacks the tyrosine kinase domain and is thought to reside in the membrane of the transduced cells. The latter produces a defective α-chain of IGF-IR and should thus be a secreted form that may affect signal transduction in adjacent cells in addition to the transduced cells. We then constructed adenoviruses expressing two IGF-IR/dns, Ad-IGF-IR/dns (Ad-IGF-IR/482st and Ad-IGF-IR/950st).

In vitro effects and signal transduction of IGF-IR/dn

The Ad-IGF-IR/dns effectively reduced ligand dependent DNA synthesis, an index of mitogenesis, and colony formation, an index of *in vitro* tumorigenicity. IGF-IR/dns induced apoptosis and upregulated stressor (serum starvation, heat, and ethanol)-induced apoptosis.

IGF-IR/482st is a secreted protein and has a bystander effect, which suggest that IGF-IR/482st might enhance antitumor effects.

The IGF-IR/dns reduced ligands-induced phosphorylated Akt-1, but did not influence those of ERKs significantly. IGF-IR/dn can block not only IGF-I but also IGF-II stimulation, broadening the potential activity of IGF-IR/dn as an antitumor therapeutic. Although insulin induced Akt-phosphorylation, IGF-IR/482st did not block this phosphorylation, indicating that Ad-IGF-IR/dn has a high degree of receptor selectivity.

In vivo effects of IGF-IR/dn in GI tumor cells

When the GI cancer cells expressed IGF-IR/dn, the subcutaneous (SC) tumor formation was diminished significantly. Moreover, tumors derived from IGF-IR/dn expressing cells showed limited invasion into the underlying muscle. These results indicate that IGF-IR/dn effectively downregulates *in vivo* tumorigenicity and invasiveness.

Intratumoral (it) injection of Ad-IGF-IR/dn resulted in growth retardation or shrinkage of established GI tumors. The anti-tumor effect of IGF-IR/482st was stronger than that of IGF-IR/950st, undoubtedly due to the bystander effect of IGF-IR/482st. Moreover, IGF-IR/dn suppressed the invasiveness of SC tumors via downregulation of matrilysin expression and increased the number of apoptotic cells in the tumors.

In addition, GI cancer cells form peritoneal tumor

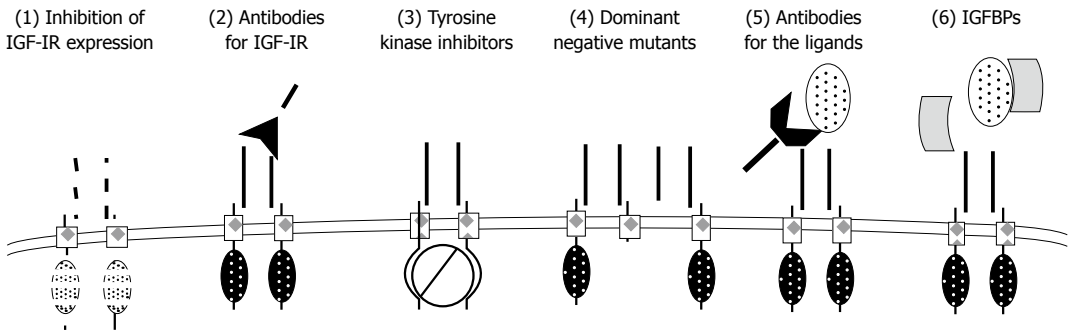

Figure 4 The summary of strategies to inactivate type I insulin-like growth factor receptor system. (1) Inhibition of type I insulin-like growth factor receptor (IGF-IR) protein expression by blocking its translation [with antisense oligodeoxynucleotides and short interfering RNA (siRNA)]; (2) IGF-IR function can be blocked with inactivating monoclonal antibodies (mAb); (3) The tyrosine kinase activity of IGF-IR can be abolished with small-molecule inhibitors (TKI); (4) IGF-IR mutants lacking β-subunits can act as dominant-negative (dn) receptors; (5) Ligand availability can be reduced by mAb for IGFs; and (6) IGF binding proteins (IGFBPs) can reduce active forms of IGFs.

nodules after intraperitoneal (ip) transplantation. Tumor bearing mice were treated by administration (ip) of Ad-IGF-IR/482st. IGF-IR/dn reduced the number of masses and resulted in a significant prolongation of survival in these mice, indicating that IGF-IR/dn can prevent and treat peritoneal cancer dissemination.

Combination effects with chemotherapy or radiotherapy

IGF-IR/dn enhanced chemotherapy (5FU and cisplatin)-induced apoptosis in GI cancer cells. The effects of the combinations were greater than addition of the effects of each monotherapy. IGF-IR/dn also upregulated radiation induced apoptosis. The combination of IGF-IR/482st (it) and 5FU (ip) for established SC tumors on mice was more effective than each single compound, and one-third of masses on the mice treated with this combo were cured; neither monotherapy cured any masses. This indicates that IGF-IR/dn has the potential to enhance the effectiveness of standard cancer therapies. Primary resistance to cytotoxic drugs is a serious problem in GI carcinomas and this approach has the potential to overcome this lack of responsiveness.

METHODS FOR THE BLOCKADE OF IGF/IGF-IR AXIS

Figure 4 shows six methods of disrupting IGF/IGF-IR signaling in cancer: (1) Blocking IGF-IR translation [with antisense (AS) oligodeoxynucleotides, AS RNA constructs, and RNA interference (RNAi)] or transcription (with triple helices) can bring about reduction or elimination of IGF-IR protein expression; (2) Binding of mAbs to IGF-IR can abolish its function; (3) Small-molecule TKIs can reduce the activity of IGF-IR; (4) Defective IGF-IRs, either mutated or lacking the tyrosine kinase domain, can act as dn receptors; (5) mAbs for the ligands can reduce their binding to the receptor; (6) Excess IGF binding proteins or inhibition of ligand expression (at the transcriptional or post-transcriptional level) can reduce the active ligands. There are several other ways to inactivate IGF-IR signals[50]; (7) IGF mimetic peptides can compete with the natural ligands; (8) Expression of a myristoylated IGF-IR C-terminus, which is a domain with intrinsic pro-apoptotic activity, can downregulate signals; (9) GHRH antagonists could diminish IGF-I levels[51]; and (10) Adnectins™ (Bristol-Myers Squibb), a novel class of targeted biologics, are proteins designed to either block or stimulate therapeutic targets of interest[52]. Recently, an optimized Adnectins specific that specifically blocks IGF-IR has been developed.

Agents useful for blocking IGF/IGF-IR signaling in cancer are listed in Table 1. Two of the ways to inhibit IGF-IR expression are RNAi technology and the AS technique[53,54]. We constructed a recombinant adenovirus expressing an AS to IGF-IR that decreases receptor numbers and inhibits soft agar colony forming efficiency, and treatment with this virus can significantly prolong the survival of nude mice bearing human lung tumor xenografts[55]. ATL-1101 (Antisense therapeutics) is an AS oligodeoxynucleotide and was developed for the treatment of psoriasis (stopped after a phase I study)[56]. We have also reported that adenoviral vectors expressing this short-hairpin RNA from IGF-IR induced effective IGF-IR silencing in lung and five GI cancers, as manifested by effective blocking of the downstream pathway of IGF-IR and by antitumor effects[57,58]. Although an adenoviral vector has several advantages, certain side effects have been reported for gene therapy using adenovirus vectors. Thus, there are some unsolved hurdles in practical application.

Many mAbs for IGF-IR had been developed over the years. Although αIR3[59] is a famous mAb for IGF-IR and inhibited cancer cell growth *in vitro*; however, it did not inhibit xenograft growth of breast cancer cell, MCF-7[60]. Thus, none of the first generation mAbs had the precise characteristics for clinical use. Recently, great advances have been in the cloning and production of mAbs by several pharmaceutical companies, e.g. figitumumab (CP-751,871)[61] by Pfizer, SCH 717454[62] by Schering-Plough, IMC-A12[63] by imClone systems, R1507[64] by Roche, AMG 479[65] by AMG, BIIB022[13] by Biogen Idec, MK-0646[66] by Merck, and AVE1642[67] by Sanofi-Aventis. The first six are whole human type mAbs and the latter two are humanized mAbs. These mAbs may have the qualities necessary for clinical usage and currently under phase study. Current IGF-IR targeting mAbs seem to

Table 1 Type I insulin-like growth factor receptor targeting agents

Class	Name	Company	Other targets than IGF-IR	Clinical study	Target organs of GI	Target organs other than GI
Inhibition of IGF-IR expression	Antisense oligonucleotide Antisense RNA siRNA					
Antibodies for IGF-IR	Figitumumab (CP-751,871)[1]	Pfizer		Phase III	Colon	Lung, head and neck, breast, prostate, sarcoma, advanced solid tumor

[1]Fully human antibody; [2]Humanized antibody; [3]Adenosine triphosphate (ATP) antagonists; [4]Non-ATP antagonists. IGF-IR: Type I insulin-like growth factor receptor; GI: Gastrointestinal; HCC: Hepatocellular carcinoma; CMPD: Chronic myeloproliferative disorder; FAK: Focal adhesion kinase; CML: Chronic myeloid leukaemia; MDS: Myelodysplastic syndromes; IGFBP: IGF binding protein.

share a common mechanism of drug action, namely to blocking ligand binding, decreasing cell surface receptor expression through receptor internalization, and blocking intracellular signaling, particularly through the PI3K/Akt pathway[63,68]. Most mAb are IgG1 class, humanized or fully human, to reduce immunogenicity. IgG1 and IgG3 classes can mediate antibody-dependent cellular cytotoxicity[63,68], which might strengthen anticancer activity and lymphocytic toxicity through recruitment of immune effector cells to antibody-antigen complexes. However, IGF-IR-mAb-directed cellular cytotoxicity could also enhance toxicity to normal IGF-IR-bearing tissues. As

CP-751,871 is an IgG2 subtype, which are usually poor activators of cellular immune response, and BIIB022 is a nonglycosylated IgG4 antibody, ongoing clinical studies should clarify whether these agents have significantly different properties from IgG1 class.

Small molecular TKIs for IGF-IR are synthesized by several companies. Novartis pharma produced three agents, NVP-ADW742[69], NVP-AEW541[70], and NVP-TAE226[71], which has dual targets on IGF-IR and focal adhesion kinase (FAK). Bristol-Myers-Squibb constructed three materials, a specific inhibitor of IGF-IR, BMS-536924[72], and dual inhibitors for InsR and IGF-IR, BMS-554417[73] and BMS-754807[74]. OSI-906[75] is made by OSI pharma and A-928605[76] by Abbott. Tea polyphenol (-)-epigallocatechin-3-gallate (EGCG) is also identified as a TKI for IGF-IR[77]. These nine medicines inhibit IGF-IR kinase activity by an ATP-competitive mechanism. In contrast, there are two compounds that are IGF-IR TKI non-ATP antagonists, cyclolignan picropodophyllin (PPP)[78] and INSM-18[13]. The latter is a dual TKI for IGF-IR and Her2. XL-228 is a multi-target TKI for IGF-IR, Bcl-Abl, SFK, Src, and Aurora kinase A[13]. At least five TKIs are currently in clinical studies.

We used two dn inhibitors of IGF-IR, as detailed above. Several groups have used IGF-IR/486STOP[79,80] and IGF-IR/952STOP[81,82], the former resembles our IGF-IR/482st and the latter is similar to our IGF-IR/950st.

mAbs for IGF-I and IGF-II, KM1468[83,84], KM3168[85], and KM3002, are made by Kyowa Hakko. KM1468 neutralized both ligands and inhibited bone metastasis in an animal model.

The last approach is a recombinant human IGFBP-3 protein, which is available for intravenous injection[86] and is beginning clinical testing.

TOXICITY AND COMBINATION OF IGF-IR TARGETING STRATEGIES

The two major potential toxicities of IGF-IR blockade are based on the IGF-IR expression in normal tissues and homology between IGF-IR and InsR. Long-term IGF-IR blockade might cause growth retardation during childhood and might influence the function of IGF-dependent tissues, including the myocardium and brain at any age[87,88]. IGF-IR-inhibitory drugs are predicted to influence glucose tolerance. TKIs might directly inhibit the InsR kinase in some degree, because of binding to a well-conserved ATP binding pocket. In fact, some TKIs can inhibit both receptors, e.g. NVP-TAE226, BMS-554417, and INSM-18. Several anti-IGF-IR mAbs, such as scFv-Fc and EM164, might induce downregulation of InsR *via* endocytosis of hybrid receptors or InsR, which was observed in cancer cells expressing both receptors, but not in cells expressing InsR only[89]. This suggests that anti-IGF-IR mAbs will not inhibit InsR function in insulin-responsible tissues, e.g. hepatocytes, which do not express IGF-IR. In addition, both IGF-IR mAbs and TKIs might result in loss of the hypoglycemic effects of IGF-I, and blockade of pituitary IGF-IRs might result in a compensatory increase in serum concentration of GH, which could contribute to insulin resistance[90].

Although IGF-IR mAbs are exquisitely specific inhibitors of receptor function (by inducing rapid internalization and down-regulation of the receptor), TKIs suffer from a lack of selectivity. TKIs, in general, do not lead to internalization or downregulation of IGF-IR, and will probably represent a broad spectrum of specificity against IGF-IR and InsR and a unique profile of toxicity. Possible toxicity of the central nervous system deserves particular attention during treatment with TKIs, because other molecules in this class have been shown to infiltrate the blood-brain barrier in central nervous system tumors[91]. Nevertheless, IGF-IR TKIs offer several advantages, such as oral administration and of the ability to control the duration of drug exposure, in contrast to long-acting mAbs.

Recently, it has been revealed that the insulin/InsR axis has certain roles in carcinogenicity and tumor development. Chronic hyperinsulinaemia might be a cause of colon and pancreas cancers[92]. IGFs have some potential for binding to and activating InsR. In addition, hybrid receptors of IGF-IR and InsR exist on malignant cells. Thus, blockade of InsR is another matter of concern to eliminate cancer cells. Thus, dual targeting TKIs for IGF-IR and InsR have merits for terminating tumor cells; however, they would, again, have adverse effects of glucose homeostasis.

According to several clinical studies, it has been reported that the adverse effects of IGF-IR mAb are hyperglycemia, mild skin toxicities (rash, flushing, pruritus, and acne), and fatigue as common toxicities of these antibodies[64,93,94]. Other observed toxicities, such as CD4+ lymphocytopenea, thrombocytopenia, and transaminitis, do not seem to be related to the mechanism of their specific action. An IGF-IR mAb caused hyperglycemia in around 20% of patients, but was tolerable, mild to moderate (grades 1 and 2), reversible, and manageable with oral hypoglycemic drugs. Patients with previous glucose intolerance or with steroids usage were at risk of hyperglycemia.

IGF-IR is a mediator of resistance to therapy. IGF-IR activation is known to protect tumor cells against apoptosis induced by cytotoxic drugs, and might also influence the repair of DNA damage[95,96]. There is considerable preclinical data to support the view that IGF-IR inhibition can enhance sensitivity to chemotherapy and radiotherapy. In addition, blockade of IGF-IR might have combination effects with other molecular targeting therapies, especially for RTKs.

Recently, a new role for IGF-IR has been proposed in that its signals might be an escape pathway in cancer cells for drug resistance. Many patients who achieve an initial response to trastuzumab acquire resistance within one year of treatment initiation. Two mechanisms for this trastuzumab resistance have been reported; one is overexpression of IGF-IR[97] and the other is the formation of a IGF-IR/Her2 heterodimer[98]. In addition, IGF-induced PI3-K/Akt activation mediates resistance to EGFR blockade in glioblastomas[99].

Thus, there is a hypothesis for horizontal blockade of two different growth factor receptors, such as Her/EGFR and IGF-IR. Several groups have tried these dual targeting therapies. Recently, a candidate combination treatment with an IGF-IR TKI, BMS-536924, and EGFR/Her2 inhibitors was reported[100].

On the other hand, nonselective inhibitors might have a different profile and alternative benefits. Some TKIs inhibit other kinases, such as Src (XL-228) or Her2 (INSM-18), and these multi-kinase inhibitors can expand the activity of the agent. It could also add toxicity mediated by target and off-target effects, complicating the combination with other agents.

Treatment with CP-751,871 decreased both total circulating tumor cell count and IGF-IR-positive circulating tumor cell count, suggesting that circulating tumor cells could be used as a biomarker of drug effect[93]. High concentrations of serum free IGF-I might be a marker of high responder of patients with non small cell lung carcinoma treated with figitumumab.

Apart from mAbs and TKIs, there are individual approaches using short interfering RNA (siRNA), peptides, proteins, or antisense oligonucleotides to antagonize IGF-IR. As mentioned above, several group, including ours, have revealed that both dn and siRNA for IGF-IR show powerful anti-tumor effects. However, the delivery systems of these approaches represent a significant hurdle for clinical use. Given a suitable delivery tool for humans, we would want to start using both dn and siRNA for IGF-IR in the patients with GI cancer.

CONCLUSION

The IGF/IGF-IR axis plays pivotal roles in the carcinogenicity and progression of GI cancers. We have presented the efficacy of IGF-IR targeting strategies using our data of IGF-IR/dn against GI cancers. Blockade of IGF-IR suppresses carcinogenicity, and upregulates apoptosis-induction and the effects of chemotherapy, both *in vitro* and *in vivo*. We summarized several approaches to blocking IGF-IR signals and discussed the merits and demerits of each strategy. In addition to combination with classical chemotherapy, several attempts at dual targeting for IGF-IR and other growth factor receptors have been made. Many drugs blocking IGF-IR function are now entering clinical trials. Thus, IGF-IR might be a candidate therapeutic molecular target in gastrointestinal malignancies.

Abstract

The role of chronic inflammation, acting as an independent factor, on the onset of gastrointestinal carcinogenesis is now well accepted. However, even if there is an increase in the number of elements directly involving polymorphonuclear leukocytes (PMNL), as a major actor in digestive carcinogenesis, the different cellular and molecular events occurring in this process are still not completely understood. The transepithelial migration of PMNL, which is the ultimate step of the afflux of PMNL into the digestive mucosa, is a complex phenomenon involving sequential interaction of molecules expressed both on PMNL and on digestive epithelial cells. Chronic inflammatory areas rich in PMNL [so-called (chronic active inflammation)] and iterative transepithelial migration of PMNL certainly evoke intracellular signals, which lead toward progressive transformation of epithelia. Among these different signals, the mutagenic effect of reactive oxygen species and nitrates, the activation of the nuclear factor-κB pathway, and the modulation of expression of certain microRNA are key actors. Following the initiation of carcinogenesis, PMNL are involved in the progression and invasion of digestive carcinomas, with which they interact. It is noteworthy that different subpopulations of PMNL, which can have some opposite effects on tumor growth, in association with different levels of transforming growth factor-β and with the number of CD8 positive T lymphocytes, could be present during the development of digestive carcinoma. Other factors that involve PMNL, such as massive elastase release, and the production of angiogenic factors, can participate in the progression of neoplastic cells through tissues. PMNL may play a major role in the onset of metastases, since they allow the tumor cells to cross the endothelial barrier and to migrate into the blood stream. Finally, PMNL play a role, alone or in association with other cell parameters, in the initiation, promotion, progression and dissemination of digestive carcinomas. This review focuses on the main currently accepted cellular and molecular mechanisms that involve PMNL as key actors in digestive carcinogenesis.

Key words: Neutrophils; Intestinal epithelial cells; Carcinogenesis; Cytokines; Nuclear factor-κB pathway; MicroRNA; Reactive oxygen species

INTRODUCTION

The link between a chronic active inflammatory process (i.e. chronic inflammation rich in neutrophils) and the onset of carcinoma, in association or not with another factor such as a pathogen, is now convincingly demon-

strated with epidemiological, experimental, and molecular data obtained for different tissues[1-10]. In particular, this relationship is well-established at the gastric and intestinal mucosal level[11-18]. Different factors are involved in digestive carcinogenesis, but the association of these factors and their importance in cancer onset are certainly variable from one disease to another and among individuals. Thus, predisposing genetic factors, infectious factors and inflammatory factors can be involved in digestive carcinogenesis[19]. Inappropriate innate immunity induces cellular infiltration of the digestive mucosa composed of polymorphonuclear leukocytes (PMNL), dendritic cells, natural killer cells, and then secondarily, an afflux of adaptive immune cells such as T lymphocytes. The intensity of this polymorphous cellular infiltrate varies according to the period of the active phases of the digestive disease[20]. In this regard, inflammatory infiltration can be present at variable time periods and at a variable frequency. Among the different populations of cells which migrate into the digestive mucosa, the PMNL play a central role in the pathophysiology of inflammatory digestive diseases[21]. Thus, previous epidemiological and histological studies have convincingly demonstrated a direct link between the clinical symptoms (pain and diarrhea) and the presence of PMNL in the digestive mucosa. More particularly, the periods of acute diarrhea certainly correlate with transepithelial migration of PMNL into the digestive lumen. It is noteworthy that during interaction between the intestinal epithelial cells (IEC) and PMNL different intracellular events are triggered, leading to neoplastic transformation of the digestive epithelia. The molecular phases involved in PMNL transepithelial migration are complex, but it is crucial to understand these phases to better comprehend the initial steps in digestive carcinogenesis. The progression from an *in situ* carcinoma to a microinvasive and invasive digestive carcinoma is associated with several molecular events, in particular, cytoskeleton modification, modulation of adherence molecules and metalloprotease production. Among these different events, some directly implicate PMNL. Currently, the pros and cons of the role of PMNL in tumor progression are debatable[22,23]. PMNL produce elastases[24], which favor tumor cell extracellular matrix invasion and release of pro-angiogenic factors, which creates a favorable microenvironment for tumor progression[25-30], but also produce defensins, which have an anti-tumor effect. Recently, a dual function of PMNL, in regard to their action on carcinoma cells, has been proposed[31,32]. Thus, two different populations of PMNL can be present in tumors, a population that favors tumour progression, the tumor-associated neutrophils 1 (TAN1) and a population that decreases tumor progression, the TAN2[31,32]. Accordingly to the proportion of TAN1 and TAN2 in a carcinoma the level of tumor progression can vary. This phenomenon can be present in colonic adenocarcinomas. Finally, previous studies implicate PMNL in the pathophysiology of metastases. This phenomenon can occur in colonic adenocarcinoma dissemination. In particular, PMNL allow transendothelial migration of tumor cells and then their migration into the blood stream.

Previous studies and reviews have focused on the role of the immune system during cancer development[33] but the impact of PMNL in the different phases of the natural history of cancer (Figure 1) has been poorly described to date. In this review, I describe the role of PMNL and the direct events induced by PMNL in the mechanisms of the different steps in digestive carcinogenesis (cancer initiation, progression and dissemination).

THE BIOLOGY OF THE NEUTROPHIL-INTESTINAL EPITHELIAL CELL INTERACTION

After transendothelial migration, following the crossing of the matrix of the lamina propria, which is mainly induced by a gradient of interleukin (IL) 8[34], PMNL adhere to the basal side of the glandular and crypt cell epithelium, and then transmigrate to the digestive lumen. This transepithelial migration is associated with sequential steps and with dynamic and transitory interactions between some surface molecules that are present on cytoplasmic membranes of PMNL and IEC[35,36] (Figure 2). Studies using *in vitro* models, such as the T84 model, have greatly improved our knowledge concerning these different cellular interactions. Thus, PMNL transepithelial migration can be induced by different stresses on epithelial cells, such as bacteria, bacterial products, toxins, or hypoxia[37,38]. Using this T84 model, the different steps of PMNL transepithelial migration and the different mechanisms involved in cell-cell interactions have been described[39-41]. Briefly, PMNL adhere to the basal side of the digestive epithelia through their CD11b/CD18 molecules (for which the ligand on epithelia is still unknown), then they migrate using a paracellular pathway through an homophilic CD47 interaction, which is expressed both on PMNL and IEC[42,43]. A more recent study showed that CD47 regulates neutrophil transmigration through close cross-talk with one toll-like receptor, TLR-2[44]. Other interactions occur at the desmosome and tight junction levels, which involve JAM and SIRPα[45-47]. After crossing the epithelial barrier PMNL interact with ICAM1 at the apical membrane through CD11b/CD18. During this transepithelial migration, the actin cytoskeleton of epithelial cells is reorganized[48]. Activated PMNL release 5'-adenosine monophosphate, which is secondarily cleaved by an epithelial membrane ectonucleotidase into adenosine, and finally produce chloride secretion on the epithelial apical side[49,50]. More recently, other molecular mechanisms have been described to occur during interaction between PMNL and the IEC[44,51]. Serine protease-mediated activation of epithelial protease-activated receptors has been shown to increase permeability. It has been demonstrated that transmigrating PMNL can regulate barrier function through epithelial protease-activated receptor activation[51]. Thus, transepithelial resistance decreased significantly after contact of PMNL with basolateral sur-

faces of T84 monolayers or after incubation with PMNL elastase and proteinase-3[51].

ROLE OF CHRONIC ACTIVE INFLAMMATION IN INITIATION OF DIGESTIVE CARCINOGENESIS

Beside these different events, which are associated with rapid paracellular migration of PMNL, different studies using the T84 model demonstrated the modulation of different molecules expressed on epithelial cells, which may be potentially involved in the initiation of carcinogenesis in direct or indirect pathways, by inducing an amplified inflammatory response rich in PMNL[52,53]. Moreover, paracellular migration of PMNL induced the onset of apoptosis, and, then potentially increases turnover of epithelium regeneration[54]. Thus, there is certainly a tight association between this chronic active inflammation and the onset of digestive carcinoma. An increased level in oxidative stress is present in the mucosa of inflammatory bowel diseases[55-57]. In this regard, an inflammatory microenvironment rich in PMNL can increase the rate of mutation, in addition to enhancing the proliferation of mutated cells[58]. Activated PMNL serve as sources of reactive oxygen species (ROS) and reactive nitrogen intermediates that are capable of inducing DNA damage and genomic instability[59]. Interestingly, release of ROS can occur during epithelium adhesion, but also during transepithelial migration and during post transepithelial migration of PMNL[60]. Alternatively, activated PMNL may use cytokines such as tumor necrosis factor (TNF)-α, which is implicated in carcinogenesis, to stimulate ROS and nitric oxide accumulation in neighboring epithelial cells[61,62]. Moreover, nitric oxide synthase can activate cyclooxygenase-2 in epithelial cells[63]. Different studies focus primarily on the effect of early mediators of inflammation, such as TNF-α, in stimulating tumor cell growth by activating nuclear factor (NF)-κB[64]. Conversely, decreased production of TNF-α in mice can reduce digestive carcinogenesis associated with chronic colitis[65]. However, chronic inflammation involves many other cytokines in the host microenvironment, which may also affect tumor growth in an NF-κB-dependent manner. While most inflammatory cytokines are released from activated macrophages following stimulus-induced transcription, others are secreted from intracellular pools and display later kinetics during the inflammatory response. Furthermore, the fact that NF-κB inhibition does not completely prevent tumor formation in these studies suggests that cytokines could also promote tumorigenesis *via* alternative pathways[66]. Mutations in p53, caused by oxidative damage, were found in both cancer cells and in a non-dysplastic epithelium in cancer associated colitis, suggesting that chronic inflammation causes genomic changes[67]. Finally, ROS can also cause direct oxidative inactivation of mismatch repair enzymes[5].

Other mechanisms have been described, which involve PMNL in the early steps of initiation of carcino-

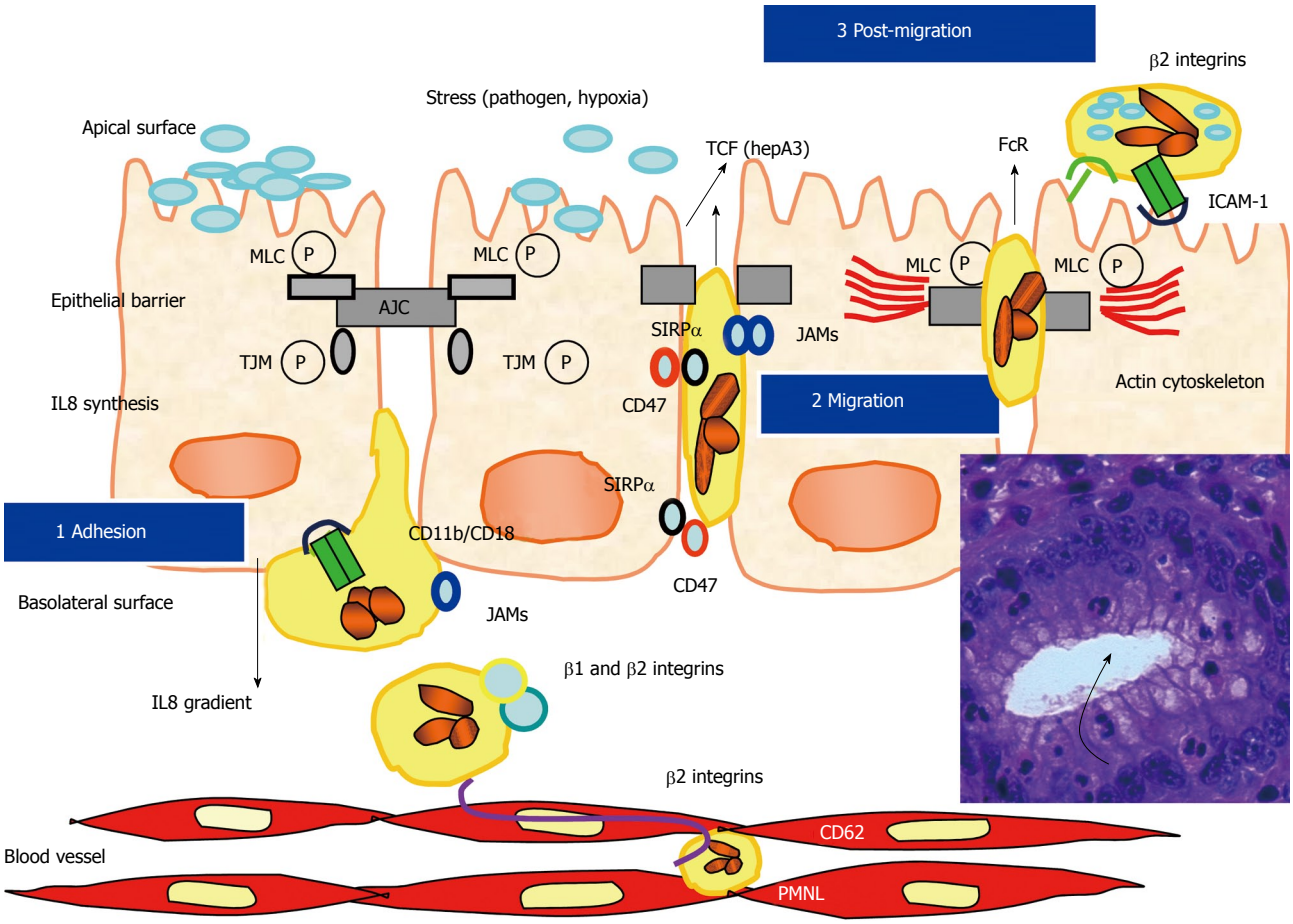

Figure 2 Cross-talk between polymorphonuclear leukocytes and intestinal epithelial cells. Different steps and molecules involvement in polymorphonuclear leukocytes transepithelial migration. genesis. Using animal models that reproduce digestive carcinogenesis linked to colitis, the molecule vanin 1 has been recently implicated in the onset of carcinoma[68]. Interestingly, it has been described that protein expression of cyclooxygenase-2 and the hypoxia-inducible factor-1 is up-regulated and associated with inflammation in early steps of digestive carcinoma[69]. The role of ROS and nitrates, largely suggested by previous studies, has been highlighted by different recent studies[70-76]. Interestingly, the myeloperoxidase (MPO) released by activated PMNL can inhibit nucleotide excision repair in certain epithelial cell lines[77]. In this regard, mutagenic products of MPO such as 5-chlorouracil and 5-bromouracil are released into inflammatory tissues. Moreover, the role of PMNL in initiation of carcinogenesis is probably more complex[78-80].

MicroRNA have been mainly investigated in oncology. However, microRNA are also implicated in inflammatory mechanisms, and their deregulation during some inflammatory diseases, in particular at the digestive level, could be associated with the molecular events that link chronic inflammation to cancer development[81-87]. The action of PMNL in this process is currently difficult to define, but through ROS release, and/or by the production of different enzymes, PMNL probably participate in deregulation of the RNA network in digestive epithelial cells.

IMPLICATION OF NEUTROPHILS IN PROGRESSION OF DIGESTIVE CARCINOMA

Recent studies have demonstrated that the presence of intratumoral PMNL can be associated with shorter disease specific survival in certain cancer patients[88]. Following the initiation of digestive carcinoma, processes allow the tumor to grow from a single initiated cell into a developed primary adenocarcinoma. In this context, tumor growth depends on increased cell proliferation and reduced cell death, both of which can be stimulated by PMNL-driven mechanisms. This inflammation-induced tumor promotion may occur early or late in tumor development and leads to activation of premalignant lesions that have been dormant for many years. As for tumor-associated macrophages[89-91], PMNL probably promote tumor growth but the putative mechanisms have not yet been determined. However, it has been shown that accelerated intestinal epithelial cell turnover caused by chronic active inflammation and epithelial damage might predispose the mucosa to DNA damage, resulting in an elevated risk of mutation, which is in line with dysplasia and carcinoma development in patients with ulcerative

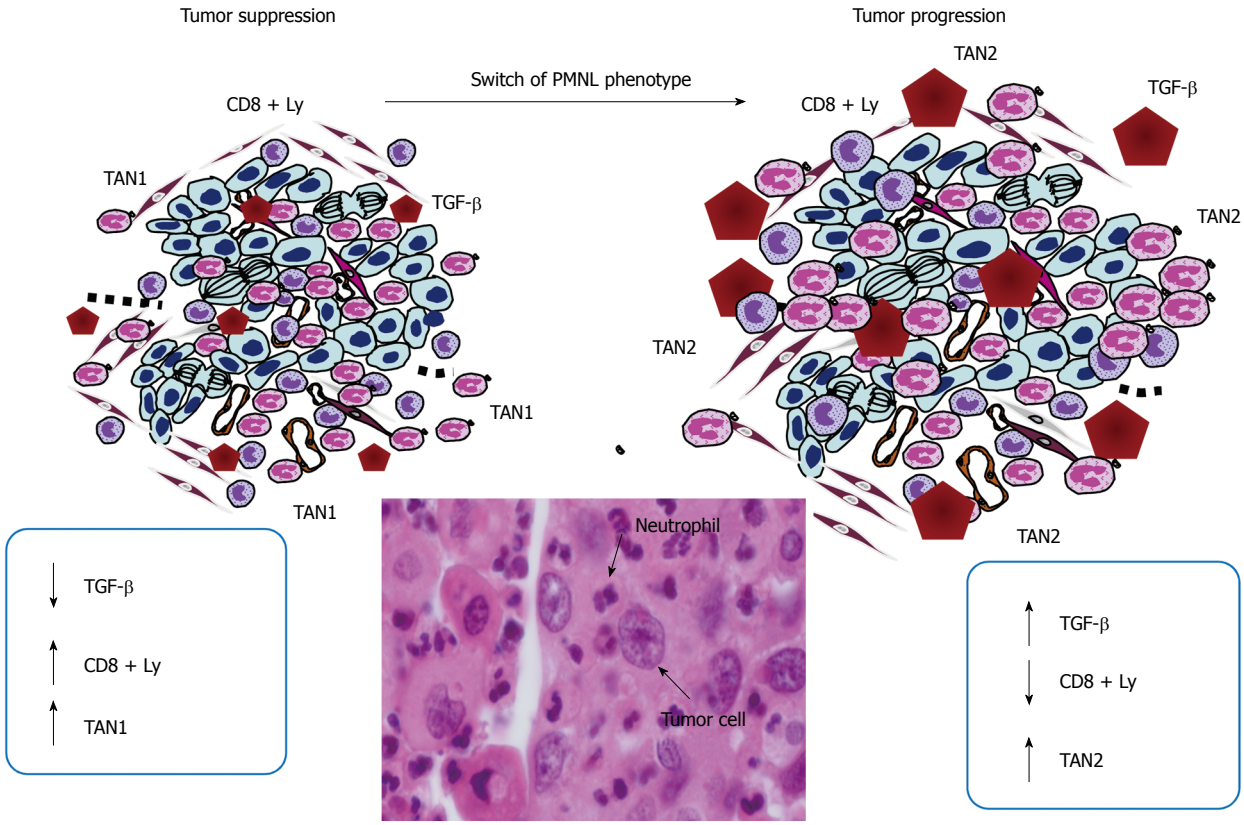

Figure 3 Speculative role of tumor-associated neutrophils in progression of digestive carcinoma. The microphotograph shows neutrophils tightly associated with digestive carcinoma cells. TAN: Tumor-associated neutrophils; TGF: Transforming growth factor.

colitis[92]. In parallel, the repeated inflammatory process could act on COX-2 expression which is down-regulated by the adenomatous polyposis coli (APC) gene and up-regulated by nuclear beta-catenin accumulation, and additionally implicate the Wnt signaling transduction pathway in colon carcinogenesis[93].

Secreted PMNL factors, such as human neutrophil peptides 1-3 (HNP1-3), have been found to be elevated in patients with digestive carcinoma, both in tissues and plasma, and to correlate with Dukes' stages[94]. Other molecules such as neutrophil gelatinase-associated lipocalin or neutrophil elastase are able to suppress or to increase the invasion of carcinoma cells[95-97]. Among the cytokines involved in carcinoma progression, Transforming growth factor (TGF)-β is certainly one of the most studied, to date. It has been reported recently in a mouse model of carcinoma that TGF-β controls maturation of a sub-type of PMNL, the so-called TAN-2. TANs could function in parallel with tumor-associated macrophages (TAMs)[98,99]. Conversely, inhibition of the TGF-β activity leads to the differentiation of PMNL in anti-tumor TAN-1 cells (Figure 3). While TAN-2 inhibit the cytotoxic response of CD8+-T lymphocytes, which infiltrate the intestinal mucosa and thereby allow tumor cells to circumvent immune surveillance, TAN-1 enhance the anti-tumor action of CD8+ T-lymphocytes. TGF-β blockade not only activates CD8+T cells, but also increases the recruitment of hypersegmented neutrophils, their NI polarization (high expression of TNF-α, ICAM-1 and FAS) and their anti-tumor activity. Moreover, N1 neutrophils produce T cell-attracting chemokines including CCL3, CXCL9 and CXCL10. By contrast, TGF-β stimulation polarizes PMNL to the so-called N2 state with increased expression of arginase and chemokines such as CCL2 and CCL5. N1 are cytotoxic for tumors, whereas N2 display pro-tumor properties.

We may speculate that this mechanism is universally found in carcinomas arising in different organs. Finally, it is noteworthy that the prognostic value of a high number of PMNL in different carcinomas correlates with poor outcome in previous studies[100].

In addition to TGF-β, other cytokines produced by PMNL may be involved in carcinoma progression. Thus, TNF-β secreted by PMNL can stimulate a positive loop of inflammation by inducing production of chemokines such as IL8 and Groα by epithelial tumor cells and probably inducing renewed recruitment of PMNL[101]. Moreover, other mechanisms may exist such as carcinoma cell stimulation of PMNL to produce oncostatin M[102].

Although it is not yet established, we can speculate that some miRNA expressed by PMNL, in particular mir-223, may also play a crucial role in modulating progression of digestive tumors. Mir-223 was found to possess a crucial role in regulating neutrophil proliferation and activation[103]. Moreover, the expression of mir-223 may be modulated by some cytokines released by tumor cells and may influence the phenotype of TAN-1 or

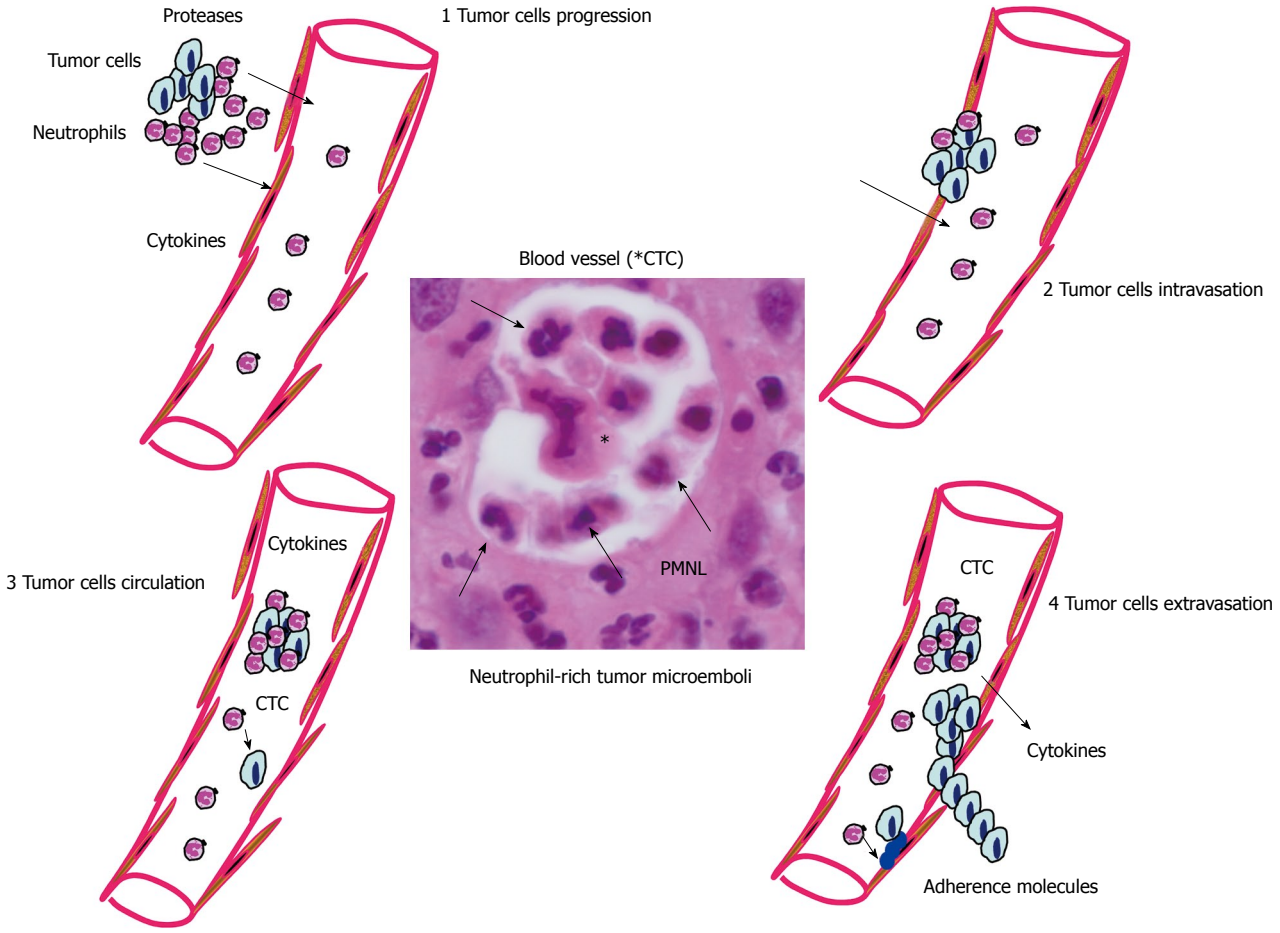

Figure 4 Speculative role of polymorphonuclear leukocytes in digestive carcinoma dissemination. The microphotograph shows circulating tumor cells associated with polymorphonuclear leukocytes (PMNL). CTC: Circulating tumor cells.

TAN-2. In this regard, different molecules have recently been reported as markers and/or promoters of inflammation-associated cancers[104]. Thus, we can speculate that the level of expression of mir-223 in carcinoma might be a marker of tumor progression.

THE NEUTROPHIL AS AN ACTOR OF THE PATHOBIOLOGY OF DIGESTIVE CARCINOMA METASTASIS

Inflammation is a key actor of metastasis onset[105]. In this regard, different studies have demonstrated the role of PMNL in tumor metastasis through different steps[106,107]. PMNL can participate in the transendothelial migration of adenocarcinoma cells, as well as their dissemination into the blood (Figure 4)[108,109]. Cytokines produced by PMNL can increase vascular permeability and upregulation of certain adhesion molecules located on endothelial cells[110]. In addition, PMNL are important sources of proteases that degrade the extracellular matrix and may alter the vascular barrier allowing entry of tumor cells into the blood stream. Interestingly, in a model of invasive colon cancer, CCR1+ myeloid cells, the recruitment of which is driven by the chemokine CCL9 produced by cancer cells, promote invasiveness through secretion of the matrix metalloproteinases MMP2 and MMP9[111]. It has been demonstrated that extracellular ATP can be released by activated PMNL[112]. This release of ATP occurs through a conformational opening of membrane Cx43 hemichannels in response to PMNL activation[113]. Moreover, the extracellular ATP released by activated PMNL may act both on epithelial cells, through activation of some purinergic receptors expressed by epithelial cells[53], and on endothelial cells[112]. More specifically, ATP released by activated PMNL is auto-hydrolyzed to AMP through CD39 on the surface of PMNL. CD39 may function as an immunomodulatory control point, requiring a close and special relationship with CD73-positive cells, such as endothelial cells. In addition to regulating the endothelial barrier function, a role for PMNL-dependent ATP release in directed movement of PMNL has been reported[114]. ROS released by activated PMNL can generate mitochondrial DNA mutations that regulate tumor cell metastasis[115].

Once metastatic cells enter the circulation, they need to survive in suspension and resist detachment-induced cell death or anoikis. The survival of circulating cancer cells is affected by inflammatory mediators released by immune cells in response to cancer-derived stimuli[116]. In the same way, the presence of a variety of cytokines

released by activated PMNL present in the tumor microenvironment, including TNF-α, can promote the survival of circulating metastatic seeds[117]. PMNL can also favor the circulation in the blood of tumor cells, in a similar way to that of platelets or blood macrophages which can be physically linked to cancer cells, allowing them to travel together through the circulation[118]. Thus, single circulating tumor cells (CTC), which are no longer present in an immunosuppressive environment, may be targeted again by immunosurveillance. In this regard, the interaction of circulating cancer cells with PMNL may protect them from cell death, thereby overcoming immunosurveillance[119]. The journey of CTC ends upon integrin-dependent arrest on the endothelium, followed by extravasation. In this regard, systemic inflammation enhances attachment of CTC to endothelial cells, and this process is governed by neutrophil-dependent upregulation of adhesion molecules[120]. Thus, the production of high levels of proinflammatory cytokines by the PMNL can upregulate expression of certain adhesion molecules on endothelial cells and thereby increase the probability of metastatic cell attachment and potentialize the passage of tumor cells from the circulation into the extracellular space and then to develop micrometastases[90,105].

CONCLUSIONS AND PERSPECTIVES IN THERAPIES TARGETING NEUTROPHILS

Different proinflammatory molecules and inflammatory cells have been suggested to be potential candidate targets for therapeutic strategies for cancer[99,121,122]. One study has shown that different drugs that prevent inflammation can inhibit carcinogenesis[123].

The role of PMNL in the onset and progression of digestive carcinoma, in particular those occurring in inflammatory bowel diseases, is complex. However, recent studies highlight new aspects of the pathophysiology of the PMNL-epithelial cells interaction, in particular, the effect of ROS release by activated PMNL on digestive epithelial cells at the molecular level or the effect of different TAN on tumor progression. Interestingly, these novel findings on the role of PMNL in the initiation and progression of carcinogenesis open up therapeutic avenues for the treatment of digestive cancers[124]. It is noteworthy that immunotherapy against cancer has been explored as a coadjuvant and has been based mostly on the properties of the adaptative immune system (i.e. B and T lymphocytes, dendritic cells) and of some components of the innate system (macrophages, NK cells, or complement proteins)[125,126]. PMNL have been rarely considered as a weapon against cancer. However, studies highlighting the anti-tumor efficacy of PMNL have been published. For example, suppression of the secreted protein acidic and rich in cystein, which is associated with the capacity of tumor cells to migrate and invade tissues, in malignant cells, led to the promotion of PMNL recruitment and induced tumor rejection[127]. However, the mode of action of PMNL that leads to the killing of tumor cells is not fully understood. It probably depends on the maturation of PMNL since in an animal model of lung tumors, only a subpopulation of PMNL i.e. TAN2 had an anti-tumor effect[31]. PMNL produce cytotoxic agents such as proteases, ROS, and defensins, all of which can directly damage the target cells. However, the cytotoxic effect of PMNL on tumors is greatly enhanced in the presence of target-specific antibodies. Finally, another strong argument for the anti-cancer effect of PMNL comes from studies using animal models in which tumor cells were genetically engineered to release immunoregulatory molecules (cytokines and chemokines). These molecules did not affect the proliferation of the tumors directly, but activated a host immune reaction that was strong enough to overcome their oncogenic capacity. For instance, G-CSF-releasing colon adenocarcinoma cells were found to lose their tumorigenic activity through the massive attraction of PMNL to the tumor injection site[128]. These PMNL distinguished between G-CSF-producing and nonproducing cancer cells. Moreover, tumor inhibition *in vivo* was accompanied by intimate physical contact between PMNL and G-CSF-producing tumor cells[129]. However, future research should be done in order to better target the different subpopulations of TAN, since only one population of PMNL would have an anti-tumor effect and should be considered.

Abstract

The risk factors for hepatocellular carcinoma (HCC) development have been established, and include chronic hepatitis B and C, heavy alcohol consumption, and aflatoxins. In fact, 5%-30% of patients with HCC still lack a readily identifiable risk factor. It has been reported that the majority of "cryptogenic" HCC may be attributed to nonalcoholic fatty liver disease, the hepatic presentation of the metabolic syndrome (MS). Obesity is associated with the development of the MS. Recently, adipose tissue has been considered as an endocrine organ because of its capacity to secrete a variety of cytokines, which are collectively known as the adipokines. Leptin, the product of the obese gene, is mainly produced by adipose tissue. Since leptin was first characterized in 1994, accumulated literature has demonstrated the involvement of this adipokine in several areas of human physiology. After binding to its receptor, leptin initiates a cascade of signaling events and subsequent cellular effects. In addition to being the regulatory mediator of energy homeostasis, several *in vitro* studies have demonstrated the fibrogenic role of leptin in the liver. Furthermore, the deregulated expression of leptin and its receptor have been demonstrated to be associated with a variety of metabolic disorders as well as human cancers. Most importantly, direct evidence supporting the inhibitory and/or activating role of leptin in the process of carcinogenesis and progression of human HCC has been accumulating rapidly. This review aims to provide important insights into the potential mechanisms of leptin in the development of HCC. Hopefully, further investigations will shed light on a new therapeutic target in HCC.

Key words: Adipokine; Hepatocellular carcinoma; Leptin; Liver cirrhosis; Metabolic syndrome; Obesity; Steatohepatitis

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most com-

mon cancer worldwide and the third leading cause of cancer death[1]. Due to its high mortality, the annual fatality ratio is close to 1.0, indicating that the patients who develop HCC will die within 1 year[2]. Furthermore, recent data have shown that there are 662 000 deaths per year from liver cancer[3]. In addition, using the linked Surveillance, Epidemiology and End Results and Medicare dataset to estimate the annual direct and indirect costs associated with HCC, Lang *et al*[4] pointed out the considerable economic impact of HCC on the health care system in the United States. Thus, further understanding of the causation and potential mechanisms of HCC is urgently needed.

Recently, obesity has become a worldwide health issue, because it increases the risk for a variety of human diseases. It is said that the prevalence of obesity has increased substantially over the past decade in most industrialized countries, and a further increase is expected in the future[5]. The International Association for the Study of Obesity reported that approximately 40%-50% of men and 25%-35% of women in the EU were overweight [defined as a body mass index (BMI) between 25.0 and 29.9 kg/m^2], and an additional 15%-25% of men and 15%-25% of women were obese (BMI $\geqslant$ 30.0 kg/m^2)[6]. A similar observation was also found in the US population and the prevalence continues to increase despite all efforts to oppose it[7]. Diseases which have been associated with obesity include hypertension, type 2 diabetes, dyslipidemia and coronary heart disease[8,9]. Further evidence suggests that obesity is also a risk factor for certain types of cancer[10].

In spite of many well-defined risk factors for HCC [including hepatitis B virus (HBV), hepatitis C virus (HCV), and alcohol], Caldwell *et al*[11] have shown that 5%-30% of patients with HCC lack a readily identifiable risk factor. The majority of "cryptogenic" HCC in the United States is attributed to nonalcoholic fatty liver disease (NAFLD)[12]. In addition, a number of studies have observed an increased risk (1.5 to 4-fold) of HCC among obese individuals[13-15]. Therefore, experts have attempted to elucidate the possible events by which obesity might be linked to these diseases. Of note, it should be remembered that adipose tissue is central to the understanding of metabolic abnormalities associated with the development of obesity. In recent years, adipose tissue has been considered as an endocrine organ because of its capacity to secrete a variety of proteins with broad biological activities[16]. These proteins, collectively referred to as adipokines, play an important role in the physiology of adipose tissue, including food intake and nutrient metabolism, insulin sensitivity, stress responses, reproduction, bone growth, and inflammation.

Leptin, the product of the obese (*ob*) gene, has undoubtedly been the most studied adipokine since this protein was first characterized by Zhang *et al*[17] in 1994. Leptin is best known as a regulator of food intake and energy expenditure *via* hypothalamic-mediated effects. It is currently appreciated that this adipokine has many additional effects, often as a consequence of direct peripheral actions. These include angiogenesis, hematopoiesis, lipid and carbohydrate metabolism and effects on the reproductive, cardiovascular and immune systems. More importantly, a recent study considered leptin as a fibrogenic factor in all types of chronic liver disease[18]. In addition, leptin has been demonstrated to be crucial in the progression of NAFLD, the hepatic presentation of the metabolic syndrome (MS), into liver fibrosis[19]. Thus, the aim of this review is to discuss the updated information on leptin and its receptor, the proinflammatory effects of leptin on chronic liver disease of different etiologies, and the potential impact of leptin on HCC progression. Hopefully, leptin will shed light on a new therapeutic target in HCC treatment.

LEPTIN - A VERSATILE ADIPOKINE

Leptin, the product of the *ob* gene, is mainly produced by adipose tissues and, to a lesser extent, by tissues such as the stomach, skeletal tissue and placenta[17]. Leptin is secreted into the blood stream in a circadian rhythm and proportional to body fat mass. Although leptin serves as a regulatory mediator between the brain and the periphery through modulating the hypothalamo-pituitary-adrenal (HPA) axis, its circulating level is also regulated by hormones secreted by the HPA system, including corticosteroids, prolactin, and insulin[20,21]. Furthermore, leptin expression can be negatively regulated by fasting, beta-adrenergic agonists and thiazolidinediones. In addition, leptin secretion is higher in females than in males for any given age and body fat mass, i.e. it is sexually dimorphic.

Leptin is known to regulate energy homeostasis[22]. However, leptin-deficient (*db*/*db*) mice are not only severely obese, but also have a number of abnormalities. Research efforts have since expanded to elucidate leptin's role in human physiology and have resulted in a fundamentally renewed understanding of its role in the regulation of neuroendocrine function, reproduction, gastroduodenal mucosa defense, and metabolism of bone[23]. Indeed, changes in plasma leptin concentrations or in leptin action have important and wide-ranging physiological implications.

Recently, mounting evidence has advocated leptin to have a regulatory function in immunity similar to the function of a pro-inflammatory cytokine. Several studies have found that circulating leptin levels increase during infection and inflammation, suggesting that leptin is part of the immune response and host defense mechanisms. Leptin levels are acutely increased by many acute phase factors, such as tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6, and during bacterial infection, or lipopolysaccharide (LPS) challenge[24]. Leptin acts on monocytes/macrophages by inducing eicosanoid synthesis, nitric oxide and several pro-inflammatory cytokines. Moreover, leptin induces chemotaxis of neutrophils and the release of oxygen radicals. The role of leptin in the innate and adaptive immune responses has also been reviewed recently[25].

LEPTIN RECEPTOR AND ITS SIGNALING PATHWAY

The leptin receptor (OBR), belongs to the class I cytokine

receptor family (which includes receptors for IL-6, IL-12 and prolactin), and exists in at least six alternatively spliced forms with cytoplasmic domains of different length, known as OBRa, OBRb, OBRc, OBRd, OBRe and OBRf. These receptors are membrane-spanning glycoproteins with fibronectin type Ⅲ domains in the extracellular region and with a shared 200-amino-acid module containing four conserved cysteine residues and two membrane proximal cytokine-like binding motifs, Trp-Ser-Xaa-Trp-Ser[26]. Only the long form of the leptin receptor can signal intracellularly, whereas the short forms do not[27]. The short forms of the leptin receptor are expressed by several non-immune tissues and seem to mediate the transport and degradation of leptin. The long form of OBR, known as OBRb, is expressed by the central nervous system in areas that are responsible for the secretion of neuropeptides and neurotransmitters that regulate appetite, body weight and energy homeostasis[28]. Interestingly, OBRb is also expressed by endothelial cells, pancreatic β-cells, the ovary, CD34+ hematopoietic bone-marrow precursors, monocytes/macrophages, and T and B cells[25].

After binding leptin, OBRb initiates a cascade of signaling events. Foremost, the receptor-associated Janus-family tyrosine kinase 2 becomes activated by auto- or cross-phosphorylation, and subsequently tyrosine phosphorylates the cytoplasmic domain of the receptor[29]. At least three phosphorylated tyrosine residues in the cytoplasmic domain of OBRb function as docking sites for cytoplasmic adaptors: Tyr_{985}, Tyr_{1077} and Tyr_{1138}. Each of these phosphorylation sites lies in a unique amino acid motif, and each of these residues thus recruits a distinct set of downstream signaling proteins when phosphorylated.

In cultured cells, phosphorylated Tyr985 recruits the SRC homology 2 domain-containing phosphatase 2 to mediate the first step in the activation of the extracellular signal regulated kinase cascade[30]. Phosphorylated Tyr1138 recruits the signal transducer and activator of transcription-3 (STAT3), a latent transcription factor that then becomes phosphorylated, translocates to the nucleus, and mediates the regulation of gene expression[31]. Tyr1138→STAT3 signaling promotes the expression of SOCS3, as the afferent arm of a feedback loop that attenuates OBRb signaling[32]. The phosphorylation of Tyr1077 promotes the recruitment, tyrosine phosphorylation and transcriptional activation of STAT5, although Tyr1138 may also play a minor role in the regulation of STAT5 phosphorylation[33].

LEPTIN AND MS

Obesity, particularly abdominal obesity, is associated with resistance to the effects of insulin on peripheral glucose and fatty acid utilization, often leading to type 2 diabetes mellitus. Insulin resistance, the associated hyperinsulinemia and hyperglycemia, and the production of adipokines may lead to vascular endothelial dysfunction, an abnormal lipid profile, hypertension, and vascular inflammation, all of which promote the development of atherosclerotic cardiovascular disease (CVD). Therefore, the co-occurrence of metabolic risk factors for both type 2 diabetes and CVD (abdominal obesity, hyperglycemia, dyslipidemia, and hypertension) suggests the existence of a "MS"[34].

A study by Zimmet *et al*[35] reported the association of leptin with fasting insulin in several populations, raising the possibility that hyperleptinemia was an additional component of the MS, or perhaps even underlay the syndrome. Subsequent study also found that leptin was strongly, positively correlated with BMI, fasting insulin, and mean blood pressure after adjusting for age and sex irrespective of glucose tolerance status. Linear regression models indicated that leptin was associated with insulin sensitivity independent of age, BMI, waist/hip ratio, triglycerides, HDL cholesterol, and hypertension[36]. The associations between leptin and components of the MS (insulin, blood pressure, triglycerides), independent of obesity measures, suggest that leptin is more than a mere "iostat" or indicator of obesity. Thus, hyperleptinemia or leptin resistance may also be an important etiological component of the MS, either directly or *via* its influence in regulating insulin sensitivity.

ESTABLISHED RISK FACTORS OF HCC AND THEIR POTENTIAL LINKS TO LEPTIN

The established risk factors for HCC include HBV or HCV infection, alcohol intake, tobacco smoking, and aflatoxins. Their respective hepatocarcinogenesis and potential relationship with leptin will be reviewed in this section.

Chronic hepatitis B

To date, two major HBV-specific mechanisms have been indicated to contribute to HCC development. The first is the integration of the viral genome into the host chromosome causing cis-effects, resulting in loss of tumor suppressor gene functions, and/or activation of tumor-promoting genes[37]. The second mechanism involves the expression of trans-activating factors derived from the HBV genome, which have the potential to influence intracellular signal transduction pathways and alter host gene expression. A major player involved in this form of viral transactivation is the X protein (HBx). The HBx protein has been found to display pleiotropic functions and has been implicated in the malignant transformation of chronically-infected liver cells. By disrupting cellular gene expression, viral products such as HBx may modulate cellular growth, repair and death, consequently resulting in the transformation of hepatocytes to an oncogenic state[37,38].

Recent clinical data, which investigated serum leptin concentrations in patients with chronic viral hepatitis, indicated that cirrhotic patients due to HBV infection had significantly higher leptin levels compared to the controls, and serum leptin levels were associated with the stage of liver fibrosis. In addition, it was suggested that increased serum leptin levels might represent a negative prognostic factor for response to lamivudine monotherapy in patients

with chronic hepatitis B[39]. Another report, which evaluated the expression of leptin and ObR in patients with chronic viral hepatitis, found that the HBV patients expressed significantly lower ObR mRNA levels in peripheral blood mononuclear cells and had decreased serum leptin levels in comparison to the healthy controls. This implied involvement of the leptin system in the immunopathology of chronic viral hepatitis[40].

Chronic hepatitis C

Chronic HCV infection is characterized by inflammatory lesions in the liver, often accompanied by intrahepatic lipid accumulation (steatosis) and progressive fibrosis of variable degree, and long-term progression to cirrhosis and HCC[41]. The mechanisms underlying the progression of HCV infection to HCC still remain ill-defined. Unlike HBV, HCV does not integrate into its host genome and has a predominantly cytoplasmic life cycle[42]. Hepatocarcinogenesis of HCV, therefore, must involve several indirect mechanisms including the interplay between chronic inflammation, steatosis, fibrosis and oxidative stress and their pathological consequences. For example, the accumulation of oxidative stress and DNA damage in a setting of restricted cell cycle checkpoint control and/or accelerated cell division is thought to compromise gene and chromosome stability and to form the genomic basis for malignant transformation. Markers of intracellular oxidative stress have also been found to be increased in patients with chronic HCV infection as well as HCV core transgenic mice[43]. In addition, several HCV proteins have been shown to have direct oncogenic effects and to upregulate mitogenic processes[44]. In fact, direct interactions of the various HCV proteins with host cell factors have also been shown to lead to changes in cellular signaling cascades involved in regulation of cell metabolism and division and seem to be sufficient to induce hepatocarcinogenesis. Overall, it is thought that the synergism between chronic inflammation and direct virus-host cell interactions triggers the malignant transformation of hepatocytes. The requirement for such a synergism would also explain the slow "multi-step" transformation process that underlies human HCC development[45,46].

A previous study has demonstrated that chronic HCV infection could induce abnormal lipid accumulation in the liver[41]. Therefore, the association of leptin with this metabolic disorder has been reviewed. Some authors showed the link between leptin and obesity as well as hepatic steatosis development in patients with chronic HCV infection, however, this observation was not found in another report[47,48]. Likewise, higher leptin levels were shown to be associated with cirrhosis development due to chronic HCV infection[39], but not with their histological features[49]. These controversial results regarding the association of leptin with chronic HCV hepatitis needs further investigation.

Alcohol consumption

Chronic alcohol consumption has long been associated with the development of hepatic cirrhosis and subsequent HCC. Many deleterious effects of alcohol have been attributed to alcohol metabolism in hepatocytes. In general, alcohol is almost metabolized by alcohol dehydrogenase (ADH) located in the cytoplasm of hepatocytes. Acetaldehyde, which forms *via* ADH-dependent alcohol metabolism, is clearly of great significance during the initiation and progression of alcohol-related liver disease. It is said that acetaldehyde can alter the integrity of DNA in a variety of ways[50]. Chronic alcohol consumption can alter the balance of bacterial flora within the GI tract and the permeability to LPS[51]. The vascular architecture linking the GI tract to the liver, thus, leads to increased intrahepatic LPS levels and the stimulation/activation of the liver's resident macrophage kupffer cell (KC) population[52]. Once activated, KCs synthesize and release a range of proinflammatory cytokines, which can act in both an autocrine and paracrine manner to further activate KCs or neighboring cell populations[53,54]. The activation of KCs and associated cytokine release may affect hepatic responsiveness to alcohol in several different ways. For example, hepatic stellate cells (HSCs) can undergo rapid activation in the presence of hepatic insult including increases in proinflammatory cytokines, oxidative stress, and/or levels of hepatotoxins[55]. A central mechanism underlying ethanol-induced activation of HSCs is dependent on the generation of reactive oxygen species[56].

As mentioned above, chronic alcohol consumption activates KCs and subsequently releases a number of proinflammatory cytokines. A study from India, investigating the effect of exogenous leptin and/or ethanol on the secretion of TNF-α, IL-6 and transforming growth factor (TGF)-β1 both *in vivo* and *in vitro*, found that leptin could downregulate ethanol-induced secretion of proinflammatory cytokines and growth factor[57]. This implies that leptin could be useful in preventing the damage produced by ethanol, which might be of therapeutic interest.

Aflatoxins

Ecological studies in the 1970s and 1980s first reported correlations between aflatoxin levels in crops or food and HCC rates[58]. Aflatoxin B1 (AFB1) is the most common and potent of the aflatoxins. In areas of high aflatoxin exposure, up to 50% of HCC patients have been shown to harbor a specific AGG to AGT point mutation in codon 249 of the TP53 tumor suppressor gene (codon 249^{ser} mutation)[59,60]. Interestingly, one prospective epidemiological study has shown a more than multiplicative interaction between HBV and aflatoxins in terms of HCC risk[61]. A number of potential mechanisms have been mentioned, for example, the fixation of AFB1-induced mutations in the presence of liver regeneration and hyperplasia induced by chronic HBV infection, and predisposition of HBV-infected hepatocytes to aflatoxin-induced DNA damage[62]. On the other hand, one recent study also suggested that aflatoxin-albumin adducts were associated with more advanced liver disease in individuals infected with HCV[63].

In addition to being a strong carcinogen, AFB1 is also

known to evoke a decrease in food intake and body weight gain. In one *in vitro* experiment, it was demonstrated that AFB1 had a weak effect on adipocytes, but no significant influence on leptin release[64]. Another animal model found that AFB1 could decrease food intake and body weight, and significantly depress serum leptin levels[65].

NAFLD: A NEW RISK FACTOR FOR HCC

NAFLD is a spectrum of disorders ranging from simple steatosis to nonalcoholic steatohepatitis (NASH) and cirrhosis. It is believed to account for up to 90% of cases of elevated liver function tests in patients without an identifiable cause of liver disease (e.g. viral hepatitis, alcohol, inherited liver disease, and medications)[66]. Given the fact that patients with NASH can enter a final cirrhotic pathway similar to that in patients with alcoholic cirrhosis or in patients suffering from chronic hepatitis B or C, it is not surprising that NASH appears to be a new risk factor for HCC[67].

A close relationship between NFLD, obesity and the MS

Obesity is found in 30%-100% of subjects with NAFLD. In obese persons, steatosis is 4.6-fold higher than in normal weight persons[66]. Clinical, epidemiological and biochemical data strongly support the concept that NAFLD is the hepatic manifestation of the MS. According to Kotronen *et al*[68], 90% of individuals with NAFLD have at least one risk factor for MS, and 33% have all the features of MS. In addition, liver fat content is significantly increased in subjects with the MS as compared with those without the syndrome, independently of age, gender, and BMI. The presence of multiple metabolic disorders such as diabetes mellitus, obesity, dyslipidemia and hypertension is associated with a potentially progressive, severe liver disease[69].

Pathogenesis of NAFLD

Insulin resistance, oxidative stress, and an inflammatory cascade are believed to play integral roles in the pathogenesis and progression of NAFLD[70]. In insulin-resistant states, adipose and muscle cells preferentially oxidize lipids, resulting in the release of FFA. FFA can then be taken up by the liver, resulting in steatosis. Animal studies show that FFA, once released from muscle and adipose cells, can be incorporated into triglycerides in the liver or undergo oxidation in mitochondria, peroxisomes or microsomes. Oxidized by-products are harmful adducts that can cause liver injury, resulting in subsequent fibrosis[71]. Lipid peroxidation and oxidative stress result in increased production of hydroxynonenal and malondialdehyde that upregulate liver fibrosis *via* activation of stellate cells and result in increased production of TGF-β[72].

Recently, scientists have focused on the role of KCs in the pathogenesis of NAFLD. KCs are the resident macrophages of the liver and function in both innate and adaptive immunity as active phagocytosing agents and antigen-presenting cells (*via* toll-like receptors, among others) to T-cells. While inactivation of KCs is associated with NAFLD and impaired hepatic regenerative capacity, elimination of resident KCs has been associated with improvement of NASH, suggesting that overactivation of a Kupffer-cell-mediated immune response might underlie liver injury in NAFLD. It is thought that KC physiology becomes altered in the setting of increased hepatic lipid content possibly due to overcrowding of liver sinusoids resulting in prolonged exposure of KCs to antigens, reduced KC outflow, and a resulting sustained inflammatory response. Uncoupling proteins, are molecules that dissipate the proton gradient in the inner mitochondrial membrane and thereby reduce the energy needed for oxidative phosphorylation. Insufficient uncoupling protein production in KCs, possibly due to LPS-induced activity, might contribute to the pathogenesis of NAFLD[73].

Leptin in the pathogenesis of NAFLD

Leptin is thought to participate in the development of NAFLD. In animal models of NAFLD, leptin contributes to the development of insulin resistance and subsequently steatosis. Furthermore, in the context of liver insult, leptin has a proinflammatory role and is considered to be an essential mediator of liver fibrosis. In rats treated with carbon tetrachloride (CCl4), leptin injections have been shown to result in the increased expression of procollagen-I, TGFβ1 and smooth muscle actin, a marker of activated HSCs, and eventually to increased liver fibrosis[74].

In human studies, leptin levels were initially found to be significantly higher in 47 NASH patients than in 47 controls and correlated with the severity of hepatic steatosis but not to necroinflammation or fibrosis[75]. A subsequent study showed that leptin levels are significantly higher in NASH patients than in patients with chronic viral hepatitis and correlate with more severe fibrosis in univariate analysis[76]. However, another study failed to show any significant difference in leptin levels between NASH patients and controls or any independent association with liver fibrosis[77]. Thus, it is doubtful whether leptin is upregulated in patients with NASH and larger studies with a homogenous population and carefully matched healthy controls are needed. For the time being, leptin cannot be used as a noninvasive marker for the diagnosis of NASH.

LEPTIN PLAYS A FIBROGENIC ROLE IN THE LIVER

The development of fibrosis, which is critical for the progression of all chronic liver diseases, comprises a series of events, including inflammation, activation of fibrogenic myofibroblasts (e.g. HSCs), deposition of fibrillar extracellular matrix, and possibly neo-angiogenesis[78]. The data on the role of leptin in the regulation of these steps have been accumulating rapidly. Several *in vivo* studies, which evaluated the effect of leptin in animal models of chronic liver injury, including dietary steatohepatitis, bile duct ligation, and infection with eggs of *Schistosoma mansoni*, provided obvious support to the role of leptin as a critical mediator of fibrosis[79-81]. Importantly, when assessing

the response of ob/ob mice, the decreased fibrogenic response was reverted by supplementation with recombinant leptin. These findings suggest that leptin is a critical factor for the development of fibrogenesis in rodents.

Different cell types have been mentioned to participate in the response of leptin to liver injury, including KCs, sinusoidal endothelial cells and myofibroblast-like cells, which are derived from the activation of HSCs and from other mesenchymal cells. Ikejima *et al*[82] demonstrated that ObRb is expressed by sinusoidal endothelial cells and KCs, where exposure to recombinant leptin up-regulates the expression of TGF-β. A number of successive studies also indicated that HSCs express functional ObRb and are directly responsive to leptin. Expression of ObRb is low in quiescent HSCs, and increases during the activation process, suggesting that in activated HSCs the effects of leptin are amplified[83]. In addition, incubation of HSCs with recombinant leptin stimulates the expression of type I procollagen, potentiates the effects of TGF-b, and up-regulates expression of the tissue inhibitor of metalloproteinase-1, thus blocking collagen degradation[84,85].

A recently identified effect of leptin on fibrogenic cells is the induction of vascular endothelial growth factor (VEGF) *via* oxygen-independent activation of hypoxia-inducible factor 1a, a master switch of the angiogenic response[86]. These observations may potentially have an impact on liver fibrosis, as formation of new blood vessels is a key component of the wound-healing response and has been suggested to play a role in the irreversibility of established cirrhosis. Together, these observations suggest the fibrogenic role of leptin in the liver.

EVIDENCE REGARDING THE ASSOCIATION OF LEPTIN WITH HCC DEVELOPMENT

Yang *et al*[87] first explored whether obesity might increase the risk for HCC, and found that ob/ob mice developed liver hyperplasia at the earliest stage of NAFLD and eventually HCC. This observation raised the intriguing issue that obesity-related fatty liver, itself, might be a premalignant condition. A number of studies have attempted to elucidate the possible effects of leptin in HCC development. Wang *et al*[88], who investigated whether leptin might be involved in the etiogenesis of HCC in cirrhotic patients, found that increased serum leptin was significantly correlated with cirrhotic change, but not with HCC occurrence. This finding was consistent with previous studies, indicating the fibrogenic effect of leptin in the liver. Another study, which evaluated the expression of leptin and its receptor in HCC specimens and adjacent non-tumorous tissues, first pointed out the involvement of leptin in the carcinogenesis of HCC[89]. However, the authors suggested further investigations should be carried out to define the inhibitory and/or activating role of leptin in the process of carcinogenesis and progression of human HCC.

A recent study found that, without leptin signaling, neither fibrosis nor HCC developed in the rat NASH experimental model, suggesting that leptin might play a pivotal role in the progression of fibrogenesis and carcinogenesis in NASH[19]. Further *in vitro* assay demonstrated the necessity of leptin-mediated neo-vascularization coordinated with VEGF in this progression. The involvement of leptin/OBR in the angiogenesis of human HCC was also shown in a recent study[90]. Notably, one *in vitro* assay demonstrated the proliferative and anti-apoptotic effects of leptin in HCC cells *via* Janus kinase 2-linked signaling[91]. Taken together, these findings implied that leptin-induced effects implicated in HCC development seemed to be inhibitory.

In fact, several studies have reported the contradictory effects of leptin in HCC growth. Elinav *et al*[92] first showed that exogenous leptin significantly decreased tumor size and improved survival rate in a murine model of HCC. The authors further demonstrated that the majority of these leptin-induced inhibitory effects might be mediated by the induction of natural killer cell proliferation and activation. Moreover, Wang *et al*[93,94], who evaluated the expression of leptin and its receptor in HCC specimens by immunostaining, further correlated the expression profile with Ki-67 expression, intratumor MVD, as well as overall survival, provided clinical evidence on the prognostic roles of leptin and OBR in HCC patients. First, OBR expression was inversely correlated with vascular invasion of HCC. Furthermore, high leptin expression was associated with better survival in patients with HCC, treated postoperatively with medroxyprogesterone acetate, a synthetic variant of human progesterone. As a result, it was suggested that both high leptin and OBR expression in HCC tissues could predict better overall survival.

CONCLUSIONS AND FUTURE DIRECTIONS

Leptin has an increasingly crucial role in a variety of human metabolic disorders and cancers. This parallels the increasing prevalence of NAFLD in patients with HCC. This work reviews the updated information on leptin, including its receptor and related signaling pathway, and provides important insight into the association between leptin and the MS and NAFLD as well as well-known risk factors for HCC. Moreover, research studies have demonstrated that leptin can exert a fibrogenic effect in the liver. In addition, evidence regarding the direct link between leptin and HCC development has been accumulating rapidly. This demonstrates the potential of the leptin-mediated effects in the carcinogenesis and progression of HCC, however, there is ample room for further research on its inhibitory and/or activating role. In addition, the role of leptin in the response of HCC to hormonal therapy deserves further research.

Abstract

Celiac disease is a mucosal disorder of the small intestine that may be triggered by dietary exposure to gluten in genetically-susceptible individuals. The disorder is often associated with diarrhea, malabsorption and weight loss along with other extra-intestinal complications. Reproductive changes have been described, including impaired fertility and adverse pregnancy outcomes possibly related to immune-mediated mechanisms or nutrient deficiency. Other possible pathogenetic factors that may alter placental function include maternal celiac disease autoantibodies binding to placental transglutaminase, and genetic mutations that may facilitate microthrombus formation. Reports noting activation during pregnancy or the puerperium may be important, and suggest that celiac disease may also be hypothetically precipitated by maternal exposure to one or more fetal antigens.

Key words: Celiac disease; Infertility; Pregnancy; Postpartum celiac disease; Fetal outcome

INTRODUCTION

Celiac disease is an immune-mediated mucosal disorder primarily affecting the small intestine in genetically-susceptible individuals[1]. It may be triggered by dietary exposure to gluten, and frequently causes chronic diarrhea, malabsorption and weight loss[1]. In some patients, extra-intestinal or autoimmune changes may occur, e.g. hepatobiliary[2], neurological[3], or endocrine disorders, such as hypothyroidism and insulin-dependent diabetes in children[4]. Of particular interest has been the effect of celiac disease and its treatment on fertility and pregnancy[5]. In recent years, there has been an increased recognition of possible changes in male and female fertility in celiac disease as well as the potential for adverse outcomes in pregnancy and the post-partum period that may lead to miscarriages and premature low birth weight fetal deliveries (Table 1).

ALTERATIONS IN FEMALE FERTILITY

Celiac disease continues to be increasingly recognized as a clinically silent disorder with limited or few intestinal symptoms, such as mild diarrhea. Often, females with reproductive disorders or pregnancy complications have no overt symptoms, or at most, fatigue associated with iron-deficiency anemia. As a result, reduced fertility in females or changes that include delayed menarche, amenorrhea and early menopause may conceivably be the initial clinical feature that ultimately results in a diagnosis of celiac disease. As serological screening has resulted in an appreciation that celiac disease may occur in up to 1%-2% of the general population, it is not surprising that this disorder is more readily detected in young women of childbearing age. Indeed, young women are still the most common

Table 1 Reproductive changes in celiac disease

Altered female fertility	Delayed onset of menarche, amenorrhea, early menopause, recurrent abortions, reduced rates of pregnancy
Altered male fertility	Gonadal dysfunction, altered sperm morphology and motility, reduced sexual activity
Alterations in pregnancy	Repeated miscarriages, premature delivery an impaired fetal growth with low birth weight, abnormal placental function
Postpartum activation of celiac disease	Hormonal or immune changes

group diagnosed with celiac disease. If changes in fertility can be documented in celiac disease, these may reflect underlying autoimmune complications of celiac disease or the negative nutritional effects of untreated disease.

Although some early case reports noted a possible association between celiac disease and infertility[6,7], systematic investigations have been limited and the precise definition of infertility *per se* may vary between studies. An extensive serological evaluation of 150 women with infertility from Finland demonstrated an apparently increased rate of celiac disease (i.e. overall rate, 2.7%)[8]. Similar results were later reported in 99 couples from Northern Sardinia (i.e. 3.03% of females)[9], and later, using more modern serological screening methods [i.e. tissue transglutaminase (tTGA), endomysial (EMA) antibodies] in 192 Arab women with unexplained infertility from Israel (i.e. 2.65%)[10]. In all three of these studies, small bowel biopsies were positive if abnormal serological screening results were present. As in most screening studies, however, biopsies in the serologically-negative screened populations were not done. Moreover, other studies have suggested that the evidence may not be quite as strong for a definite association with celiac disease. In a report from another center in Finland[11], a higher frequency of celiac disease in women with infertility or recurrent miscarriage could not be defined. A Czech study showed increased seropositivity in women with infertility, but unfortunately, biopsies were not reported[12]. Finally, in a selected Italian cohort of infertile women undergoing assisted reproduction techniques, a statistically significant result was not achieved[13].

Delayed onset of menarche, amenorrhea, early menopause, recurrent abortions and reduced rates of pregnancy in celiac disease may reflect an impairment of fertility. In 74 celiac patients from the United Kingdom[5], the reproductive period was longer for those on a gluten-free diet compared to those not on a diet but maternal health was not seriously impaired. A lower incidence of spontaneous abortions in celiacs on a gluten-free diet was also recorded. Similar results were reported in an Italian study[14]. In consecutively diagnosed celiacs compared to age- and "sexual behavior"-matched healthy controls, there was a significant delay in the mean age of menarche in untreated celiac patients (13.5 years compared to 12.1 years). Amenorrhea and repeated abortions were more common in the celiac group, but onset of menopause did not significantly differ. Studies from Poland and Italy[15,16] also evaluated menarcheal age of celiac girls with reference to maternal menarcheal age. In one[15], menarcheal age of celiac girls appeared to be regulated by a gluten-free diet, while in the other[16], menarcheal age in celiac disease was not delayed, but was affected by maternal menarcheal age. A further evaluation from the United Kingdom[17] suggested that celiacs are subfertile with an increased incidence of stillbirths and perinatal deaths. However, after diagnosis of celiac disease and treatment with a gluten-free diet, some markers of infertility (e.g. miscarriage rates) may be corrected. Finally, in a study from Brazil[18], adherence to a gluten-free diet and resultant nutritional status was emphasized as an important and relevant factor in reproductive disorders developing in untreated celiac disease.

Nutritional studies in celiac disease during pregnancy are very limited. For example, zinc, selenium and folic acid deficiency have been noted in some studies[19-21], but most of these have been completed in children so that these studies do not appear to offer a definitive explanation for altered fertility in women during their reproductive years with untreated disease. Others have offered contradictory data in untreated celiac disease: reduced vitamins and trace elements were not evident, or significant malnutrition was not present[7-10]. In another report, evidence of poor vitamin status in celiacs despite a gluten free diet was reported[22], but this was contradicted by a detailed and more recent and important evaluation that documented histological recovery[23]. An alternative mechanism for reduced fertility may be immune-mediated, possibly by compromising placental function[24].

Clearly, further studies are needed to precisely define the role of altered absorption and resultant nutritional changes on female fertility in untreated celiac disease as well as the effects of a gluten-free diet, especially with restoration of normal nutritional status. In addition, immune-mediated changes in placental function need to be explored in celiac disease.

ALTERATIONS IN MALE FERTILITY

Studies estimating prevalence of male infertility in celiac disease have been rare. In an infertile couples study from Northern Sardinia[9], a single male out of 99 (or about 1%) tested positive for celiac antibodies, including EMA. Later the typical small bowel biopsy findings of untreated celiac disease were detected. Although the prevalence in a comparable control population was not provided, it is likely that an effective evaluation for infertility in a couple would best include assessment of both sexes for underlying celiac disease.

Early studies from the United Kingdom on male gonadal dysfunction described a reversible state of androgen resistance in celiac disease[25]. Later, in a further series of studies[26-29] on male gonadal function, consecutive males with celiac disease were evaluated and compared to males of similar age and nutritional status with Crohn's disease. Almost 20% of married celiacs had infertile marriages[26]. Semen analysis revealed marked abnormalities in sperm morphology and motility, similar to Crohn's disease, with sperm morphology apparently improving following removal of dietary gluten[26]. Others reported the presence

of oligospermia[27]. Specific nutrient deficiencies and detection of anti-sperm antibodies did not appear to be a factor in male infertility[26]. Plasma hormone levels were also determined[28]. Plasma testosterone and free testosterone index were increased while dihydrotestosterone was reduced. These hormone levels appeared to normalize, with an improved small bowel architecture on a gluten-free diet. Serum luteinizing hormone was also raised and interpreted to reflect androgen resistance. These endocrine changes, suggestive of androgen resistance and hypothalamic-pituitary dysfunction, were interpreted to be relatively specific to celiac disease, but an association with disordered spermatogenesis was not determined[28]. Further studies of gonadotropins were also performed[29]. Exaggerated gonadotrophin responses were apparently unrelated to plasma concentrations of testosterone, dihydrotestosterone, estradiol or the free testosterone index. Elevated prolactin levels were also noted but these were not related to impotence or infertility. These studies that suggested deranged pituitary regulation of gonadal function in celiac disease in males were hypothesized to be part of a wider disturbance of central regulatory mechanisms of endocrine function in celiac disease. Interestingly, less significant, but similar alterations in male sex hormone status occur in dermatitis herpetiformis[30], a skin disorder closely linked to celiac disease. These changes possibly also reflect, in part, the recognition of an autoimmune pituitary process associated with celiac disease and reported to be directly associated with an impairment in linear growth[31].

As many of these studies appeared almost three decades ago, it is striking that very little additional new, even descriptive, information on male infertility in celiac disease has appeared. However, two more recent Italian publications have explored sexual behavior[32,33]. In one study, sexual behaviors in treated and untreated celiac disease patients were examined using a questionnaire and compared to healthy controls[32]. Sexual satisfaction, including frequency of intercourse, was reduced in celiac patients, but improved after a year of treatment with a gluten-free diet. In the other[33], sexual habits appeared to be very different in celiacs who were never treated with a gluten-free diet.

ALTERATIONS IN PREGNANCY

Celiac disease, especially if untreated, appears to increase the risk of repeated miscarriages and premature deliveries, and impaired fetal growth with reduced birthweight[34]. In addition, adverse effects on the mother may also occur, as indicated by a recent German study which demonstrated that the rate of cesarean delivery was increased if the parents had celiac disease compared to other digestive disease controls as well as controls from eye or dental outpatient clinics[35].

In a case-control study from Italy that evaluated 94 untreated and 31 treated celiacs, the relative risks of either abortion or delivering a low birthweight baby were increased while the duration of breast feeding was significantly reduced[36]. All of these changes were apparently corrected with a gluten-free diet[36]. Higher incidences of either miscarriages or spontaneous abortions were also recorded from other centers located in different countries including Argentina, Italy and the United Kingdom[5,14,17,37].

Reduced birthweight and intrauterine growth retardation have also been recorded in several other studies from different European centers[38-41]. In one of these studies from Italy[39], the investigators also noted that celiac disease was a more common disorder than most of the diseases normally screened for in pregnant women in their healthcare facility. In another of these studies[40], undiagnosed maternal celiac disease appeared to be a far greater risk factor than diagnosed celiac disease, but in a subsequent report, undiagnosed celiac disease was not associated with an unfavorable outcome of pregnancy[42]. Other studies noted that paternal celiac disease did not appear to be a risk for an adverse pregnancy outcome[43,44].

Mechanisms involved in the impairment of pregnancy outcome in celiac disease have been explored to a limited degree. The placentas in mothers affected with celiac disease appear to be abnormal. In particular, tTG expression and apoptosis were reported to be increased in trophoblast cells using immunohistochemical analysis and *in situ* hybridization methods, suggesting a possible mechanism of injury in both the fetal and maternal parts of the placenta[45]. Others have noted that maternal celiac disease autoantibodies bind directly to the syncytiotrophoblast and inhibit placental tissue transglutaminase activity suggesting a possible mechanism for compromised placental function[24]. Furthermore, recent studies in celiac women on the role of genetic prothrombin variants in early pregnancy loss suggested that the 4G variant of the plasminogen activator inhibitor-1 gene may predispose to miscarriage[46]. Early pregnancy loss could conceivably relate to some alteration in coagulation affecting placental or fetal microvascular function. Additional studies are needed to further explore and elucidate these mechanisms.

FURTHER CONCLUDING ISSUES

Interestingly, delivery of a preterm infant has been conversely linked to later definition of underlying celiac disease in the parent, particularly underlying maternal celiac disease. In 905 preterm infants born in Lombardy, Italy, 1714 parents (868 women, 846 men) were screened for celiac disease using EMA and tTGA (followed by duodenal biopsy confirmation). In these, a higher prevalence of celiac disease in mothers of low birthweight infants was defined[47]. Thus, selective screening for celiac disease may be useful. However, the potential value and cost-effectiveness of screening for celiac disease in all women of reproductive age has not been fully determined.

Also intriguing is the repeated, but uncommon, definition of underlying maternal celiac disease following delivery in the puerperium[48-51]. Activation of celiac disease during the puerperium has been hypothesized to be related to immunologic or hormonal factors, or both[48]. Occasionally, anemia is evident during the prior pregnancy[49] or the presentation may be acute[50] leading to speculation

that activation of celiac disease may result from maternal exposure to fetal antigens[50]. In addition, presentation of underlying celiac disease may not be evident during an initial pregnancy, but may only appear after a second or later pregnancy[51]. Additional studies that explore the specific immunological changes occurring during the post-partum period may shed additional light on immune-mediated changes that occur in unrecognized celiac disease.

Toll-like receptor 9 gene mutations and polymorphisms in Japanese ulcerative colitis patients. *World J Gastroenterol* 2010; 16(46): 5815-5821 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i46/5815.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i46.5815

Abstract

AIM: To investigated gene mutations and polymorphisms of *TLR9* in Japanese ulcerative colitis (UC) patients.

METHODS: Three single nucleotide polymorphisms (SNPs) in *TLR9* were identified in healthy controls, and were assessed in 48 UC patients and 47 healthy controls. Control subjects were matched for age, sex and date of blood sampling from among a subgroup of participants.

RESULTS: *TLR9* -1486CC, 1174GG and 2848AA increase the risk of UC [odds ratio (OR) 2.64, 95% confidence interval (95% CI): 1.73-6.53, P = 0.042], and *TLR9* -1486TT, 1174AA and 2848GG decrease the risk of UC (OR 0.30, 95% CI: 0.10-0.94, P = 0.039), although there were no correlations between SNPs and disease phenotype or *TLR9* mRNA expression.

CONCLUSION: *TLR9* polymorphisms are associated with increased susceptibility to UC.

INTRODUCTION

Inflammatory bowel diseases (IBDs), which include ulcerative colitis (UC) and Crohn's disease (CD), are chronic inflammatory disorders of the digestive tract. Although the pathogenesis of IBDs is complex and remains unclear, it has been suggested that immunologic, environmental and genetic factors contribute to their etiology[1]. Both clinical studies of IBD and studies of animal colitis models implicate luminal bacteria as necessary for initiating and perpetuating intestinal inflammation[2,3].

Among several candidate IBD-related chromosomal regions and genes, the caspase recruitment domain 15 (*CARD15*) gene coding for the nucleotide oligomerization domain 2 (*NOD2*) gene was identified as having the strongest linkage for CD susceptibility[4,5]. *NOD2/CARD15* is an intracytoplasmic receptor that binds bacterial peptidoglycan-derived muramyl dipeptide. While three common variants of this gene (R702W, G908R and L1007fsinsC) have been reported in CD patients in Western countries, there were no variants found in Japanese patients[6].

Similarly to NOD2, Toll-like receptors (TLRs) are essential components of innate immunity that recognize microbial compounds from bacteria, fungi and viruses[7-9]. While TLR activation leads to transcription of inflammatory and immunoregulatory genes, recent studies have demonstrated that TLR signaling in intestinal sites can inhibit inflammatory responses and maintain colonic homeostasis[10-12]. *TLR9*, which recognizes unmethylated CpG DNA in bacteria and viruses[13,14], and its signaling pathway protect mice from experimental colitis through production of type I interferons (IFN)[15]. Therefore, we need to know whether *TLR9* is a protective molecule not only in a mouse model but also in human IBD.

As the relationships between UC and *TLR9* gene variation have not been reported to date, we focused on *TLR9* gene mutations or polymorphisms in UC. Our results demonstrate that *TLR9* genetic polymorphisms are associated with an increased risk of UC in the Japanese population.

MATERIALS AND METHODS

Human subjects

After obtaining written informed consent based on the Declaration of Helsinki of the World Medical Association, 48 UC patients and 47 healthy controls were enrolled in this study. All subjects were Japanese, and visited our hospital between December 2005 and January 2007. UC diagnoses were confirmed by review of medical charts by clinicians. Standard clinical, endoscopic and histological criteria were used[16-18]. The following clinical characteristics were analyzed: sex, age at diagnosis, disease location and disease severity. Control subjects were matched for age, sex and date of blood sampling from a subgroup of participants who were healthy volunteers, free from IBD and malignant tumors. Clinical characteristics of these subjects are shown in Table 1. This study was approved by the Ethics Committee of Fukushima Medical University.

Quantitative real-time reverse transcription-polymerase chain reaction

Peripheral blood mononuclear cells (PBMC) from UC patients and healthy controls were isolated from heparinized blood by Ficoll Paque density-gradient centrifugation (Lymphoprep, Axis-Shield PoC AS, Oslo, Norway). Total cellular RNA was extracted from isolated PBMC using TRIzol® Reagent (Invitrogen, Carlsbad, CA, USA).

cDNA was generated by using the HotStarTaq Master Mix Kit (QIAGEN GmbH, Hilden, Germany). Quantitative real-time reverse transcriptase-polymerase chain reaction (RT-PCR) was performed using a TaqMan® fast universal PCR master mix (Applied Biosystems, Foster City, CA, USA) and on-demand gene-specific primers, assessed using StepOne™ real time PCR system (Applied Biosystems). The primers were as follows: *TLR9* (Hs00370913_s1) and *GAPDH* (Hs02786624_g1). Both primers were purchased from Applied Biosystems. Relative quantification was achieved by normalizing to the values of the *GAPDH* gene.

SNP discovery

Genomic DNA from UC patients and healthy controls was extracted from heparinized whole blood samples using the PUREGENE® DNA purification kit (Gentra Systems, Minneapolis, MN, USA).

All exons, introns and approximately 1500 bases of the 5'-flanking region and 1500 bases of the 3'-flanking region of the *TLR9* gene were amplified from the genomic DNA of one healthy control. The genomic sequences were based on the GenBank reference sequence NM_017442 and AC097637.2 for *TLR9*. The subject was selected at random. Thirteen *TLR9* gene segments were amplified by PCR with the primer pairs shown in Table 2, *Taq* DNA polymerase (QIAGEN GmbH, Hilden, Germany) and genomic DNA from a healthy control as a template. Amplified products were purified using the GFX™ PCR DNA and Gel Band Purification Kit (Amersham Biosciences UK Limited, Buckinghamshire, UK), and were subjected to direct sequencing with the GenomeLab™ DTCS-Quick Start Kit (Beckman Coulter, Fullerton, CA, USA) on a CEQ2000 DNA Sequencer (Beckman Coulter). SNP offsets were calculated relative to the A base of the *TLR9* ATG start codon, such that SNPs in the promoter region upstream of the first intron have negative position numbers.

Genotyping

Three common SNPs (-1486T/C, 1174A/G, 2848G/A) were analyzed for genotyping. The -1486T/C SNP was genotyped by restriction fragment length polymorphism (RFLP). Briefly, genomic DNA fragments containing -1486T/C SNP were amplified by PCR. PCR products were digested with the restriction enzyme Afl II (TAKARA SHUZO Co., Ltd., Shiga, Japan), run on a 3% aga-

rose gel and subsequently stained with ethidium bromide to visualize the bands. The other two SNPs (1174A/G and 2848G/A) were confirmed by direct sequencing. The primers used for PCR or sequencing are shown in Table 2.

Statistical analysis

Statistical analyses were performed using SPSS version 11.0.1 and SNPAlyze version 6.0 (Dynacom Co., Ltd. Yokohama, Japan). Cases and controls were compared using Fisher's exact test (Tables 3-6) for categorical items. Simple logistic regression models were used to analyze Genotype-Diplotype associations. The results are expressed as odds ratio (OR) with corresponding 95% confidence intervals (95% CI). The level of significance was set at 5%. We examined Lewontin's D' (|D'|) and the linkage disequilibrium coefficient r^2 between each pair of SNPs using the expectation-maximization (EM) algorithm in SNPAlyze software.

RESULTS

TLR9 mRNA expression

In order to confirm whether there were differences in *TLR9* expression, we performed quantitative RT-PCR of *TLR9* using PBMC from UC patients and healthy controls. There were no significant differences in *TLR9* mRNA expression (Figure 1).

SNPs and their allele frequencies

We sequenced both exons and approximately 1500 bases of the 5'- and 3'-regions of *TLR9* in one healthy control. Offsets for each SNP were calculated relative to the transcription start site of *TLR9* mRNA (GenBank Accession No. NM_017442). We identified three SNPs in the regions sequenced. Their locations in chromosome 3 and in the *TLR9* gene are illustrated in Figure 2. These SNPs were confirmed in dbSNP (http://www.ncbi.nlm.nih.gov/SNP/) and JSNP (http://snp.ims.u-tokyo.ac.jp/index_ja.html). The remainder of the analysis will focus on these three relatively common SNPs.

We found a marginally significant association between the SNPs at -1486, 1174, 2848 and UC. Elevated risk for UC was associated with a C allele at -1486 (Fisher's exact test, P = 0.013), a G allele at 1174 (Fisher's exact test, P = 0.013), and an A allele at 2848 (Fisher's exact test, P = 0.013) (Table 3).

Table 4 Genotype frequencies in ulcerative colitis cases and disease-free controls for *Toll-like receptor 9* single nucleotide polymorphisms at -1486, 1174, 2848 *n* (%)

Genotype at *TLR9*		UC (*n* = 48)	Controls (*n* = 47)
-1486	CC	20 (41.7)[a]	10 (21.3)
	CT	23 (47.9)	24 (51.1)
	TT	5 (10.4)[a]	13 (27.7)

Diplotype			UC (*n* = 48)	Controls (*n* = 47)
-1486	1174	2848		
CC	GG	AA	19 (39.6)[a]	9 (19.1)
CC	GG	AG	1 (2.1)	1 (2.1)
CT	GA	AG	23 (47.9)	24 (51.1)
TT	AA	GG	5 (10.4)[a]	13 (27.7)
				[a]$P < 0.05$

[a]P value by Fisher's exact test, ulcerative colitis (UC) cases *vs* controls.

Genotype frequencies

We then analyzed genotype frequencies between UC patients and healthy controls. As shown in Table 4, a pattern of increased prevalence of CC genotypes at -1486 (Fisher's exact test, $P = 0.047$), GG genotypes at 1174 (Fisher's exact test, $P = 0.047$), AA genotypes at 2848 (Fisher's exact test, $P = 0.042$), and a decreased prevalence of TT at -1486 (Fisher's exact test, $P = 0.039$), AA genotypes at 1174 (Fisher's exact test, $P = 0.039$), GG genotypes at 2848 (Fisher's exact test, $P = 0.039$) was observed in UC patients, as compared with controls.

Pairwise linkage disequilibrium and estimation of haplotypes

We observed absolutely identical allele frequencies for the three common SNPs. Table 7 shows that three SNPs are in strong linkage disequilibrium (LD) in both UC patients and healthy controls. We also inferred three SNP haplotypes by using an expectation-maximization algorithm. The number of statistically inferred haplotypes is eight (i.e. 2^3). A total of three of the eight possible haplotypes are observed in Table 5. The usage of haplotype C-G-A was more frequent in UC patients when compared with healthy controls, and the difference was statistically significant. (Fisher's exact test, $P = 0.013$, Table 5).

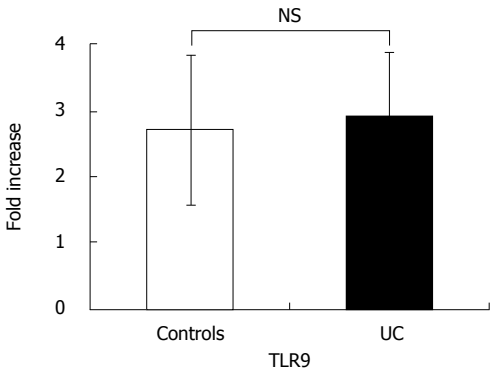

Figure 1 *Toll-like receptor 9* mRNA expression in peripheral blood mononuclear cells from ulcerative colitis patients and controls. Total RNA was prepared from peripheral blood mononuclear cells and Toll-like receptor 9 (TLR9) mRNA expression was analyzed by quantitative reverse transcriptase-polymerase chain reaction. There were no significant differences between ulcerative colitis (UC) patients and controls. NS: No significance.

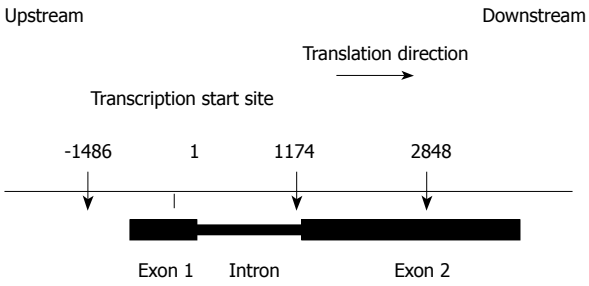

Figure 2 Gene structure and location of identified *Toll-like receptor 9* single nucleotide polymorphisms. We sequenced both exons and approximately 1500 bases of the 5'- and 3'-regions of *Toll-like receptor 9* in one healthy control. We identified three single nucleotide polymorphisms (-1486, 1174, 2848) in the regions sequenced.

Table 7 Linkage disequilibrium among single nucleotide polymorphisms of *Toll-like receptor 9* in ulcerative colitis cases and disease-free controls

SNPs		UC (*n* = 48)		Controls (*n* = 47)	
		|D′|	r^2	|D′|	r^2
-1486 T/C	1174 A/G	1	1	1	1
-1486 T/C	2848 G/A	1	0.9522	1	0.9581
1174 A/G	2848 G/A	1	0.9522	1	0.9581

Lewontin's D′ (|D′|) and the linkage disequilibrium coefficient r^2 between each pair of single nucleotide polymorphisms (SNPs) were examined by the expectation-maximization algorithm of SNPAlyze software. UC: Ulcerative colitis.

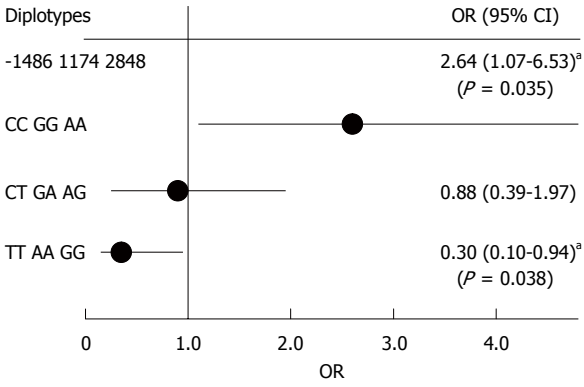

Figure 3 ***Toll-like receptor 9*** **gene diplotypes and disease sensitivity (expressed as odds ratios).** There was an increased risk of ulcerative colitis with the CCGGAA diplotype, and a decreased risk with the TTAAGG diplotype, as compared with controls. OR: Odds ratio; CI: Confidence interval. $^aP < 0.05$.

Diplotype frequencies

We next analyzed diplotype frequencies as pairs of haplotypes. Table 6 shows the distribution of three diplotype loci by disease status; an increased prevalence of CCGGAA diplotypes (Fisher's exact test, $P = 0.042$) and a decreased prevalence of TTAAGG diplotypes (Fisher's exact test, $P = 0.039$) was noted among UC cases, as compared with controls. Thus, we found an increased UC risk among CCGGAA diplotypes (OR 2.64, 95% CI: 1.73-6.53, $P = 0.042$) and a decreased UC risk among TTAAGG diplotypes (OR 0.30, 95% CI: 0.10-0.94, $P = 0.039$) (Figure 3). These data suggest that CCGGAA diplotypes are more susceptible to UC.

Genetic association with clinical phenotypes

In order to further examine the contribution of genetic variations in *TLR9* to UC phenotypes, we analyzed various clinical characteristics among UC patients: sex, age at diagnosis, disease location and disease severity. However, we did not observe any statistically significant correlations between disease status and diplotype, genotype or specific *TLR9* allele.

DISCUSSION

In this study, we found that genetic variations of *TLR9* are associated with an increased risk of UC in the Japanese population. *TLR9*, which is activated by unmethylated CpG DNA, triggers innate immune responses[19,20]. Although no variants have been found in Japanese patients, the *NOD2/CARD15* gene was found to indicate CD susceptibility in Western populations[5,6], suggesting that abnormal innate immune responses toward luminal bacteria are involved in pathogenesis of IBD. With regard to TLRs, previous reports have indicated that *TLR4* Asp299Gly polymorphism is associated with CD and UC in Caucasian populations[21]. Török *et al*[22] investigated possible associations between genetic variations in *TLR9* and IBD in the German population, but did not detect any associations between *TLR9* gene variations and UC susceptibility. Thus, as UC is a heterogeneous polygenic disease, association studies are expected to reveal various sets of susceptibility genes depending on the ethnic background of the study populations. Further genetic studies in different ethnic groups will resolve the role of the TLRs in UC susceptibility.

Associations between TLR9 and several autoimmune diseases or infectious diseases have been studied[23-26]. These reports have suggested that the -1237T/C SNP in *TLR9* is associated with an increased risk of allergic asthma[27], while 2848G/A was associated with myocardial infarction, deep vein thrombosis and chronic obstructive pulmonary disease[27], and 1635A/G was associated with HIV phenotype[28]. In addition, there were no associations between *TLR9* gene polymorphisms and susceptibility to systemic lupus erythematosus (SLE) and related phenotypes in Caucasian American subjects[23], but such an association was observed in a Japanese population[24]. These observations show that several candidate genes showing initial positive associations have generated negative findings in replication studies due to issues related to insufficient power or sample heterogeneity.

In this study, although relatively low numbers of subjects were enrolled, we observed statistically significant differences. According to the statistical methods used in this research, statistical differences in a category that has more than one subject indicate a reliable result. Moreover, we can expect to obtain the same results if more samples are added to the experiment. Therefore, we did not increase the power of this study, although more studies with large cohorts are necessary to characterize the role of *TLR9* SNPs in the etiology of UC.

We demonstrated that a C allele at -1486 (located in promoter region), a G allele at 1174 (located in intron 1) and an A allele at 2848 are associated with an increased risk of UC. SNPs in promoter regions potentially affect gene expression levels by altering the binding of gene transcription factors and SNPs in introns, thereby affecting mRNA splicing and/or enhancement of gene transcription. We were unable to identify down-regulation in *TLR9* expression in UC patients. Evaluating the relationship between the *TLR9* polymorphism and predefined clinical characteristics or biological markers also failed to demonstrate any impact on a particular UC phenotype. Taken together, these results indicate that *TLR9* polymorphism is associated with the development of disease itself, which is probably based on functional impairment of *TLR9*.

A recent study suggested that TLR9-triggered type-1 IFN protects mice from experimental colitis[15]. It also underscores the important protective role of type-1 IFN in intestinal homeostasis, suggesting that type-1 IFN produced by *TLR9* signaling affects the pathogenesis of IBD. Although further experiments are needed in order to identify the functional roles of *TLR9* polymorphism, either downstream molecules of the *TLR9* signaling pathway or cytokine production participating in the development of IBD is expected to be affected by these gene polymorphisms.

In conclusion, we identified an association between *TLR9* polymorphisms and UC in Japanese patients. Our findings indicate the importance of *TLR9* in the genetic

control of reactions to intestinal microbes in UC. Studying SNPs among the molecules involved in bacterial recognition will be essential to understanding the individual responses to bacterial components and to define the genetic background associated with risk of IBD.

COMMENTS

Background

The pathogenesis of inflammatory bowel diseases (IBDs), which include ulcerative colitis (UC) and Crohn's disease (CD), is multi-factorial, involving susceptibility genes as well as immunological and environmental factors. Recent studies on IBD have provided some evidence that commensal bacteria play a key role in the pathogenesis of the disease, and that the Toll-like receptor (TLR) signaling pathway activated by commensal bacteria plays an important role in maintaining colonic homeostasis. The signaling pathway of *TLR9*, which recognizes unmethylated CpG DNA in bacteria and viruses, protects mice from experimental colitis. As the relationships between UC and *TLR9* gene variation have not been reported to date, in this report we focused on *TLR9* gene mutations or polymorphisms in UC.

Research frontiers

Among several candidate IBD-related chromosomal regions and genes, the caspase recruitment domain 15 (*CARD15*) gene coding for the nucleotide oligomerization domain 2 (*NOD2*) gene was identified as having the strongest linkage for CD susceptibility. Similarly to NOD2, TLRs are essential components of innate immunity that recognize microbial compounds from bacteria, fungi and viruses. While TLR activation leads to transcription of inflammatory and immunoregulatory genes, recent studies have demonstrated that TLR signaling in intestinal sites can inhibit inflammatory responses and maintain colonic homeostasis. A gene variation in *NOD2/CARD15* has been reported in CD patients in Western countries, but this variation has not been identified in Japanese CD patients.

Innovations and breakthroughs

As the relationships between UC and *TLR9* gene variation have not been reported to date, in this report we focused on *TLR9* gene mutations or polymorphisms in UC. Three single nucleotide polymorphisms (SNPs) in *TLR9* were identified in healthy controls, and were assessed in 48 UC patients. The authors found that *TLR9* -1486CC, 1174GG and 2848AA increase the risk of UC, and *TLR9* -1486TT, 1174AA and 2848GG decrease the risk of UC.

Applications

The authors' findings indicate the importance of *TLR9* in the genetic control of reactions to intestinal microbes in UC. Studying SNPs among the molecules involved in bacterial recognition will be essential to understanding the individual responses to bacterial components and to define the genetic background associated with risk of IBD.

Terminology

TLR9 is a mammalian Toll-like receptor homologue that appears to function as an innate immune pattern recognition protein for motifs that are far more common in bacterial than in mammalian DNA.

Peer review

It is interesting that the authors identified an association between *TLR9* polymorphisms and UC in Japanese patients. My main concern is the sample size (not too large) and the fact that the *P* values obtained are not extremely significant (almost marginally significant on some occasions). This may limit the validity of the present work.

Abstract

AIM: To retrospectively evaluate the magnetic resonance imaging (MRI) features of adult retrorectal tumors and compare with histopathologic findings.

METHODS: MRI features of 21 patients with preoperative suspicion of retrorectal tumors were analyzed based on the histopathological and clinical data.

RESULTS: Fourteen benign cystic lesions appeared hypointense on T1-weighted images, and hyperintense on T2-weighted images with regular peripheral rim. Epidermoid or dermoid cysts were unilocular, and tailgut cysts were multilocular. Presence of intracystic intermediate signal intensity was observed in one case of tailgut cyst with a component of adenocarcinoma. Six solid tumors were malignant lesions and showed heterogeneous intensity on MRI. Mucinous adenocarcinomas showed high signal intensity on T2-weighted and mesh-like enhancing areas on fat-suppressed T2-weighted images. There was a fistula between the mass and anus with an internal opening in mucinous adenocarcinomas arising from anal fistula. Gastrointestinal stromal tumors displayed low signal intensity on T1-weighted images, and intermediate to high signal intensity on T2-weighted images. Central necrosis could be seen as a high signal on T2-weighted images.

CONCLUSION: MRI is a helpful technique to define the extent of the retrorectal tumor and its relationship to the surrounding structures, and also to demonstrate possible complications so as to choose the best surgical approach.

INTRODUCTION

Tumors occurring in the retrorectal space are extremely rare in the adult population, with an estimated incidence of 0.0025-0.014 in the large referral centers[1,2]. The ret-

rorectal space is a potential space that only becomes real when a mass grows within it. The boundaries of the retrorectal region include the posterior wall of the rectum anteriorly and the sacrum posteriorly. This space extends superiorly to peritoneal reflection and inferiorly to the rectosacral fascia and the supralevator space. Laterally, the area is bordered by the ureters and the iliac vessels and the sacral nerve roots.

This region contains the confluence of the embryologic hindgut, neuroectoderm, and the bony pelvis. As such, multiple different tissue types can give rise to retrorectal tumors. Retrorectal tumors may be classified as congenital, neurogenic, osseous or miscellaneous[3,4]. Two-thirds are congenital[2-4], caused by embryological sequestration, abnormalities in midline fusion and incomplete embryological regression. Cystic congenital lesions include epidermoid and dermoid cysts, tailgut cyst (also called mucus-secreting cyst), enterogenic cyst, teratoma, and teratocarcinoma. Neurogenic (including anterior sacral meningoceles), osseous and miscellaneous tumors each account for approximately 10% of retrorectal tumors[3]. Majority of these masses in adults are benign and asymptomatic, however, malignant tumors accounted for 21%[5]. Malignant transformation has also been documented in tailgut cysts and epidermoid cysts[6-8]. Symptoms include pain, change in bowel habit, difficulty with micturition, and neurological signs in the lower limb and perineum[3,4,9].

Retrorectal tumors are often found late and may be managed suboptimally. The current consensus is that the cardinal therapy for patients with retrorectal tumors is surgical[9-11]. Curative resection requires complete excision of the tumor, with an intact capsule for clinically well-circumscribed benign lesions and en bloc resection with clear resection margins for malignant tumors[9,11]. Accurate diagnosis of these conditions before operation is crucial because it can significantly alter clinical management. MRI is a useful technique to evaluate pelvic disorders because of its multiplanar imaging capability and its good soft tissue contrast[2,4,6,8,9,11]. We retrospectively evaluated the MRI features of retrorectal tumors in 21 patients and compared with pathological findings to further characterize the MR imaging findings encountered in retrorectal tumors.

MATERIALS AND METHODS

Patients

We reviewed the clinical and radiological findings in 21 patients (13 women, 8 men; age range, 16-74 years; mean age, 39.3 years) with preoperative suspicion of retrorectal tumor who were treated at our hospital between January 2006 and December 2008. Institutional review board permission was obtained for retrospective review without informed consent. MRI was performed in all patients with a standardized protocol. Data from clinic charts, hospital medical records, radiological and pathological reports of these patients were collected retrospectively. The clinical findings at presentation included rectal fullness (n = 7), low back pain (n = 2), constipation (n = 6), symptoms due to recurrent perirectal abscess and/or fistula (n = 5) and no apparent symptom (n = 1). Only two patients had postanal dimples. Digital examination of the rectum revealed a mass located posteriorly or laterally to the rectum in 20 patients. Laboratory tests demonstrated elevated carcino-embryonic antige (CEA) in two patients (2/21).

MR technique and parameters

All 21 patients underwent preoperative MRI. MR examinations were achieved on a 1.5-T unit using an eight-channel phased-array pelvic coil (Siemens, MR Magnetom Sonata, Germany). Neither bowel preparation nor Ⅳ contrast enhancement was performed. Before performing MR, the rectum was distended by a balloon filled with 60-80 mL saline. The MR examination was performed with the patient in a supine position. MR examination protocol included sagittal, axial, coronal T2-weighted images, and axial (n = 21) T1-weighted images. T2-weighted imaging (TR/TE, 4000/97; echo-train length 13, field of view 20 cm, 4 mm slice thickness, no interslice gap, 256 × 256 matrix) were performed in the sagittal plane (n = 21), axial plane (n = 21) and coronal plane (n = 9), and followed with fat-suppression in sagittal and axial plane. Imaging parameters for T1-weighted sequences were: TR/TE, 620/12; echo-train length 1, field of view 22 cm, 4 mm slice thickness, no interslice gap, 320 × 240 matrix. Overall acquisition time varied from 20 to 30 min.

Image review

Magnetic resonance images were reported by two experienced radiologists. Four features of the retrorectal tumor were assessed. (1) the tumor location and extent were defined by the most cephalad sacral vertebra involved; (2) tumor size was measured in the largest two dimensions; (3) tumor morphology was assessed by examining the internal signal characteristics and the tumor margin. A cystic tumor was diagnosed when the lesion displayed over 80% cystic elements and a solid tumor when the lesion showed more than 80% solid elements; the remainders were classified as heterogeneous tumors; and (4) the tumor margin was assessed as well-defined (a smooth or lobular contour without surface projections), irregular (with surface projections) or clearly invasive (the tumor breached an adjacent structure).

RESULTS

Eighteen patients underwent surgery for retrorectal tumor. One patient with a gastrointestinal stromal tumor (GIST) arising from the rectum received abdominal perineal resection (APR). Two patients, diagnosed as having mucinous adenocarcinoma arising from fistulae-in-ano, received radiochemotherapy because the patients refused surgery. Histopathological studies demonstrated 7 malignant tumors (2 mucinous adenocarcinomas arising from fistula, 2 gastrointestinal stromal tumors, 1 tailgut cyst

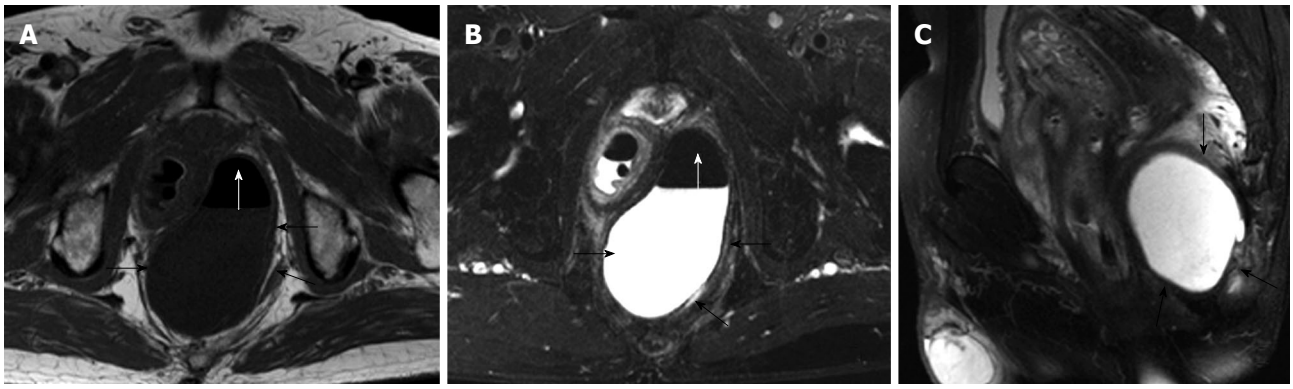

Figure 1 Dermoid cyst in a 63-year-old man, who was misdiagnosed as having abscess. Axial T1-weighted (A), T2-weighted fat-suppression (B) and Sagittal T2-weighted (C) magnetic resonance (MR) images show a thin regular peripheral rim (black arrows) circumscribing a retrorectal cyst and containing some air (white arrows). The cyst lesion extends to the left ischiorectal fossa, and is hypointense on T1-weighted (A) and hyperintense on T2-weighted MR images (B, C).

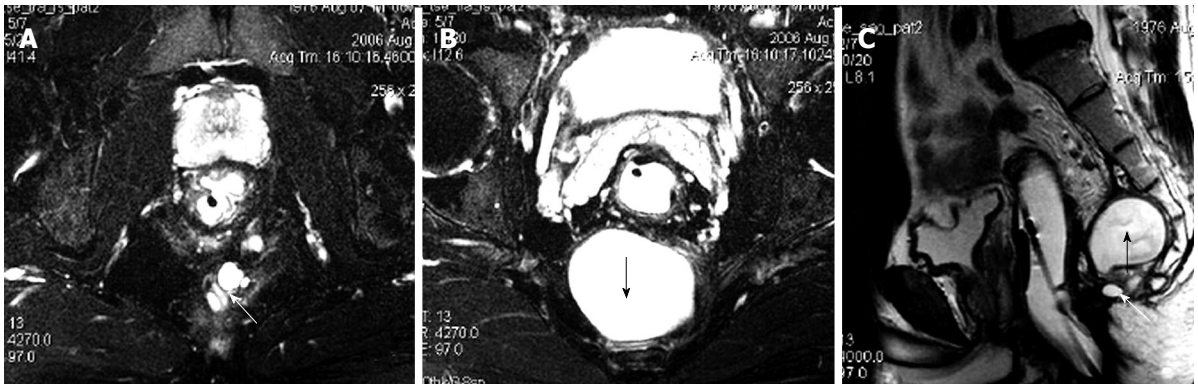

Figure 2 Tailgut cyst in a 30-year-old man. On T2-weighted fat-suppression (A, B) and Sagittal T2-weighted images (C), small cysts are composed to form a honeycomb (white arrows) adjacent to a main larger cyst (black arrows).

with component of mucinous adenocarcinoma, 1 adenocarcinoma of the anal duct, and 1 primary retrorectal adenocarcinoma) and 14 benign cysts (6 epidermoid cysts, 7 tailgut cysts and 1dermoid cyst). Patients with malignant tumors were significantly older than those with benign tumors (52.5 years *vs* 34.6 years). There was no gender difference in malignant tumors (male/female ratio, 4/3), and women comprised a larger proportion of the patients with benign cysts (male/female ratio, 3/11).

MRI demonstrated that benign cystic lesions were primarily located in the retrorectal space in 12 cases, with downward and lateral extension to ischiorectal fossa in two cases (Figure 1). The rectum appeared anterior or lateral in five patients. The mean largest diameter of the lesions was 4.8 cm (range 0.7-10 cm). Both epidermoid cysts and dermoid cysts were unilocular (Figure 1). There were numerous cysts in all tailgut cysts, shown as a large main cyst and associated with other smaller cysts in the same location (Figure 2). All the cystic lesions appeared hypointense on T1-weighted images, and hyperintense on T2-weighted images. As far as non-complicated cysts (10/14) were concerned, the cystic mass was well-circumscribed by a regular peripheral rim. The rim was hypointense on all sequences. The borders of the cystic lesions were irregular in 4 patients, who had an operative history with a misdiagnosis as having abscess or fistulae.

Heterogeneous tumor was found in one case of tailgut cyst with a component of adenocarcinoma (Figure 3). The rectum was compressed anteriorly but without evidence of invasion. The cystic portion appeared hypointense on T1-weighted images and hyperintense on T2-weighted images with irregular borders. The malignant portion presented as intermediate signal intensity on T2-weighted and fat-suppression with irregular margin.

The six solid tumors were malignant lesions confirmed by histopathology. Three patients were diagnosed as having mucinous adenocarcinoma, two as having mucinous adenocarcinomas arising from chronic perianal fistulae, and 1 as having adenocarcinoma of the anal duct (Figure 4). MRI showed a larger mass in the pelvis, extending to the ischiorectal fossa. The mucin, which forms the major tissue component of mucinous tumor, showed high signal intensity on T2-weighted fast SE images and mesh-like enhancing areas on fat-suppressed T2-weighted images (Figure 5). As for mucinous adenocarcinoma arising from fistula-in-ano, there was a fistula between the mass and the anus with an internal opening in anorectum (Figure 6). One was diagnosed as primary presacral adenocarcinoma after operation, and MRI identified a well-circumscribed 3.5 cm × 4 cm solid lesion with irregular margin in the

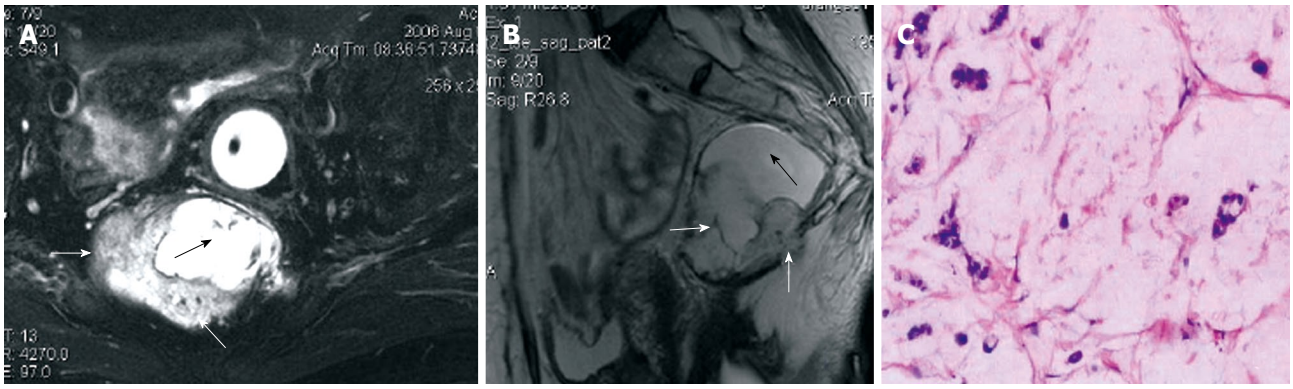

Figure 3 Tailgut cyst associated with mucinous adenocarcinoma in a 52-year-old woman. A, B: The rectum is compressed and shifted to the front but without evidence of invasion. The cystic portion (black arrows) is hyperintense, and the malignant portion (white arrows) presents as irregular margin with intermediate signal intensity on T2-weighted fat-suppression (A) and Sagittal T2-weighted images (B); C: Photomicrograph of the tumor shows a small cluster of atypical cells in stroma.

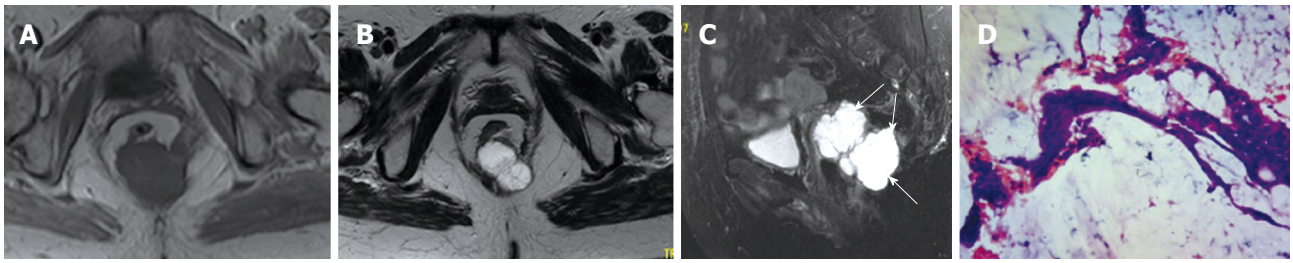

Figure 4 Adenocarcinoma of the anal duct in a 71-year-old woman. A, B: Axial T1-weighted magnetic resonance (MR) image shows a low signal mass with irregular marginal in the retrorectal space and high signal on T2-weighted MR image; C: The mucin, which forms the major tissue component of mucinous tumor, shows high signal intensity (white arrows) on fat-suppressed T2-weighted image; D: The gland shows irregular features with cellular hyperchromatin and the stroma shows marked desmoplasia.

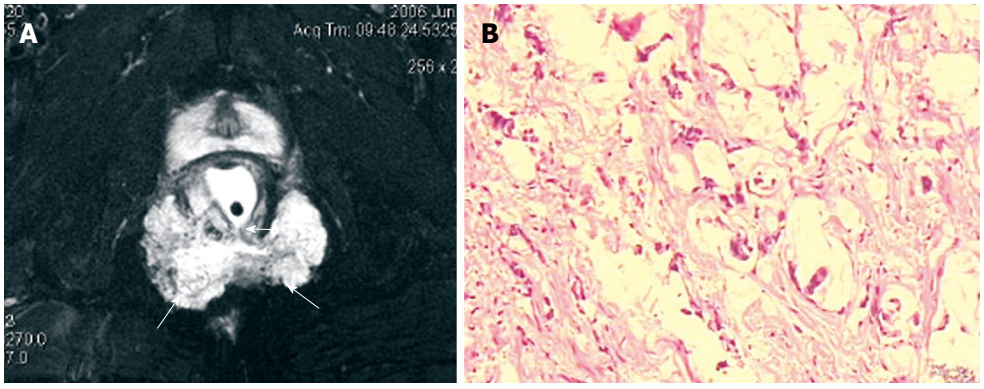

Figure 5 A 59-year-old man with mucinous adenocarcinoma caused by anal fistula. A: Axial fat-suppressed T2-weighted magnetic resonance image shows a horse-shoe mass with typical mesh-like enhancing areas (arrows). The mass has a internal fistula connected to the anorectum (arrows); B: Microscopy shows a single or small cluster of atypical cells floating in mucin pool and bundles of collagen with hyaline degeneration in stroma.

presacral space, not involving sacrum or rectum (Figure 7). The other two were diagnosed as gastrointestinal stromal tumors (GISTs), one appeared to arise from the rectum (Figure 8), and the other appeared in presacral space (Figure 9A and B). Tumors were larger than 5 cm in at least one transverse dimension. MRI showed low signal intensity on T1-weighted image, and heterogeneous signal intensity on T2-weighted image. We suspected a central necrosis based on the T2-weighted imaging with a high signal. In immunohistochemical studies, diffuse and strong immunoreactivity for CD34 and CD117 were seen throughout the tumors (Figure 9C and D). Conversely, the tumor cells were negative for both muscle markers (smooth muscle actin, desmin) and neural markers (S-100 protein, neuron specific enolase).

DISCUSSION

The boundaries of the presacral region include the posterior wall of the rectum and the sacrum. This space extends superiorly to peritoneal reflection and inferiorly to rectosacral fascia and the supralevator space. Laterally, the area is bordered by the ureters, the iliac vessels, and the sacral nerve roots. Because this area contains totipotential

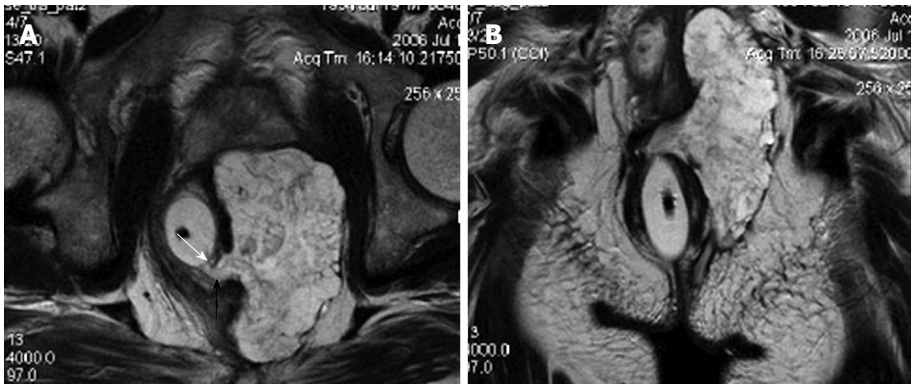

Figure 6 A 52-year-old man with mucinous adenocarcinoma caused by anal fistula. A, B: The mass displays heterogeneous intensity on T2-weighted magnetic resonance image. There is a fistula between the mass and the anus (black arrow) and an internal opening in anorectum (white arrow).

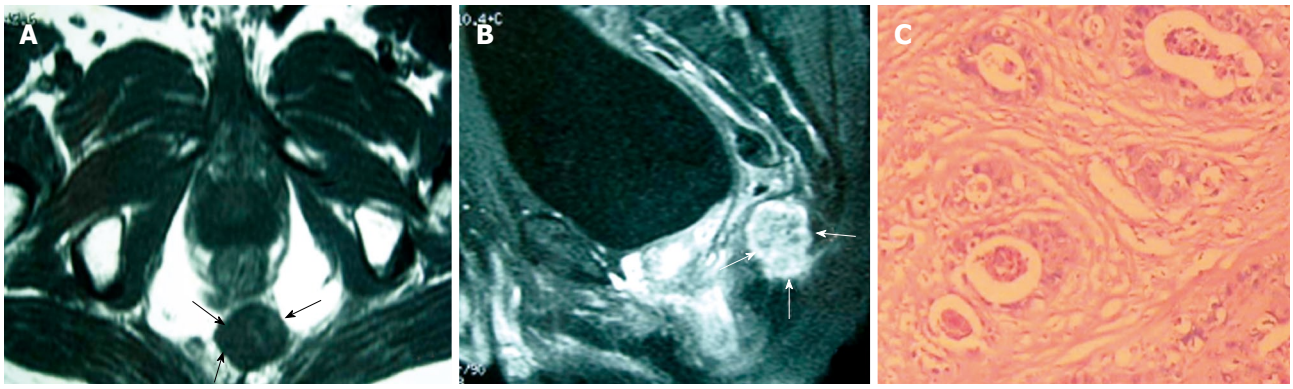

Figure 7 Primary retrorectal adenocarcinoma in a 33-year-old man. A, B: The mass displays low signal intensity, without rim (black arrows) on T1-weighted magnetic resonance (MR) image, and high signal intensity of the irregular border (white arrows) on fat-suppressed T2-weighted MR image; C: Microscopy shows irregular glands of variable sizes and atypical tumor cells. The stroma shows desmoplasia.

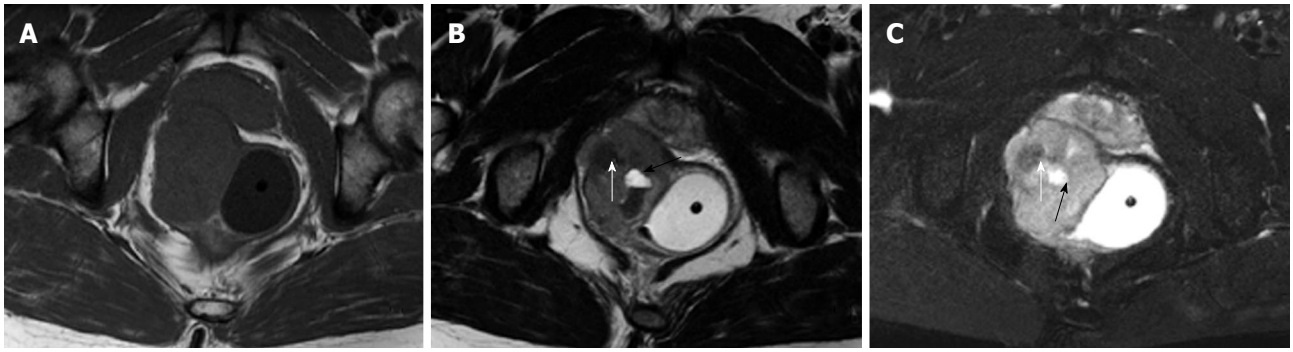

Figure 8 Gastrointestinal stromal tumors of rectum in a 44-year-old man. A well-circumscribed, smooth, intramural mass with exophytic growth expanded from the rectal wall and extended to the right ischiorectal fossa. The tumor displays low signal intensity on T1-weighted image (A), and high signal intensity on T2-weighted image (B, C). There are some areas of necrosis (black arrows) and fibrotic tissues (white arrows) in the tumor.

cells that differentiate into three germ cell layers, a multitude of tumor types may be encountered. Traditionally, these lesions are divided into congenital, inflammatory, neurogenic, osseous and miscellaneous types[3,4]. Clinical diagnosis may be delayed because of non-specific symptoms. Symptomatic patients typically complain of vague, longstanding pain in the perineum or low back, and change in bowel habit[1,5,8]. Because detection is often difficult and delayed, patients frequently present with tumors that have reached a considerable size and involve multiple organ systems, thus complicating their treatment. Singer *et al*[12] reported 7 patients who underwent an average of 4.7 invasive procedures or operations before the correct diagnosis of a retrorectal lesion was made.

The diagnosis and management of these tumors has evolved in recent years because of improved imaging modalities, especially the MRI. MRI is often used in diagnosing and managing the patients with presacral tumors, as it can provide excellent anatomic detail and soft-tissue contrast. Kim *et al*[13] asserted that for the evaluation of a

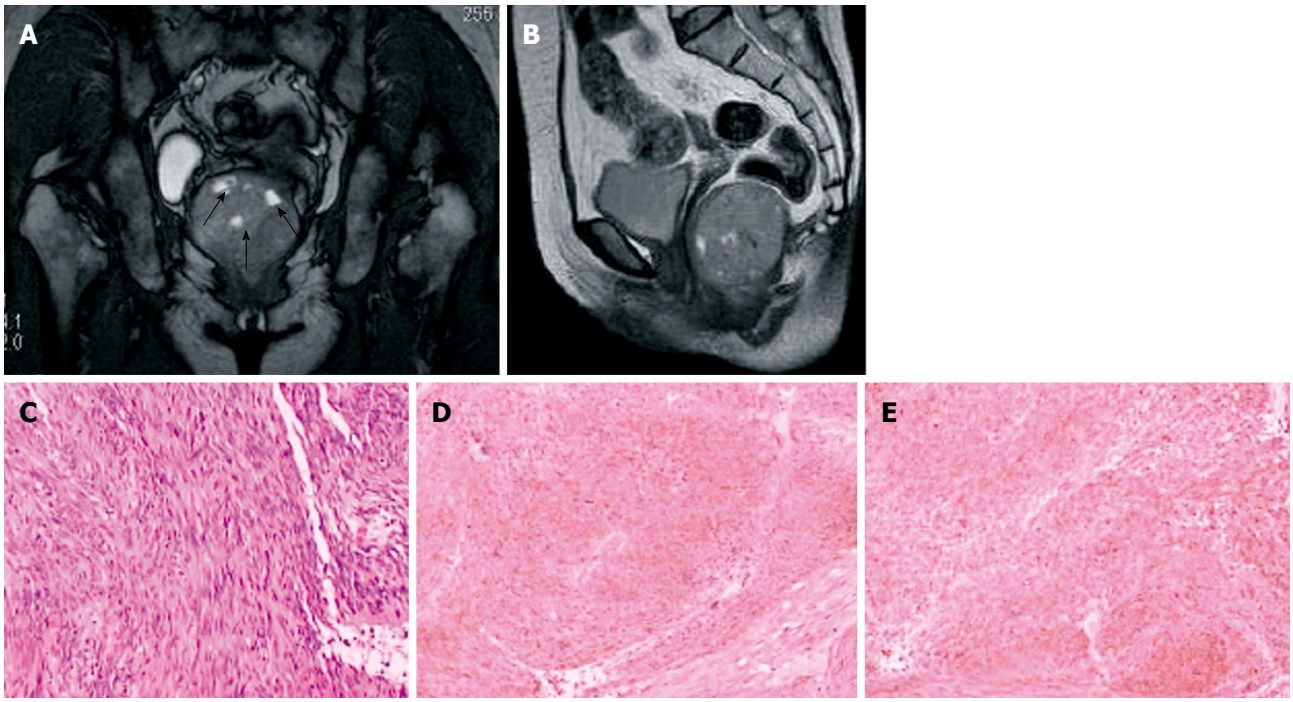

Figure 9 Retrorectal gastrointestinal stromal tumors in a 51-year-old woman. A, B: T2-weighted magnetic resonance images show a large retrorectal mass, in which some necrosis presents hyperintensity (black arrows); C: Histopathology shows spindle cells and cytoplasmic vacuoles; D, E: On immunohistochemical studies, diffuse and strong immunoreactivity for CD117 and CD34 are seen.

presacral mass, MRI has the advantage over CT of being able to offer multiplanar capabilities and good tissue contrast. MRI is a valuable tool for preoperative evaluation, imaging and characterizing lesions, estimating their extent and the risk of malignancy, distinguishing organ-confined disease from tumor spread into adjacent structures, and deciding upon the most appropriate intervention strategies and imaging follow-up requirements.

About half of the presacral tumors are congenital lesions, and most of them are developmental cysts (epidermoid, dermoid, tailgut cysts, and teratomas). On MRI, presacral cyst usually has low signal intensity on T1-weighted images and high signal intensity on T2-weighted images[8]. However, it may have high signal intensity on T1-weighted images due to presence of mucinous materials, high protein content, or hemorrhage in the cyst[6,8]. All of the presacral cysts in our cases were hypointense on T1-weighted images and hyperintense on T2-weighted images. Among the presacral cystic masses, epidermoid cyst, dermoid cyst, rectal duplication cyst, and meningocele are usually unilocular[14]. The presence of fat content on fat-saturated images is suggestive of a dermoid cyst[8]. Rectal duplication cysts often communicate with the rectal lumen and are anterior to the rectum. Anterior meningocele is a well-defined unilocular thin-walled, fluid-filled lesion of the retrorectal space with a stalk that may be seen communicating with the thecal sac. In contrast, tailgut cyst is usually multicystic[6]. In our study, we observed that epidermoid cysts and dermoid cysts appeared unilocular on MRI, and tailgut cysts appeared as a large cyst accompanied by small peripheral cysts. We believe that the unilocular or multilocular characteristics are very important because of the malignant potential of a tailgut cyst. A few cases of degenerated tailgut cysts have been documented in the literature[6,15-17]. The possibility of malignant transformation must be considered in the presence of heterogeneous tumor. Our findings, that a cystic lesion displayed heterogeneous signal intensity on T2-weighed MR images with markedly irregular wall, and the malignant portion presented as irregular margin with intermediate signal intensity on T2-weighted and fat-suppression, are consistent with what has been described in the literature[6,17].

MRI is useful in predicting whether a tumor is benign or malignant. A cystic tumor with a smooth, well-circumscribed margin and no features of invasion or enhancement with gadolinium is benign, and a heterogeneous tumor, or a solid tumor with an irregular margin, is usually malignant[9]. The six solid tumors were malignant confirmed by histopathology in this series. Two patients with adenocarcinoma arising from fistula-in-ano displayed presacral tumor. Several characteristic MRI findings may help diagnose mucinous adenocarcinoma arising from fistula-in-ano. Histopathologically, mucinous colorectal carcinomas comprise large pools of extracellular mucin lined by columns of malignant cells, cords and vessels, which give rise to a typical mesh-like internal structure[18]. The mucin, which forms the major tissue component of mucinous tumors, has high signal intensity on T2-weighted fast SE images. Two authors reported that a fistula between the mass and the anus is a characteristic finding of mucinous adenocarcinoma arising from fistula-in-ano on MRI[19,20]. Two patients showed a fistula tract between the mass and the anus in agreement with the previous reports.

GIST is a non-epithelial neoplasm arising from the

wall of the gastrointestinal tract. GIST is thought to originate from the interstitial cell of Cajal, an intestinal pacemaker cell[21]. GISTs are most often located in the stomach (39%-70%) and small intestine (20%-35%), whereas the colon and rectum (5%-12%) are less common locations[22-25]. Some GISTs primarily arise in the omentum, mesentery, or retroperitoneum and are unrelated to the tubular gastrointestinal tract. It is even rarer that GIST originates from presacral space. On MRI, solid portions of tumor typically show low signal intensity on T1-weighted images, intermediate to high signal intensity on T2-weighted images, and enhancement after administration of gadolinium[26]. The markedly high signal seen on T2-weighted MRI should be considered as a feature strongly indicating a diagnosis of GIST[27]. GISTs usually involve the muscularis propria of the gastrointestinal wall, so the characteristic image is that of a well-circumscribed, smooth, intramural mass with exophytic growth. The case with rectal GIST in this series presented as well-defined, eccentric mural mass that expanded the rectal wall and extended into the right ischiorectal fossa. As in GISTs at other locations, central areas of necrosis could be seen in our cases.

Adenocarcinomas of the presacral region are distinctly unusual. Most of the cases represent direct extension or metastatic spread from rectal cancer. Although malignant replacement of these cysts is possible, complete replacement of the cyst epithelium and other elements by adenocarcinoma has not been reported[5]. However, potential sources such as gastrointestinal, pancreatic and prostatic tissues were eliminated and no evidence of a developmental cyst was found histopathologically in this case. The tumor described in the present report should be regarded as a primary presacral adenocarcinoma, as reported by Zamir *et al*[5] and Puccio *et al*[28]. Pelvic MRI demonstrated a retrorectal heterogeneous solid lesion on both T1-weighted and T2-weighted images and a markedly high signal was seen on T2-weighted images after fat-saturation.

A further benefit of MRI being confirmed is whether routine preoperative biopsy is necessary[29]. Historically, the role of preoperative biopsy of retrorectal tumors has been a controversial topic in the general surgery. When preoperative MRI is available, the indications for biopsy can be limited to patients whose mass may represent metastatic disease or lymphoma[9]. The risk of a routine biopsy can, therefore, be avoided.

Retrorectal tumors can be best managed by surgery. Careful surgical planning is important by selecting appropriate approaches, such as an anterior approach (abdominal), posterior approach (perineal), or a combined abdominoperineal approach. MRI will help define the margins of resection and the relationship between the tumor and the sacral level. If the tumor is positioned below the midbody of S3, a perineal approach can be considered. All tumors that extend above S3 often require an abdominal or combined approach.

In conclusion, retrorectal tumor is a rare entity that is difficult to diagnose. Our series supports that MRI is a useful examination when a retrorectal tumor is suspected. Cystic lesions with a smooth wall on MRI are typically benign, whereas heterogeneous or solid tumors are usually malignant. However, final diagnosis should be based on the pathological examination after surgical resection. MRI is a helpful technique to define the extent of the tumor, its relationship to the surrounding structures and also to demonstrate possible complications in order to choose the best surgical approaches.

COMMENTS

Background

Tumors occurring in the retrorectal space are extremely rare in the adult population. Retrorectal tumors may be classified as congenital, neurogenic, osseous or miscellaneous types. Majority of these masses are benign and asymptomatic, however, malignant tumors accounted for 21%. Curative resection requires a complete excision of the tumor, with an intact capsule for clinically well-circumscribed benign lesions and en bloc resection with clear resection margins for malignant tumors. Accurate diagnosis of these conditions before operation is crucial because it can significantly alter clinical management.

Research frontiers

The diagnosis and management of retrorectal tumors have evolved in recent years because of improved imaging modalities, especial magnetic resonance imaging (MRI). MRI is a valuable tool for preoperative evaluation, imaging and characterizing lesions, estimating their extent and the risk of malignancy, distinguishing organ-confined disease from tumor spread into adjacent structures, and deciding upon the most appropriate intervention strategies and imaging follow-up requirements.

Innovations and breakthroughs

This series supports that MRI is a useful examination when a retrorectal tumor is suspected. Cystic lesions with a smooth wall on MRI are typically benign, whereas heterogeneous or solid tumors are usually malignant. MRI is a helpful technique to define the extent of the tumor, its relationship to the surrounding structures and also to demonstrate possible complications in order to choose the best surgical approach.

Applications

MRI is a useful technique to evaluate retrorectal tumors. It can provide optimal information about tumor location, size, extent, the risk of malignancy and strategy for therapeutic intervention in the patients with retrorectal tumor.

Terminology

Retrorectal space, also called presacral space, is a potential space limited anteriorly by the fascia propria of the rectum and posteriorly by Waldeyer's rectosacral fascia. Laterally, it is limited by the iliac vessels and the ureters and extends along the lateral ligaments of the rectum, communicating superiorly at the level of the peritoneal reflection with the retroperitoneal space.

Peer review

This article well documented the MRI features of retrorectal lesions, and this will interest our readers.

Abstract

AIM: To test the occurrence of the Pro12Ala mutation of the peroxisome proliferator-activated receptor-γ (PPARγ)2-gene in patients with non-alcoholic fatty liver disease (NAFLD) or alcoholic fatty liver disease (AFLD).

METHODS: DNA from a total of 622 specimens including 259 blood samples of healthy blood donors and 363 histologically categorized liver biopsies of patients with NAFLD (n = 263) and AFLD (n = 100) were analyzed by Real-time polymerase chain reaction using allele-specific probes.

RESULTS: In the NAFLD and the AFLD collective, 3% of the patients showed homozygous occurrence of the Ala12 PPARγ2-allele, differing from only 1.5% cases in the healthy population. In NAFLD patients, a high incidence of the Ala12 mutant was not associated with the progression of fatty liver disease. However, we observed a significantly higher risk (odds ratio = 2.50, CI: 1.05-5.90, P = 0.028) in AFLD patients carrying the mutated Ala12 allele to develop inflammatory alterations. The linkage of the malfunctioning Ala12-positive PPARγ2 isoform to an increased risk in patients with AFLD to develop severe steatohepatitis and fibrosis indicates a more prominent anti-inflammatory impact of PPARγ2 in progression of AFLD than of NAFLD.

CONCLUSION: In AFLD patients, the Pro12Ala single nuclear polymorphism should be studied more extensively in order to serve as a novel candidate in biomarker screening for improved prognosis.

INTRODUCTION

Fatty liver diseases are becoming a common cause of chronic liver diseases in the Western countries encountering in about 20% of the general adult and child population[1-5]. Excessive accumulation of triglycerides in hepatocytes occurring in etiologically diverse conditions causes hepatic steatosis characterized by more than 5%-10% fat stored either in macrovesicles or in microvesicles of hepatocytes[6,7]. Whereas in the past, regular and excess alcohol consumption was the most common reason for hepatic steatosis[8,9], fatty liver diseases are now most frequently associated with obesity, insulin resistance and type 2 diabetes due to an unbalanced and rich diet in industrial nations[3,5].

The spectrum of fatty liver diseases (FLD) independent of causative agents ranges from simple steatosis to steatohepatitis, which can progress to liver fibrosis ending up in cirrhosis or hepatocellular carcinoma[3,5,10-13]. Thus, 5%-10% of non-alcoholic fatty liver disease (NAFLD) patients with steatosis develop a steatohepatitis accompanied by a high risk of progression to fibrosis[3,4]. Although fatty liver diseases can have various causes, features of steatohepatitis in NAFLD and alcoholic fatty liver disease (AFLD) are difficult to distinguish histologically[6,7]. Both are characterized by foci of liver cell necrosis and lobular inflammatory infiltrates with polymorphonuclear leukocytes. Furthermore, the onset of steatohepatitis is accompanied by ballooned hepatocytes, often harboring Mallory's hyaline and megamitochondria or undergoing apoptosis[14]. Whereas steatosis seems to be more pronounced in non-alcoholic steatohepatitis (NASH) than in alcoholic steatohepatitis (ASH), features of necroinflammatory and cholestatic activity are more prominent in ASH liver biopsies[6]. Progression of steatohepatitis then results in pericellular fibrosis[6,7,15] involving myofibroblastic activation of sinusoidal hepatic stellate cells responsible for elevated extracellular matrix deposition[16].

Members of the peroxisome proliferator-activated receptors (PPAR) seem to play a key role in the pathophysiology of FLD by modulating increased glucose uptake and hepatic triglyceride accumulation, but also perform anti-inflammatory signals when steatohepatitis has occurred[17-19]. The PPAR family consists of PPARα, PPARγ, and PPARδ nuclear receptors, functioning as transcription factors, that mediate transcriptional response to insulin resulting in glucose uptake, increased fatty acid oxidation, lipogenesis and lipid storage, respectively[17]. Whereas the PPARα is highly present in hepatocytes, the splice variants PPARγ1 and 2 triggering adipogenesis are mainly expressed in adipose tissues and only to a minor extent in the liver. PPARγ increases the expression of genes that promote fatty acid storage, whereas it represses genes that induce lipolysis in adipocytes. In patients suffering from FLD, hepatic expression of PPARγ is shown to be involved in insulin sensitivity, triglyceride clearance and hepatic steatosis[20].

Due to its high impact as an insulin-sensitising transcription factor involved in adipogenesis and lipogenesis, the occurrence of single nucleotide polymorphisms (SNP) in the PPARγ gene was recently addressed by numerous reports studying subjects with insulin resistance, type 2 diabetes, arteriosclerosis, and hypertension[21-23]. A prevalent SNP association with impaired lipid homeostasis was observed in terms of the N-terminal proline alanine exchange (Pro12Ala) of the extra domain in the PPARγ2 variant. This PPARγ splice form includes 30 additional amino acids[24], which are responsible for a 5-6-fold increase of PPARγ's transcriptional activity. The Pro12Ala exchange in the activating extra region of the PPARγ2 is the result of a cytosine to guanine substitution in the PPARγ gene, as a consequence encoding the Ala-allele form with a heavily reduced function[23]. In several populations, the association of the Pro12Ala polymorphism with insulin-sensitivity, type 2 diabetes, obesity and adipositas have been shown[25-27]. However, the role of the Pro12Ala polymorphism of PPARγ gene in occurrence and progression of fatty liver diseases is not yet defined.

In the present study, we analyzed the frequency of the Pro12Ala polymorphism in the PPARγ gene by a highly sensitive LNA-probe based polymerase chain reaction (PCR) approach in a total of 622 subjects of a Caucasian population, suffering from fatty liver disease (n = 359) or being healthy blood donors (n = 263). In agreement with reports showing a high Ala allele prevalence in patients with impaired lipid metabolism in obese and adipose patients[26,28], in FLD patients the Ala allele also occurs more often than in the healthy control group. Interestingly, the interpretation and linkage of the allele frequency to histological evaluation and clinical data demonstrates a prominent risk in AFLD patients bearing the Ala allele to develop severe steatohepatitis and fibrosis. Furthermore, our data revealed for the first time a higher anti-inflammatory impact of PPARγ in progression of human AFLD than NAFLD.

MATERIALS AND METHODS

Patients, biopsies and liver disease classification

From a total of 622 cases, 259 blood samples and 363 biopsies were studied for occurrence of the Pro12Ala exchange in the PPARγ gene. Local research ethics guidelines were followed. We collected 363 cases from the files of the Department of Gastroenterology and Hepatology, University Hospital of Essen (GER) and the Institute for Pathology, University Hospital of Cologne (GER) according to their histological criteria of fatty liver disease (Table 1). 263 tissue specimens from patients were classified as NAFLD according to the clinical information about alcohol consumption (less than 20 g alcohol per day). One hundred specimens of patients who consume more than 20 g alcohol per day met the definition of AFLD as described by Neuschwander-Tetri *et al*[29]. Clinical data, such as GOT, GPT, and γGT, were compiled along with the state of diabetes. There was no appreciable difference between the mean age of AFLD (53.93 ± 10.63, range 20-81 years) and NAFLD (50.48 ± 15.25, range 16-80 years). All specimens, stained with haematoxylin and eosin (HE) and by the Gomori method for visualization of reticular fibers, were independently classified by three experienced liver pathologists (Hardt A, Drebber U, Dienes HP), according to

the histological score described by Kleiner *et al*[15] (Table 1). Additionally, 259 DNA extracts from blood samples of healthy blood donors were taken as references for local gene distribution.

Automatic DNA extraction from formalin fixed and paraffin embedded biopsies

Extraction of DNA from 363 formalin fixed and paraffin embedded (FFPE) biopsies was performed from three 7 μm-microtome sections after deparaffinization and proteinase K treatment, as previously described[30]. Then, DNA was purified by means of magnetic bead technology (FormaPure™ Kit of Agentcourt, Beverly MA, USA). All DNA purification steps were carried out by the BioMek FX laboratory automatic workstation (Beckman Coulter, USA) according to the work file and recommendations of Agentcourt.

Furthermore, DNA from 259 blood samples was prepared by the robotic workstation using the Genfind™ Kit of Agentcourt according to the manufacturer's instructions.

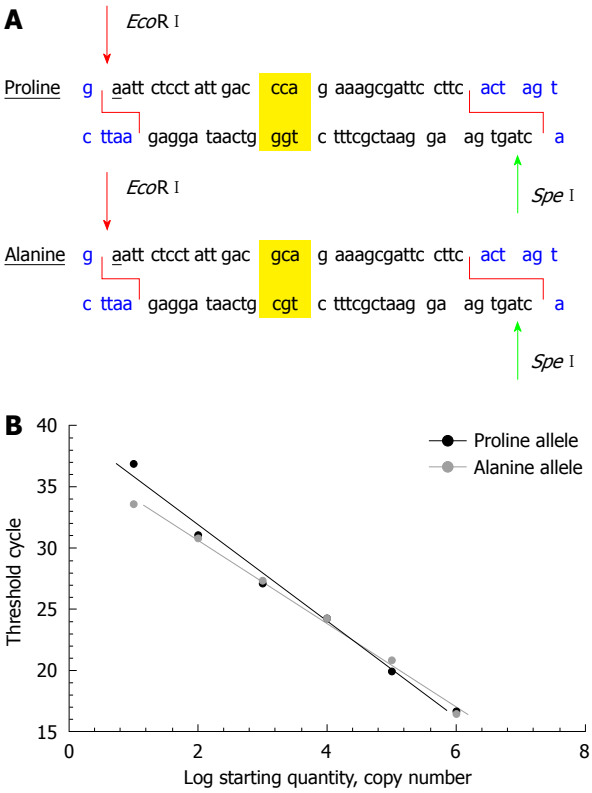

Figure 1 Cloning strategy and validation of a reference system. A: Cloning strategy for the generation of a reference system. The Pro12Ala mutation locus of the peroxisome proliferator-activated receptor-γ gene was synthesized as the proline or the alanine encoding oligonucleotides sequence. The proline or the alanine codon is indicated in yellow. The chemically synthesized oligonucleotide dimers, flanked by the overhangs of the *Eco*R I and the *Spe* I restriction sites (red/green), respectively, were used for insertion into pBluescript SKII plasmids; B: Real-time polymerase chain reaction (PCR) of the Pro12Ala locus depending on different copy numbers of reference sequences. Real-time PCR was performed using the LNA probes (Table 2) specific for the proline encoding sequence or the alanine encoding allele, respectively. 10^6, 10^5, 10^4, 10^3, 10^2, 10 copies of the plasmid reference sequences encoding either the Ala12 or the Pro12 locus were each diluted in 10 ng salmon sperm DNA and used for LNA probe based real-time PCR assays. Up to 10 copies per ng total DNA of both reference sequences were efficiently detected by the corresponding LNA probe labelled either by Hex or Fam fluorochrome.

Cloning of reference sequences into pBluescript

For construction of a reference system with sequences of the Pro12Ala locus (rs1805192) carrying either the mutation or the wild type sequence of PPARγ2 gene we used oligonucleotides comprising the proline or alanine encoding sequences (Figure 1). These oligonucleotides were dimerized in 150 mmol/L NaCl, 5 mmol/L EDTA, 50 mmol/L Tris pH 7.4, creating *Eco*R I and *Spe* I compatible overhangs and inserted into pBluescript SKII (+) (Stratagene, Texas, USA) by the respective restriction sites (Figure 1).

Allelic discrimination of the PPARγ2 by real-time PCR

The Pro12Ala exchange of the PPARγ gene (rs1801282) was examined in DNA from normal blood donors and patients by a Taqman probe associated real-time PCR. Genomic DNA was amplified by real-time PCR in a total vol-

Table 2 Real-time polymerase chain reaction primers and probes

TM LNA probe wt	5'-6FAM-CTATTGACCCAGAAAGC--BHQ1	Target and reference DNA
TM LNA probe mut	5'-YAK-CTATTGACGCAGAAAGC--BHQ1	

Bold letters indicate the single nuclear polymorphism and underlined letters indicate the insertion of locked nucleotides (LNA). PPARγ: Peroxisome proliferator-activated receptor-γ; PCR: Polymerase chain reaction.

ume of 10 μL using the Eppendorf MasterMix (Hamburg, Germany) and 0.3 μL of each primer (10 μmol/L). The Plas A and Plas S primer set was used for amplification of reference plasmids; the PPARγ A and PPARγ mis primer set was used for genomic DNA samples (Table 2).

Allelic discrimination was achieved by adding 0.4 μL of 2.5 μmol/L LNA probes (TIB Molbiol, Berlin, Germany) recognizing the wild type and the mutant variant of the Pro12Ala locus of the PPARγ2 gene (Table 2). In parallel to the allelic Pro12Ala discrimination, plasmid reference sequences diluted from 10^5 to 10 copies in herring's sperm DNA (1 ng/mL) were applied to all assays as positive controls. Amplification and analyses were accomplished by the following cycling conditions using a MX3000P qPCR System of Stratagene (Texas, USA): initial denaturation at 95℃ for 2 min, following 50 cycles 95℃ for denaturation, 55℃ for annealing, 65℃ for extension, each step lasting 20 s.

Statistical analysis

Pro12Ala distribution was evaluated using the SPSS software 17 of IBM® (Chicago, USA). Significance of cross-classification was calculated by the Fisher's exact test. Odds ratios were used to describe the risk of disease progression.

RESULTS

Prominent occurence of the PPARγ alanine variant in patients with fatty liver disease

In order to detect the Ala12Pro polymorphism in patients with fatty liver disease we established an assay using locked nucleotide acid (LNA) probes for allelic discrimination. For this purpose, both variants of the Ala12Pro locus were cloned (Figure 1A) and the sequences, encoding either the proline or the alanine variant, were used as reference sequences for efficient allele detection and discrimination. The LNA probe hybridization assay linked to real-time PCR efficiently detected both, the proline wild type and the alanine mutated variant of the PPARγ gene (Figure 1B). Up to 10 copies of each reference sequence were successfully proven. In addition to the high sensitivity, application of the reference sequences attested that the LNA probe based PCR assay was highly specific, enabling the differentiation of the alanine and the proline encoding sequence.

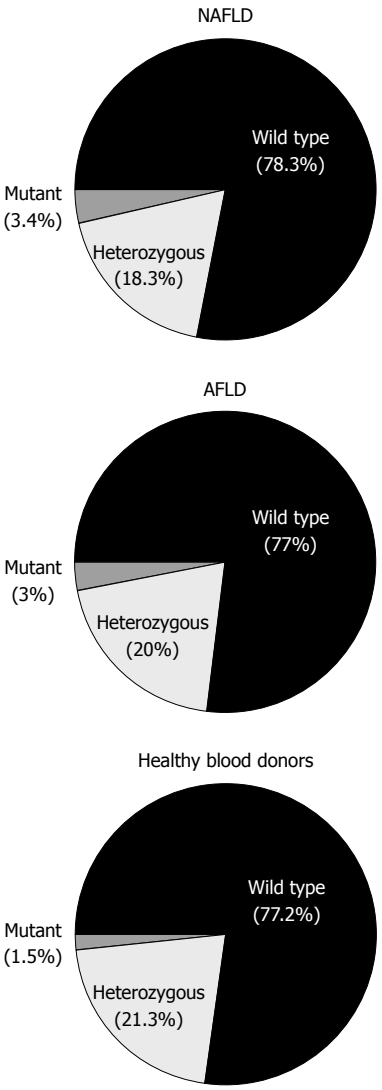

Figure 2 Frequency of the Pro12Ala polymorphism in patients with non-alcoholic fatty liver disease (*n* = 263), alcoholic fatty liver disease (*n* = 100) and in healthy blood donors (*n* = 259). The wild type allele, which is the Pro allele, is indicated in grey, the heterozygous genotype (Pro/Ala) in black and the homozygous Ala/Ala mutant in pale-grey. Genotype analyses revealed a higher prevalence of the homozygous Ala/Ala genotype in non-alcoholic fatty liver disease (NAFLD) and alcoholic fatty liver disease (AFLD) patients.

In the 259 healthy blood donors the assay accounted for 1.5% homozygous variants carrying the alanine encoding sequence (Figure 2). Analyses of the Pro12Ala distribution in the collective of patients with fatty liver disease (n = 363) revealed an increased incidence of the alanine mutant (3%) compared to the healthy population (1.5%). However, the difference was not statistically significant.

In order to identify the association of enhanced alanine occurrence, clinical data of patients with fatty liver disease were considered, revealing that 263 patients suffered from NAFLD, whereas fatty liver disease was linked to alcohol consumption in 100 cases (Table 3). In both cohorts, 12%-14% of the subjects were diabetes positive.

Furthermore, we analyzed the transaminase values in the two cohorts, showing a GPT/GOT ratio of 2 in

NAFLD patients, but a GPT/GOT ratio of 1 in sera of AFLD patients (Figure 3). The high GPT values in NAFLD patients are in accordance with numerous reports, characterizing the progress of steatohepatitis due to non-alcoholic steatosis in comparison to alcoholic steatosis[31]. With respect to the distribution of the Pro12 and the Ala12 alleles in these two cohorts, we found that in both the AFLD and the NAFLD collective the frequency of the alanine genotype was higher (about 3%) compared to the healthy population (Figure 2).

Association of the alanine allele with inflammation and fibrosis in fatty liver disease

We next addressed the question whether the elevated incidence of the alanine allele in the population of fatty liver diseases is associated with the grade of steatosis, ballooning, steatohepatitis, or liver fibrosis (Table 4).

The degree of steatosis is traditionally classified into mild (< 30%), moderate (30%-60%), and severe (> 60%). More than 50% of the patients with NAFLD and AFLD had developed severe steatosis, however, in patients carrying the alanine allele severe steatosis occurred slightly more often. Pronounced ballooning was observed likewise often in NAFLD patients with the mutant or the wild type isoform of the PPARγ2 (Table 5).

Histological scoring for inflammatory alterations and fibrosis according to the recommendations described by Kleiner *et al*[15] (Table 1) revealed that in most of the patients steatosis was accompanied by moderate, mild or severe steatohepatitis. In particular, in patients suffering from AFLD steatohepatitis has passed over to fibrosis in 71% of the cases.

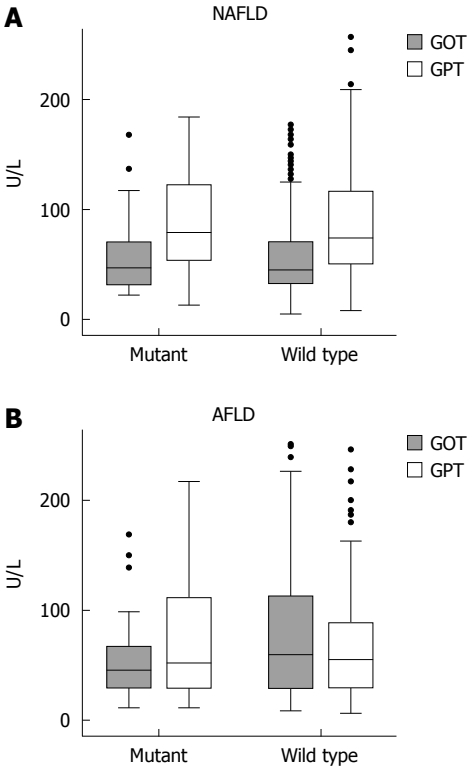

Figure 3 GOT and GPT levels in sera of non-alcoholic fatty liver disease (A) or alcoholic fatty liver disease (B) patients carrying the Ala mutated allele or the Pro wild type allele of the peroxisome-proliferator-activated receptor-γ2 gene. NAFLD: Non-alcoholic fatty liver disease; AFLD: Alcoholic fatty liver disease. Dots (●) indicate outliers that are not included between the whiskers.

Whereas in NAFLD patients inflammation was not significantly associated with the allelic incidence, in AFLD patients the frequency of the Ala12 variant of the PPARγ2 gene was significantly increased when prominent inflammation had occurred (P = 0.028). The higher risk of AFLD patients developing several inflammatory processes ending in liver fibrosis was also shown by elevated Odds ratios (Odd $_{\text{inflammation}}$ = 2.50, CI: 1.05-5.90 and Odd $_{\text{fibrosis}}$ = 2.48, CI: 0.81-7.53) (Table 6).

DISCUSSION

FLD has a high incidence of approximately 20% worldwide and is regarded as a major cause of liver-related morbidity and mortality due to its risk of progression into cirrhosis or hepatocellular carcinoma. Since the transcription factor PPARγ as been shown to be markedly involved in adipogenesis, hepatic lipid storage and metabolism, we first analyzed the frequency of the Pro12Ala polymorphism of the PPARγ gene in a German cohort of patients with FLD compared to German healthy blood donors. A highly sensitive and robust test was established which was certain to distinguish the Ala and the Pro alleles, even

NAFLD: Non-alcoholic fatty liver disease; AFLD: Alcoholic fatty liver disease.

though only low copy numbers from some FFPE biopsies might be available. The genotype distribution (77.5% wt, 21.2% heterozygous, and 1.5% homozygous Ala/Ala mutants) in the collective of the healthy blood donors resembles previous data collected on more than 600 Caucasians by Yen *et al*[32] and Ghoussaini *et al*[33]. This genotype distribution in Caucasians, however, differs from the Asian or African frequency, in which less Ala alleles of the PPARγ occur[23,32]. In contrast to the data of healthy blood donors, PCR analyses of DNA from subjects with FLD revealed an increased frequency of the homozygous Ala-subtype up to almost 3.5% in both the AFLD and the NAFLD collectives. Recent meta-analyses summarized data of the Pro12Ala polymorphism in patients with diabetes and identified the mutated Ala variant as a protection factor of diabetes type 2[34-36]. The malfunctioning Ala variant was also shown to be associated with coronary heart disease[37] and with obesity indicated by significant higher BMI in homozygous Ala carriers than in subjects expressing the heterozygous or the wild type PPARγ2 form[38,39]. Although in some reports higher insulin sensitivity and BMI could not be confirmed[40,41], a comprehensive study on 1170 British patients with coronary heart disease[42] and a meta-analysis including 19 136 subjects clearly identified the Ala carriers as individuals with significant higher BMI[43]. Additionally, cholesterol, LDL-cholesterol and apolipoprotein B concentrations are elevated in Ala carriers[42,44]. Therefore, this Ala-associated hyperlipidemia is assumed to be a reason for the 2-fold higher incidence of the Ala genotype in patients with FLD compared to healthy blood donors. Since free fatty acids are shown to be involved in upregulation of Fas/CD-95 death receptor[45], enhanced levels of circulating fatty acids due to impaired PPARγ function in Ala/Ala patients may result in apoptosis and inflammatory processes. In contrast to NAFLD, where no or only a moderate link of inflammatory progression to the Pro12Ala polymorphism was shown, a prominent risk of developing steatohepatitis was observed in AFLD patients carrying the Ala allele. This difference in the associated frequency of the Ala variant encoding the minor active PPARγ2 form[23] argues for a divergent role of the PPARγ2 in mechanisms of AFLD and NAFLD progression. The PPARγ2 isoform is upregulated by phosphatidylinositol 3-kinase activation in response to free fatty acids or by insulin[46]. In post-ischemic liver injury and also in alcohol-induced fibrosis, the PPARγ1 andγ2 variants were shown to be downregulated and to function protectively[47,48]. Therefore, the 2-3-fold higher risk of ALFD patients, but not of NAFLD patients, to develop inflammatory and fibrotic progression if they carry the malfunctioning Ala variant of PPARγ2, emphasizes a more prominent anti-inflammatory impact of the PPARγ2 in AFLD than in NAFLD wt-carriers.

The anti-inflammatory action of PPARγ was also demonstrated by previous studies on hepatic stellate cells[49,50], which take centre stage of sinusoidal liver fibrosis due to their tremendous matrix production and secretion of pro-inflammatory and pro-fibrotic mediators after myofibroblastic transition in chronic liver injury[16]. The authors show that PPARγs repressed in myofibroblastic hepatic

stellate cells. Additionally, the inflammatory chemokine expression by hepatic stellate cells is markedly inhibited in response to the activation of PPARγ by the agonistic ligand glitazone[49,50]. Taken into account that the malfunctioning Ala variant is associated with a higher risk of progression into steatohepatitis in AFLD patients these results lead to the suggestion that in particular inflammation and fibrosis of AFLD wt-patients can be attenuated by a treatment with PPARγ thiazolidinedione ligands such as rosiglitazone and pioglitazone. Patients with NASH, however, may benefit from glitazone therapy by other mechanisms like improved insulin sensitivity, decreased hyperlipidemia and impeded steatosis as a result of the therapeutic approach[51,52].

In conclusion, our data of a comprehensive study of the Pro12Ala polymorphism on biopsies with FLD, well classified concerning inflammatory and fibrotic alterations, revealed for the first time an association of the Pro12Ala polymorphism with the risk of developing ASH and suggests a more prominent anti-inflammatory influence of the PPARγ2 on progression of human AFLD than on NAFLD. Therefore, the Pro12Ala polymorphism should be studied on an expanded cohort of AFLD patients, in order to be later integrated in a panel of genetic markers applied for future improved prognosis of disease progression.

ACKNOWLEDGMENTS

We thank Dr. Kasper HU (Institute for Pathology, Medical Centre Muenster, Germany) for his support in histopathological evaluation of the AFLD biopsies and part of the NAFLD biopsies. Furthermore, we thank Melanie Ruhrlaender and Katharina Wendland for excellent technical assistance.

COMMENTS

Background

Fatty liver diseases are becoming a common cause of chronic liver diseases in the Western countries encountered in about 20% of the general adult and child population. The spectrum of fatty liver diseases (FLD) independently of causative agents ranges from simple steatosis to steatohepatitis, which can progress to liver fibrosis ending up in cirrhosis or hepatocellular carcinoma. Members of the peroxisome proliferator-activated receptors (PPAR) seem to play a key role in the pathophysiology of FLD by modulating increased glucose uptake and hepatic triglyceride accumulation, but also perform anti-inflammatory signals when steatohepatitis has occurred. Since the transcription factor PPARγ has been shown to be markedly involved in adipogenesis, hepatic lipid storage and metabolism, we analyzed the frequency of the Pro12Ala polymorphism of the PPARγ gene in a German cohort of patients with FLD compared to German healthy blood donors.

Research frontiers

Due to its high impact as an insulin-sensitising transcription factor involved in adipogenesis and lipogenesis, the occurrence of single nucleotide polymorphisms (SNP) in the PPARγ gene was recently addressed by numerous reports studying subjects with insulin resistance, type 2 diabetes, arteriosclerosis, and hypertension. A prevalent SNP association with impaired lipid homeostasis was observed in terms of the N-terminal proline alanine exchange (Pro12Ala) of the extra domain in the PPARγ2 variant. The authors analyzed the frequency of the Pro12Ala polymorphism in the PPARγ gene by a highly sensitive LNA-probe based polymerase chain reaction approach in a total of 622 subjects of a Caucasian population, suffering from fatty liver disease (n = 359) or healthy blood donors (n = 263). In agreement with reports showing a high Ala allele prevalence in patients with impaired lipid metabolism in obese and adipose patient, the Ala allele also occurs more often in FLD patients than in the healthy control group. Interestingly, the interpretation and linkage of the allele frequency to histological evaluation and clinical data demonstrates a prominent risk in alcoholic fatty liver disease (AFLD) patients bearing the Ala allele to develop severe steatohepatitis and fibrosis.

Innovations and breakthroughs

In order to detect the Ala12Pro polymorphism in patients with fatty liver disease the authors established an assay using locked nucleotide acid probes for allelic discrimination. The authors' data of a comprehensive study of the Pro12Ala polymorphism on biopsies with FLD, well classified concerning inflammatory and fibrotic alterations, revealed in patients with AFLD, but not with non-alcoholic fatty liver disease (NAFLD), an significant association of the Pro12Ala polymorphism with the risk to develop steatohepatitits. Therefore, PPARγ is suggested to exert a higher anti-inflammatory impact in progression of human AFLD than NAFLD.

Applications

The association of the Pro12Ala polymorphism with the risk of developing inflammatory progression in patients with AFLD suggests a more prominent influence of PPARγ2 on progression of human AFLD than on NAFLD. Therefore, the Pro12Ala polymorphism should be studied on an expanded cohort of AFLD patients, in order to be later integrated in a panel of genetic markers applied for future improved prognosis of disease progression and therapy planning.

Peer review

This review article provides an overview of SLE-related gastrointestinal system involvements, and there are only few review article in the international literatures in recent years.

Abstract

AIM: To translate into Greek and validate the chronic liver disease questionnaire (CLDQ).

METHODS: Two hundred and six consecutive adult patients with the diagnosis of a chronic liver disease from 2 general hospitals in Athens were enrolled in the study from May to September 2008. In order to assess their quality of life (QOL) the CLDQ was applied. The instrument was translated from English, back translated and reviewed in focus groups within the framework of a large multicenter study. The measurements that were performed included: 2 independent sample *t* tests, one-way analysis of variance, reliability coefficients, explanatory factor analysis using a varimax rotation and the principal components method.

RESULTS: One hundred and twenty five (61%) patients were men, half were aged 40-59 years and > 33% were > 60 years old. Among the patients, 48 (23%) were hospitalized and 97 (47%) were cirrhotic according to the Child-Pugh score. The internal consistency of the Greek CLDQ version using Cronbach's alpha coefficient was found to be 0.93. Exploratory factor analysis identified 7 domains accounting for 65% of the variance of CLDQ items and only partially overlapping with those found in the original version. The area under the receiver operating characteristics curve was calculated at 0.813 and the logistic estimate for the threshold score of 167.50 provided a sensitivity of 74.3% and a specificity of 71.6% for the model.

CONCLUSION: Our data confirmed the validity of the Greek version of the CLDQ in identifying the QOL among patients with chronic liver disease.

INTRODUCTION

Chronic liver disease encompasses a wide range of illnesses characterized by liver inflammation and progression to cirrhosis. Quality of life (QOL) is a concept that incorporates many aspects of an individual's experience, general well being and satisfaction, as well as social and physical functioning[1]. Health-related QOL is important when measuring the impact or burden of a chronic disease, such as liver disease, and is highly correlated with fatigue, loss of esteem, depression and disease complications[2]. In the last few decades, the assessment of health-related QOL has become an important outcome measure in clinical research in both gastroenterology and hepatology[3]. Whilst a variety of generic QOL measures have been developed, there is a need to develop specific instruments endowed with sufficient sensitivity to document clinically significant changes over time[4].

The chronic liver disease questionnaire (CLDQ) is a specific health-related QOL instrument designed for patients with liver disease, regardless of the underlying etiology and degree of disease. Its original version was developed first by Younossi *et al*[5] and has demonstrated appropriate validity and reliability. The CLDQ has already been cross-culturally adapted and validated into different languages in recently published studies[6-10]. Consequently, the aim of this paper was to: (1) report on the development of the Greek version of the CLDQ and on the validation procedures carried out; (2) examine the factorial structure of the Greek CLDQ; and (3) evaluate the sensitivity of the Greek CLDQ in assessing QOL over a range of cut-off scores among liver disease patients.

MATERIALS AND METHODS

CLDQ

The CLDQ is a 29-item self-reported scale consisting of statements describing QOL, and is divided into 6 domains including abdominal symptoms, fatigue, systemic symptoms, activity, emotional function and concern. All items refer to the previous 2 wk on a 7-point Likert scale, with 1 corresponding to the maximum frequency labeled as "all of the time" and 7 to the minimum labeled as "none of the time". Permission to reproduce and validate the CLDQ was provided by Younossi *et al*[5].

Greek version of CLDQ - translation and pilot study

The 29 items of the CLDQs were translated by 2 independent bilingual translators. Another native English speaker who did not have knowledge of the original instrument then back translated the Greek version. The backward translation was sent to a group of English experts for comments. The translated questionnaire was culturally adapted through a cognitive debriefing process that was used to identify any language problems and to assess the degree of respondents understanding of the item' s content that was meant to be elicited[5].

During this stage the reconciled Greek version of the CLDQ was pilot tested among 10 patients. As part of the cultural adaptation process, in-depth interviews were implemented with regard to the respondents understanding of the questionnaire with the purpose of revealing inappropriately interpreted items and translation alternatives. The participants gave their impression on the clarity of each item, the relevance of the content to their situation, the comprehensiveness of the instructions and their ability to complete it on their own. They were also encouraged to make suggestions whenever necessary. Finally, written comments made by the participants were included in the final Greek version of CLDQ.

Sample and data collection

Consecutive adult patients diagnosed with chronic liver disease, confirmed by laboratory tests, imaging studies and in most cases by liver histology, were asked to participate in our study. Enrolment started in May and ended in September 2008 among patients of the Gastroenterology Clinics of 2 general hospitals in Athens. Inclusion criteria were fluency in the spoken and written Greek language, age > 18 years and the existence of liver disease symptoms during the previous 3 mo. Non-Greek-speaking patients, patients who had undergone liver transplantation, patients with dementia or psychosis, and patients with refractory encephalopathy (grade Ⅱ and more) were excluded. To asses the severity of liver disease, the patients' Child-Pugh scores were calculated and patients' were classified as cirrhotic or not[11]. In total, 220 patients were approached and 206 patients agreed to participate (rate of attendance 93.6%). CLDQs were also completed by healthy participants (n = 208, controls) in order to perform receiver operating characteristics (ROC) analysis. The control group was selected randomly from a list of the Athens county population and was matched with cases by gender, age and educational background. One control was selected for one case participant. Both patients and healthy participants completed the CLDQ in the presence of a nurse.

All participants entering the study provided written informed consent after receiving a complete description of the study and having the opportunity to ask for clarifications. Along with the questionnaires there was a cover letter explaining the purpose of the study, providing the researchers' affiliation and contact information, and clearly stating that answers would be confidential and anonymity would be guaranteed in the final data reports.

Statistical analysis

Descriptive characteristics were determined for the sociodemographic variables of the sample and Student t tests were performed on the descriptive characteristics of the study population and the CLDQ score. All P-values were based on 2-sided tests and significance was defined as $P < 0.05$. The assumptions of normality, homogeneity and independence of the sample were checked. Reliability coefficients as measured by Cronbach's alpha were calculated for the CLDQ in order to assess reproducibility and consistency of the instrument. The underlying dimensions

Table 1 Patients' demographic and medical characteristics

	n (%)	Mean score	*P*-value
Sex			
Men	125 (60.7)	4.77 (1.26)	0.61
Women	81 (39.3)	4.85 (1.13)	
Age (yr)			
≤ 39	40 (19.4)	5.19 (1.15)	0.02

Autoimmune hepatitis	12 (5.8)	4.72 (1.31)	
Cirrhosis	36 (17.5)	3.92 (1.22)	
Other	15 (7.3)	4.87 (1.10)	

of the scale were checked with an explanatory factor analysis using a varimax rotation and principal components method as a descriptive method for analyzing grouped data[12]. Factor analysis using principal component analysis with varimax rotation was carried out to determine the dimensional structure of CLDQ using the following criteria: (1) eigenvalue > 1[13]; (2) variables should have a load > 0.50 on only one factor and < 0.40 on more factors; (3) the interpretation of the factor structure should be meaningful; and (4) the screen plot is accurate in the case where the means of communalities are above 0.60[14]. Computations were based on a covariance matrix, as all variables were receiving values from the same measurement scale[15]; Bartlett's test of sphericity with $P < 0.05$ and a Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy of 0.6 were used when performing this factor analysis. A factor was considered as important if its eigenvalue exceeded 1.0[13]. As the factor analysis found 2 independent domains, subsequent Cronbach's alpha measurements were separately performed for each domain, highlighting how the items were grouped together.

Sensitivity and specificity

The sensitivity and specificity were calculated at several cut-off scores of the CLDQ. A ROC analysis was carried out; this method allows the display of all the pairs of sensitivity and specificity values achievable as the threshold is changed from low to high scores, plotting the true-positive rate (sensitivity) on the vertical axis and the false-positive rate (1-specificity) on the horizontal axis. The area under the ROC curve is a quantitative indicator of the information content of a test and it may be interpreted as an estimate of the probability that a liver disease patient at random will, at each threshold, have a lower test score than a healthy participant.

Table 2 The 29 Greek chronic liver disease questionnaire items

	CLDQ item	mean ± SD
Q1	Abdominal bloating	5.08 ± 2.01
Q2	Tiredness or fatigue	3.98 ± 2.14
Q3	Bodily pain	5.22 ± 2.03
Q4	Sleepiness during the day	4.96 ± 1.89
Q5	Abdominal pain	5.67 ± 1.84
Q6	Shortness of breath	5.42 ± 2.02
Q7	Not eating enough	4.78 ± 2.35
Q8	Decreased strength	4.50 ± 2.21
Q9	Trouble in carrying or lifting heavy objects	4.59 ± 2.49
Q10	Anxiety	3.40 ± 2.29
Q11	Decreased energy	4.50 ± 2.25
Q12	Unhappiness	4.67 ± 2.02
Q13	Drowsiness	5.04 ± 1.87
Q14	Bothered by a limitation of the diet	3.17 ± 2.50
Q15	Irritability	4.33 ± 2.12
Q16	Difficulty in sleeping at night	4.91 ± 2.15
Q17	Abdominal discomfort	5.16 ± 2.05
Q18	Worries about the impact of the liver disease	3.95 ± 2.22
Q19	Mood swings	4.55 ± 2.01
Q20	Difficulty falling asleep at night	5.07 ± 2.15
Q21	Muscle cramps	5.50 ± 1.87
Q22	Worries that symptoms will develop into major problems	4.21 ± 2.05
Q23	Dry mouth	5.17 ± 2.06
Q24	Depression	4.74 ± 2.04
Q25	Worries that the condition is getting worse	4.28 ± 2.12
Q26	Problems	5.75 ± 1.74
Q27	Itching	5.78 ± 1.91
Q28	Worries about never feeling any better	4.46 ± 2.22
Q29	Concerned about the availability of a liver in the case of a transplant	6.41 ± 1.42

CLDQ: Chronic liver disease questionnaire.

RESULTS

Patients' demographic and medical characteristics are shown in Table 1. Almost 61% of the sample were men and nearly half of the sample ($n = 99$, 48%) were aged 40-59 years with 33% ($n = 67$) aged ≥ 60 years old. Seventy four (36%) had a primary level of education, 41% ($n = 85$) a secondary level and 23% ($n = 47$) had higher education. The majority of the patients (70%) were married. Regarding the patients' disease status, 23% were hospitalized while 47% were classified as having severe cirrhotic liver disease based on the Child-Pugh classification. The most common etiology for their liver disease was viral hepatitis (69.5%) and cirrhosis (18%). Table 1 also depicts the differences in the mean total score of CLDQ according to the patients' characteristics. More specifically, older age, lower educational level and cirrhotic disease were found to be associated with lower CLDQ scores and therefore with lower QOL among patients.

The mean score of the CLDQ was 4.81 [standard deviation (SD) 2.01] and ranged from 3.17 to 6.41 (Table 2). The communalities for the Greek CLDQs are presented in Table 3. The internal consistency characteristics of the

Factor Ⅶ	Question 10	0.72	1.68	5.78	64.81	0.67
	Question 15	0.73				

Greek CLDQ showed good reliability as the Cronbach's alpha was 0.93 for the total scale (Items 1-29). The exploratory factor analysis on the 29 items of the CLDQ revealed 2 orthogonal d (KMO measure of sampling adequacy = 0.886 and Bartlett's test of sphericity = 3422.25, df = 406, $P < 0.001$). Factor analysis indicated there are 7 principal domains in the model which explained 64.81% as presented in Table 4. The first domain (F1) included the following items: 2 (fatigue), 8 (decreased strength), 9 (trouble lifting heavy objects) and 11 (decreased level of energy) and this domain was named as "Fatigue". The second domain (F2) was composed of items 18 (concern about the impact of liver disease on the family), 22 (concern that symptoms will develop into a major symptom), 25 (concern about the condition getting worse) and 28 (concern about never feeling any better). Therefore F2 represented "Concern". The third factor (F3) included the following items: 1 (abdominal bloating), 5 (abdominal pain) and 17 (abdominal discomfort) and was named as "Abdominal symptoms". The fourth domain (F4) included the following items: 4 (feeling sleepy during the day) and 13 (drowsiness) and we named this as "Activity". The fifth factor (F5) was composed of items 12 (unhappiness) and 24 (feeling depressed). Therefore F5 represents "Emotional function". The sixth domain (F6) was composed of items 20 (unable to fall asleep at night) and 16 (difficulty sleeping at night). Therefore F6 represents "Sleeping disorders". The seventh domain (F7) was composed of items 10 (anxiety) and 15 (irritability). Therefore F7 represents "Anxiety". Cronbach's alpha for the 7 domains ranged from 0.67 (F7) to 0.93 (F2).

The Greek version of the CLDQ was well accepted by the patients. It was easily and very quickly (approximately 10 min) completed. The questions appeared to be relevant, reasonable, unambiguous and clear. Therefore, face validity was considered to be very good. The overall accuracy of the Greek CLDQ, as an instrument for assessing QOL among liver disease patients can be described as the area under its ROC curve calculated as 0.813 (SD = 0.021, Asymp. Sig < 0.0001). Table 5 presents the sensitivity and specificity values for the different cut-off values of the ROC analysis. A 167.50 cut-off score of the CLDQ provided the best sensitivity (74.3%) and specificity (71.6%). Figure 1 depicts the accuracy of the Greek CLDQ for assessing the level of QOL among patients with liver disease.

Table 5 Sensitivity and specificity values of different cut-off scores of the Greek chronic liver disease questionnaire for identifying level of quality of life

Threshold scores	Sensitivity (%)	Specificity (%)
147.50	57.8	99.0
157.50	64.6	82.2
167.50	74.3	71.6
175.50	85.4	55.8
185.50	92.2	37.0
194.50	98.5	16.8

DISCUSSION

CLDQ is a non-generic, disease-specific instrument for assessing QOL among liver disease patients. Our validation study provided a Cronbach's alpha equal to 0.93 and the factor analysis identified 7 domains with Cronbach's alpha ranging from 0.67 to 0.93 and included "Fatigue", "Concern", "Abdominal symptoms", "Emotional function", "Sleeping disorders", "Anxiety" and "Activity". Those domains explained 65% of the total variance. The ROC analysis presented the highest sensitivity and specificity at the overall score of 167.50, which can be considered as the cut-off score under which QOL can be assessed accurately.

CLDQ has already been validated in many countries

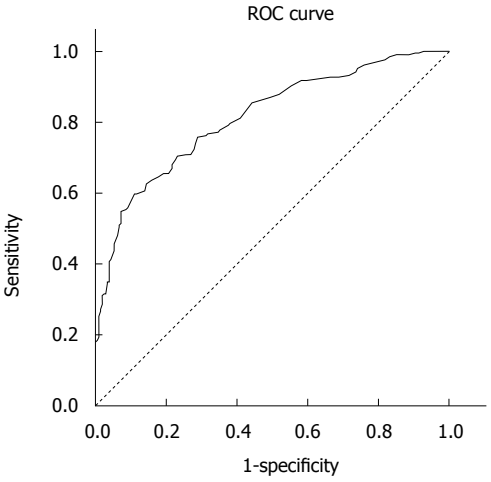

Figure 1 Receiver operating characteristics curve for the Greek chronic liver disease questionnaire. Diagonal segments are produced by ties. ROC: Receiver operating characteristics.

including Spain, Italy, Germany, Lithuania and Thailand and has shown remarkable reproducibility and comparability[6-10]. The overall Cronbach's alpha for the Greek CLDQ was found to be the same as those reported by the Spanish, Lithuanian and Thailand validation teams whereas the German validation study reported a Cronbach's alpha ranging from 0.69 to 0.95 among different domains. The cumulative variance of the Greek validated questionnaire is similar to the Spanish (68%) and Italian (65.4%) versions.

In comparing the structure of the Greek CLDQ with those of other countries we identified both discrepancies and similarities. The factor analysis of the Greek questionnaire revealed significance in 18 out of the 29 items included in the original one. The Greek validated version of CLDQ revealed a 7 domain structure similar to the Spanish validated questionnaire as opposed to the 6 domains of the original U.S. version[5] and the Italian version[10]. Additionally, the Greek version did not include questions regarding systemic symptoms which are included in the original version and in the existing validated versions of the questionnaire (Italian and Spanish)[9,10]. Sleepiness and drowsiness constitute a new domain in the Greek validation which was named "Activity" where as in both the Spanish[9] and in the original validation[5] they are included under the domain "Fatigue" and in the Italian version[10] under the domain "Somatic symptoms". "Anxiety" (including anxiety and irritability items) also consist of a separate domain in our validation whereas in the other validation studies these items are included in the domain of "Emotional symptoms". The "Fatigue" domain included the definitions of "felt drowsy" and "felt sleepy during the day" in the original and Spanish version[9] whereas in the Greek version these items are included in a new domain which was named as "Sleeping disorders". Only the factor comprising items that explored patient concern is common among the different versions.

The ROC analysis confirmed the effectiveness of CLDQ in assessing health-related QOL in the range of cut-off scores proposed. In our study, the high sensitivity (74.3%) of the 167.50 score allows the use of this cut-off score in the clinical assessment of QOL. If a health professional would like to use the Greek CLDQ for QOL assessment then these different cut-offs should be used. It is very important for the CLDQ to be used as a diagnostic tool in clinical practice which may allow health care professionals to understand the impact of health care interventions on the patient's everyday life, rather than the effects of treatment on their bodies[16]. Additional, the Greek CLDQ's use provides a basis for the holistic view of the patient and therefore may help facilitate a dialogue with patients with low QOL.

In general, this is the first study to validate the Greek CLDQ which is recommended to be incorporated into research and clinical practice to allow international comparison of the results of separate national studies[4]. An important strength of our study is that this is the first study to perform a ROC analysis which provided us with a cut-off score for assessing QOL accurately among patients with liver disease. Our findings also revealed a different structure of the questionnaire after the factor analysis which underlines the necessity of cultural validation and adaptation of the questionnaire before its use in specific countries. A limitation of this validation study was that there was no test-retest, because it may have resulted in a low correlation due to an actual change in the QOL symptoms. Additionally, the high percentage of patients with a cirrhotic liver disease might have affected the CLDQ score as the complications associated with cirrhosis, such as hepatic encephalopathy, have been shown to negatively influence physical and mental domains of QOL[17]. On the other hand, the exclusion of the patients with hepatic encephalopathy of grade Ⅱ or more might have reduced this error. In addition, the ethnic and cultural background of the patients may have had an effect on the score of CLDQ whereas previous studies have reported no differences in the CLDQ score among different ethnic groups[8,17].

The Greek version of the CLDQ has shown a satisfactory reliability and the factor analysis indicated 7 factors that were of interest. We can therefore assert that it is a reliable and valid tool for identifying QOL among liver disease patients and it can be used by health professionals in their clinical practice to improve assessment of patients with low scores. Our findings, however, need to be confirmed by future cross-sectional and cohort studies.

The authors gratefully acknowledge Zobair M Younossi, who gave his permission to use his CLD questionnaire.

COMMENTS

Background

Chronic liver disease questionnaire (CLDQ) is a disease specific instrument for assessing quality of life (QOL) among liver disease patients. In the last few decades, the assessment of QOL related to chronic liver disease has become an important outcome measure in clinical research.

Research frontiers

The CLDQ has already been cross-culturally adapted and validated into different languages. In the current study, the authors aimed to translate and validate the Greek version of the CLDQ.

Innovations and breakthroughs

The authors' findings revealed a different structure of the questionnaire after the factor analysis, which underlines the necessity of cultural validation and adaptation of the questionnaire before its use in specific countries. This is the first study to validate the Greek CLDQ which therefore should be incorporated into research and clinical practice so as to allow international comparison of the results of separate national studies. An important strength of the study is that this is the first study to perform a receiver operating characteristics (ROC) analysis which provided us with a cut-off score for accurately assessing QOL among patients with liver disease.

Applications

The Greek version of the CLDQ has shown a satisfactory reliability. The authors can therefore assert that it is a reliable and valid tool for identifying QOL among liver disease patients and it can be used by health professionals in their clinical practice to improve assessment of patients with low scores.

Terminology

ROC curve: a graphical plot of the sensitivity, or true positives, *vs* (1-specificity), or false positives, for a binary classification system as its discrimination threshold is varied.

Peer review

Dr. Zoi Kollia and colleagues validated the Greek version of the CLDQ to assess QOL factors for patients with chronic liver diseases. The establishment of QOL measures or indices is very important to assess what physical or mental status a patient is in and to compare multinational patients. This study provides an important clue to assess QOL of patients with chronic liver diseases.

Abstract

AIM: To study whether immune-activation stage in serum of adult Crohn's disease (CD) patients correlates with disease activity and with treatment response to anti-tumor necrosis factor-α (TNF-α) therapy.

METHODS: Serum samples were obtained from 15 adult CD patients introduced to anti-TNF-α therapy. The individual stage of immune activation was studied applying our new *in vitro* assay, in which target cells (donor derived peripheral blood mononuclear cells) were cultured with patient serum and the T-cell activation induced by the patient serum was studied using a panel of markers for effector [interferon γ (IFNγ), interleukin (IL)-5] and regulatory T-cells [forkhead transcription factor 3 (FOXP3) and glucocorticoid-induced tumour necrosis factor receptor (GITR)]. The endoscopic disease activity was assessed with the Crohn's disease endoscopic index of severity (CDEIS) before and 3 mo after therapy with an anti-TNF-α agent.
