RESULTS: Low induction of FOXP3 and GITR in target cells cultured in the presence of patient serum was associated with high disease activity i.e. CDEIS assessed before therapy (r = -0.621, P = 0.013 and r = -0.625, P = 0.013, respectively). FOXP3 expression correlated inversely with pre-treatment erythrocyte sedimentation rate (r = -0.548, P = 0.034). Low serum induced FOXP3 (r = -0.600, P = 0.018) and GITR (r = -0.589, P = 0.021) expression and low IFNγ secretion from target cells (r = -0.538, P = 0.039) associated with treatment response detected as a decrease in CDEIS.

CONCLUSION: The immune-activation potency in the patient serum prior to anti-TNF-α therapy reflected intestinal inflammation and the therapeutic response.

Key words: Crohn's disease endoscopic index of severity; Forkhead transcription factor 3; Glucocorticoid-induced tumour necrosis factor receptor; Infliximab; Inflammatory bowel disease

Serum immune-activation potency and response to anti-TNF-α therapy in Crohn's disease. *World J Gastroenterol* 2010; 16(46): 5845-5851 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i46/5845.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i46.5845

INTRODUCTION

Tumor necrosis factor-α (TNF-α), a pro-inflammatory protein secreted mainly by monocytes, macrophages and T-cells, has a central role in the disease pathogenesis of Crohn's disease (CD)[1-3]. TNF-α is elevated in stools and mucosa of CD patients[4-6].

The chimeric TNF-α-antibody infliximab and human IgG_1 TNF-α-antibody adalimumab are indicated for the treatment of moderate to severe CD[7,8]. During treatment with an anti-TNF-α agent, clinical improvement is accompanied by significant healing of endoscopic lesions and the disappearance of mucosal inflammatory infiltrate[9]. The therapeutic response, however, is not uniform and a significant proportion of patients are non-responders. In the ACCENT I study, 58% of patients with moderate CD responded to the first infusion of infliximab and with adalimumab 24%-36% of TNF-α-antibody naïve patients responded to the induction of therapy[7,8].

There are a few studies exploring immunological markers that reflect treatment response to anti-TNF-α therapy in CD. Elevated concentration of mucosal nuclear NFκBp65 and high secretion of TNF-α by cells of peripheral blood cultivation precede clinical relapse[10]. In the study by Mäkitalo *et al*[11], the expression profile of the macrophage tissue inhibitor of metalloproteinase (TIMP)-1 and stromal TIMP-3 in the intestine correlated positively with the Crohn's disease endoscopic index of severity (CDEIS) and the down regulation of matrix metalloproteinase-9 (MMP9) production of macrophages correlated with histological improvement during anti-TNF-α therapy. Further, in another study serum MMP9 levels seemed to decrease particularly in those CD patients who responded to infliximab therapy[12].

Recently, we described a novel approach to study individual treatment responses at an early phase of glucocorticoid therapy. In that study we investigated pediatric patients with inflammatory bowel disease (IBD) introduced to systemic glucocorticoids and showed that patient serum modified the expression of T-cell signalling markers on target cells (peripheral blood mononuclear cells from a healthy donor)[13].

Encouraged by this finding we applied the same method to study the individual immune-activation potency in adult CD patients starting anti-TNF therapy. We measured the expression of the regulatory T-cell markers forkhead transcription factor 3 (FOXP3) and glucocorticoid-induced tumour necrosis factor receptor (GITR), and cytokines interferon γ (IFNγ), interleukin-5 (IL-5) and IL-17 induced in the target cells by patient serum in 15 adult CD patients at the beginning of anti-TNF-α therapy. We found that prior to anti-TNF-α therapy the ability of patient serum to modulate the FOXP3 and GITR activation of the target cells mirrored the disease activity and the individual therapeutic response in the gut assessed with the CDEIS.

MATERIALS AND METHODS

Subjects

Fifteen adult patients (6 females) with established CD were introduced to an anti-TNF-α agent due to an acute flare ($n = 6$), chronic active disease (6), or rapid postoperative reoccurrence of the disease (3; Table 1). Fourteen patients received infliximab infusion 5 mg/kg at week 0 and 8. One patient received an adalimumab induction dose 80 mg subcutaneously (*s.c.*) at week 0, followed by 40 mg *s.c.* every other week until week 8. After the beginning of the anti-TNF-α treatment, corticosteroids were tapered off.

CDAI at baseline, median (range)	158 (49-605)	
CDAI at week 12, median (range)	66 (24-202)	

CDAI: Crohn's disease activity index; TNF: Tumor necrosis factor.

All patients underwent an ileocolonoscopy before the introduction of anti-TNF-α therapy (median 7 d, range 1-38 d) and the endoscopic assessment of treatment response was performed at week 12 (week 10 for the adalimumab-treated patient). The endoscopic activity was graded according to the CDEIS[14,15]. This score is based on the presence of superficial or deep ulcerations, proportion of affected and ulcerated surface, and presence of either ulcerated or non-ulcerated stenosis in the terminal ileum and four segments of the colon (right, transverse, left colon and sigmoid, and rectum)[14]. Clinical disease activity was assessed with the Crohn's disease activity index (CDAI)[16].

Exclusion criteria were contraindication to anti-TNF-α treatment, pregnancy, history of extensive bowel resection, ostomy, long-term use of nonsteroidal anti-inflammatory drugs, or perianal fistulating disease without luminal inflammation.

Blood samples and fecal calprotectin

A serum sample for the target cell assay was provided at the time of the first ileocolonoscopy. The routine blood samples for serum C-reactive protein (CRP, normal value < 10 mg/L), erythrocyte sedimentation rate (ESR) and

fecal samples for measurement of calprotectin (PhiCal Test, Calpro AS, Oslo, Norway[17,18]) were obtained by the time of the endoscopies and 3 mo after the first anti-TNF-α dose[15].

Laboratory assay for systemic immunological effects

The assay for the assessment of individual stages of immunoactivation by applying patient serum in an in vitro culture of donor derived peripheral blood mononuclear cells (PBMC, target cells) is described recently in detail[13]. In brief, healthy donor (male 34 years) derived PBMC were separated by Ficoll-Paque (Amersham Biosciences) centrifugation (800 × G, 25 min) and cultured in the presence of the patients inactivated (35 min in 56℃) serum at an end concentration of 8%, either at resting state or activated with mitogen phytohemagglutin (PHA, 5 μg/mL). Serum of a healthy donor (male 27 years) was used as the methodological control between cell culture plates. After 72 h incubation at 37℃ in humified atmosphere with 5% CO2/air the supernatants were collected and stored at -70℃. This assay was performed with serum samples drawn prior to first anti-TNF-α infusion.

ELISA for IFNγ, IL-5 and IL-17

IFNγ, IL-5 and IL-17 were measured with ELISA in duplicate from the supernatants collected from the target cell cultures (see above) incubated with patient serum. IFNγ and IL-5 was detected as described before[19,20]. IL-17 was measured according to the manufacturer's protocol (Catalogue no: DY317; R&D Systems, United Kingdom). We subtracted the non-stimulated value from the stimulated value to obtain the Δ-value for statistical analyses.

Quantitative reverse transcriptase-polymerase chain reaction

Quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) process was recently described in detail[13]. Briefly, total RNA was isolated from cell samples with the GenElute Mammalian total RNA miniprep kit (Sigma-Aldrich), and the RNA concentration was measured by a spectrophotometer (ND-1000, NanoDrop Technologies Inc, Wilmington, DE, USA). Reverse transcription was performed by using TaqMan Reverse Transcription reagents (Applied Biosystems, Foster City, CA, USA) with additional treatment of total RNA at 10 ng/μL with DNAse I (0.01 U/μL) (Roche Diagnostics, Mannheim, Germany) to eliminate genomic DNA. Quantitative RT-PCR was performed using predesigned FAM-labelled TaqMan Gene Expression Assay reagents (Applied Biosystems) and the ABI Prism 7700 Sequence Detection System (Applied Biosystems) in triplicate wells. Assay reagents for FOXP3 (Hs00203958_m1), GITR (Hs00188346_m1), IFNγ (Hs00174143_m1) and 18s RNA (Hs99999901_s1) were used. The difference value (ΔCt) is the normalised quantitative value of the expression level of the target gene achieved by subtracting the Ct value of the reference gene (18s) from the Ct value of the target gene. An exogenous cDNA pool calibrator was collected from PHA stimulated PBMC and considered as an interassay standard to which normalized samples were compared. ΔΔCt is the difference between the ΔCt of the analyzed sample and ΔCt of the calibrator. Calculation of $2^{-\Delta\Delta Ct}$ gives a relative amount of the target gene in analyzed sample compared with the calibrator, both normalized to an endogenous control (18S). For presentations the relative amount of target genes was multiplied by 1000 and expressed as relative units.

Statistical analysis

Results are reported as median. Comparison between two dependent samples was calculated with Wilcoxon rank test and two independent samples was calculated with Mann-Whitney *t*-test. The two-tailed Spearman's rho was used for calculation of the correlations and Kruskall-Wallis test served in exploring associations between groups (SPSS 16.0 program). $P < 0.05$ was set for statistical significance.

Ethics

All patients gave their informed written consent for participation in this study approved by the ethics committee of the Helsinki University Central Hospital.

RESULTS

Patient serum induced IFNγ, FOXP3 and GITR specific mRNA expression and secretion of IFNγ, IL-5 and IL-17 from target cells

The expression levels of IFNγ, FOXP3 and GITR specific mRNA in both resting and activated target cells cultured in the presence of CD patient serum obtained before anti-TNF-α therapy is shown in Table 2. Also, the secretion of IFNγ, IL-5 and IL-17 from activated target cells is shown in Table 2. The secretion of IFNγ, IL-5 and IL-17 from resting target cells was below detection limits.

The type of CD or localization was not associated with the level of IFNγ, FOXP3 and GITR specific mRNA expression or IFNγ, IL-5 and IL-17 secretion from target cells (all P = NS).

CDEIS

During anti-TNF-α therapy the CDEIS decreased from a median of 13 points (range 1.8-25) to 4.8 points (range 0-11, P = 0.002). 12/15 patients responded to therapy, while 3 patients had no decrease in the CDEIS.

Correlations between the target cell responses and pre-treatment the CDEIS

The expression of regulatory T-cell markers FOXP3 and GITR specific mRNA in activated target cells cultured with patient serum correlated inversely with the pre-treatment CDEIS (FOXP3 r = -0.621, P = 0.013 and GITR r = -0.625, P = 0.013; Figure 1). A trend towards an inverse correlation between IFNγ mRNA expression and the pre-treatment CDEIS was observed (r = -0.446, P = 0.095). There was no correlation between IFNγ, IL-5 or IL-17 secretion from target cells and the pre-treatment CDEIS (*P*

Table 2 The effect of Crohn's disease patient serum withdrawn before anti-tumor necrosis factor-α therapy on forkhead transcription factor 3, glucocorticoid-induced tumour necrosis factor receptor and interferon γ specific mRNA expression (relative units) and interferon γ, interleukin-5 and interleukin-17 secretion (pg/mL) from peripheral blood mononuclear cells obtained from healthy volunteers (target cells)

Secretion of interferon (IFN) γ, interleukin (IL)-5 and IL-17 from naive target cells was below detection limit. Phytohemagglutin (PHA) = Target cells activated with phytohemagglutin. RT-qPCR: Quantitative reverse transcriptase-polymerase chain reaction; GITR: Glucocorticoid-induced tumour necrosis factor receptor; FOXP3: Forkhead transcription factor 3.

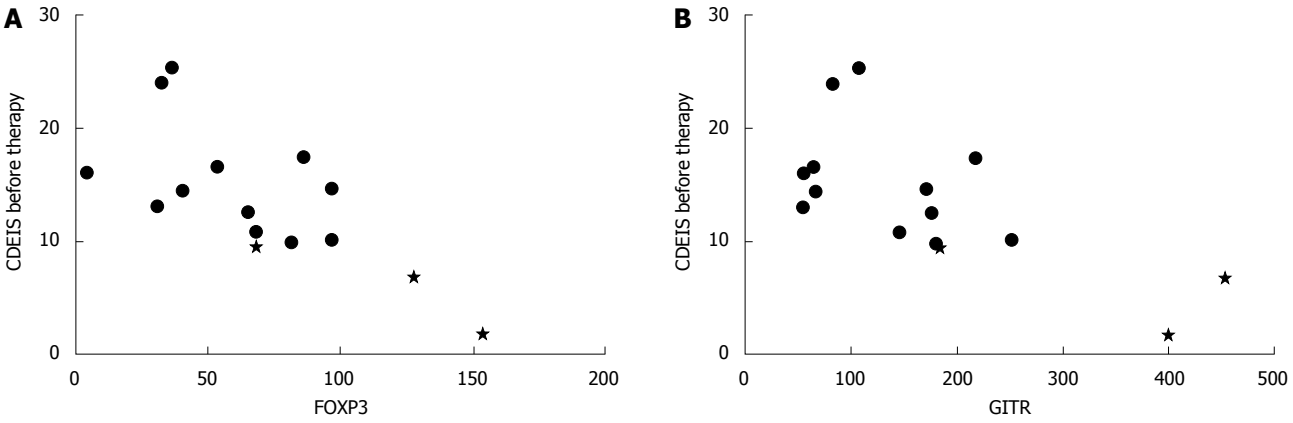

Figure 1 Patient serum withdrawn before anti-tumor necrosis factor-α therapy induced forkhead transcription factor 3 (A) and glucocorticoid-induced tumour necrosis factor receptor (B) specific mRNA expression (relative units) in activated target cells that correlated negatively with pre-treatment Crohn's disease endoscopic index of severity. [points; forkhead transcription factor 3 (FOXP3) r = -0.621, P = 0.013; glucocorticoid-induced tumour necrosis factor receptor (GITR) r = -0.625, P = 0.013]. Patients who had no decrease in Crohn's disease endoscopic index of severity (CDEIS) during therapy are marked with star.

= 0.241 for IFNγ, P = 0.286 for IL-5 and P = 0.980 for IL-17).

Correlations between target cell responses and the change of CDEIS during anti-TNF-α therapy

Low patient serum induced FOXP3, GITR and IFNγ specific mRNA expression in target cells was associated with a remarkable change of CDEIS observed during 3 mo therapy (FOXP3 r = -0.600, P = 0.018; GITR r = -0.589, P = 0.021; IFNγ r = -0.486, P = 0.066; Figure 2). Accordingly, in resting target cells GITR specific mRNA expression correlated with the change of CDEIS (r = -0.550, P = 0.034).

Also low serum induced IFNγ and IL-5 secretion from activated target cells was associated with a high change of CDEIS (r = -0.538, P = 0.039; r = -0.504, P = 0.055). IL-17 secretion from activated target cells did not correlate with the change of CDEIS (P = 0.467).

Findings related to fecal calprotectin

Fecal calprotectin decreased from a median of 1170 μg/g (range 88-15300) to a median of 130 μg/g (range 13-1400) within the 3 mo anti-TNF-α treatment (P = 0.001). No correlation was observed between target cell responses and calprotectin levels before or after treatment.

Findings related to ESR and CRP

ESR decreased from a median of 18 mm/h (range 6-58) to a median of 10.6 mm/h (range 1-40; P = 0.001) and CRP decreased from a median of 10 mg/L (range 0-54)

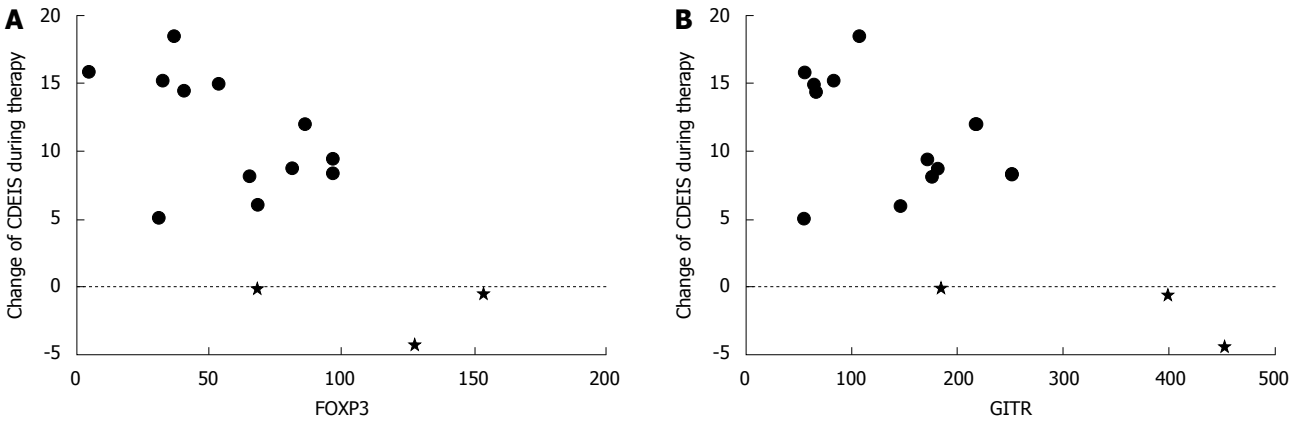

Figure 2 Patient serum withdrawn before anti-tumor necrosis factor-α therapy induced (A) forkhead transcription factor 3 (r = -0.600, P = 0.018) and (B) glucocorticoid-induced tumour necrosis factor receptor (r = -0.589, P = 0.021) specific mRNA expression (relative units) in activated target cells that had a negative correlation with the change of Crohn's disease endoscopic index of severity during three months therapy. The change of Crohn's disease endoscopic index of severity (CDEIS) corresponds with the decrease in points along improvement and is given as a positive value to illustrate the magnitude of therapeutic response. Patients who showed no decrease in the CDEIS during therapy are marked with star. GITR: Glucocorticoid-induced tumour necrosis factor receptor; FOXP3: Forkhead transcription factor 3.

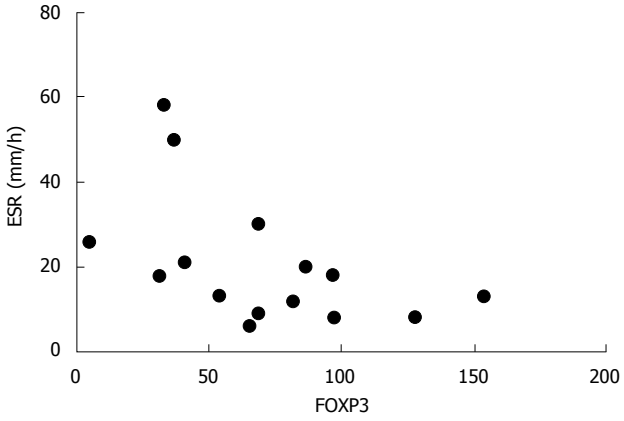

Figure 3 Patient serum withdrawn before anti-tumor necrosis factor-α therapy induced forkhead transcription factor 3 specific mRNA expression (relative units) in activated target cells that correlated negatively with erythrocyte sedimentation rate. ESR: Erythrocyte sedimentation rate. r = -0.548, P = 0.034.

to a median of < 5 mg/L (range < 5-11, P = 0.005) within 3 mo after introduction of anti-TNF-α therapy.

FOXP3 specific mRNA expression in activated target cells correlated negatively with pre-treatment ESR (r = -0.548, P = 0.034, Figure 3). There was no correlation between pre-treatment ESR and GITR ($P \geqslant 0.210$) or IFNγ ($P \geqslant 0.109$) specific mRNA expression or cytokine secretion from target cells (IFNγ P = 0.755, IL-5 P = 0.434, IL-17 P = 0.511).

FOXP3, GITR or IFNγ specific mRNA expression in target cells or IFNγ, IL-5 or IL-17 secretion from target cells did not correlate with the change of ESR or CRP during 3 mo anti-TNF-α therapy (all P = NS, data not shown).

DISCUSSION

We found that serum samples obtained from patients with CD before the introduction of anti-TNF-α therapy modulated the expression of regulatory T-cell (T-reg) markers FOXP3 and GITR and secretion of inflammatory cytokines IFNγ, IL-5 and IL-17 from target cells (peripheral blood mononuclear cells from healthy donors). The serum induced FOXP3, GITR and IFNγ responses of target cells correlated with the pre-treatment endoscopic status and also with therapeutic responses, i.e. mucosal improvement assessed with CDEIS within 3 mo.

In our previous study of children with IBD we found that the attenuation of systemic inflammation after the start of oral glucocorticoids was mirrored in the target cell responses induced by the patient serum[13]. We underline that we measured cytokine secretion and transcription markers of the target cells (donor derived PBMCs) modulated by the patient serum and not the activation stage of the PBMC from the patient. To our knowledge the ability of patient serum to activate signalling of normal T-cells has not previously been studied in adult CD patients at induction of anti-TNF-α therapy. It is remarked that post-treatment samples are not comparable here since the serum taken after the treatment contains an anti-TNF-α agent.

We found an inverse correlation between the expression of T-reg markers FOXP3 and GITR in target cells and the endoscopic disease activity before therapy. A similar inverse correlation existed also between FOXP3 and pre-treatment ESR. Since FOXP3 inhibits T-cell activation by its suppressive effect on transcription of cytokine genes[21] it is reasonable to assume that those patients whose serum environment seemed to mediate enhanced FOXP3 up-regulation as a response to T-cell stimulation had endoscopically milder disease. However, the serum induced expression of FOXP3 in target cells was not directly reflected in the cytokine activation of the target cells and cytokine response did not correlate with the pre-treatment CDEIS. Impaired up-regulation of GITR in the patient serum environment may be related to poor suppression of T-cell activation[22,23].

Interestingly, we also found that low expression of FOXP3 and GITR specific mRNA induced by patient serum obtained prior to therapy was associated with a good therapeutic response within 3 mo. These parameters were associated with high clinical activity and thus enhanced inflammation *in vivo*. High inflammatory activity at the early phase of anti-TNF-α therapy has been connected to the lack of therapeutic response in rheumatoid arthritis (RA). Previously non-responders to anti-TNF-α agents had a higher number of blood T-cells expressing chemokine receptors (CCR 3 and CCR 5) before the introduction of therapy[24]. In another study, high levels of serum IL-2 were associated with poor therapeutic response[25]. In our study, the group of patients that had high potency for FOXP3 induction in target cells showed poor clinical response to anti-TNF treatment. It was also evident that their disease activity before treatment was milder. TNF blocking has been shown to induce FOXP3 expression in patients with RA. Recovery of regulatory mechanisms has been proposed to be one of the mechanisms of action for TNF blocking[26]. It is possible that non-responders whose serum induced high FOXP3 up-regulation in target cells do not benefit from further activation of FOXP3 but their disease activity should be down-regulated by other mechanisms.

The majority of CD patients driven to anti-TNF-α therapy are on immunosuppressive medication such as azathioprine or methotrexate as here also. However, there was no correlation between patient serum induced expression or secretion of inflammatory cytokines from target cells and pre-treatment disease activity. We suggest that individual differences in target cell responses mediated by patient serum represents the net effect of maintenance medication, disease activity and patients immunological heterogeneity that together reflect the patients further capability to respond to biological therapy.

Fecal calprotectin correlates with the CDEIS and CRP[15,27]. In this study we failed to find statistically significant correlations between calprotectin or CRP and target cell responses. This finding was similar to the finding in our previous study of IBD children. Fecal calprotectin excretion reflects increased neutrophils and mononuclear cell migration into the gut lumen through the inflamed mucosa[28] and CRP is an acute phase protein produced predominantly in the liver in response to stimulation by IL-6, TNF-α and IL-1β[29]. It seems that the ability of patient serum to activate target cells reflects the immunological net effects in circulation in CD patients rather than inflammatory cell accumulation in the intestine reflected in fecal calprotectin.

To conclude, there are few studies of the mechanisms of treatment failure during anti-TNF-α therapy. An impaired response to anti-TNF-α therapy in CD has been suggested to be a result of early reactivation of the inflammatory cascade caused by individual intrinsic immunological mechanisms[10]. Also the inflammatory activity of the disease itself may play a role in the therapeutic response. We found that the immune activation potency of the patient serum that is monitored by gene expression profile of human PBMC is individual and correlates to later mucosal healing during anti-TNF-α therapy. Characterization of the key factors in serum that mediated the effects observed with this method, such as up-regulation of FOXP3 and GITR, could be one step toward better understanding of *in vivo* actions of anti-TNF-α therapies.

COMMENTS

Background

Since the FDA approval of infliximab in 1999 for the treatment of severe Crohn's disease (CD), the use of tumor necrosis factor-α (TNF-α)-antagonist agents has emerged in treatment of severe inflammatory bowel disease. A significant proportion of patients, however, do not respond to the treatment. To date there are no means to foresee the therapeutic response or to monitor the response at an early phase of therapy with an TNF-α-antagonist agent.

Research frontiers

Recently, the authors applied a novel immunological assay for assessment of therapeutic response to glucocorticoids in pediatric patients with inflammatory bowel disease. In that study they showed that the therapeutic effect of corticosteroid therapy can be measured from patient serum at an early phase of the therapy. In the *in vitro* assay, a sample of patient serum is used to stimulate human white blood cells and the effect on specific white blood cell (T cell) markers is assessed. This kind of testing seems a promising means to predict individual responses to immunological therapies.

Innovations and breakthroughs

There are few studies exploring the immunological markers that reflect treatment response to anti-TNF-α therapy in CD. Here the authors used a recently described assay to measure therapeutic response to TNF-α-antagonist therapy from a patient serum sample. Disease activity and response to therapy is reflected in the patient serum and can be measured before the introduction of therapy. Serum induced changes in the specific white blood cell markers [forkhead transcription factor 3 (FOXP3), glucocorticoid-induced tumour necrosis factor receptor (GITR)] seemed to reflect individual response to anti-TNF-α therapy.

Applications

The results suggest that the effect of therapy with an anti-TNF-α agent can be measured from patient serum at an early phase. The study group was small and the results are preliminary, thus more studies are warranted to establish whether this kind of serum testing is suitable for predicting the individual response to anti-TNF-α therapy in clinical practice.

Terminology

Forkhead box P3, FOXP3, is a gene regulating the development and function of specific white cells, regulatory T cells. GITR is glucocorticoid-induced tumour necrosis factor receptor. FOXP3 and GITR are commonly used markers for regulatory T-cell activity.

Peer review

This study raises some interesting points never raised before about the T regulatory cell responses with biological agents.

Abstract

AIM: To assess the effect of nitric oxide (NO) on the large conductance potassium channel (BK_{Ca}) in isolated circular (CM) and sling (SM) muscle cells and muscle strips from the cat lower esophageal sphincter (LES) to determine its regulation of resting tone and relaxation.

METHODS: Freshly enzymatically-digested and isolated circular smooth muscle cells were prepared from each LES region. To study outward K^+ currents, the perforated patch clamp technique was employed. To assess LES resting tone and relaxation, muscle strips were mounted in perfused organ baths.

RESULTS: (1) Electrophysiological recordings from isolated cells: (a) CM was more depolarized than SM (-39.7 ± 0.8mV *vs* -48.1 ± 1.6 mV, $P < 0.001$), and maximal outward current was similar (27.1 ± 1.5 pA/pF *vs* 25.7 ± 2.0 pA/pF, $P > 0.05$); (b) The NO donor sodium nitroprusside (SNP) increased outward currents only in CM (25.9 ± 1.9 to 46.7 ± 4.2 pA/pF, $P < 0.001$) but not SM (23.2 ± 3.1 to 27.0 ± 3.4 pA/pF, $P > 0.05$); (c) SNP added in the presence of the BK_{Ca} antagonist iberiotoxin (IbTX) produced no increase in the outward current in CM (17.0 ± 2.8 *vs* 13.7 ± 2.2, $P > 0.05$); and (d) L-NNA caused a small insignificant inhibition of outward K^+ currents in both muscles; and (2) Muscle strip studies: (a) Blockade of the nerves with tetrodotoxin (TTX), or BK_{Ca} with IbTX had no significant effect on resting tone of either muscle; and (b) SNP reduced tone in both muscles, and was unaffected by the presence of TTX or IbTX.

CONCLUSION: Exogenous NO activates BK_{Ca} only in CM of the cat. However, as opposed to other species, exogenous NO-induced relaxation is predominantly by a non-BK_{Ca} mechanism, and endogenous NO has minimal effect on resting tone.

Key words: Circular smooth muscle; Feline; K^+ channel; Lower esophageal sphincter; Nitric oxide; Sling; Tone

INTRODUCTION

Nitric oxide (NO) is the main neurotransmitter for active inhibition and relaxation of the lower esophageal sphincter (LES)[1-4]. In the esophageal body and in the LES circular muscle, NO activates the large conductance potassium channel (BK_{Ca}) and causes membrane hyperpolarization[5-9] as one potential mechanism leading to LES relaxation. NO has also been shown to be one putative neurotransmitter responsible for the membrane hyperpolarization of the inhibitory junction potential (IJP) in the LES circular muscle of the opossum, guinea pig, dog and mouse[6,10-15]. Activation of the BK_{Ca} by NO is a factor in production of the IJP membrane hyperpolarization[15].

In the cat, the BK_{Ca} channel plays a role in setting the resting membrane potential (RMP) in LES muscles[16]. This modulation of the RMP by the BK_{Ca} is also present in the opossum LES circular muscle and blockade of the BK_{Ca} results in an increase in tone attributed to a balance between the calcium-activated BK_{Ca} and chloride (Cl^-) channels that raise the RMP to the point where ongoing spiking activity is produced[17]. In the dog LES circular muscle, the activation of the BK_{Ca} in setting the RMP involves at least an endogenous source of NO[18,19]. It is not known to what extent endogenous NO is similarly involved in BK_{Ca} regulation of LES tone in other species.

The LES is composed of at least two separate muscle components, the circular and the oblique sling muscles[19]. In humans, the circular muscle forms only a partial ring (or semicircular clasp), whereas in other species including the cat, the circular muscle fully encircles the distal esophagus[19,20]. The circular and the sling muscles are functionally different with unique motor and electrophysiological properties. The circular muscle has significant spontaneous myogenic resting tone but is poorly responsive to cholinergic stimulation, whereas the sling muscle has little intrinsic myogenic tone but contracts vigorously to cholinergic stimulation, whereby it maintains its resting tone *in vivo*[21-26]. There are regional differences within the feline LES in terms of distribution, nature and function of ion channels[16,17,27-30]. In particular, the BK_{Ca} density is greater in circular muscle than in the sling muscle[16].

The objective of the present study was to determine in the cat, whether the BK_{Ca} in LES circular and sling muscles is influenced by exogenous and/or endogenous NO to regulate muscle resting tone and/or relaxation. These studies utilized isolated smooth muscle cells and strips taken from the feline LES circular and sling regions. The effect of endogenous *vs* exogenous sources of NO on the outward K^+ currents was also assessed and compared. A portion of this work has appeared in abstract form[31].

MATERIALS AND METHODS

Animal model

The cat was chosen as our animal model because of several important similarities between the cat and human esophagus. These similarities include (1) a significant portion of the distal esophageal body is composed of smooth muscle[20]; (2) the cholinergic sensitivity of the smooth muscle esophagus and LES are similar[22,23]; and (3) the placement of the gastroesophageal junction is similarly placed relative to the diaphragm[20].

Animal preparation

Experiments were approved by the University Health Network Animal Care Committee. Fasted, adult cats of either sex, weighing 2.5 to 5.0 kg were anesthetized with ketamine hydrochloride (0.15 mL/kg *im*; Bimeda-MTC, Cambridge, ON, Canada) and euthanized with pentobarbital sodium (0.5 mL/kg *iv*; Bimeda-MTC). At laparotomy, an esophago-gastric segment from 5 cm above the LES and including a 4 cm cuff of the stomach was carefully excised and placed into Krebs solution equilibrated with 95% O_2/5% CO_2 and maintained at pH 7.40 ± 0.05. The tissue was freed from surrounding fascia, stretched to its *in situ* length, and then cut along the greater curvature of the stomach. The mucosa was then gently removed to expose the LES circular and sling regions[22]. To consider regional differences within the LES circular *vs* sling muscles, muscle strips and isolated smooth muscle cells were prepared from each region.

Muscle strip studies

Muscle strips, 2 mm wide and 8 mm long, were obtained from the long axis of the circular and oblique sling muscles. Muscle strips were individually mounted in a 25 mL water-jacketed tissue bath. For isometric tension measurement (transducer model FT-03; Grass Instruments, Quincy, MA, USA) Force transducer data were acquired (Digi-Data 1200B analog-to-digital converter, Axon Instruments, Union City, CA, USA) and analyzed using pCLAMP software (version 8; Axon Instruments, Union City, CA, USA). Transmural electrical field stimulation (EFS) was delivered (Grass stimulator SP-9) through platinum wire electrodes with. 0.5 ms square-wave pulses in a 5 s train at a frequency of 10 Hz and a strength of 70 V.

Initially muscle strips were hung with 0.5 g tension for a 1 h equilibration period, and the length was then measured and defined as L_0 (initial length). Strips were then slowly stretched twice at increments of 25% of L_0 with 15 min between each stretch[24]. At study length of 150% L_0, EFS of the sling muscle resulted in an initial contraction in all strips and EFS of circular muscle resulted in relaxation in all strips studied[25].

The relative contribution of the BK_{Ca} channel to tension as affected by an exogenous or endogenous myogenic source of NO was assessed with the nerves intact or blocked with tetrodotoxin (TTX) and using the following protocols: (1) TTX alone (10^{-6} mol/L) or with blockade of the BK_{Ca} channel with iberiotoxin alone (IbTX, 10^{-7} mol/L), or the two in combination TTX (10^{-6} mol/L) + IbTX (10^{-7} mol/L); and (2) TTX (10^{-6} mol/L) + SNP [sodium nitroprusside (10^{-4} mol/L)] ± IbTX (10^{-7} mol/L) or TTX (10^{-6} mol/L) + IbTX (10^{-7} mol/L) ± SNP (10^{-4} mol/L). The chemicals were successively added and allowed 15-30 min to act, the strips were not washed in between experimental steps.

The data were normalized and expressed as tension: tension (mmol/L per mm^2) = [tone (g) × 9.81 m/s^2]/[cross-sectional area (mm^2)]; where the cross-sectional area (mm^2) = [tissue weight (mg)]/[1.05 mg/mm^3 × study length (mm)], and where 1.05 mg/mm^3 is the density of smooth muscle[32]. The unstimulated tension was referred to as baseline resting tension. After an experiment, each muscle strip was blotted onto a filter paper and weighed.

Isolated smooth muscle cell studies

Freshly enzymatically-digested and isolated circular smooth muscle cells were prepared from each LES region[30]. Two to three pieces (about 2 mm^2) of LES tissues were cut and placed into a test tube with 1 mL of dissociation solution and stored at 4℃ for up to 36 h. For cell dissociation of the cells, each of the following chemicals was added to the test tube: papain (2 mg/mL), collagenase Sigma blend type F (1.3 mg/mL), 1,4-dithio-L-threitol (154 μg/mL) and bovine serum albumin (1 mg/mL) were added and the tube was incubated at 35℃ for 30-60 min. Following rinsing in enzyme-free dissociation solution and gentle mechanical agitation, isolated spindle-shaped single smooth muscle cells were allowed to settle and adhere to a 1 mL glass bottom recording chamber, mounted on the stage of an inverted microscope. After 30 min, cells were washed with external solution and used within 4 h of isolation. Recordings were performed at room temperature (22-25℃).

To study outward K^+ currents, the perforated patch clamp technique was employed, with the pipette tip resistance between 2-4 MΩ. The pipettes were front-filled with the pipette solution and back-filled with the nystatin solution. With a giga ohm seal the cell was held at -50 mV and a whole-cell configuration was achieved within 5 min. Once a stable access resistance (i.e. below 20 MΩ) had been achieved and maintained, the RMP was measured. To study the effect of NO, two approaches were employed: (1) puffing sodium nitroprusside (SNP, NO donor, 10^{-4} mol/L) onto the muscle cell with a picospritzer[29] positioned 100 μm from the cell (to mimic NO release from nerves); and (2) adding N^G-nitro-L-arginine (L-NNA; NO synthase inhibitor; 10^{-4} mol/L) to the recording dish (to assess the potential contribution of endogenous NO). BK_{Ca} channel currents were blocked by the addition of iberiotoxin (IbTX, 200 nmol/L).

To record outward K^+ currents, voltage-ramp protocols (starting and ending with the holding potential of -50 mV), from -140 to +60 mV or from -70 to +70 mV over 500 ms were generated by a pClamp 9.0 software (Axon Instruments, Union City, CA,USA) and recorded by an Axopatch 200B amplifier (Axon Instruments). Before digitization, all signals were sampled at 10 kHz, filtered at 1 kHz by an on board eight-pole Bessel filter, and digitized (Digidata 1320 converter, Axon Instruments). Cell capacitance was determined by integration of the capacitance transient, and the maximal current density was normalized for cell size. Peak outward currents were compared after each pharmacological manipulation. Recordings were analyzed using Clampfit 9.0 software (Axon Instruments).

Chemicals and solutions

Atropine (atropine sulfate), TTX (Alomone Labs, Jerusalem, Israel), IbTX (Alomone Labs) and the dissociation enzymes were reconstituted into deionized distilled water. SNP was diluted into the external solution. Seventy-five mg of L-NNA was added into 5 mL of 0.1 mol/L HCl, heated gently until dissolved, and then brought up to 10 mL with water. For nystatin, 0.006 g of the powder was dissolved into 200 μL DMSO and 13 μL of that stock was further diluted into 2 mL of pipette solution. If not otherwise stated, all chemicals were purchased from Sigma-Aldrich (Oakville, ON, Canada).

For the muscle strip studies, the Krebs solution (115 mmol/L NaCl, 4.6 mmol/L KCl, 1.2 mmol/L $MgSO_4 \cdot 7H_2O$, 1.2 mmol/L $NaH_2PO_4 \cdot H_2O$, 22 mmol/L $NaHCO_3$, 2.0 mmol/L $CaCl_2 \cdot 2H_2O$ and 11 mmol/L dextrose) was maintained at 37℃ with 95% O_2/5% CO_2 in the organ bath. For the isolated smooth muscle studies, the dissociation solution (135 mmol/L KCl, 10 mmol/L HEPES, 10 mmol/L glucose, 10 mmol/L taurine, 1 mmol/L $CaCl_2$, 1 mmol/L $MgCl_2$, 0.25 mmol/L EDTA; pH 7.0 adjusted with 1 mol/L KOH), the external solution (130 mmol/L NaCl, 5 mmol/L KCl, 20 mmol/L HEPES, 10 mmol/L glucose, 1 mmol/L $CaCl_2$, 1 mmol/L $MgCl_2$; pH 7.4 adjusted with 1 mol/L NaOH) and the pipette solution (140 mmol/L KCl, 20 mmol/L HEPES, 10 mmol/L glucose, 0.1 mmol/L EGTA, 1 mmol/L $MgCl_2$; pH 7.2 adjusted with 1 N KOH) all had an osmolarity between 285 and 310 mOsm.

Statistical analysis

All data are expressed as mean ± SE, where "*n*" represents the number of muscle strips (*n* = 6-11) or cells (*n* = 6-13) studied per group of 2-5 cats per experiment. Each muscle strip or cell served as its own control. SAS software (SAS Institute, Cary, NC, USA) was used to determine statistical differences between groups by a repeated measure ANOVA, followed by a *post hoc* Bonferroni adjusted paired-wise comparison test. A Student's *t*-test was also used to determine statistical differences between means. An alpha value of 0.05 was considered significant.

RESULTS

Effects of NO on the BK_{Ca} channel in LES isolated smooth muscle cells

The RMP of the LES circular smooth muscle cells (no added drugs) was significantly more depolarized than the sling smooth muscle cells (-39.7 ± 0.8 mV *vs* -48.1 ± 1.6 mV, $P < 0.001$, data not shown). Ramp protocols elicited outward potassium currents at potentials greater than -35 mV. The maximal total outward current was similar in isolated smooth muscle cells from the LES circular and sling regions (27.1 ± 1.5 pA/pF *vs* 25.7 ± 2.0 pA/pF, $P > 0.05$).

To mimic the effect of NO release from nerves, the NO donor, SNP, was puffed onto the smooth muscle cells, and a ramp protocol from -140 to +60 mV was used. SNP increased outward potassium currents of LES circular

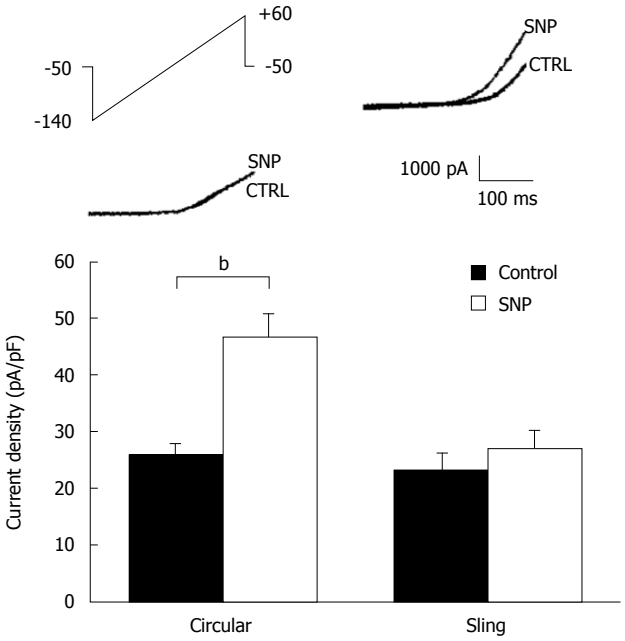

Figure 1 Representative traces (last 300 ms of trace shown) and quantification of the effect of sodium nitroprusside (10^{-4} mol/L) on elicited outward K^+ currents using a ramp protocol from -140 to +60 mV of lower esophageal sphincter circular (n = 13) and sling (n = 8) smooth muscle cells. The maximal total outward current was similar in isolated smooth muscle cells from the lower esophageal sphincter (LES) circular and sling regions. The nitric oxide donor sodium nitroprusside (SNP) increased outward potassium currents of LES circular smooth muscle cells. In contrast, SNP did not significantly cause an increase in the outward K^+ currents in LES sling muscle. [b]$P < 0.001$.

smooth muscle cells from 25.9 ± 1.9 to 46.7 ± 4.2 pA/pF ($P < 0.001$, Figure 1); an 80% increase, and hyperpolarized the cells (from -42.2 ± 1.3 to -63.4 ± 5.0 mV, $P < 0.05$, Table 1). In contrast, SNP did not cause a significant increase in the outward K^+ currents (from 23.2 ± 3.1 to 27.0 ± 3.4 pA/pF, $P > 0.05$, Figure 1) of sling cells, and no significant change in the RMP (Table 1) was observed. SNP also activated outward potassium currents in circular smooth muscle from both proximal (21.9 ± 3.0 to 38.5 ± 9.6 pA/pF, n = 5) and distal (23.5 ± 2.3 to 39.1 ± 6.0 pA/pF, n = 8) esophageal body sites.

In the LES, since the effect of the exogenous NO donor (SNP) was seen only in the circular muscle cells, we then pharmacologically isolated the portion of the recorded outward potassium currents attributed to the BK_{Ca} channel currents only in the circular muscle cells[16]. The BK_{Ca} channel was blocked with 200 nmol/L IbTX, and a voltage-ramp protocol, from -140 to +60 mV, was employed where the different steps of the protocol were performed on the same LES circular smooth muscle cells. SNP induced a significant increase in elicited outward potassium currents *vs* control current density (37.9 ± 4.9 pA/pF *vs* 26.7 ± 3.5 pA/pF, $P < 0.05$, n = 8, Figure 2). IbTX alone blocked a significant portion of the control outward potassium currents (13.7 ± 2.2 pA/pF *vs* 26.7 ± 3.5 pA/pF, $P < 0.05$, n = 8, Figure 2). SNP added in the presence of IbTX, produced no significant increase in the outward currents (17.0 ± 2.8 *vs* 13.7 ± 2.2, $P > 0.05$ for IbTX+SNP *vs* IbTX alone, n = 8, Figure 2). In separate experiments, blockade of K_{DR} with

Table 1 Resting membrane potential (mV) of isolated cells from the lower esophageal sphincter circular and sling regions in the absence or presence of sodium nitroprusside or L-NNA

	Circular	Sling
Control	-42.2 ± 1.3	-53.0 ± 1.2
Sodium nitroprusside	-63.4 ± 5.0[a]	-50.3 ± 3.1
Control	-40.5 ± 1.4	-44.0 ± 1.1
L-NNA	-33.8 ± 1.5[a]	-38.8 ± 2.3

[a]$P < 0.05$ *vs* control.

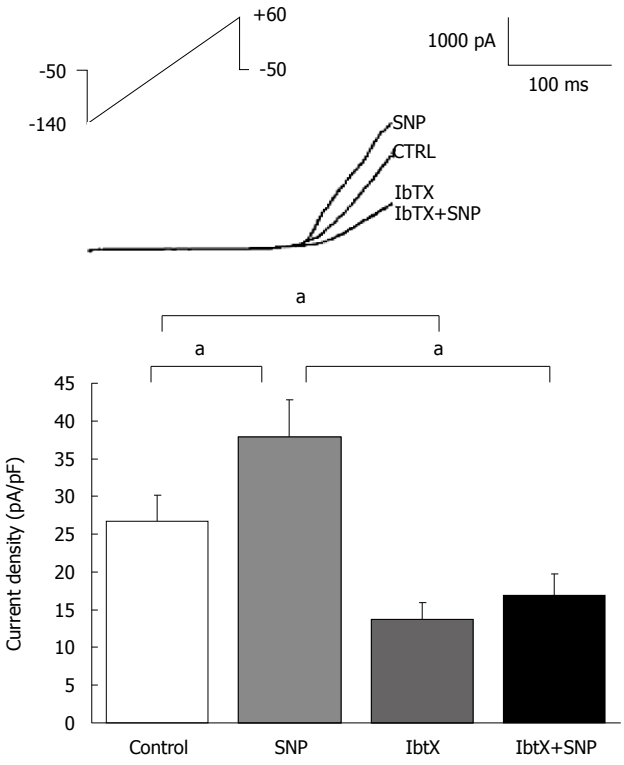

Figure 2 Pharmacological identification, with iberiotoxin (200 nmol/L), of the portion of the elicited outward K^+ currents, using a ramp protocol from -140 to +60 mV, corresponding to BK_{Ca} channel currents in lower esophageal sphincter circular (n = 8) smooth muscle cells. Last 300 ms of representative traces shown. Sodium nitroprusside (SNP) induced a significant increase in elicited outward potassium currents *vs* control current density. Iberiotoxin (IbTX) alone blocked a significant portion of the control outward potassium currents. SNP added in the presence of IbTX, produced no significant increase in the outward currents. [a]$P < 0.05$.

DTX (200 nmol/L) did not inhibit SNP induced outward potassium currents. Thus, for the circular smooth muscle cells, SNP, an exogenous source of NO, produced a significant activation of the BK_{Ca} channel.

To assess the potential contribution of an endogenous source of NO in the two LES regions, the NO synthase inhibitor, L-NNA, was added and a voltage-ramp protocol from -70 to +70 mV was used. Addition of L-NNA led to an insignificant 14% decrease in outward potassium currents in the circular smooth muscle cells (from 29.1 ± 2.6 to 25.0 ± 2.4 pA/pF, $P > 0.05$, Figure 3), however, L-NNA significantly depolarized the cell (from -40.5 ± 1.4 to -33.8 ± 1.5 mV, $P < 0.05$, Table 1), a 17% change in the

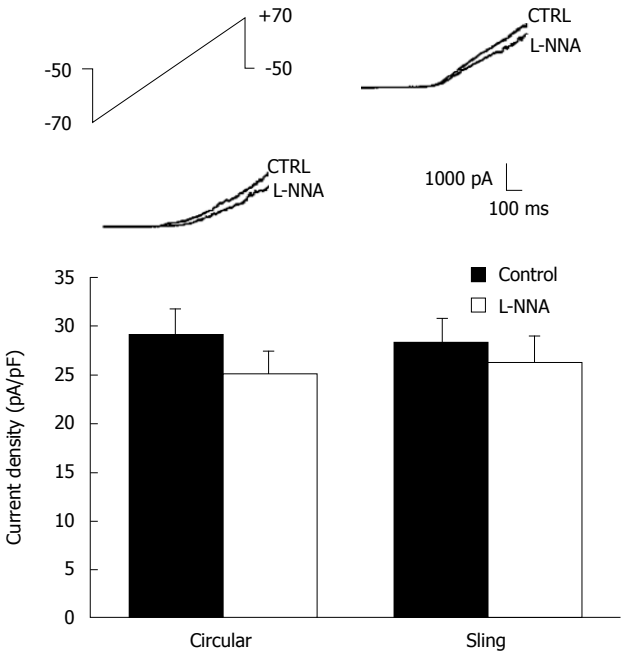

Figure 3 Representative traces and quantification of the effect of L-NNA (10^{-4} mol/L) on elicited outward K^+ currents using a ramp protocol from -70 to +70 mV of lower esophageal sphincter circular (*n* = 8) and sling (*n* = 8) smooth muscle cells. Addition of L-NNA led to an insignificant 14% decrease in outward potassium currents in the circular smooth muscle cells. In the sling smooth muscle cells, the addition of L-NNA led to an insignificant 7% reduction in current density.

RMP. In the sling smooth muscle cells, there was a smaller reduction in current density (from 28.2 ± 2.5 to 26.3 ± 2.7 pA/pF, $P > 0.05$, Figure 3), a 7% decrease, and only a 3% increase in the RMP (from -44.0 ± 1.1 to -38.8 ± 2.3 mV, $P > 0.05$, Table 1). Thus, an endogenous source of NO may modulate outward potassium currents and RMP, but to a small extent, and the effect is more pronounced in the circular muscle.

Effects of NO on the BK_{Ca} channel in LES smooth muscle strips

In view of the small effect of endogenous NO on the RMP of both circular and sling muscle cells, we investigated the myogenic contribution of the BK_{Ca} channel to basal resting smooth muscle tone. Nerves were blocked with TTX and the BK_{Ca} channel was inhibited with IbTX. For the circular muscle, TTX (tension 14.5 ± 3.4 mmol/L per mm^2 *vs* 18.2 ± 4.7 mmol/L per mm^2) or IbTX (tension 14.5 ± 2.3 mmol/L per mm^2 *vs* 15.0 ± 2.3 mmol/L per mm^2) did not significantly change the resting tension ($P > 0.05$, Figure 4A). The combined blockade of the nerves and the BK_{Ca} channel also resulted in no significant change in the overall muscle tone (7.3 ± 1.3 mmol/L per mm^2 *vs* 8.3 ± 1.1 mmol/L per mm^2, $P > 0.05$, Figure 4A). Similarly, for the sling muscle, TTX (tension 10.3 ± 2.0 mmol/L per mm^2 *vs* 10.5 ± 2.4 mmol/L per mm^2) or IbTX (tension 7.3 ± 1.2 mmol/L per mm^2 *vs* 7.3 ± 1.3 mmol/L per mm^2) or TTX and IbTX together (tension 6.3 ± 1.5 mmol/L per mm^2 *vs* 8.4 ± 2.4 mmol/L per mm^2) did not significantly modulate the basal resting tone ($P > 0.05$, Figure 4B).

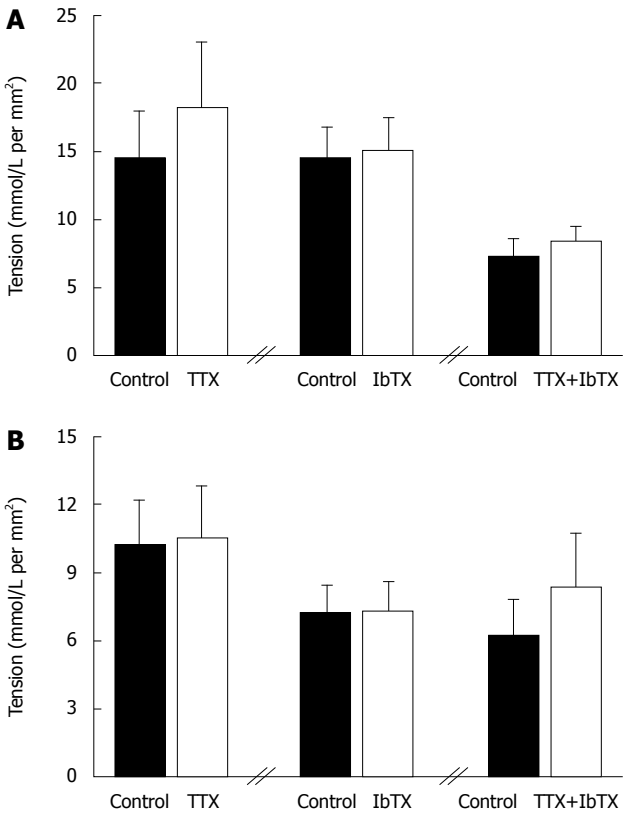

Figure 4 Effect of the blockade of the BK_{Ca} channel with iberiotoxin (10^{-7} mol/L) of lower esophageal sphincter (A) circular (*n* = 6-8) and (B) sling (*n* = 7-11) smooth muscle tone with intact nerves or blocked with tetrodotoxin (10^{-6} mol/L). A: For the circular muscle, tetrodotoxin (TTX) or iberiotoxin (IbTX) did not significantly change the resting tension ($P > 0.05$). The combined blockade of the nerves and the BK_{Ca} channel also resulted in no significant change of the overall muscle tone ($P > 0.05$); B: Similarly, for the sling muscle, TTX, IbTX or TTX and IbTX together did not significantly modulate the basal resting tone ($P > 0.05$). //: Separates different experiments.

To study the effect of exogenous NO on the BK_{Ca} channel in muscle strips, SNP was added in the presence or absence of IbTX, and *vice versa*, with the nerves blocked with TTX. In LES circular muscle, SNP decreased the resting tension by 17.4 ± 5.7 mmol/L per mm^2, the tension was unchanged with further addition of IbTX ($P > 0.05$, Figure 5). When IbTX was added first, there was no significant change in tension, while the subsequent addition of SNP (IbTX+SNP in the presence of TTX) significantly decreased the change in tension (1.1 ± 0.5 mmol/L per mm^2 *vs* -6.3 ± 1.2 mmol/L per mm^2, $P < 0.001$, Figure 5). For the sling muscle, similar changes were observed. SNP or SNP+IbTX decreased the tension to the same extent, IbTX alone produced no significant change in resting tension, and IbTX+SNP decreased the tension by 4.1 ± 1.0 mmol/L per mm^2 ($P < 0.001$, Figure 5). Therefore, in the cat, whether the BK_{Ca} channel is blocked or not, exogenous NO causes relaxation in both sling and circular smooth muscles.

The effects of IbTX on neural responses induced by Electrical Field Stimulation (EFS) were assessed. The addition of TTX was omitted in these studies. In circular muscle, EFS caused transient relaxation of resting tone

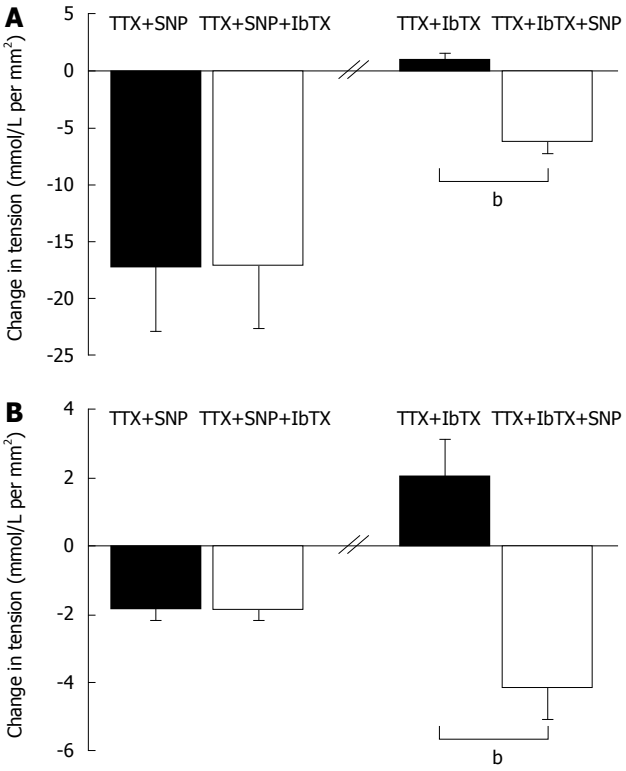

Figure 5 Effect of sodium nitroprusside (10^{-4} mol/L) ± iberiotoxin (10^{-7} mol/L), and iberiotoxin (10^{-7} mol/L) ± sodium nitroprusside (10^{-4} mol/L) on smooth muscle tone relative to basal tone in the presence of tetrodotoxin (10^{-6} mol/L) in muscle strips of lower esophageal sphincter (A) circular (*n* = 6) and (B) sling (*n* = 6-9) muscles. A: In lower esophageal sphincter (LES) circular muscle, sodium nitroprusside (SNP) decreased the resting tension and this tension was then unchanged with further addition of iberiotoxin (IbTX) ($P > 0.05$). When IbTX was added first, there was no significant change in tension, while the subsequent addition of SNP [IbTX+SNP in the presence of tetrodotoxin (TTX)] significantly decreased the tension ($P < 0.001$); B: In LES sling muscle, SNP or SNP+IbTX decreased the tension to the same extent, and IbTX alone produced no significant change in resting tension. IbTX+SNP decreased the tension ($P < 0.001$). //: Separates different experiments. $^bP < 0.001$.

from 14.5 ± 2.3 to 3.8 ± 1.9 mmol/L per mm^2, and IbTX had no effect on LES tone (15.0 ± 2.3 *vs* 14.5 ± 2.3, $P > 0.05$) or EFS induced LES relaxation (3.9 ± 1.9 mmol/L per mm^2 *vs* 3.8 ± 1.9 mmol/L per mm^2, $P > 0.05$). In the LES sling muscle, EFS caused a transient contractile response from resting tone of 7.3 ± 1.2 to 19.3 ± 4.1 mmol/L per mm^2. IbTX had no effect on resting tone (7.3 ± 1.3 mmol/L per mm^2 *vs* 7.3 ± 1.2 mmol/L per mm^2, $P > 0.05$) or EFS induced responses (19.3 ± 4.1 mmol/L per mm^2 *vs* 23.4 ± 5.8 mmol/L per mm^2, $P > 0.05$).

DISCUSSION

In view of the part played by the activation of the BK_{Ca} by NO in the modulation of resting tone and relaxation of the LES in some species, the present study explored this role in the sling and circular muscle components of the cat LES. The BK_{Ca} responsiveness to the inhibitory neurotransmitter NO was significant only in the LES circular muscle. Furthermore, exogenous NO, whether provided by SNP or released by EFS, produced its inhibitory effect to relax LES smooth muscle predominantly through other mechanisms than the activation of the BK_{Ca} channel. There may be a small endogenous source of NO that has a small inhibitory effect to slightly reduce resting tone in both muscles. These findings add to the other known physiological properties of the two muscles and their regional differences. Any NO-BK_{Ca} relaxant effect, if needed, would be directed primarily to facilitate relaxation of the high intrinsic myogenic tone of the LES circular muscle.

Since SNP produced a large and significant activation of the BK_{Ca} channel only in the circular smooth muscle cells, a difference in sensitivity of the BK_{Ca} to NO is one possible explanation for this disparity, assuming that the two muscles express a similar number of channels[33]. This disparity could also reflect regional differences in K^+ channel molecular constitution through expression of different regulatory subunits leading to channel isoforms with different channel activity and sensitivity to voltage and intracellular calcium[15,34]. In the human esophagus there are at least four different splice variants of BK_{Ca} with differences in expression at various sites of the esophageal body and LES[33].

It is generally accepted that *in vivo*, NO is the main neurotransmitter for active inhibition of the LES[1-4]. The circular muscle with its high intrinsic tone relaxes predominantly due to the neural release of the inhibitory neurotransmitter NO as well as some non-NO inhibitory influence[2,3,9,13,25,35-39]. The sling muscle with its tone maintained by cholinergic excitation[21-24,26,40], presumably relaxes predominantly by switching off this excitatory influence, although NO can also relax the sling when contracted by cholinergic stimulation[24,30].

The primary mechanism for NO-mediated relaxation is considered to be *via* a cyclic guanosine monophosphate (cGMP) pathway[41-43]. There are several potential intracellular pathways whereby NO can lead to smooth muscle relaxation. Activation of the BK_{Ca} by NO could potentially occur directly or indirectly through interaction with a number of these mechanisms. For example, the PKG-pathways are accepted intracellular messengers that can lead ultimately to LES circular muscle relaxation in dog, opossum and cat[44-51]. In addition, an involvement of the contractile proteins has been proposed in the sequence of events targeted by NO for LES relaxation in opossum[14]. The BK_{Ca} channel integrates changes in both intracellular Ca^{2+} and membrane potential, and the cGMP pathway can in counter-part influence these latter parameters[15]. Moreover, cross-talk between NO and the ion channel may be facilitated by a close spatial relationship between ion channels and NOS sequestered in or in the vicinity of caveolae, seen in dog LES circular muscle[52-54]. Although it is unclear why endogenous NO had minimal effect on resting LES tone in this study of the cat, variability in the effect of different NO donors and NO states on gut smooth muscle physiology as well as species differences have also been reported and are likely contributing factors[55]. The apparent species and smooth muscle differences open the door to further experimentation. Our aim in this paper was not

directed to a study of the potential intracellular pathways and mechanisms underlying these differences.

Although the BK_{Ca} current density is greater in the circular muscle, the channel plays a role in setting the RMP in both LES muscles[16]. IbTX causes significant membrane depolarization in both LES muscles, as confirmed in the present study. This modulation of the RMP by the BK_{Ca} is also present in the opossum LES circular muscle[17]. Our present experiments in isolated smooth muscle cells of the cat LES, show that this activation of the BK_{Ca} in setting the RMP involves at least an endogenous source of NO in both LES regions, consistent with findings in dog LES circular muscle[9,18].

Although the BK_{Ca} contributes to setting the RMP, and[16,17], in the current muscle strip studies, blockade of the BK_{Ca} with IbTX did not result in a significant increase in muscle tension in either muscle. This is unlike the esophageal body where both IbTX and tetra ethyl ammonium increase tonic and phasic contractility[8]. In the opossum LES circular muscle, blockade of the BK_{Ca} results in an increase in tone when the RMP is raised to the point where ongoing spiking activity is produced. In those experiments, BK_{Ca} blockade changed the RMP only slightly (from -43.4 to -37.8 mV). The further transient depolarizations associated with the spike-like action potentials then are associated with calcium (Ca^+) entry through the L-type channel[17]. The findings fit with the knowledge that Ca^{2+} is required for, and Ca^{2+} availability can alter LES circular smooth muscle motor response in dog and opossum[7,14,18,56].

The lack of major effect of IbTX on resting tone in both cat LES muscles in the present experiments would occur if membrane depolarization is unable to sufficiently activate channels for entry of extracellular calcium for tension development, either directly or through the stimulation of spiking activity. In the LES muscles, L-type calcium channel activation is only seen at membrane potentials more positive than about -20 mV[27,57], levels not reached in the sling (-42 mV) or in the circular muscle (-31 mV) with IbTX or other blockade of the BK_{Ca}[16,17]. Furthermore, we have shown that resting tone in both muscles utilizes both intracellular and extracellular calcium sources, the circular muscle more dependent on an extracellular, and the sling on an intracellular source[28]. In addition, the two muscles utilize different calcium entry portals, the circular muscle using the L-type and the sling a non L-type channel. Therefore, our findings in the cat indicate that if endogenous NO is acting on the BK_{Ca} to modulate resting tone, this modulation is mainly through an indirect action, and augmented by its other mechanisms of action[7,14,15,18,49]. Furthermore, there appears to be a more complex relationship in the LES between active changes in membrane potential such as spiking activity or slow wave activity and levels of LES tone[58-63]. Our present findings, taken together with findings in other species, indicate that changes in resting tone are likely dependent on Ca^{2+} entry associated with the active changes in membrane potential rather than entry with any small changes in the RMP[17]. Further studies are required to assess which mechanisms and pathways are involved.

In terms of resting tone in the LES, our findings have potential functional significance. In the present *in vitro* study in the cat, TTX blockade of excitatory as well as inhibitory nerve activity failed to significantly affect basal tension in circular smooth muscle strips. This finding supports the concept that *in vivo*, intrinsic ongoing myogenic contraction underlies resting tone of the circular muscle. The intrinsic tone in the circular muscle is not significantly modulated by cholinergic excitation and/or nitrergic inhibition[3,4]. On the other hand, cholinergic neural influence, normally vagally-driven, acts to augment and maintain the low intrinsic basal resting tone in the sling.

A better understanding of the asymmetries of both circular and sling LES muscles at the cellular level could give insights into the pathogenesis of and potential therapeutic usefulness for patients with motor disorders such as achalasia and gastroesophageal reflux disease. For instance, in human and cat, addition of atropine decreases the leftward resting LES pressure where the sling is located, with little effect in the other radial orientations[22,40]. Although in the present cat experiments, exogenous NO causes smooth muscle relaxation of both the LES circular and sling smooth muscles, whether the BK_{Ca} channel is blocked or not, activation of the BK_{Ca} channel by NO provides another potential mechanism to augment the muscle relaxing effect of the cGMP pathway. Whether such a mechanism may become more important, for example in circumstances where NO release to produce relaxation of the circular muscle is decreased, as in patients with achalasia, requires further study[64-68]. Hence, regional differences in muscle cell BK_{Ca} responsiveness to NO hold the potential for selective modulation of LES function in health and disease.

COMMENTS

Background

The lower esophageal sphincter (LES) is normally closed to prevent reflux of gastric acid, but opens with a swallow to allow passage of the bolus into the stomach. The LES has two main components, the circular and sling muscles. To maintain closure, the circular muscle has significant resting tone but is poorly responsive to neural cholinergic excitation. On the other hand, the sling has little resting tone, and its closing contraction is maintained by vagal release of acetylcholine. Opening of the LES with a swallow requires relaxation of the two muscles. Relaxation of the circular muscle is therefore dependent on active relaxation induced by an inhibitory neurotransmitter such as nitric oxide (NO), while relaxation of the sling can readily occur with vagal excitation turned off.

Research frontiers

Although NO can relax smooth muscle by a number of cellular mechanisms, in some species activation of the BK_{Ca} by NO is important for the modulation of resting tone and relaxation of the LES. The importance of this mechanism was assessed in isolated cells and in strips of muscle from the two muscle components of the cat LES. The cat esophagus is very similar to the human esophagus with a significant portion of the distal esophagus composed of smooth muscle.

Innovations and breakthroughs

The BK_{Ca} responded to the inhibitory neurotransmitter NO, administered as sodium nitroprusside (SNP), only in the LES circular muscle, the muscle with high resting tone. Furthermore and as opposed to other species, exogenous NO, whether provided by SNP or released by electrical field stimulation, provided its inhibitory effect to relax LES smooth muscle predominantly through other mechanisms than the activation of the BK_{Ca} channel.

Applications

Any NO-BK_{Ca} relaxant effect, if needed, would be directed primarily to facilitate

relaxation of the high intrinsic myogenic tone of the LES circular muscle. Such a mechanism may become more important, for example in circumstances where NO release to produce relaxation of the circular muscle is decreased, as in patients with achalasia. Since NO provided its inhibitory effect to relax LES smooth muscle predominantly through other mechanisms than the activation of the BK_{Ca} channel, further research should be directed to these other mechanisms. Such studies hold the potential for new therapeutic approaches applicable to the human esophagus.

Terminology

Achalasia: a condition where swallowing difficulty is due to obstruction of the esophagus at the LES resulting from failure of LES relaxation due to absence of the inhibitory neurotransmitter NO.

Peer review

This is a well-designed and interesting study that provides convincing evidence regarding the activation of large conductance potassium channels within the circular smooth muscle during administration of exogenous nitric oxide. The role of endogenous nitric oxide appears to be relatively less significant.

Abstract

AIM: To evaluate the effects of meal size and three segmentations on intragastric distribution of the meal and gastric motility, by scintigraphy.

METHODS: Twelve healthy volunteers were randomly assessed, twice, by scintigraphy. The test meal consisted of 60 or 180 mL of yogurt labeled with 64 MBq ^{99m}Tc-tin colloid. Anterior and posterior dynamic frames were simultaneously acquired for 18 min and all data were analyzed in MatLab. Three proximal-distal segmentations using regions of interest were adopted for both meals.

RESULTS: Intragastric distribution of the meal between the proximal and distal compartments was strongly influenced by the way in which the stomach was divided, showing greater proximal retention after the 180 mL. An important finding was that both dominant frequencies (1 and 3 cpm) were simultaneously recorded in the proximal and distal stomach; however, the power ratio of those dominant frequencies varied in agreement with the segmentation adopted and was independent of the meal size.

CONCLUSION: It was possible to simultaneously evaluate the static intragastric distribution and phasic contractility from the same recording using our scintigraphic approach.

Key words: Gastric motility; Phasic contractions; Proximal stomach; Scintigraphy; Meal size

Effects of meal size and proximal-distal segmentation on gastric activity. *World J Gastroenterol* 2010; 16(46): 5861-5868 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i46/5861.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i46.5861

INTRODUCTION

Scintigraphy is the gold standard for measuring gastric emptying and offers the advantage of completely characterizing the complex physiology of intragastric distribution of the meal (IDM) between the proximal and the distal regions[1-3]. Quantification of intragastric distribution could help to define abnormal physiology and explain certain functional dyspeptic symptoms[4], especially when global gastric emptying values are normal[3]. Proximal-distal segmentation approaches employed to divide the stomach in proximal and distal regions remain a challenge for studying IDM; therefore, a validation is necessary before incorporating it into clinical practice[3].

At least three segmentation approaches were adopted, based on the proximal stomach defined immediately after a meal, to divide the stomach into two equal areas and using the incisura[1,2,4-7]. No previous studies have compared the results obtained by those three approaches, and several studies have perceived that there may be problems regarding the division of gastric segments into proximal and distal regions[6,8]. In particular, the two gastric compartments might not be easily identifiable, the incisura may not be pronounced, and somewhat arbitrary definitions cannot be always applied[8].

Apart from the well-known phasic motor activity of 3 cpm (cycle per minute) in the distal stomach, a phasic activity of 1 cpm was observed in dogs and humans using different techniques and appears to be concentrated in the proximal region[9-12]. Thus, considering that each frequency of contraction can be associated with one gastric region, the dominant frequencies could facilitate the characterization of the proximal and distal regions of stomach. The functions of the stomach regions can vary according to the nutrient content[7], and there is a clinical recommendation for consumption of smaller and more frequent meals to avoid postprandial symptoms in patients with common gastrointestinal disorders[13,14]. However, there is little information about the effects of meal size on intragastric distribution, especially for semisolid small meals. The aim of this study was to evaluate the effects of meal size and three proximal-distal segmentations on intragastric distribution and gastric motor activity by scintigraphy.

MATERIALS AND METHODS

Subjects

Twelve healthy volunteers (three female and nine male) with a range of body mass indices of 18.5-24.9 kg/m^2 and an age of 25-45 years participated in the studies. None had a history of digestive disease or abdominal surgery. Informed written consent was obtained from each participant. The studies were performed in agreement with Declaration of Helsinki and the local Ethics Committee approved the protocol.

Study protocol

Each volunteer was evaluated twice on separate occasions for ingestion of 60 and 180 mL of a semisolid test meal (yogurt containing 1 kcal/mL). The yogurt was chosen to simulate a small meal that is commonly ingested between large meals. *In vitro* tests were achieved to assure that the Tc-99m tin colloid and the yogurt were adequately blended[12]. The studies were performed in the morning, after an overnight fast, in a randomized order, and were separated by an interval of one wk. Both test meal were labeled with 64 MBq ^{99m}Tc-tin colloid as a nonabsorbable carrier and consumed with the volunteers standing upright in front of the gamma camera.

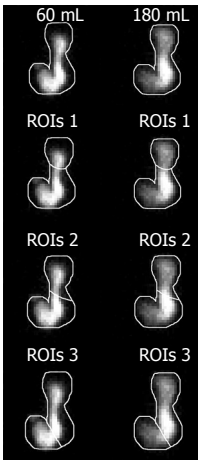

Figure 1 Scintigraphic images showing the composite images after meals with 60 mL and 180 mL, and the three proximal-distal image segmentations (ROIs) adopted. ROIs: Regions of interest.

A dual-head gamma camera (Sopha Vision, Model DST, Sophycammera; Medical Sopha Vision America, Twinsburg, OH, USA) equipped with a parallel-hole low-energy and high-resolution collimator was used. The gamma camera was set up to record activity around the 140-keV photopeak of ^{99m}Tc. A dynamic set of 1080 frames (1 frame/s) was acquired for 18 min and images were stored in a 64 × 64 matrix for further analysis. A geometric mean of the anterior and posterior gastric counts was determined for each time point and corrected for radionuclide decay[3].

Data analysis

All digital images were analyzed in MatLab (Mathworks Inc., Natick, MA, USA). The total stomach was outlined in the composite image (summation of all images) with a cursor over the largest anterior gastric image obtained by ingestion of 180 mL. The outline for each 180 mL analysis was individually copied and fitted in the 60 mL image of the same subject. This outline was then subdivided into two regions of interest (ROIs) corresponding to the proximal and distal stomach, according to each method used (Figure 1): ROIs 1: The proximal stomach region was the "reservoir" area seen in all subjects in the first postprandial frames and the line used to divide proximal/distal stomach was drawn immediately below this region[2,7,15]; ROIs 2: The image was divided into two equal areas, designated the proximal and distal stomach, by a mid-length separation in the longitudinal axis of the stomach[1,4,16]; and ROIs 3: The proximal and distal regions of the stomach were separated by a fainter band of radioactivity coinciding with the angula; thus the stomach was arbitrarily divided by drawing a line across the incisura angularis[5,6].

Intragastric distribution of the meal

The time for meal consumption was measured individually. Thus, a value considering 100% retention of the meal was dependent of the activity at the end of the lag phase (the frame before any activity appeared in the small intestine) and immediately after meal completion. Time zero started when the retention was 100%. For each region (total, proximal and distal stomach) activity time curves, expressed as percentages of activity in the total stomach with 100% of meal retention, were obtained.

The intragastric distribution of 60 and 180 mL were assessed from activity time curves derived from each region and considering the three proximal-distal segmentations by calculating the following parameters: (1) initial retention: the percentage of initial activity (%) contained in the total, proximal and distal stomach at time zero; (2) final retention: the percentage of final activity (%) contained in the total, proximal and distal stomach at 18 min; (3) proximal emptying half-time ($T_{1/2}$): expressed as the time (min) when the initial retention in the proximal stomach decreased by 50%; (4) maximal distal content: the highest activity value (%) in the distal stomach at any time point in the study; and (5) gastric emptying of the whole stomach (representing% retention over time) was obtained from time zero to 18 min.

Comparisons of the data for three proximal-distal segmentations were made for both meals employing area under curves (AUC) and statistical moment analysis. The AUC derived from the proximal or distal stomach was expressed as percentage of AUC obtained from total stomach. The statistical moment (minutes) was obtained through the temporal average from the proximal or distal distribution curve, normalized by AUC[17]. This quantification allowed determination of a distribution time that could be associated with the midpoint of the proximal and distal distribution curves.

Contractility

Fast fourier transform (FFT) was employed to analyze phasic contractions in both gastric regions (proximal and distal) and for each type of proximal-distal segmentation. A bi-directional Butterworth band-pass filter with a cutoff frequency at 5-75 mHz (0.3-4.5 cpm) was applied.

Dominant frequencies were expressed as the frequency at which the highest FFT power spectrum was observed in the proximal and distal regions. Values were expressed as power ratios (%), determined by dividing the power of each dominant frequency by the total power (sum of both frequencies), and multiplying the results by 100 for each stomach region in all proximal-distal segmentations[18].

Statistical analysis

Data were expressed as mean ± SE. The hypothesis of a normal data distribution was confirmed using Shapiro-Wilk's test. Data obtained by meals of 60 and 180 mL were compared using Student's *t* test and *P*-values less than 0.05 were considered significant. Comparisons among types of proximal-distal segmentation were analyzed by one-way ANOVA and Tukey's test, with $P < 0.05$ considered significant.

RESULTS

Our data demonstrated a significant effect of meal size and the three proposed proximal-distal segmentations on intragastric meal distribution and gastric contractility. After ingestion, both meals were rapidly dispersed through the whole stomach with a minimal lag phase. There was no difference between the lag-phase for 60 mL (1.9 ± 0.2 min) and for 180 mL (2.3 ± 0.2 min).

The three proposed proximal-distal segmentations (ROIs) could be applied to all volunteers. Figure 2 shows the profile of IDM of the 60 and 180 mL meal over 18 min for the three types of proximal-distal segmentations. A redistribution of food from the proximal to the distal stomach according to employed segmentation was observed.

There was greater proximal retention after 180 mL ingestion compared to 60 mL, which was proportional to the increase in the area of proximal stomach generated by the type of proximal-distal segmentation. ROIs 1 presented a smaller proximal region and a fast redistribution of the meal for the distal area occurred. By contrast, in ROIs 3, the initial retention in the proximal region was greater than in the other proximal-distal segmentations and presented a slow redistribution of the meal for the distal area. ROIs 2 showed an intermediate pattern. Thus, there was a significant difference among the three ROIs segmentations employed ($P < 0.05$).

No difference was found in the percentage of the meal retained in the total stomach after 60 mL (13.3% ± 3.0%) and 180 mL (13.0% ± 2.4%) ingestion over 18 min. Table 1 compares the effect of meal size and proximal-distal segmentation in IDM parameters, reinforcing the relationship between proximal area and parameters of regional gastric emptying.

Table 2 presents the mean area under the curve and the statistical moment for the proximal and distal regions, for each of the three types of segmentation, after ingestion of the test meals. For the smaller meal, there was a significant difference among ROIs, while the increased meal size generated a difference only between ROIs 1 and 3.

Moment calculation demonstrated that the differences between the ROIs were only evident with 60 mL but not with 180 mL meal for the three types of proximal-distal segmentation. Comparison of moments for the distal region for both meals showed no significant differences. The statistical moment obtained in the proximal area was influenced by the type of segmentation adopted (Table 2), representing an option to quantify a time related to intragastric distribution.

An important finding was both dominant frequencies were recorded in the proximal stomach (16.0 ± 1.0 mHz or 1 cpm and 50.0 ± 2.0 mHz or 3 cpm) and in the distal stomach (16.0 ± 1.0 and 50.0 ± 1.0 mHz), independently of gastric segmentation. The dominant frequencies were

[a]$P < 0.05$ *vs* ROIs 1; [c]$P < 0.05$ *vs* ROIs 2; [e]$P < 0.04$ *vs* 60 mL; [g]$P < 0.03$ *vs* 60 mL; [i]$P < 0.003$ *vs* 60 mL. ROIs: Regions of interest.

observed to overlap in the signal of proximal stomach at different time points (Figure 3). Power ratio calculations indicated that there was a rearrangement of the maximum power of each frequency (1 and 3 cpm) according to the segmentation type.

The difference is shown in the power spectrum of these frequencies according to the type gastric segmentation (Figure 4). A difference could be observed in the distal region between 60 and 180 mL: for 180 mL meal there was an increase of the 1 cpm and a decrease of the 3 cpm in ROIs 2 and 3. There were no significant changes for ROIs 1.

DISCUSSION

The results showed that meal distribution in the human stomach differs according to the volume used (60 or 180 mL) and noticeably according to proximal-distal image segmentation used. Dynamic gastric scintigraphy was effective for determining two dominant frequencies (1 and

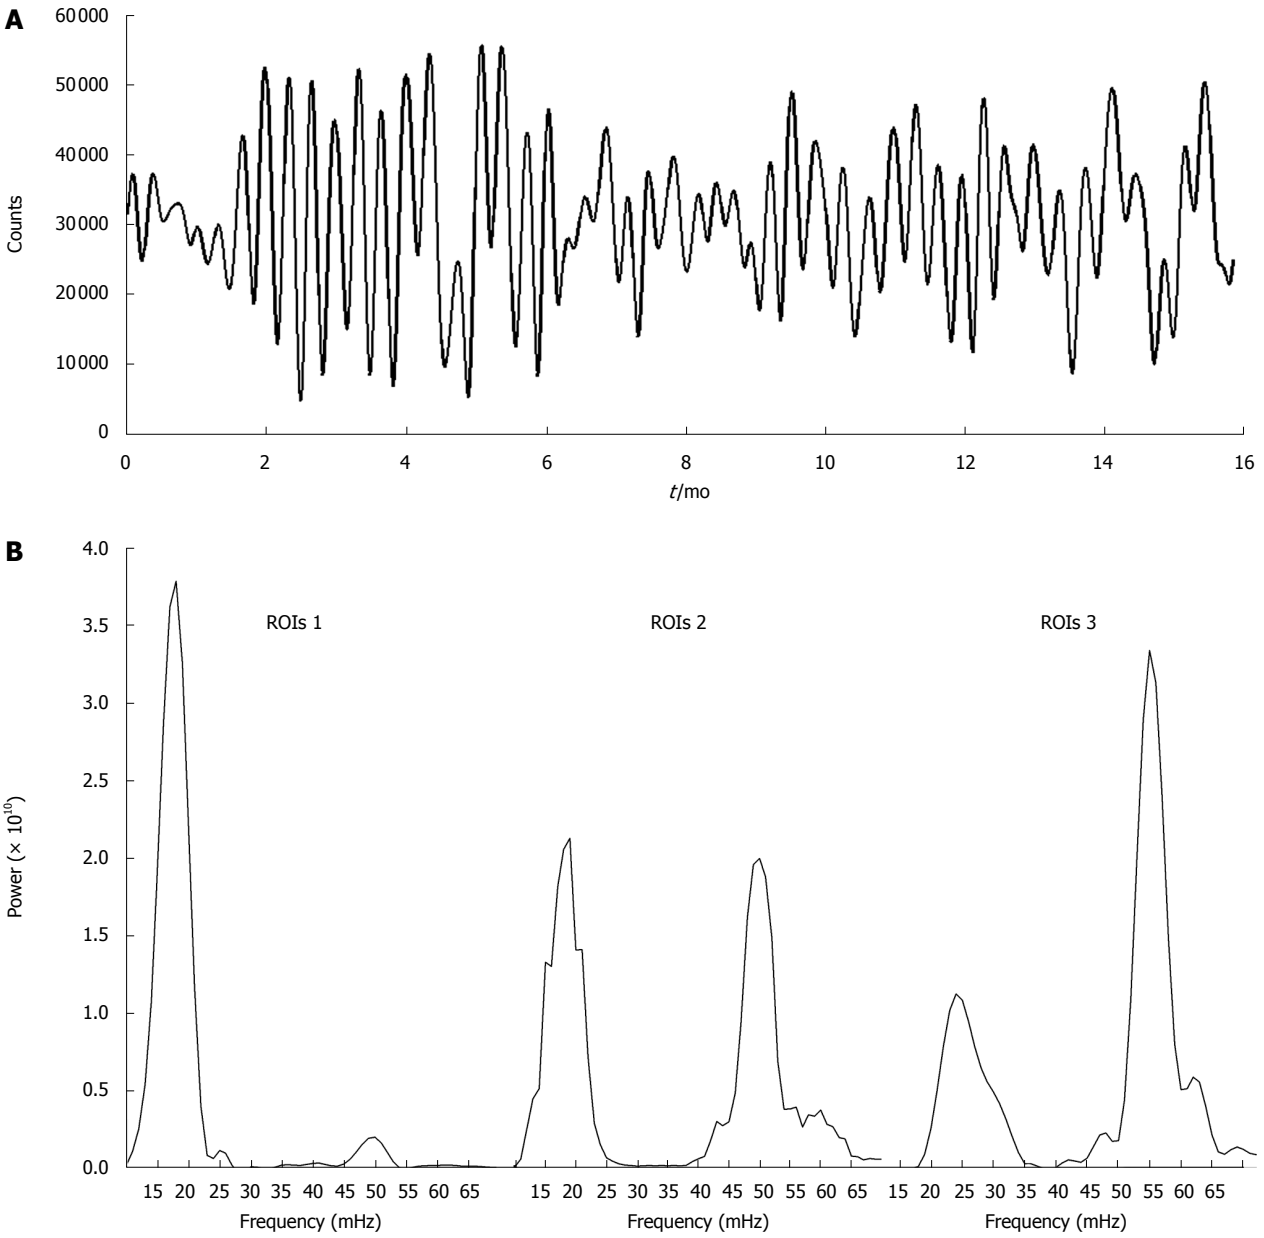

Figure 3 Both dominant frequencies (1 cpm or 17 mHz and 3 cpm or 50 mHz) can be observed overlapping in the signal of the proximal stomach (A), the power ratio of this signal indicated that there was a rearrangement of the maximum power of each of the frequencies (1 and 3 cpm) in agreement with the segmentation type B).

3 cpm), and the magnitude of these contractions in both the proximal and distal stomach.

It has been previously shown that volume and meal size influenced gastric emptying[19,20]; thus, it seems logical to advise patients to decrease the size and increase the frequency of meals during certain conditions, such as pregnancy, gastroesophageal reflux disease, and functional dyspepsia[14]. Our meals were chosen to investigate IDM and motility patterns using semisolid small meals in order to establish a pattern in healthy volunteers. Thereafter, our approach can be applied in patients to verify IDM and gastric motor activity after the recommended consumption of a smaller meal.

The emphasis of most previous studies was on total gastric emptying[19], despite the fact that regional gastric emptying is more frequently abnormal than total gastric emptying[2]. The partitioning of ingested meals between the proximal and distal stomach is related to the genesis of dyspeptic symptoms, such as early satiety, fullness, and nausea[1,4,21]. The meal distribution within the area of the stomach might strongly influence the way in which the stomach is subdivided[4]. Unfortunately, the methods used for defining these two areas are still controversial and poorly defined[15]. Our data demonstrated a direct relationship between gastric compartment size and IDM. The choice of the segmentation technique should consider variations in the stomach shape[16] and the objective of the study. For example, using ROIs 1 it is possible analyze details of the fundic accommodation process' whereas employing ROIs 2 both dominant frequencies

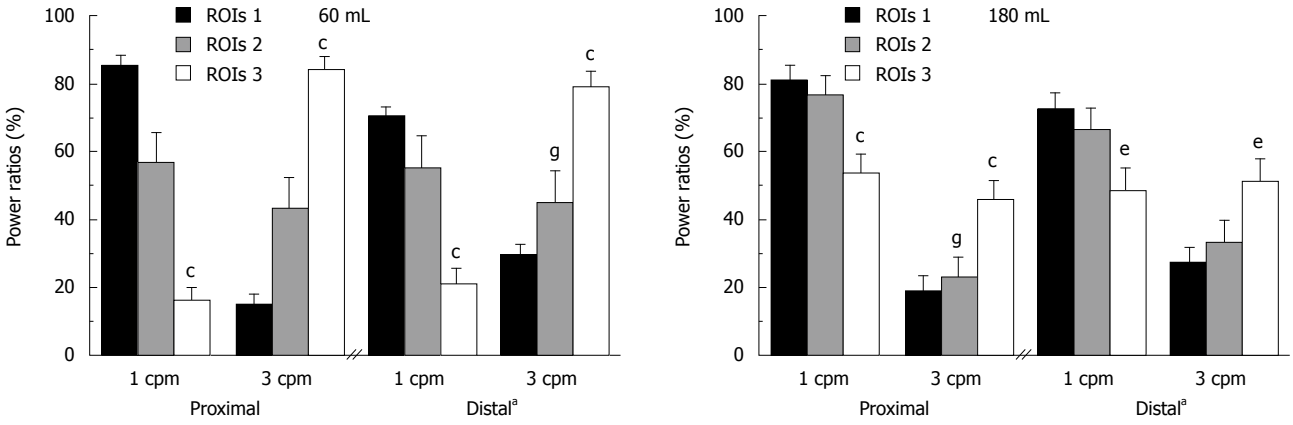

Figure 4 The power ratios showed the presence of both frequencies (1 cpm and 3 cpm) in the proximal and distal stomach, and that their intensities depend on the adopted proximal-distal segmentation and on the meal size ingested. [a]$P < 0.03$ between 60 and 180 mL for both frequencies in distal region, [c]$P < 0.005$ between ROIs 1 and ROIs 3, [e]$P < 0.05$ between ROIs 1 and ROIs 3, [g]$P < 0.05$ between ROIs 2 and ROIs 3. can be equally observed, and ROIs 3 is useful to evaluate antral contractility.

Generally, twenty minutes after the ingestion of a larger meal, a gradual decrease in proximal stomach activity begins, with a corresponding increase in the distal stomach, indicating a redistribution of food from the proximal to the distal stomach[1,4,5]. Hence, our IDM data were obtained during this initial stage, showing that the 60 mL meal quickly began to be redistributed to the distal region; whereas, using 180 mL, there was a slower redistribution from proximal to distal stomach in all segmentations adopted (Figure 2). In the curves obtained from ingestion of 180 mL was impossible calculate $T_{1/2}$ from the proximal stomach during the 18 minutes of recording, except for ROIs 1, reinforcing the retention in the proximal region. In the final retention values, there was a significant difference between three ROIs segmentation and both meals ingested (Table 1).

To quantify the IDM, we used the statistical moments, which have previously been utilized only in pharmaceutical approaches[17], and the traditional AUC. The statistical moments and AUC provide complementary information about the data observed. Both quantification methods showed that proximal-distal segmentations have more effect for the 60 mL meal than for 180 mL. However, there was no difference in the statistical moment between ROIs in the distal curve profile, whereas there was a significant difference in AUC. Distal accumulation time was defined previously by our group as the time elapsing from the meal ingestion until the activity reached 99% of the maximum value in the sigmoidal tracing over the distal stomach curves[12]. The distribution time obtained by the statistical moment was very close to the distal accumulation time, but can be employed for any kind of curve, including proximal stomach curves.

It is important to emphasize that partitioning of ingested meals between the proximal and distal stomach is related to gastric accommodation. Abnormal IDM might be a consequence of disturbed proximal stomach accommodation[4] in a considerable subset of patients with functional dyspepsia and might have a role in symptom production, such as early satiety and weight loss[6]. Studies of dyspepsia have shown a preferential accumulation in the distal stomach, suggesting defective postprandial relation of the proximal stomach; however, it is difficult to draw general conclusions because each study employed a different proximal-distal partition. It would be interesting to provide data on the relationship between meal size, proximal-distal segmentation, IDM, and accommodation in this patient group. Information on the accommodation

process will have clinical value, especially for studying patients with dyspepsia and normal gastric emptying, and it may contribute directly to improved medical therapy[22].

Fast Fourier transformation of our scintigraphic recordings defined two dominant frequencies in the distal as well as the proximal stomach, in all volunteers (Figure 3). Meal size did not affect the dominant frequencies of the contractions or their power, but there was a large difference in the power spectra of these frequencies, based on image segmentation. The power ratio of the proximal signal was rearranged for the maximum power of each frequency (1 and 3 cpm), according to segmentation type. Hence, there was a power gradient from ROIs 1 to ROIs 3, where 1 cpm decreases and 3 cpm increases in the human proximal stomach (Figures 3 and 4). This motor activity around 1 cpm on the proximal stomach[9,10,23] has not been extensively documented in humans, although it has been correlated with functional dyspepsia[9], mainly due to methodological issues, such as differences in barostat systems[24] and/or filter parameters employed in data analysis[12].

In summary, the results of research and/or diagnosis can be deeply influenced by the proximal-distal segmentation method adopted. Two dominant frequencies (1 and 3 cpm) can be simultaneously registered in the proximal and distal stomach, but the proximal-distal segmentation should be considered carefully to analyze their power spectra. The protocol developed in this study can be applied in patients with several disorders, with the advantages of simultaneous evaluation of IDM and gastric contractions.

COMMENTS

Background

The stomach is composed of two distinct functional regions. The distal stomach is capable of generating 3 vigorous contractions per minute (cpm), which cause reduction in size of ingested particles and subsequent emptying. The proximal stomach is primarily concerned with storage of the ingested food, with a slight contraction activity around 1 cpm. During a meal, the stomach continuously adapts its size to the content by gradually relaxing its musculature, performing the so-called accommodation to distension. Intragastric distribution of the meal (IDM) between the proximal and distal stomach is related to the accommodation process, and is useful for defining abnormal physiology and for explaining certain functional disease symptoms.

Research frontiers

Proximal-distal segmentation approaches employed to divide the stomach into proximal and distal regions remain a challenge in the study of IDM. Unfortunately, the methods used for defining these two areas are still controversial and poorly defined. Validation is necessary before incorporating these methods into clinical practice. Two dominant frequencies (1 and 3 cpm) can be registered simultaneously in the proximal and distal stomach, but the proximal-distal segmentation should be considered carefully to analyze their power spectra. The motor activity around 1 cpm on the proximal stomach has been correlated with functional dyspepsia. In this context, the frequency of contraction can be explored to elucidate certain disease patterns.

Innovations and breakthroughs

Scintigraphy already is the gold standard for measuring gastric emptying and offers the advantage of completely characterizing the complex physiology of IDM between stomach regions. New studies can be exploited to refine and extend its use in clinical practice. The functions of the stomach regions can vary according to the nutrient content and there is a clinical recommendation for consumption of smaller and more frequent meals to avoid postprandial symptoms in patients with common gastrointestinal disorders. However, there is little information about the effects of meal size on intragastric distribution, especially for semisolid small meals. In the area of functional disorders research, considerable effort is being expended on how to convert basic knowledge into benefits for patients' treatment. Therefore, in the present study we compared three kinds of segmentation in normal volunteers and showed that segmentation is remarkably important in the evaluation of IDM and gastric motility. This observation is particularly relevant when assessing patients.

Applications

Abnormal IDM might be a consequence of disturbed proximal stomach accommodation in a considerable subset of patients with functional dyspepsia and might have a role in symptom production, such as early satiety and weight loss. Studies of dyspepsia have shown a preferential accumulation in the distal stomach, suggesting defective postprandial accommodation in the proximal stomach; however, it is difficult to draw general conclusions, because each study employed a different proximal-distal partition. Thus, providing data on the relationship between meal size, proximal-distal segmentation, IDM, and accommodation in this patient group is very important. Information about the accommodation process will have clinical value, especially in the study of patients with dyspepsia and normal gastric emptying, and might directly influence medical therapy.

Terminology

IDM represents the distribution of gastric contents between the proximal and distal stomach during gastric emptying. Dyspepsia is a medical condition characterized by chronic or recurrent pain in the upper abdomen, bloating, and fullness.

Peer review

The authors evaluated the effects of meal size and three segmentations on intragastric distribution of meal and gastric motility by scintigraphy. This paper is an interesting report.

Abstract

AIM: To determine if proton pump inhibitor use in cirrhotic patients with endoscopic findings of portal hypertension is associated with a lower frequency of gastrointestinal bleeding.

METHODS: Patients with cirrhosis and endoscopic findings related to portal hypertension, receiving or not receiving proton pump inhibitor (PPI) therapy, were included retrospectively. We assigned patients to two groups: group 1 patients underwent PPI therapy and group 2 patients did not undergo PPI therapy.

RESULTS: One hundred and five patients with a median age of 58 (26-87) years were included, 57 (54.3%) of which were women. Esophageal varices were found in 82 (78%) patients, portal hypertensive gastropathy in 72 (68.6%) patients, and gastric varices in 15 (14.3%) patients. PPI therapy was used in 45.5% of patients (n = 48). Seventeen (16.1%) patients presented with upper gastrointestinal bleeding; in 14/17 (82.3%) patients, bleeding was secondary to esophageal varices, and in 3/17 patients bleeding was attributed to portal hypertensive gastropathy. Bleeding related to portal hypertension according to PPI therapy occurred in 18.7% (n = 9) of group 1 and in 14% (n = 8) of group 2 (odds ratio: 0.83, 95% confidence interval: 0.5-1.3, P = 0.51).

CONCLUSION: Portal hypertension bleeding is not associated with PPI use. These findings do not support the prescription of PPIs in patients with chronic liver disease with no currently accepted indication.

Key words: Drug prescription; Liver cirrhosis; Portal hypertension; Proton pump inhibitors; Upper gastrointestinal bleeding

INTRODUCTION

Since their first clinical use, proton pump inhibitors (PPIs)

have provided benefits in the management of gastrointestinal diseases. This class of drugs is clearly indicated for the treatment of peptic ulcer disease, gastroesophageal reflux disease (GERD), and nonvariceal upper gastrointestinal bleeding, and for prophylaxis in selected users of nonsteroidal anti-inflammatory drugs (NSAIDs)[1,2]. Unfortunately, the unnecessary prescription of PPIs has become an important problem, which increases economic costs in daily clinical practice[3,4]. According to previous studies in the clinical context, only 12.3% of cirrhotic patients have an appropriate indication for the prescription of these drugs[5]. Congestive gastropathy and esophageal and gastric varices are risk factors for the inappropriate use of PPIs[5].

Few studies, other than pharmacological studies, have investigated the safety and utility of PPIs in cirrhotic populations[6-9]. There are reports of possible hepatotoxicity associated with the use of PPIs in patients with chronic liver disease (CLD)[9], but there have been no clinical or experimental trials on the adverse effects of PPIs in the treatment of acute or chronic complications in patients with cirrhosis and portal hypertension (PH). Some data on the possible use of PPIs for the long-term prophylaxis of variceal bleeding exist[10], and a recent controlled trial by Zhoe *et al*[11] compared the efficacy of octreotide, vasopressin, and omeprazole for controlling acute bleeding associated with portal hypertension gastropathy. However, more clinical evidence is required. The use of this class of drugs in cirrhotic patients seems more habit-related than evidence-based, ultimately leading to an increase in health costs.

In patients with cirrhosis and PH, upper gastrointestinal bleeding has an annual frequency of 25%-35%, and 80%-90% is of variceal origin. The mortality related to variceal bleeding is about 30% per episode, and is recurrent in 70% of patients after the first year[12-15].

Considering the current paradigm of evidence-based medicine, the use of PPIs in patients with cirrhosis and endoscopic findings of PH is based only on expert opinion, with insufficient evidence to justify the use of these drugs as prophylaxis for variceal bleeding. The aim of this study was to determine whether the use of PPIs in patients with cirrhosis and endoscopic findings of PH (esophageal or gastric varices, or portal hypertensive gastropathy) is associated with a reduction in the frequency of gastrointestinal bleeding secondary to PH.

MATERIALS AND METHODS

We conducted a retrospective, observational, longitudinal, comparative study of outpatients with CLD and endoscopic evidence of PH, receiving or not receiving treatment with PPIs, between December 1, 2004 and January 1, 2006. The endoscopic data considered for PH were esophageal varices, gastric varices, and portal hypertensive gastropathy. The sample comprised a series of consecutive patients with clinical, biochemical, endoscopic, radiological, and/or histological signs of cirrhosis and PH who attended our gastroenterology and liver clinic. We included all patients over 18 years of age who had been reviewed on at least two visits over the course of one year during the period of the study. All patients with incomplete electronic or paper charts, with no confirmatory endoscopic study at the time of the bleeding episode, were excluded from the study. These patients formed a subset of patients included in our previous work[5]. Reasons for exclusion from the present study were absence of endoscopic evidence of PH (n = 80), and no previous endoscopy (n = 28).

The primary demographic and medical variables were age, sex, etiology of CLD, diagnosis of hepatocellular carcinoma, liver function tests, presence of ascites, encephalopathy, the model end-stage liver disease (MELD) score, and previous use of NSAIDs (at least five times per week during the last six months), cyclooxygenase-2 inhibitors, corticosteroids, anticoagulants, and aspirin. Any hospital stay associated with portal hypertensive bleeding was also recorded.

An endoscopic procedure was performed in all patients as an initial approach. Any patient with first endoscopy at the time of an episode of active bleeding was included. The primary endpoint of our study was the presence of portal hypertensive bleeding. We defined bleeding related to PH as any bleeding episode secondary to the rupture or erosion of esophageal or gastric varices and/or portal hypertensive gastropathy, manifested clinically as melena or hematemesis. All patients with suspected variceal bleeding during the period of the study were required to have an endoscopic procedure in the first 24 h after presentation. A regular diagnostic endoscope was initially used (GIF-100, GIF-130, GIF-140, or GIF-160; Olympus, Japan). The presence of esophageal or gastric varices, portal hypertensive gastropathy, red signs, and the size of the varices were recorded according to the Baveno Ⅳ consensus[16]. Other variables assessed included nonliver-related findings such as esophagitis, hiatal hernia, erosive gastritis, and duodenal or gastric ulcer.

The use of PPIs and other medical prescriptions within the six months preceding the study were identified in the patients' records. We defined PPI users as those patients with cirrhosis who had taken 20 mg of omeprazole (or an equivalent dose of any other PPI) for at least eight weeks before the episode of portal hypertensive bleeding or initial evaluation (first considered visit). Confirmation of the patients' compliance with the PPI treatment was based on chart records. A diagnosis of GERD was made according to the definition: "a condition that develops when the reflux of stomach contents causes troublesome symptoms and/or complications"[17]. Troublesome symptoms were defined by the patient as affecting his/her quality of life. The symptoms considered were heartburn, regurgitation, reflux-related chest pain, extraesophageal syndromes of GERD (laryngitis, cough, asthma) confirmed by their resolution with PPI therapy, pH monitoring, or endoscopic evidence of esophagitis, according to the Los Angeles classification (grades B, C, or D)[17].

Statistical analysis

The results are expressed as distributions, absolute frequencies, relative frequencies, medians and ranges, or

means ± SD. For comparison, patients were classified into two groups: patients who used PPIs and patients who did not use PPIs. The quantitative data were compared using the Student's *t*-test for variables with a normal distribution, and the Mann-Whitney *U* test for other variables. Differences between the proportions of categorical data were evaluated with Fisher's exact test when the number of expected subjects was less than five and otherwise with the χ^2 test. A multivariate logistic regression model was used to assess the independent association between PPI use and bleeding related to PH. A *P* value of < 0.05 was considered statistically significant.

Sample size calculation

According to data published by Hajime *et al*[10] the frequencies of variceal bleeding in patients with and without PPI use were 10% and 52.4%, respectively (a difference of 42%). According to these data, to detect a difference of at least 42%, we required at least 25 patients for each group (group 1, patients with cirrhosis and PPI use; and group 2, patients with cirrhosis and no PPI use). All statistical analyses were conducted with SPSS statistical software (v. 12.0; SPSS Inc., Chicago, IL, USA).

RESULTS

We initially evaluated 135 patients. Thirty patients were excluded because of incomplete data, therefore, a total of 105 patients were included in the study. The characteristics of the included patients are shown in Table 1. The most frequent endoscopic finding was esophageal varices in 82 (78%) patients, 16 (19.5%) of whom were recorded as having large varices and/or red signs. Portal hypertensive gastropathy was found in 72 patients (68.6%) and gastric varices in 15 patients (14.3%). Of those patients with gastric varices, 13/15 (86.6%) also had esophageal varices. Other findings not related to CLD were erosive gastropathy in 14 patients (13.3%), hiatal hernia in eight patients (7.6%), duodenal ulcer (Forrest Ⅲ) in three patients (2.9%), and gastric ulcer (Forrest Ⅲ) in three patients (2.9%). Other comorbidities are shown in Table 1. There was a tendency [odds ratio (OR): 1.3, 95% confidence interval (CI): 0.72-2.6, $P = 0.2$] to non-portal hypertension-related bleeding episodes ($n = 20$; erosive gastropathy, duodenal ulcer, and gastric ulcer) in patients not using PPIs.

Forty-eight (45.5%) patients underwent PPI therapy. Most of these patients used omeprazole, although 10 used pantoprazole. During the period of evaluation, 16.1% ($n = 17$) presented with upper gastrointestinal bleeding related to PH, and in 82.3% of these patients ($n = 14$), this bleeding was secondary to esophageal varices, whereas in three patients it was attributable to portal hypertensive gastropathy. We recorded no episodes of bleeding secondary to gastric varices. When we analyzed the presence of variceal bleeding in patients classified according to their pattern of PPI use (group 1, patients using PPI, $n = 48$; and group 2, patients not using PPI, $n = 57$), the frequency was 18.7% ($n = 9$) in group 1 and 14% ($n = 8$) in group 2 (OR: 0.83, 95% CI: 0.5-1.3, $P = 0.51$). When we evaluated only those patients with upper gastrointestinal bleeding secondary to esophageal varices, we observed frequencies of 12.5% in group 1 and 14% in group 2 (OR: 1.07, 95% CI: 0.56-2.0, $P = 0.81$). A comparison of the characteristics of patients using PPIs and those not using PPIs is shown in Table 1.

Table 1 Characteristics of the patients included in the study classified by proton pump inhibitor use (mean ± SD) *n* (%)

Variable	Patients using PPIs ($n = 48$)	Patients not using PPIs ($n = 57$)	*P* value

CPT: Child-pugh-turcotte class; GERD: Gastroesophageal reflux disease; MELD: Model for end stage liver disease; PPIs: Proton pump inhibitors; ALT: Alanine aminotransferase; NSAID: Non-Steroidal anti-inflammatory drugs; BMI: Body mass index (calculated as patient body weight divided by the square of their height expressed in kg/m^2).

The overall prevalence of GERD was 11.4% ($n = 12$), corresponding to 14.5% of group 1 ($n = 7/48$). Only seven (57.1%) patients with GERD received PPIs. Of the total number of patients with portal hypertensive bleeding, 11.7% ($n = 2/17$) had GERD. The presence of GERD was not statistically significantly associated with the presence of upper gastrointestinal bleeding (OR: 0.53, 95% CI: 0.15-1.8, $P = 0.31$). Univariate and multivariate analyses of the variables associated with gastrointestinal bleeding secondary to PH are shown in Table 2.

DISCUSSION

In this study, we observed that in patients with CLD and endoscopic evidence of PH, the presence of gastrointes-

CPT C: Child-pugh-turcotte class C; GERD: Gastroesophageal reflux disease; MELD: Model for end stage liver disease; PPI: Proton pump inhibitor; LEV: Large Esophageal varices; NSAID: Non-steroidal anti-inflammatory drugs; OR: Odds ratio; CI: Confidence interval.

tinal bleeding secondary to variceal or portal hypertensive gastropathy was not associated with the use of PPIs. This is a very important finding because it has been reported that the presence of PH on endoscopy is associated with an unacceptable, and according to our data, unnecessary prescription of PPIs in patients with cirrhosis[5,18].

Soon after the introduction of PPIs into clinical practice, these drugs demonstrated their effectiveness in several gastrointestinal diseases. However, the overuse of this class of drugs has important economic implications. In patients with cirrhosis, many factors influence the appropriate prescription of PPIs[5,18]. It was observed in previous studies that patients in the early stages of Child-Pugh-Turcotte classification, and with a low MELD score, were more likely to be prescribed PPIs appropriately than those in the more advanced stages of the disease or with endoscopic findings of PH[5,18]. According to the scarce evidence available regarding the use of these drugs in the clinical context, it seems that physicians tend to consider the use of PPIs in cirrhotic patients as possibly beneficial for variceal bleeding. It has also been postulated in the past that gastroesophageal reflux may contribute to esophagitis and variceal bleeding in patients with CLD[19]. In fact, there are few data on the use of PPIs in these patients, and these data are predominantly related to the pharmacological properties of the drugs[20]. The findings of our study are consistent with those of other studies, which have reported that patients with PH, and especially those with portal hypertensive gastropathy, display increased bicarbonate production and an elevated gastric pH. The increased circulatory rate in these patients, the high gastric pH level, and the increased prevalence of hypochlorhydria are factors associated with lower pepsin activity[21-25].

The main limitation of our study is its retrospective design. However, data concerning the association of portal hypertensive bleeding with the use of PPIs are scarce and are based on only one study, published as an abstract[10]. There is an absence of data from randomized trials, thus, prospective studies are still required to develop more reliable recommendations regarding the use of PPIs in this context. The diagnosis of PH in this study was based on esophageal varices, gastric varices, and hypertensive gastropathy, therefore, it is possible that some patients with a hepatic venous pressure gradient above 12 mmHg were overlooked. However, our study focused on patients with endoscopic findings related to PH.

In conclusion, our data support the hypothesis that the use of PPIs is not associated with upper gastrointestinal bleeding related to PH in cirrhotic patients. Therefore, these findings do not support the use of PPIs in patients with CLD and endoscopic evidence of PH without a currently accepted indication.

COMMENTS

Background

Gastrointestinal bleeding secondary to portal hypertension is a major complication in patients with cirrhosis, and proton pump inhibitors are frequently used to prevent it. These drugs have provided benefits in the management of many gastrointestinal disorders; unfortunately, the unnecessary prescription of these drugs has become an important problem, which increases costs in daily practice. Considering the current paradigm of evidence-based medicine, their use in patients with cirrhosis and portal hypertension is based only on expert opinion, with insufficient evidence to justify the use of these drugs as prophylaxes.

Research frontiers

Proton pump inhibitors are widely used among patients with chronic liver disease and endoscopic findings of portal hypertension with the aim of preventing bleeding, however, there is no appropriate evidence to support their use for this condition. In this study, the authors demonstrate that the use of proton pump inhibitors is not associated with a lower frequency of gastrointestinal bleeding in cirrhotic patients.

Innovations and breakthroughs

In this study, the authors observed that in patients with chronic liver disease and endoscopic evidence of portal hypertension, the presence of gastrointestinal bleeding secondary to variceal or portal hypertensive gastropathy was not associated with the use of proton pump inhibitors. This is a very important finding because it has been reported that the presence of portal hypertension on endoscopy is associated with an unacceptable, and according to the data, unnecessary prescription of proton pump inhibitors in patients with cirrhosis.

Applications

This study provided evidence on the use of proton pump inhibitors in patients with chronic liver disease and endoscopic findings of portal hypertension, and does not support their use without a currently accepted indication for their prescription in this group of patients.

Terminology

Proton pump inhibitors are a class of drugs that reduce the secretion of HCl in the stomach, consequently increasing gastric pH. The current principal accepted indications for these drugs include peptic ulcer disease and gastroesophageal reflux disease. Esophageal varices and hypertensive gastropathy are referred to as endoscopic findings of portal hypertension. Portal hypertension is the main cause of gastrointestinal bleeding in patients with cirrhosis, and its prevention is very important in clinical practice.

Peer review

This is a clear cut-off of the question of non-steroidal anti-inflammatory drugs with/without proton-pump inhibitors administration dilemma. The clinical problem is well addressed and presented, and the authors provide a rationale for their conclusions.

Abstract

AIM: To elucidate the underlying mechanisms of metastasis and to identify the metabolomic markers of gastric cancer metastasis.

METHODS: Gastric tumors from metastatic and non-metastatic groups were used in this study. Metabolites and different metabolic patterns were analyzed by gas chromatography, mass spectrometry and principal components analysis (PCA), respectively. Differentiation performance was validated by the area under the curve (AUC) of receiver operating characteristic curves.

RESULTS: Twenty-nine metabolites were differentially expressed in animal models of human gastric cancer. Of the 29 metabolites, 20 were up-regulated and 9 were down-regulated in metastasis group compared to non-metastasis group. PCA models from the metabolite profiles could differentiate the metastatic from the non-metastatic specimens with an AUC value of 1.0. These metabolites were mainly involved in several metabolic pathways, including glycolysis (lactic acid, alaline), serine metabolism (serine, phosphoserine), proline metabolism (proline), glutamic acid metabolism, tricarboxylic acid cycle (succinate, malic acid), nucleotide metabolism (pyrimidine), fatty acid metabolism (docosanoic acid, and octadecanoic acid), and methylation(glycine). The serine and proline metabolisms were highlighted during the progression of metastasis.

CONCLUSION: Proline and serine metabolisms play an important role in metastasis. The metabolic profiling of tumor tissue can provide new biomarkers for the treatment of gastric cancer metastasis.

Key words: Gastric cancer; Metastasis; Metabolite; Metabolomics; Gas chromatography and mass spectrometry

INTRODUCTION

Gastric cancer is one of the most common malignancies and the second cause of cancer-related death worldwide and in most Asian countries, such as China[1,2]. So far, surgical resection remains the only curative treatment option[3]. However, because of its asymptomatic properties,

most patients are frequently misdiagnosed until local and distant metastases occur, leading to a poor prognosis of gastric cancer patients with a 5-year survival rate of less than 30%. Most gastric cancer-related deaths occur as a result of metastasis. Metastatic recurrence is the main obstacle to the improvement of therapy for gastric cancer. No effective treatment modality is available for this deadly disease at present. Similarly, almost no prophylactic therapies can block dissemination of gastric cancer cells and prevent its metastasis. Currently, histological staging of gastric cancer is mainly based on the depth of its invasion and metastasis, both of which are considered the most important indicators of recurrence and prognosis of gastric cancer after curative resection. It has been shown that some gene candidates, such as cell adhesion molecules, are involved in the process of gastric cancer metastasis[3-5]. However, no routine molecule markers for predicting gastric cancer metastasis and prognosis are available because of their high variability in expression levels.

The prognosis of patients with advanced gastric cancer remains very poor because the molecular mechanism underlying its metastasis is not fully understood[3,5]. Gastric cancer metastasis, which is a complex and multistep process, involves release, migration and penetration of its cells through the vessel walls, arrest of its cells in microcirculation of distant organs and their subsequent migration and growth at the metastatic sites. To get a better insight into the mechanism of such a process, metastasis and non-metastasis animal models of gastric cancer were established using the human gastric cancer cell line SGC-7901. Because of the same genetic backgrounds, the animal is a suitable comparative system for studying the molecular changes in gastric cancer metastasis. At present, most investigations are focused on the identification of altered genes and proteins that play an important role in gastric cancer progression[6-9]. However, only a few reports are available on the identification of key metabolites characterizing gastric cancer metastasis[6,10,11]. Metabolomics, an omic science in systems biology, is the comprehensive and simultaneous profiling of metabolic changes occurring in living systems in response to genetic, environmental, or lifestyle factors[11]. The missing link between genotype and phenotype can be established, which may provide information about gastric cancer that is complementary to genomics and proteomics analysis, thus improving our understanding of the pathogenic mechanisms and metabolic phenotype of gastric cancer. It has been recently shown that metabolomic method has great potentials in identifying the new diagnostic markers and therapeutic targets for different cancers, such as breast, prostate, pancreatic, liver, colon and gastric cancers[12-18], suggesting that metabolic alterations play a role in the biology of cancer. A more recent metabolomic analysis showed that increased sarcosine synthesis is an important metabolic change during prostate cancer progression[6]. However, to our knowledge, there is no metabolomic study on metastasis of gastric cancer[6,10].

In this study, metabolomic difference in metastasis and non-metastasis models of gastric cancer was detected by gas chromatography (GC) and mass spectrometry (MS), respectively, in accordance with our hypothesis that there were metabolite clusters associated with metastasis of gastric cancer.

MATERIALS AND METHODS

Chemicals

Tetrahydrofuran (THF), N-methyl-N-t-butyldimethylsilyltrifluoro-acetamide (MBDSTFA) and chromatographic pure were purchased from Sigma Chemical Co. (St Louis, MO, USA). Pyridine, sodium hydroxide, chloroform, anhydrous ethanol, and anhydrous sodium sulfate, purchased from China National Pharmaceutical Group Corporation (Shanghai, China), were of analytical grade. Vacuum dryer was the product of Shanghai NOTED Technologies (China). Distilled water was obtained from the Milli-Q System (Millipore, MA, USA).

Animals

Male mice with severe combined immune deficiency (SCID) at the age of 6 wk, weighing 20-25 g, were obtained from Shanghai Experimental Animal Center, Chinese Academy of Sciences (China). The mice were housed under specific pathogen-free conditions with free access to food and drinking water. Experiment was performed in accordance with the Chinese National Guidelines for the Care and Use of Laboratory Animals and the relative ethical regulations of our university.

Animal treatment

Twenty-two SCID mice were randomly divided into metastasis group (n = 8), non-metastasis group (n = 8), and control group (n = 6). An animal model of metastasis was induced by orthotopic implantation of histologically intact tissue of human gastric carcinoma as previously described[19] with some minor modifications. Human gastric cancer SGC-7901 (Shanghai Cancer Institute), a poorly-differentiated adenocarcinoma line, was originally derived from a primary tumor and maintained by passage in subcutis of nude mice. Tumors were removed aseptically with necrotic tissues cleaved away. The adjacent healthy tissues were cut into pieces (about 3 mm × 4 mm) in Hank's balanced salt solution, weighed and adjusted to 100 mg. After the SCID mice were anesthetized with 4.3% trichloraldehyde hydrate, an incision was made through the left upper abdominal pararectal line of mice in metastasis group with the peritoneal cavity carefully exposed. A part of the serosal membrane in middle of the greater curvature of stomach was mechanically injured using scissors. One hundred mg of tumor pieces was fixed at each injured site on the serosal membrane surface. After the stomach was returned to the peritoneal cavity, the abdominal wall and skin were closed. After the SCID mice were anesthetized with 4.3% trichloraldehyde hydrate, an incision was made in the left oxter of mice in non-metastasis group. Then, 100 mg of tumor tissue pieces was implanted into the subcutis (ectopic implantation) of mice. Meanwhile, the mice in non-metastasis group underwent the same ortho-

topic operation as those in metastasis group but with no tumor implantation into the gastric wall. The mice that underwent the same procedure with no tumor implantation served as a control group. All animals tolerated the surgical procedure well with no anesthesia-related death.

Sample collection and pathological examination

After anesthesia, all mice were sacrificed and subjected to autopsy. Tumors growing at the orthotopic or subcutaneous sites were harvested. Half of each tumor was snap-frozen at -80℃, while the other half was fixed in 4% formalin and embedded in paraffin. Tissues were collected from lymph nodes and all organs, fixed in 4% formalin, and processed for routine paraffin embedding after careful macroscopic examination. The tissue was cut into 4 μm-thick sections which were stained with hematoxylin and eosin, and evaluated histologically for metastasis of lymph nodes, liver or other organs by microscopy.

Sample pretreatment and derivation

One mL stilled water and one mL anhydrous ethanol were added to each 100 mg tissue sample. Gastric carcinoma tissue samples were ground with stilled water and anhydrous ethanol (1:1, v/v). The mixture was ultrasonicated at 4℃ for 30 min and vortexed for 2 min. The tissue sample (0.1 g/mL) was centrifuged at 18 000 × *g* (10 000 r/min) for 10 min. The aqueous layer was adjusted to pH 7.8 with 0.1 mol/L potassium phosphate buffer solution, and 1.5 mL supernatant was obtained from each sample. The collected supernatant (500 μL) was evaporated to dryness at 50℃ for 24 h in a vacuum dryer. Then 150 μL tetrahydrofuran was added to each of the dried tissue extracts, vortex-mixed for 10 min and evaporated to complete dryness in a nitrogen evaporator. MBDSTFA (100 μL) was added to each sample and derived at 60℃ for 30 min. The samples were vortexed for 30 s after derivation, for GC and MS analysis.

GC and MS analysis

Each of the samples was injected into an Agilent 6980 GC system equipped with a HP5MS capillary column (30 mm × 0.25 mm, i.d., 0.25 μm), and a quadrupole mass spectrometric detector (Agilent Technologies, Palo Alto, CA, USA). Helium was used as the carrier gas with a constant flow rate of 1.0 mL/min. One μL sample was injected into the Agilent 6980 GC system at 280℃. The column temperature was initially kept at 100℃ for 3 min, and then elevated to 220℃ at an increasing rate of 10℃ per min, followed by 10℃ per min to 280℃ for 5 min. Both of the interface and ion source temperature were 200℃. MS was conducted in an electron impact ionization mode at 70eV. Mass data were obtained in a full scan mode from m/z 100 to 600. Total ion chromatograms (TIC) and fragmentation patterns of GC were acquired using the GC/MSD ChemStation Software (Agilent Technologies, Palo Alto, CA, USA). Compounds were identified by comparing the mass spectrum with a standard mass spectrum in the National Institute of Standards and Technology (NIST) Mass Spectra Library. Peaks with a similarity index more than 70% were the assigned compound names, while those with a similarity index less than 70% were considered unknown metabolites[16]. Chromatograms were subjected to noise reduction prior to peak area integration. Any known artificial peaks due to derivatization of column bleed and BSTFA should be excluded from the data set. The resulting three-dimensional matrix included sample information, peak retention time, and peak area.

Statistical analysis

Data, normalized by dividing the sum of all peak areas in the sample (1 mg) before multivariate analysis, were expressed as mean ± SD and introduced into SPSS16.0 for Windows. Metabolite levels were compared by independent *t* test for the detection of significant differences in metastasis and non-metastasis groups. $P < 0.05$ was considered statistically significant. Principal components analysis (PCA) was performed to differentiate the metabolic patterns in metastasis and non metastasis groups. The differentiation performance was validated by the area under the curve (AUC) of receiver operating characteristic (ROC) curves. Similarly, metabolomic differences in metastasis group, non-metastasis group and control group were analyzed by *t* test and PCA.

RESULTS

The mean weight of mice in three groups was 23.81 ± 0.16, 23.87 ± 0.19 and 23.98 ± 0.19 g, respectively. Microscopy showed localized poorly-differentiated adenocarcinoma in all mice of non-metastasis and metastasis groups at the implanted sites. The average tumor weight was 4.28 ± 0.20 g in non-metastasis group and 4.30 ± 0.3 g in metastasis group, indicating that the tumor grows at a similar rate in the subcutis or stomach. However, the metastatic rate was significantly different when the tumor was implanted into the ectopic or orthotopic sites. Two thirds of the mice bearing an orthotopic tumor developed metastatic tumors in the region of lymph nodes, half in liver and one fourth in other organs. In contrast, no tumor metastasis was observed in the non-metastasis group after ectopic implantation. Macroscopic and histological examination showed no gastric cancer in the mice without tumor implantation. These results indicate that GC and MS are of a high reproducibility in the retention time of metabolites. Of the 152 signals detected in the tissue samples, some were not consistently found in other samples or could not be assigned to the unique metabolites because the abundance was too low. Fifty-eight signals could be identified by comparing a standard mass chromatogram with that in the NIST Library (Table 1). According to the NIST Mass Spectra Database, most of the chromatograms were identified as endogenous metabolites, such as amino acids, organic acids, inorganic acids, fatty acids, and pyrimidines, which were involved in several metabolic pathways, including glycolysis (lactic acid, alaline), serine metabolism (serine, phosphoserine), proline metabolism (proline), glutamic acid metabolism, glutamine metabolism, tricarboxylic acid (TCA) cycle (succinate), nucleotide metabolism (pyrimidine), fatty acid

P-value was calculated by student t test. $P < 0.05$ was considered statistically significant. Fold change with a positive value indicates a relatively higher level of metabolites while a negative value indicates a relatively lower level in metastasis group than in non-metastasis group.

Student's *t* test. Marker metabolites selected by Student's *t* test are presented in Table 2. Among these metabolites, proline was the most up-regulated tissue metabolite in metastasis group, which was 2.45-fold higher than that in non-metastasis group. Glutamine was the most down-regulated tissue metabolite in the metastasis group, which was 1.71-fold lower than that in the non-metastasis group. The lactic acid, L-alanine, L-valine, leucine, malic acid, L-aspartic acid, serine, phosphoserine, dimethylglycine, glycine, L-glutamic acid, L-lysine, myo-inositol, propanedioic acid, docosanoic acid, octadecanoic acid, arginine, pyrrodine, and pyrimidine were significantly up-regulated, while the glucose, succinate, L-isoleucine, L-methionine, propanamide, L-threonic acid, and butanedioic acid were remarkably down-regulated in the metastasis group compared to the non-metastasis group. The main metabolic pathways associated with metastasis of gastric cancer included glycolysis (lactic acid, alaline), serine metabolism (serine, phosphoserine), proline metabolism (proline), tricarboxylic acid (TCA) cycle (succinate, malic acid), fatty acid metabolism (docosanoic acid, and octadecanoic acid), and methylation(glycine).

The levels of lactic acid, propanedioic acid, L-alanine,

L-valine, glycine, leucine, malic acid, pyrrodine, serine, L-proline, L-methionine, L-threonine, L-aspartic acid, phosphoserine, L-glutamic acid, L-lysine, arginine, myo-inositol, docosanoic acid, and octadecanoic acid were higher in non-metastasis group and metastasis group than in control group, while the levels of glucose, L-isoleucine, succinate, and glutamine were lower in control group than in non-metastasis group and metastasis group.

PCA was used to identify the metabolic patterns associated with gastric cancer metastasis. The PCA scores of non-metastasis group and metastasis group were scattered into two different regions. ROC analysis, which was performed using the values determined by the first two components of the PCA model, confirmed the robustness of the PCA model. The sensitivity and specificity trade-offs were summarized for each variable with the AUC. The AUC value for the PCA model was 1.00, demonstrating a good differential value for metastasis of gastric cancer.

The PCA model was also validated by ROC analysis (AUC = 1.00), showing that the growth of human gastric cancer in mice was of distinct metabolic properties compared to that in the host.

DISCUSSION

Metastasis is one of the leading causes for poor prognosis of patients with gastric cancer[20]. The approaches used in tumor staging and prognosis assessment have a large number of limitations[21,22]. Recent advances in the field of metabolomics have provided the new opportunities to identify novel diagnostic markers and therapeutic targets for gastric cancer[6,11]. It is very important to establish a relevant model of cancer metastasis. Cell lines are often used as experimental models to investigate the genetic and biochemical alterations in tumor cells[23]. However, these models have limitations due to the lack of interactions between tumor cells and host[24]. Our previous study showed that human gastric cancer growing at orthotopic sites produces metastasis, and does not result in metastasis in SCID mice when it is implanted into the ectopic sites[19]. It has been shown that a mouse gastric cancer model develops metastasis similar to human tumor[19], which is in favor of research on gastric cancer metastasis. Consistent with our results, an orthotopically implanted pancreatic cancer model is a prerequisite for identifying a differential gene expression pattern unique to metastatic human pancreatic cancer[23].

In the present study, a highly metastasis model was successfully induced by orthotopic implantation of histologically intact tissue of SGC-7901 human gastric carcinoma while a non-metastasis model was established by subcutaneous implantation of the same cancer tissue in SCID mice. Tissue samples from gastric and subcutaneous tumors were derived from the same human gastric cancer with the same genetic background. The main difference in the two tumor models was their metastatic abilities. Therefore, metabolic analysis of these samples is valuable for the elucidation of metastatic mechanisms. To our knowledge, this is the first metabolomic investigation of gastric cancer metastasis in animal models. The comparative metabolomic strategy was used to identify the marker metabolites which were differentially expressed in animal models of human gastric cancer with distinct metastatic phenotypes. Of the 29 differential metabolites detected in the tumor models, 20 were up-regulated and 9 were down-regulated in the metastasis group compared to those in the non-metastasis group, indicating that these metabolites are involved in several metabolic pathways.

The lactic acid level was higher while the glucose level was lower in metastasis group than in non-metastasis group. Lactic acid is the end product of glycolysis. Increased glucose uptake and consumption are frequently observed in many cancer cells even under normoxic conditions, known as the Warburg effect. It has been demonstrated that the lactic acid level is increased in various metastatic cancers, including renal, uterine cervix, head and neck, colorectal cancers[25-27]. Moreover, the high lactate level in tumor tissue is associated with its metastasis and poor prognosis[27]. In fact, increased lactic acid produced by tumor cells can result in acid-mediated matrix degradation, T cell inactivation, up-regulation of VEGF and HIF-1 alpha, and enhancement of cell motility, thus providing favorable conditions for metastatic spread[25,27]. Therefore, high lactic acid levels reflect an increased energy demand for tumor progression.

In the present study, GC and MS showed that proline was the most up-regulated tissue metabolite, indicating that increased proline in metastatic gastric cancer tissue may be correlated with the increased turnover of extracellular matrix in metastatic cancer cells. Tumor cells need increased degradation of collagen during the process of invasion and metastasis, thus producing a large amount of proline. Pyrroline-5-carboxylic (P5C) is the precursor of proline and also its degradation product. Proline oxidase, also known as proline dehydrogenase, catalyzes the first step of proline to P5C in mitochondria and the latter is converted to proline by the cytosolic P5C reductase. It has been demonstrated that proline oxidase can be induced by p53 due to genotoxic stress and initiates apoptosis by the mitochondrial and death receptor pathways[28]. Proline is a stress substrate and matrix metalloproteinases can degrade collagen in the extracellular matrix. So far little attention has been paid to the correlation between proline metabolism and tumor progression. It has been shown that proline consumption is increased in patients with metastatic renal cancer[29]. Increased proline biosynthesis has been recently observed in metastatic breast cancer cell lines[30]. Furthermore, proline metabolism is linked with arginine and glutamate metabolism, TCA cycle and pentose phosphate pathway (PPP) due to P5C[28], suggesting that the significantly up-regulated metabolism of proline is highly correlated with cancer metastasis.

In this study, serine metabolism was involved in the metastatic process of gastric cancer, showing alterations in the pathway. The serine and phosphoserine increased 1.48-fold and 1.56-fold, respectively in metastatic tumors. It was reported that all the three genes involving the serine biosynthesis pathway, phosphoglycerate dehydrogenase (PHGDH), phosphoserine aminotransferase 1 (PSAT1),

and phosphoserine phosphatase (PSPH) are up-regulated in highly metastatic breast cancer cells[31], which is agreement with our results. Although most amino acids are increased in gastric cancer and colorectal cancer tissue compared with their adjacent normal tissue[17], little is known about the alterations related to metastatic behaviors. In the present study, the levels of leucine, valine glutamate and lysine were higher while the levels of methionine and threonine were lower in metastatic specimens, indicating that the demand for energy is increased in metastatic progression. Glycine can derive from serine synthesized by the glycolytic intermediate phosphoglycerate and its elevated levels may be associated with glycolysis. Sarcosine, a methylation derivative of the amino acid, glycine, is related to prostate cancer progression[6]. Dimethylglycine is another methylation product of glycine and how it is up-regulated remains unclear.

The disturbed TCA cycle, observed in a large number of tumors including gastric cancer, is considered to be related to carcinogenesis[17]. In this study, the TCA cycle intermediates such as succinate and malic acid were remarkably perturbed in metastatic specimens, suggesting that enhanced glycolysis contributes to metastatic progression.

In this study, the expression patterns of metastatic and non-metastatic human carcinoma were compared by metabolomic analysis, and several important metabolic pathways associated with metastasis of gastric cancer were identified. Of note, proline and serine metabolism were highlighted in this study. Further functional and clinical sample analysis of the metabolic pathways is needed to demonstrate their role in gastric cancer metastasis. The metabolic pathways may be exploited as biomarkers for gastric cancer progression.

COMMENTS

Background

Gastric cancer is the second cause of cancer-related death worldwide, and its metastasis is one of the leading causes of cancer-related death. The molecular mechanisms underlying gastric cancer metastasis are still not fully understood. Recent metabolomic studies have shown that metabolic alterations play a role in the biology of gastric cancer. The metabolic profiling of tumor tissue is used to elucidate the underlying mechanisms and identify the metabolomic markers of gastric cancer metastasis for improving its diagnostic and therapeutic strategies.

Research frontiers

Metabolomics, an OMIC science in systems biology, is the comprehensive and simultaneous profiling of metabolic changes occurring in living systems in response to genetic, environmental, or lifestyle factors. Recently, metabolomic method has shown great potentials in identifying the new diagnostic markers and therapeutic targets for cancers. However, metabolomic study on gastric cancer metastasis remains scarce.

Innovations and breakthroughs

Recently, most investigations have been focused on identifying the altered genes and proteins that play a role in cancer progression. In this study, the expression patterns of metastatic and non-metastatic human carcinoma were compared by metabolomic analysis, and several important metabolic pathways associated with metastasis of gastric cancer were identified. This is the first report on metabolomic investigation of gastric cancer metastasis.

Applications

The results of this study indicate that the metabolic pathways can be exploited as biomarkers for gastric cancer progression, which can be used in diagnosis and treatment of gastric cancer.

Terminology

Metabolomics, an OMIC science in systems biology, is the comprehensive and simultaneous profiling of metabolic changes occurring in living systems in response to genetic, environmental and lifestyle factors. Gas chromatography (GC) and mass spectrometry (MS) have been widely applied in metabolomic investigation because of their high sensitivity, peak resolution and reproducibility.

Peer review

To elucidate the underlying mechanisms of metastasis and identify metabolomic markers of gastric cancer metastasis, the authors performed GC/MS to identify the metabolomic difference in metastatic and non-metastatic lesions. The results indicate that proline and serine metabolism play an important role in gastric cancer metastasis, and that metabolic profiling of tumor tissue can provide new biomarkers for the treatment of gastric cancer metastasis.

Abstract

AIM: To investigate the prognostic value of *KRAS* mutation, and phosphatase and tensin (PTEN) expression in Chinese metastatic colorectal cancer metastatic colorectal cancer (mCRC) patients treated with cetuximab.

METHODS: Ninety Chinese mCRC patients treated with cetuximab were evaluated for *KRAS* mutation and PTEN protein expression by DNA sequencing of codons 12 and 13 and immunohistochemistry, respectively. We then selected 61 patients treated with cetuximab, either in combination with chemotherapy, or alone as a second-line or third-line regimen to assess whether *KRAS* mutation or PTEN protein expression is associated with the response and the survival time of mCRC patients treated with cetuximab.

RESULTS: *KRAS* mutation was found in 30 (33.3%) tumor samples from the 90 patients, and positive PTEN expression was detected in 58 (64.4%) of the 90 patients. Among the 61 patients who were treated with cetuximab as a second-line or third-line regimen, the resistance to cetuximab was found in 22 patients with *KRAS* mutation and in 39 patients without *KRAS* mutation, with a response rate of 4.5% and 46.1% respectively ($P = 0.001$), a shorter median progression-free survival (PFS) time of 14 ± 1.3 wk and 32 ± 2.5 wk respectively ($P < 0.001$), a median overall survival (OS) time of 11 ± 1.2 mo and 19 ± 1.8 mo respectively ($P < 0.001$), as well as in 24 patients with negative PTEN expression and in 37 patients with positive PTEN expression respectively ($P < 0.001$), with a responsive rate of 4.2% and 48.6% respectively, a shorter median PFS survival time of 17 ± 2.0 wk and 28 ± 1.9 wk respectively ($P = 0.07$), and a median OS time of 11 ± 1.3 mo and 18 ± 1.9 mo respectively ($P = 0.004$). Combined KRAS mutation and PTEN expression analysis showed that the PFS and OS time of patients with two favorable prognostic factors were longer than those of patients with one favorable prognostic factor or no favorable prognostic factor ($P < 0.001$).

CONCLUSION: *KRAS* mutation and PTEN protein expression are significantly correlated with the response rate and survival time of Chinese mCRC patients treated with cetuximab.

Key words: Cetuximab; Metastatic colorectal cancer; *KRAS* mutation; Phosphatase and tensin protein expression

INTRODUCTION

The incidence of colorectal cancer (CRC) has been increasing in the past decades and CRC is the third-leading cause of cancer-related deaths in China. During the past few years, several new biological agents have been evaluated in metastatic colorectal cancer (mCRC) with a remarkable anti-mCRC activity. Epidermal growth factor receptor (EGFR), one of the most promising targets, can activate the proliferation and prolong the survival time of cancer cells through the Ras/Raf/mitogen-activated protein kinase (MEK)/EPH receptor B2 (ERK) pathway or the phosphoinositide-3-kinase (PI3K)/PTEN/AKT pathway[1].

Cetuximab (Erbitux®, Merck KgaA, Darmstadt, Germany), a chimeric mouse/human antibody against the extracellular domain of EGFR, has a single-agent activity in mCRC refractory to irinotecan, oxaliplatin and fluoropyrimidines, and restores chemosensitivity in irinotecan-refractory mCRC patients[2-4]. However, only a small number of patients can benefit from cetuximab. The response rate to the combined cetuximab and irinotecan is about 23%[2]. Immunohistochemical studies showed that EGFR protein expression in CRC patients is not a useful predictor for the response to cetuximab[5,6].

Recent reports are available on the EGFR pathways, such as *KRAS*/BRAF/MAPKs, and on their potential correlation with cetuximab activity. *KRAS* somatic mutation occurs in approximately 40% of CRC patients. The negative predictive value of *KRAS* mutation has been confirmed in CRYSTAL study of first-line fluorouracil, leucovorin, and irinotecan (FOLFIRI) with or without cetuximab, demonstrating that only the patients with *KRAS* wild-type mutations benefit from cetuximab treatment[7-9].

Increasing interest in anti-EGFR therapy has been focused on another EGFR pathway, and PI3K/AKT/PTEN. PTEN encodes phosphatase with phosphatidylinositol-3, 4, 5-triphosphate (PIP-3) produced by the activity of PI3K as its major substrate. Loss of PTEN function increases PIP-3 concentration, and subsequent AKT hyperphosphorylation stimulates the proliferation of cancer cells[10].

It was reported that PTEN protein expression and *KRAS* mutation can predict the outcome of mCRC patients treated with cetuximab plus irinotecan, and negative PTEN expression in mCRC patients can predict the resistance to cetuximab plus irinotecan. Combined PTEN expression and *KRAS* mutational analysis can help to identify a subgroup of mCRC patients who have a greater chance of benefiting from EGFR inhibition[11].

KRAS and PTEN are the important molecular determinants of the EGFR downstream signal pathway and play an important role in anti-EGFR therapy in Western countries. However, little is known about the correlation between *KRAS* mutation and PTEN protein expression with the activity of anti-EGFR mono-antibody in Asian populations. This retrospective study was to evaluate the prognostic value of EGFR downstream cascade members, *KRAS* and PTEN, in Chinese mCRC patients treated with cetuximab plus chemotherapy.

MATERIALS AND METHODS

Patients

We retrospectively assessed 90 mCRC patients (59 males and 31 females with a median age of 53.0 ± 13.9 years) treated with cetuximab in Sun Yat-Sen University Cancer Center and Beijing Cancer Hospital from June 2000 to August 2008. The patients had histologically proven colorectal adenocarcinoma and the tumor response to cetuximab treatment was evaluable. Tissue samples of primary colorectal tumor were taken. *KRAS* mutation and PTEN protein expression in the patients were analyzed. Of the 90 patients, 3 received cetuximab monotherapy, 58 received cetuximab in combination with irinotecan-based chemotherapy, and 29 received cetuximab in combination with oxaliplatin-based chemotherapy. Cetuximab was administered as the first- fourth lines of treatment in 29, 23, 28, and 10 patients, respectively (Table 1). Paraffin-embedded tumor tissue samples from 100 mCRC patients (69 males and 31 females with a mean age of 50.5 ± 12.1 years) not treated with cetuximab were used for gene analysis. Furthermore, *KRAS* mutation in these patients was analyzed to confirm the mutation frequency of *KRAS*.

Skin toxic effects were assessed according to the National Cancer Institute Common Toxicity Criteria, version 2. Tumor response to cetuximab was evaluated by computerized tomodensitometry according to the response evaluation criteria in solid tumors (RECIST) and classified as complete response (CR), partial response (PR), stable disease (SD) and progressive disease (PD). Patients with CR or PR and SD or PD were classified as responders and non-responders, respectively, for the analyses.

Nucleotide sequence analysis

KRAS mutation was analyzed by extracting genomic DNA from the paraffin-embedded tissue sections with a QIAamp DNA mini kit (Qiagen, Berlin, Germany) according to its manufacturer's instructions. Exon 1 of the *KRAS* gene (GenBank, L00045, nt 102 to 235) was then directly PCR-amplified in a thermal cycler. The sequences of primers used for *KRAS* analysis (codons 12 and 13) are identical to those used in a previous study[12]. PCR condi-

tions were as follows: 1 cycle at 95℃ for 9 min, 45 cycles at 94℃ for 1 min, at 55℃ for 1 min, and at 72℃ for 1 min, followed by 1 cycle at 72℃ for 5 min. After confirmed by agarose electrophoresis and ethidium bromide staining, the PCR products were purified and automatically sequenced with an ABI PRISM 3730 (Applied Biosystems, California, USA), then analyzed with Chromas software version 2.0 (Gene Codes Corporation, USA). All sequencing reactions were performed in both forward and reverse directions, by independent PCR.

PTEN protein expression

PTEN protein expression in 3-mm thick tissue sections was evaluated using the anti-PTEN clone 6H2.1 (Millipore Company, Massachusetts, USA). The sections were deparaffinized and hydrated by passing through xylene and a graded series of ethanol. Endogenous peroxidase activity of the sections was blocked by incubating them in 0.3% hydrogen peroxide for 20 min. Antigen was retrieved for 30 min at 98℃ in a 0.01 mol/L sodium citrate buffer (pH 6.4) in a microwave oven. After blocked for 30 min in 0.75% normal goat serum, the sections were incubated with 6H2.1 at a dilution of 1:100 overnight at 4℃, washed in PBS, and then incubated with biotinylated goat anti-mouse IgG followed by avidin peroxidase using a Vectastain ABC elite kit (Vector Laboratories, California, USA). The reaction products were counterstained with hematoxylin, and the sections were evaluated under a light microscope. PTEN protein expression was detected mainly in cytoplasm, although nuclear signals were occasionally observed as previously reported[13]. The intensity of reaction was assessed as a score of either 1+, 2+ or 3+, and the percentage of positive cells was classified into three groups (0%-25%, 25%-50% and > 50% of cells) and assigned to 1, 2 or 3 points, respectively. Tumors producing more than 4 points were considered PTEN-positive tumors according to the two values for the products. The evaluation was performed without knowledge of the clinical data or the results of other analyses.

Statistical analysis

Fisher's exact test was used to calculate the *P* values for *KRAS* mutation, PTEN expression, skin toxicity, and response to cetuximab. PFS time was calculated as the period of time from the first day of cetuximab treatment to the date of tumor progression, the date of death due to any factor, or the date of last follow-up. OS time was calculated as the period of time from the first day of cetuximab treatment until death due to any factor, or until the date of last follow-up. Cox proportional hazards regression model was used in survival analysis. PFS curves for PTEN expression and *KRAS* mutation were plotted using the Kaplan-Meier method, and the difference in biomarkers was evaluated using the log-rank test. Analysis was carried out with the SPSS software version 16.0 (SPSS Company, USA). $P < 0.05$ was considered statistically significant.

RESULTS

The clinical characteristics of mCRC patients treated with cetuximab are summarized in Table 1. The median follow-up time was 13.5 mo. Of the 90 patients, 34 (37.8%) had a response to cetuximab plus chemotherapy. The median PFS and OS time was 22 wk (range 8-129 wk), and 11 mo (range 2-48 mo), respectively. *KRAS* mutation was found in 30 (33.3%) tumor tissue samples from the 90 patients. Of the 30 tumor tissue samples, 25 and 5 were the single amino acid substitutions in codons 12 and 13, respectively. The *KRAS* mutations on codon 12 predominantly involved the second base of the codon, with the presence of GaT mutation (GGT-GaT, Gly-Asp, G12D), GtT mutation (GGT-GtT, Gly-Val, G12D), aGT mutation (GGT-aGT, Gly-Ser, G12C), and tGT mutation (GGT-tGT, Gly-Cys, G12C), in 16 (53.3%), 6 (20.0%), 2 (6.7%), and 1 (3.3%) out of the 30 patients, respectively. The *KRAS* mutations on codon 13 corresponded to the transition G-a at the second base of the codon (GGC-GaC, Gly-Asp, G13D). Positive and negative PTEN expression was detected in 58 (64.4%) and 32 (36.6%) of the 90 patients, respectively (Figure 1).

Of the 100 mCRC patients used for confirmation of *KRAS* mutation, 29 (29%) displayed *KRAS* mutation on codons 12 and 13, which was not significantly different from that in the 90 patients ($P = 0.213$). The *KRAS* mutations from GGT to GaT (Gly-Asp) and GtT (Gly-Val) on codon 12 accounted for 58.6% (17 of 29) and 20.7% (6 of 29) of the specified mutations, respectively. Mutations from GGC to GaC (Gly-Asp) occurred in 20.7% (6 of 29) of *KRAS* mutations on codon 13. The total mutation rate was 31% in 190 patients evaluated for *KRAS* mutations.

PD	14 (63.6)	4 (10.3)		9 (24.3)	9 (37.5)	
Total	22 (100)	39 (100)		37 (100)	24 (100)	

CR: Complete response; PR: Partial response; SD: Stable disease; PD: Progressive disease; PTEN: Phosphatase and tensin.

We attempted to assess whether the *KRAS* mutation, PTEN protein expression or skin toxicity is associated with the clinical response of mCRC to cetuximab. Sixty-one patients treated with cetuximab plus chemotherapy as a second-, third-, or greater-line regimen were enrolled for analysis. The *KRAS* mutation was detected in 22 patients (36.1%). One of the 22 patients with *KRAS* mutation responded to cetuximab, and 18 of the 39 patients without *KRAS* mutation responded to cetuximab, with a response rate of 4.5% and 46.1%, respectively ($P = 0.001$). Positive PTEN expression was detected in 37 (60.7%) out of the 61 patients. Eighteen of the 37 patients with normal PTEN expression and one of the 24 patients with negative PTEN expression responded to cetuximab, with a response rate of 48.6% and 4.2%, respectively ($P = 0.001$). The absence of *KRAS* mutation and the presence of PTEN protein expression were significantly associated with a high response rate to cetuximab (Table 2). Meanwhile, combined *KRAS* mutation status and PTEN expression analysis showed that 24 (39.3%) of the 61 patients had no *KRAS* mutation and positive PTEN expression, with a remarkably higher effective rate than other patients (70.8% *vs* 5.4%, $P < 0.001$). Fisher's exact test also showed that the skin toxicity was significantly associated with a high response rate to cetuximab ($P < 0.001$).

Furthermore, we assessed whether *KRAS* mutation, PTEN protein expression, or skin toxicity is associated with the PFS and OS time in the 61 patients. Univariate analysis of PFS time showed that *KRAS* mutation was significantly associated with a short PFS time ($P < 0.001$). The median PFS time of mCRC patients without and with *KRAS* mutation was 32 ± 2.5 wk and 14 ± 1.3 wk, respectively. The PFS time was longer in mCRC patients with positive PTEN protein expression than in those with negative PTEN protein expression (28 ± 1.9 wk *vs* 17 ± 2.0 wk, $P = 0.07$) (Figure 2). No difference was found in the median PFS time between the patients with and without skin toxicity (27 ± 2.9 wk *vs* 18 ± 1.7 wk, $P = 0.113$). The median OS time of mCRC patients without *KRAS* mutation was significantly longer than that of those with *KRAS* mutation (19 ± 1.8 mo *vs* 11 ± 1.2 mo, $P < 0.001$). The median OS time of mCRC patients with positive PTEN expression was significantly longer than that of those with negative PTEN expression (18 ± 1.9 mo *vs* 11 ± 1.3 mo, $P = 0.004$) (Figure 3). The median OS time of mCRC patients with skin toxicity was longer than that of those without skin toxicity (17 ± 1.5 mo *vs* 11 ± 1.0 mo, $P = 0.025$). Multivariate analysis of the 61 patients showed that both *KRAS* mutation and PTEN protein expression were closely related with a shorter OS time ($P < 0.001$). No correlation was found between skin toxicity and *KRAS* mutation or PTEN protein expression.

In this study, the absence of *KRAS* mutation and positive PTEN expression were found to be two favorable prognostic factors for mCRC patients. Combined *KRAS* mutation and PTEN expression analysis showed that the median PFS time of mCRC patients with the two favorable prognostic factors was longer than that of those with only one favorable prognostic factor or with no favorable prognostic factor (32 ± 2.5 wk *vs* 17 ± 1.9 wk and 11 ± 1.8 wk, $P = 0.001$) (Figure 4). The median OS time of these three groups of mCRC patients was 22 ± 2.3 mo, 11 ± 1.5 mo, and 6 ± 1.0 mo, respectively ($P < 0.001$).

DISCUSSION

KRAS serves as a mediator for the extracellular ligand

binding and intracellular transduction signals from EGFR to nuclei. RASCAL study evaluated the *KRAS* mutational in 2721 CRC patients from 22 centers and demonstrated that *KRAS* mutation is closely related with the progression and outcome of CRC[14]. In the present study, *KRAS* mutation was observed in about 40% (20%-50%) of spo-

radic CRC patients. Up to 90% of activating *KRAS* mutations were detected at codons 12 and 13, less than 70% of activating *KRAS* mutations were frequently detected at codon 12, and 70% of activating *KRAS* mutations were detected at codon 13. It has been shown that the most frequent types of *KRAS* mutation in CRC patients are GGT-GaT (Gly-Asp) and GGT-GtT (Gly-Val) transitions at codon 12[15]. In our study, 31% of *KRAS* mutations occurred in 190 CRC patients, with most specified *KRAS* mutations found at the second base of codon 12. The most common *KRAS* mutation at codon 12 was GGT to GaT. These findings are consistent with those in a previous study[15], indicating that the frequency or type of *KRAS* mutations is not different in Chinese and Western CRC patients.

It has been demonstrated that the benefit of cetuximab treatment in combination with first-line chemotherapy is restricted to CRC patients with *KRAS* wild-type mutations[9,16]. The relation between *KRAS* mutation and response to anti-EGFR therapy has also been intensively studied[11,13,17]. Lièvre *et al*[17] found that CRC patients with *KRAS* mutations are resistant to cetuximab therapy and have an unfavorable prognosis. It was reported that the PFS and OS time are shorter in CRC patients with *KRAS* mutations than in those with wild-type *KRAS* mutations[7,8]. In our study, *KRAS* mutation was found to be a powerful predictor for the resistance to cetuximab, the response rate of CRC patients with *KRAS* and *KRAS* wild-type mutations was 4.5% and 46.1%, respectively. The PFS and OS time of CRC patients with *KRAS* mutations was shorter than that of those without *KRAS* mutations. It has also been shown that treatment with tyrosine kinase inhibitors is not effective for non small cell lung cancer patients with *KRAS* mutations[18,19], indicating that *KRAS* mutations play a fundamental role in the EGFR pathway, thus rendering EGFR inhibitors ineffective[20].

In our study, the response rate of CRC patients with *KRAS* wild-type mutations was only 46.1%, indicating that there must be other unidentified genetic determinants of resistance to cetuximab therapy for CRC. The PI3K/PTEN/AKT pathway is on the other side of the two EGFR pathways. PTEN is a tumor suppressor protein that regulates the PI3K/AKT signal transduction. Its loss is associated with intrinsic activation of the AKT pathway and confers resistance to inhibitors of the HER family[21]. Thomas and Grandis demonstrated that PTEN is lost in 30% of sporadic CRC patients[22]. PTEN protein expression may be another molecular predictor for the response to cetuximab. Frattini *et al*[13] reported that loss of PTEN protein expression is associated with the lack of response to cetuximab. Sartore-Bianchi *et al*[10] showed that loss of PTEN protein expression is associated not only with the lack of objective tumor response, but also with a shorter OS time of mCRC patients treated with cetuximab. Loupakis *et al*[11] revealed that combined PTEN expression and *KRAS* mutation analysis helps identify a subgroup of mCRC patients who have a greater chance of benefiting from EGFR inhibition. In our study, positive PTEN expression was detected in 64.4% of mCRC patients, which is consistent with previous reports[10-13]. In this study, the response to cetuximab was significantly correlated with PTEN protein expression. The PFS and OS time of mCRC patients with negative PTEN protein expression was shorter than that of those with positive PTEN expression. The response rate of the 24 mCRC patients with no *KRAS* mutation and positive PTEN expression was substantially higher than that of those with *KRAS* mutation and positive PTEN expression. Combined *KRAS* mutation and PTEN protein expression analysis showed that the PFS and OS time of mCRC patients with two favorable prognostic factors was longer than that of those with one favorable prognostic factor or no favorable prognostic factor, indicating that a comprehensive analysis of *KRAS* mutation and PTEN protein expression is a better predictor for the clinical outcome of mCRC patients treated with cetuximab, which requires further confirmation in a prospective series.

It has been shown that skin toxicity is significantly associated with the response to cetuximab and OS time of mCRC patients[2,5,23,24], which is consistent with the findings in our study. In our study, the response rate of mCRC patients with skin toxicity was higher than that of those without skin toxicity, and the OS time of mCRC patients with skin toxicity was also longer than that of those without skin toxicity. However, univariate analysis showed that skin toxicity was only associated with OS time, while multivariate analysis showed that *KRAS* mutation and PTEN protein expression were the significant risk factors for OS time, indicating that skin toxicity alone is insufficient to predict the outcome of mCRC patients treated with cetuximab. Moreover, *KRAS* mutation and PTEN protein expression was detected before cetuximab treatment and can thus be included in the algorithm of treatment decision[17].

To our knowledge, this is the first study on *KRAS* mutation and PTEN protein expression in Chinese mCRC patients. Other markers were also identified in our study, which can be used to select mCRC patients who are likely to benefit from cetuximab treatment, showing that *KRAS* mutation and PTEN protein expression in Chinese mCRC patients are similar to those in other populations. In this study, skin toxicity was insufficient to predict the outcome of mCRC patients treated with cetuximab, and *KRAS* mutation and PTEN protein expression were significantly associated with the response rate to cetuximab and survival time of these patients.

In conclusion, combined *KRAS* mutation and PTEN protein expression analysis is a better predictor for the clinical outcome of mCRC patients treated with cetuximab. Prospective studies with a large number of patients are required to further confirm the results of our study.

COMMENTS

Background

The incidence of colorectal cancer (CRC) has been increasing in past decades

and CRC is presently the third-leading cause of cancer-related deaths in China. During the past few years, several new biological agents have been evaluated in metastatic colorectal cancer (mCRC) with remarkable clinical activity. Cetuximab is an important biological agent used in treatment of mCRC, but it is effective only in a subset of mCRC patients.

Research frontiers

Studies have shown that *KRAS* mutation and phosphatase and tensin (PTEN) protein expression are associated with the response to cetuximab and may have a prognostic value. However, the situation in Asian patients is unknown. The authors evaluated the prognostic value of *KRAS* mutation and PTEN protein expression in Chinese mCRC patients treated with cetuximab plus chemotherapy.

Innovations and breakthroughs

To the authors' knowledge, this is the first study on *KRAS* mutation and PTEN protein expression in Chinese mCRC patients. The results of this study show that *KRAS* mutation and PTEN protein expression in Chinese mCRC patients are significantly correlated with the response rate and survival time of patients treated with cetuximab. A comprehensive analysis of *KRAS* mutation and PTEN protein expression is a better predictor for the clinical outcome of patients treated with cetuximab.

Applications

KRAS mutation and PTEN protein expression can be used to select Chinese mCRC patients who are likely to benefit from cetuximab treatment.

Terminology

Epidermal growth factor receptor (EGFR), one of the most promising targets, can activate the proliferation and prolong the survival time of cancer cells through the Ras/Raf/mitogen-activated protein kinase (MEK)/EPH receptor B2 (ERK) or the phosphoinositide-3-kinase (PI3K)/ PTEN /AKT pathway. *KRAS* serves as a mediator for the extracellular ligand binding and intracellular signal transduction from EGFR to nuclei. PTEN is a tumor suppressor protein that regulates the PI3K/AKT signal transduction. Its loss is associated with the intrinsic activation of the AKT pathway.

Peer review

The manuscript describes the impact of *KRAS* mutation and PTEN protein expression, either alone or in combination, on cetuximab-treated Chinese colorectal cancer patients. The manuscript targets a topic that is of scientific and clinical interest.

Abstract

AIM: To assess the efficiency and toxicities of irinotecan (CPT-11)-involved regimens in patients with advanced gastric cancer.

METHODS: Randomized phases Ⅱ and Ⅲ clinical trials on chemotherapy for advanced gastric cancer were searched from MEDLINE, EMbase, Cochrane Controlled Trials Register, and EBSCO. Relevant abstracts were manually searched. A total of 657 patients were analyzed for their overall response rate (ORR), time to treatment failure (TTF), overall survival (OS) rate, and toxicities. Overall survival rate, reported as hazard ratio (HR) with 95% CI, was used as the primary outcome measure.

RESULTS: Four randomized controlled trials on chemotherapy for advanced gastric cancer were detected. The CPT-11-containing combination chemotherapy was not significantly advantageous over the non CPT-11-containing combination chemotherapy for OS rate (HR = 1.12, 95% CI: 0.92-1.36, P = 0.266) and ORR [risk ratio (RR) = 1.23, 95% CI: 0.71-2.14, P = 0.458]. However, the CPT-11-containing combination chemotherapy was significantly advantageous over the non CPT-11-containing combination chemotherapy for TTF (HR = 1.35, 95% CI: 1.12-1.64, P = 0.002). Grade 3/4 haematological toxicity (thrombocytopenia: RR = 0.20, 95% CI: 0.09-0.48; P < 0.001) and gastrointestinal toxicity (diarrhea: RR = 4.09, 95% CI: 2.42-6.93, P < 0.001) were lower in patients with advanced gastric cancer after CPT-11-containing combination chemotherapy than after non CPT-11 -containing combination chemotherapy.

CONCLUSION: CPT-11-containing combination chemotherapy is advantageous over non CPT-11 -containing combination chemotherapy for TTF with no significant toxicity. CPT-11-containing combination chemotherapy can be used in treatment of advanced gastric cancer.

Irinoteca-involved regimens for advanced gastric cancer: A pooled-analysis of clinical trials. *World J Gastroenterol* 2010; 16(46): 5889-5894 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i46/5889.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i46.5889

INTRODUCTION

Although the incidence of gastric cancer has been sharply declined during the second half of the 20th century, it remains the second leading cause of cancer-related death in the world[1]. The morbidity and mortality rate of gastric

cancer increase with age. The most effective treatment for gastric cancer is radical gastrectomy. A substantial number of patients, however, eventually die of recurrence after curative resection. Although systemic chemotherapy can improve the quality of life in patients with gastric cancer[2], the outcome of patients with unresectable gastric cancer is still extremely poor with a median survival time of 3-5 mo after the best supportive care[2-4].

Randomized clinical trial data demonstrate that the survival rate and quality of life are better in patients with advanced gastric cancer after chemotherapy than in those after the best supportive care[5]. Over the years, a number of single-agent chemotherapy trials have confirmed that gastric cancer is a relatively "chemosensitive" disease[6-9]. It is, therefore, necessary to investigate different combination chemotherapies, both in phase Ⅱ and randomized phase Ⅲ trial settings.

First line chemotherapy usually consists of different combination regimens with 5-fluorouracil (5-FU) and cisplatin, including FP (5-FU and cisplatin) and ECF (epirubicin, cisplatin, and 5-FU). It has been shown that the response rate and progression-free survival rate are better for patients with gastric cancer after FP therapy than after 5-FU or other combination therapies[10,11]. The additional survival advantage yielded by these combination therapies appears to be marginal. However, no standard regimen has yet been established. Thus, it is necessary to develop new agents and combination regimens to achieve greater survival benefits in advanced or recurrent unresectable gastric cancer. Since 2005, combination chemotherapy for advanced gastric cancer has been focused on the integration of other chemotherapy agents, including docetaxel, irinotecan, oxaliplatin, capecitabine, and S-1.

Irinotecan (CPT-11) is a water-soluble camptothecin derivative. CPT-11 and its active metabolite (SN-38) bind reversibly to the topoisomerase I-DNA complex and induce cancer cell death by preventing relegation of single-strand DNA breaks[12,13]. It has been shown that CPT-11 acts as a single agent in oesophago-gastric cancer. It was reported that the overall response rate of advanced gastric cancer patients to chemotherapy is 16%-20%[14,15]. It has been reported that CPT-11 in combination with leucovorin/5-FU (ILF)[16] or cisplatin (IP)[17] exhibits its antitumor activity against advanced gastric cancer.

Several phases Ⅱ and Ⅲ randomized trials are available on CPT-11-containing or non CPT-11-containing combination chemotherapy for advanced gastric cancer[18-21]. The meta-analysis in this study was to compare the two therapies by evaluating their clinical efficiency and toxicities.

MATERIALS AND METHODS

Literature search

Trials were searched from MEDLINE, OLD MEDLINE, CancerLit, EMbase, and ISI Web of Science, incorporating Science Citation Index, Technology Proceedings, and Current Contents Databases as far back as they go. References of selected articles and previous systematic reviews were also searched for any other relevant trials (Figure 1). The search strategy included the following key words variably combined: metastatic, metastasis, gastric, cancer, CPT-11, randomized, trial.

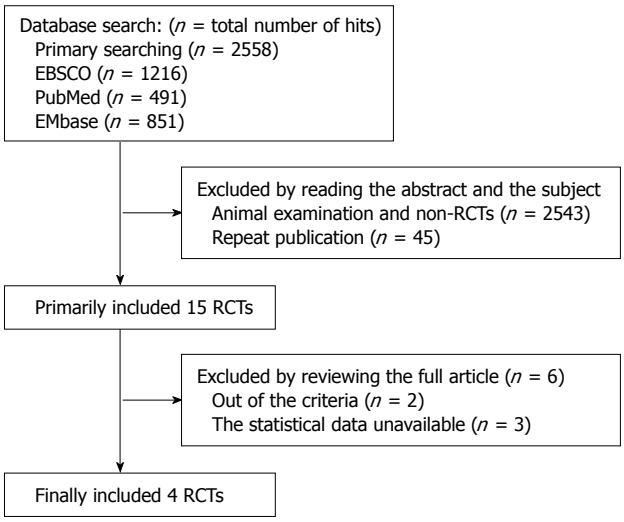

Figure 1 Article search and riddling progression. RCTs: Randomized controlled trials.

Two independent reviewers assessed the eligibility of the searched abstracts. If the eligibility of the abstract was unclear, the full article was retrieved for clarification. Any disagreements were solved by discussion. The selection criteria included study design (randomized or controlled trials), participants (patients with histologically confirmed advanced or recurrent adenocarcinoma, including diffuse type, intestinal type of the stomach or gastroesophageal junction). The exclusion criteria were nonrandomized trials, animal examination, single-arm phase Ⅱ trial, or adequate statistical analysis with information missed. Care was taken to include only primary data or data that superseded earlier works. The deadline for trial inclusion was November 6, 2009.

Statistical methods

Overall survival rate was used as the primary outcome measure. Secondary outcome measures evaluated were overall response rate (ORR: number of partial and complete responses) and toxicities (published by the authors with the most frequently reported events analyzed). Hazard ratio (HR) and 95% CI as relevant effect measures were estimated directly or indirectly from the given data. Appropriate data, such as log-rank test *P* value, were extracted for the estimation of the log HR and its variance as previously described[22,23]. Summary statistical data were extracted from the published trials according to the standard methods for survival end points, with HR and CI as preferred sources for estimation, and log-rank *P* value/event count as a second choice[22]. Standard techniques for meta-analysis[24] were used to calculate the pooled estimates. All analyses were conducted using the Stata software version 8.2 (Stata Corp LP, College Station, TX). All tests were two sided. Fixed-(primarily) and random-effect model methodology was applied. All reported *P* values

resulted from two-sided versions of the respective tests.

In consideration of possible heterogeneity across the studies, a statistical test for heterogeneity was performed as previously described[25]. $P < 0.05$ was considered statistically significant for the heterogeneity. A fixed effect approach was adopted unless there was evidence for significant unexplained heterogeneity, in which a random effect approach was used. In the absence of heterogeneity, the two methods provided identical results, because the fixed-effect model using the Mantel-Haenszel's method assumes that studies are sampled from populations with the same effect size, making an adjustment to the study weights according to the in-study variance, whereas the random-effect model using the DerSimonian and Laird's method assumes that studies are taken from populations with varying effect sizes, calculating the study weights both from in-study and between-study variances, considering the extent of variation or heterogeneity. Funnel plots and Egger's linear regression test were used to show the potential publication bias in diagnosis of advanced gastric cancer[26].

RESULTS

The results of 4 randomized phases Ⅱ and Ⅲ trials, including 2 Europe randomized phase Ⅱ trials[18,19], 1 Europe randomized phase Ⅲ trial[20], and 1 Japanese study[21], that have been published or presented at major international meetings, were included in this analysis. These studies included 657 patients with metastatic gastric cancer, of whom 315 (48%) received the CPT-11-containing combination chemotherapy. Treatment schedule and quality of each trial were evaluated (Table 1).

Overall survival time

The overall survival rate was reported in the 4 trials[18-21], during which 315 patients received CPT-11-containing combination chemotherapy and 342 patients received non CPT-11-containing combination chemotherapy. However, only 2 trials reported the HR. The other trials showed that the overall survival time of patients with gastric cancer was 11.3-14.8 mo after CPT-11-containing combination chemotherapy and 6.8-15.6 mo after non CPT-1-containing combination chemotherapy. No striking inter-study heterogeneity was found ($P = 0.535$, $I^2 = 0.0\%$) in the 4 trials. Meta-analysis of the pooled data demonstrated that the overall risk of death was not different between the two chemotherapies (HR = 1.12, 95% CI: 0.92 -1.36, $P = 0.266$, Figure 2).

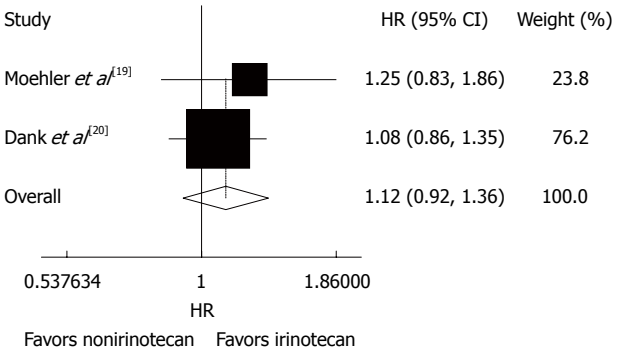

Figure 2 Overall survival rate of patients with advanced gastric cancer after irinotecan-containing and nonirinotecan-containing combination chemotherapies. HR: Hazard ratio.

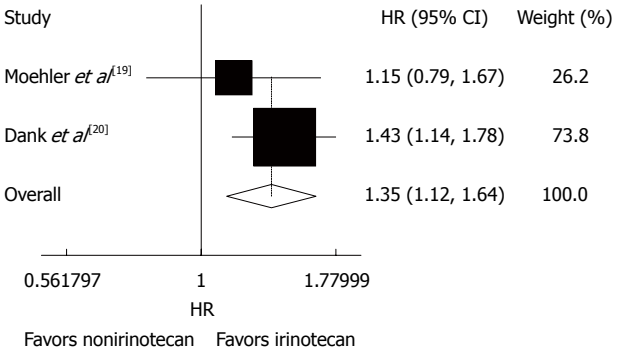

Figure 3 Time to treatment failure of patients with advanced gastric cancer irinotecan-containing and nonirinotecan-containing combination chemotherapies. HR: Hazard ratio.

Time to treatment failure

Two trials[19,20] analyzed the impact of time to treatment failure (TTF) with no striking inter-study heterogeneity ($P = 0.327$, $I^2 = 0.0\%$). The fixed-effect pooled estimation for TTF showed comparable results (HR = 1.35, 95% CI: 1.12-1.64, $P = 0.002$, Figure 3), suggesting that the outcome is significantly better in patients with advanced gastric cancer after CPT-11-containing combination chemotherapy than in those after non CPT-11-containing combination chemotherapy

Overall response rate

Risk ratio (RR) was reported in the 4 trials[18-21]. The overall response rate (ORR) of patients with advanced gastric cancer was 13%-80% to CPT-11-containing combination che-

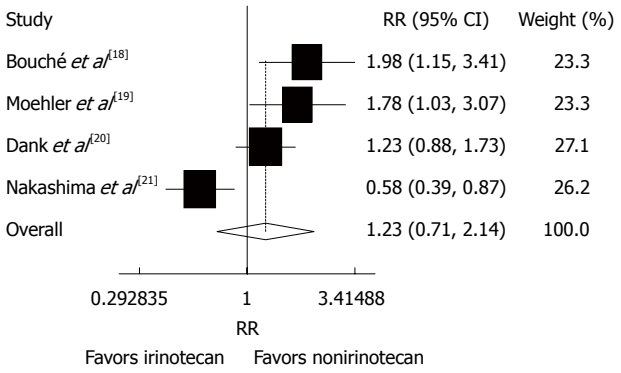

Figure 4 Overall response rate of patients with advanced gastric cancer after irinotecan-containing and nonirinotecan-containing combination chemotherapies. RR: Risk ratio.

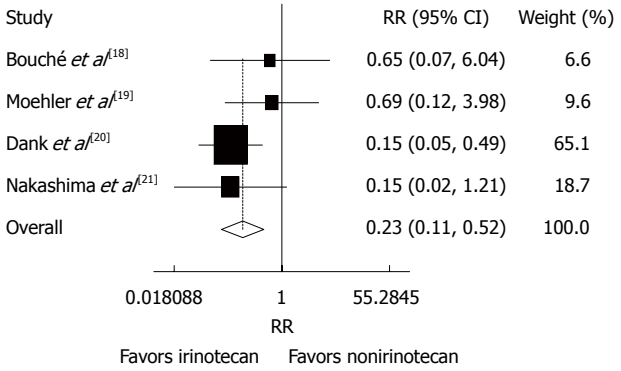

Figure 5 Grade 3/4 haematological toxicities (thrombocytopenia) in patients with advanced gastric cancer after irinotecan-containing and nonirinotecan-containing combination chemotherapies. RR: Risk ratio.

motherapy and 22%-47% to the non CPT-11-containing combination chemotherapy. A significant heterogeneity was observed ($P = 0.000$, $I^2 = 83.3\%$). The random-effect pooled estimate including 657 patients evaluated for ORR showed that the RR of CPT-11-containing combination chemotherapy was increased (RR = 1.23, 95% CI: 0.71-2.14, $P = 0.458$, Figure 4).

Toxicities

Reported toxicities were analyzed in all trials. The incidence of grade 3/4 thrombocytopenia (RR = 0.23, 95% CI: 0.11-0.52, $P < 0.001$) and diarrhea (RR = 4.00, 95% CI: 2.38-6.71, $P < 0.001$) was lower in patients after CPT-11-containing combination chemotherapy than in those after non CPT-11-containing combination chemotherapy (Figures 5 and 6). The incidence of other grade 3/4 haematological toxicities, such as neutropenia (RR = 0.60, 95% CI = 0.28-1.31, $P = 0.201$), febrile neutropenia (RR = 0.64, 95% CI: 0.37-1.10, $P = 0.108$) and leucopenia (RR = 0.85, 95% CI: 0.59-1.23, $P = 0.388$), as well as other grade 3/4 gastrointestinal toxicities, such as nausea (RR = 0.84, 95% CI: 0.46-1.54, $P = 0.582$), vomiting (RR = 0.83, 95% CI: 0.44 -1.56, $P = 0.556$), anorexia (RR = 0.66, 95% CI: 0.31-1.41, $P = 0.278$) was similar in patients with advanced gastric cancer after CPT-11-containing and non CPT-11-containing combination therapies. No evidence for heterogeneity was found except for neutropenia and alopecia.

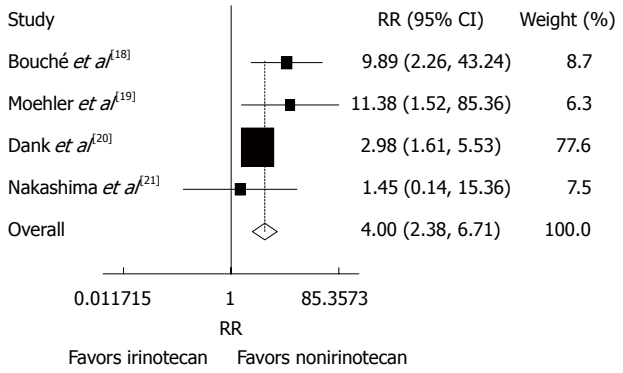

Figure 6 Grade 3/4 gastrointestinal toxicities (diarrhea) in patients with advanced gastric cancer after irinotecan-containing and nonirinotecan-containing combination chemotherapies. RR: Risk ratio.

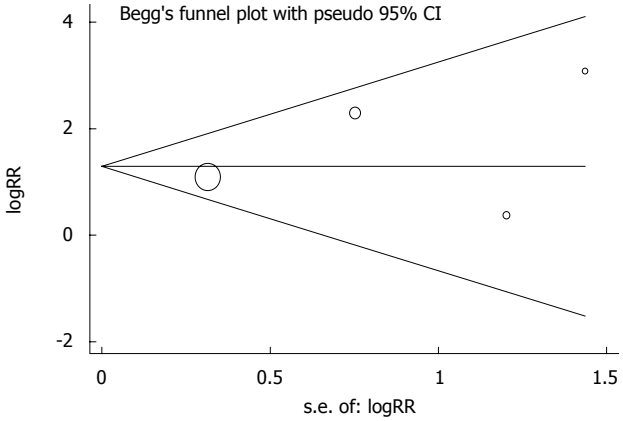

Figure 7 Funnel plots and Egger's linear regression test showing the potential publication bias in diagnosis of advanced gastric cancer[22]. RR: Risk ratio.

Publication bias

Evidence of publication bias was detected by plotting funnel plots of HR. Studies were plotted in order of decreasing variance of the log HR. Visual inspection of the funnel plots with respect to the 3 end points (OS rate, TTF and ORR) did not reveal any hint of publication bias (Figure 7). Funnel plots for all comparisons could not identify relevant publication bias, although the number of included studies was relatively small.

DISCUSSION

During the last decade, advances in treatment of patients with advanced gastric cancer have been achieved as a result of the integration of novel, effective agents into treatment algorithms. The availability of CPT-11 further enriches the options for combination therapy, because CPT-11 is effective and tolerable in patients with advanced gastric cancer.

The present systematic review revealed the major findings in ongoing debatable questions. We wonder whether

CPT-11-containing combination chemotherapy is better than non CPT-11-containing combination chemotherapy for advanced gastric cancer. One of the earlier systematic reviews on 3 randomized controlled trials (RCTs) of chemotherapy for advanced gastric cancer concluded that there is no convincing evidence that demonstrates a significant benefit in overall survival rate of patients after CPT-11-containing combination chemotherapy[27]. The resulting HR for the overall survival rate was 0.88% (95% CI: 0.73-1.06), which is in favor of CPT-11-containing combination chemotherapy. However, the study[23] did not assess other outcomes or toxicities. In our analysis, the 2 trials that assessed TTF showed that the overall summary estimate favored the CPT-11-containing combination chemotherapy with no significant inter-trial heterogeneity.

Most reported end points covered in the RCTs were searched and the most appropriate statistical methods for meta-analysis of time-to-event data extracted from published reports were used in our study. However, the quality of life was not stressed in patients with advanced gastric cancer due to the different methods used in reporting their quality of life. Although the data about response rate and adverse events were pooled to permit a clinically relevant analysis, these parameters varied. The response rate was reported according to the clinical parameters, WHO and RECIST criteria, whereas the CTC, WHO and ECOG scales were used in analysis of toxicity data.

In conclusion, there is insufficient evidence that the overall survival rate, overall response rate are better for patients with advanced gastric cancer after CPT-11-containing combination chemotherapy than after non CPT-11-containing combination chemotherapy. CPT-11-containing combination chemotherapy is advantageous over non CPT-11-containing combination chemotherapy for TTF and grade 3/4 thrombocytopenia.

Irrespective of the positive impact of presently available chemotherapy, the prognosis of patients with advanced gastric cancer remains poor, with a median survival time of 7-10 mo. Further RCTs are needed to assess which CPT-11 combination chemotherapy is least toxic.

COMMENTS

Background

The morbidity and mortality of gastric cancer increase with age. It has been shown that irinotecan (CPT-11) actis as a single agent in oesophago-gastric cancer. The aim of this meta-analysis was to assess the efficiency and toxicities of CPT-11 involved regimens in patients with advanced gastric cancer.

Research frontiers

Several phases Ⅱ and Ⅲ randomized trials have been reported comparing CPT-11-containing or non CPT-11-containing combination chemotherapy for advanced gastric cancer. The authors wonder whether CPT-11-containing combination chemotherapy is better than non CPT-11-containing combination chemotherapy for advanced gastric cancer.

Innovations and breakthroughs

This systematic review revealed the major findings in ongoing debatable questions. One of the earlier systematic reviews of 3 randomized controlled trials of chemotherapy for advanced gastric cancer concluded that there is no convincing evidence that demonstrates that the overall survival rate of patients with advanced gastric cancer is higher after CPT-11-containing combination chemotherapy than after non CPT-11-containing combination chemotherapy. However, this study did not assess other outcomes or toxicities. In the authors' analyses, 4 randomized phases Ⅱ and Ⅲ trials were included. A total of 657 patients were analyzed for their overall response rate, time to treatment failure (TTF), overall survival rate and toxicities. The two trials that assessed TTF showed that the overall summary estimate favored CPT-11-containing combination chemotherapy.

Applications

The findings in the study suggest that CPT-11 based combination chemotherapy is a candidate regimen for advanced gastric cancer. Further studies are needed to compare common chemotherapy with/without target therap.

Peer review

The authors in their meta-analysis showed that CPT-11-containing combination chemotherapy was advantageous over non CPT-11-containing combination chemotherapy for TTF, overall survival rate, overall response rate and toxicity. The availability of CPT-11 further enriches the options for combination therapy, because CPT-11 is effective and tolerable in patients with advanced gastric cancer. Further randomized control trials are needed to assess which chemotherapy provides favorable overall survival rate with less toxicity. Moreover, target therapy agents should be taken into consideration to see if they can achieve better clinical benefits in patients with advanced gastric cancer.

Abstract

AIM: To investigate the clinical significance of hepatic blood inflow occlusion without hemihepatic artery control (BIOwHAC) in the treatment of hepatocellular carcinoma (HCC).

METHODS: Fifty-nine patients with HCC were divided into 3 groups based on the technique used for achieving hepatic vascular occlusion: group 1, vascular occlusion was achieved by the Pringle maneuver (n = 20); group 2, by hemihepatic vascular occlusion (HVO) (n = 20); and group 3, by BIOwHAC (n = 19). We compared the procedures among the three groups in term of operation time, intraoperative bleeding, postoperative liver function, postoperative complications, and length of hospital stay.

RESULTS: There were no statistically significant differences (P > 0.05) in age, sex, pathological diagnosis, preoperative Child's disease grade, hepatic function, and tumor size among the three groups. No intraoperative complications or deaths occurrred, and there were no significant intergroup differences (P > 0.05) in intraoperative bleeding, hepatic function change 3 and 7 d after operation, the incidence of complications, and length of hospital stay. BIOwHAC and Pringle maneuver required a significantly shorter operation time than HVO; the difference in the serum alanine aminotransferase or aspartate aminotransferase levels before and 1 d after operation was more significant in the BIOwHAC and HVO groups than in the Pringle maneuver group (P < 0.05).

CONCLUSION: BIOwHAC is convenient and safe; this technique causes slight hepatic ischemia-reperfusion injury similar to HVO.

Key words: Hepatic blood inflow occlusion without hemihepatic artery control; Hepatocellular carcinoma; Intraoperative bleeding; Ischemia-reperfusion injury

INTRODUCTION

Intraoperative bleeding occurs most frequently during hepatic resection. Bleeding-associated blood transfusions increase the postoperative complications and mortality rate[1], especially in cases complicated with hepatocirrho-

sis[2]. Therefore, control of intraoperative bleeding is a prerequisite for reducing the number of cases requiring blood transfusions during liver resection. The common approaches to reduce blood transfusion include lowering the intraoperative central venous pressure[3-5], and using cut-ultrasound aspiration and microwave thermocoagulation in liver surgery[6,7], and hepatic inflow occlusion with or without outflow control. Hepatic inflow control (with or without outflow control) plays an important role in constructing a bloodless surgical field. However, hepatic ischemia-reperfusion injury (HIRI) occurs in all hepatic vascular occlusions to some extent. The normal liver receives 70%-75% of its blood supply from the portal vein and 40%-60% of its oxygen supply from arterial blood. Considering the differences between the distribution and oxygen content of the blood in the portal vein and that in the hepatic artery, we performed hepatic blood inflow occlusion without hemihepatic artery control (BIOwHAC)[8] to minimize HIRI by a modified surgical procedure. During BIOwHAC, the proper hepatic artery was surgically exposed, after which its left and right branches were separated. For the right and left hemihepatic occlusions, catheters were advanced and bypassed the portal vein, bile duct, and the respective branches of the hepatic artery before being tightened.

We designed a retrospective case-control study to compare BIOwHAC, Pringle maneuver and hemihepatic vascular occlusion (HVO) in terms of operation time, intraoperative bleeding, and postoperative liver function, and postoperative complications. We also assessed the merits and demerits of these three approaches.

MATERIALS AND METHODS

Inclusion criteria

Between March 2005 and January 2009, 162 patients were treated at our hospital for liver neoplasms. Of these, 59 patients who met with the following criteria were included in this trial: availability of complete data, presence of pathologically diagnosed hepatocellular carcinoma (HCC), cancers confined to half of the liver and being suitable for hepatic portal anatomical vascular occlusion, and resectable tumors. Patients who underwent pericardial devascularization, splenectomy, gastroenterostomy and biliointestinal anastomosis were excluded.

Vascular occlusion procedures

Of the 59 patients, 20 underwent Pringle maneuver, 20 underwent HVO, and 19 underwent BIOwHAC. The patients in the Pringle maneuver group underwent the Pringle's occlusion by the conventional method at the hepatoduodenal ligament using urethral catheters. Patients in the HVO group underwent vascular occlusions *via* two approaches. (1) The catheters were introduced into the confluence of the left and right hepatic ducts along the common hepatic duct without dissecting the hepatoduodenal ligament; the tangential clamp was placed at the superior hepatic capsule or inferior transverse fissura ligamenti teretis and then the internal liver parenchyma and the external Glisson sheath were bluntly separated with care; if no resistance occurred at that time, the urethral catheter was exited at the portal vein bifurcation-caudate lobe junction towards the posterior hepatoduodenal ligament and then insufflated to achieve right hemihepatic occlusion; one end of the catheter was inserted through the lesser omentum foramen to the hepatogastric ligament and insufflated to achieve left hemihepatic occlusion; and (2) The affected side of the hepatic artery and the portal vein were separated to occlude them simultaneously or individually. Patients in the BIOwHAC group underwent BIOwHAC as follows: the proper hepatic artery was surgically exposed and the left and right branches of the proper hepatic artery were separated; for right hemihepatic occlusion, the catheter bypassed the portal vein, bile duct, and the right hepatic artery and was tightened; for left hemihepatic occlusion, the catheter bypassed the portal vein, bile duct, and the left hepatic artery and was tightened (Figure 1).

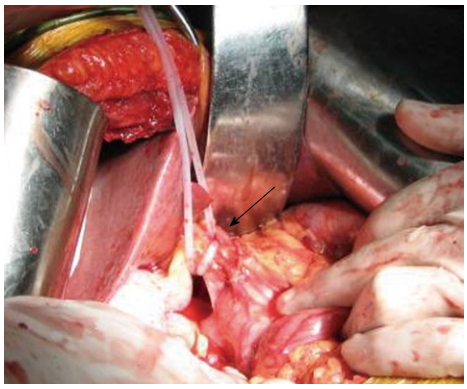

Figure 1 Application of hepatic blood inflow occlusion without hemihepatic artery control (arrow shows non-occlusive left hepatic artery).

Data collection

Complete background information, including age, sex, liver function, Child's disease grade, level of serum markers of hepatitis, and α-fetoprotein levels was collected from all the patients.

Computed tomography (CT) and magnetic resonance imaging (MRI) images and operative record were carefully previewed and information regarding the size of HCC, hepatic vascular occlusion approach, occlusion time, type of liver resection, and operation time were precisely recorded.

The levels of albumin, total bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) were recorded 1, 3, and 7 d after operation to determine the deviations from preoperative values.

Patients were observed for postoperative complications such as bleeding from hepatic section, biliary fistula, subphrenic abscess, responsive pleural effusion, hepatic encephalopathy, pulmonary infection, hemorrhage from

Table 1 Patients' background information[1] (mean ± SD)

Groups	Pringle maneuver (n = 20)	HVO (n = 20)	BIOwHAC (n = 19)
Age (yr)	54.35 ± 10.03	54.20 ± 11.34	54.26 ± 7.05
Gender (M:F)	16:4	13:7	14:5
Pathologic diagnosis	HCC	HCC	HCC
Complication hepatocirrhosis (cases)	10	9	10
Hepatitis virus positive (cases)	18	18	17
Increase in AFP (cases)	12	11	10
Child's disease grade (cases, A:B)	19:1	19:1	18:1
Serum albumin (g/L)	40.04 ± 3.42	40.87 ± 3.12	39.78 ± 2.71
Serum bilirubin (μmol/L)	12.86 ± 5.60	14.68 ± 3.37	13.08 ± 7.81
Serum ALT (U/L)	45.22 ± 32.99	45.04 ± 63.01	47.63 ± 40.48
Serum AST (U/L)	39.43 ± 17.20	40.72 ± 21.57	41.56 ± 41.01

[1]There is no significant intergroup difference (P > 0.05). BIOwHAC: Hepatic blood inflow occlusion without hemihepatic artery control; HVO: Hemihepatic vascular occlusion; AFP: α-fetoprotein; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

the digestive tract, and long-term (> 30 d) hepatic dysfunction.

Statistical analysis

Data were expressed as mean ± SD and variance analysis was performed; χ^2 test was performed for countable data. P < 0.05 indicates significant difference.

RESULTS

Background information

Patients' information on age, sex, preoperative Child's disease grade, pathologic diagnosis, and preoperative hepatic function are listed in Table 1; and the information about tumor size and type of liver resection is shown in Table 2.

Intraoperative information

In all the patients, the procedures were performed without intraoperative complications and deaths. Each group underwent vascular occlusion only once, and there were no statistically significant intergroup differences (P > 0.05) in occlusion time, type of liver resection, bleeding and blood transfusions (Table 2). BIOwHAC and Pringle maneuver required significantly shorter operation time than HVO (151.84 ± 41.77 min and 158.50 ± 43.77 min, respectively *vs* 219.25 ± 58.09 min, P < 0.05), but the time required for BIOwHAC was almost equivalent to that for Pringle maneuver (P > 0.05).

Postoperative hepatic function variation

Serum albumin level was reduced in all the patients 1 and 3 d after operation, but increased after 7 d, and no significant intergroup difference was observed (Figure 2A). The total serum bilirubin level increased 1 and 3 d after operation, but decreased after 7 d, with no significant intergroup differences (Figure 2B). In addition, there was an increase in serum ALT and AST levels 1 d after operation

but a decrease after 7 d. Patients in the Pringle maneuver group had more significant variation in the serum ALT and AST levels (P < 0.05) before and 1 d after operation than the BIOwHAC and HVO groups, but there was no significant difference between BIOwHAC and HVO groups (P > 0.05). No significant intergroup differences were noted in the serum ALT and AST levels (P > 0.05) 3 and 7 d after operation (Figure 2C and D).

Postoperative complications and length of hospital stay

The most common postoperative complication in this study was pleural effusion with pulmonary infection, occurring in 4 cases (20%) of the Pringle maneuver group, 5 cases (25%) of the HVO group, and 4 cases (21.1%) of the BIOwHAC group. No significant intergroup differences were noted in length of hospital stay among the three groups (Table 3).

DISCUSSION

Owing to the recent improvement in the liver resection technique intraoperative hepatic vascular occlusion and perioperative management, surgical complications and mortality rate have been considerably reduced[8-10]. Pringle maneuver is the commonly used method for hepatic vascular occlusion, which enables effective control of bleeding. Multiple approaches for hepatic vascular occlusions have been developed; however the Pringle maneuver is more popular because it can be used in various types of liver resection[11,12]. Man *et al*[13] reported that the Pringle maneuver is superior to non-vascular occlusion, but can lead to obvious HIRI and is time consuming, especially in cases complicated with liver cirrhosis[14]. In 1987, Makuuchi performed HVOs through portal venous branch occlusion and hepatic arterial branch occlusion[15]. HVO helps conserve the contralateral hepatic vascular inflow and facilitates the hepatic operation and mildly affects postoperative liver function in favor of patients with liver cancer and hepatocirrhosis[15]. However, HVO must be performed by surgeons who are proficient in portal vein surgery so as to avoid incident damage to the interior conduit of the Glisson sheath, hemorrhage, and biliary fistula. If there are communicating branches between the non-occluded and the occluded hemilivers, hepatic bleeding may be quite severe[16].

Although no significant intergroup differences were observed in the changes of the serum AST and ALT levels 3 and 7 d after operation, patients in the HVO and BIOwHAC groups had significantly lower AST and ALT levels than those in the Pringle maneuver group 1 d after

operation. This implies that HVO and BIOwHAC are superior to Pringle maneuver in minimizing the HIRI. In HVO, the vascular occlusion is continuous; but in the Pringle maneuver the circulation is maintained with occlusion for 15-20 min and reperfusion for 5 min, this interrupted occlusion gives rise to several problems[3]. In our study, the patients underwent only a single vascular occlusion, which is the reason why no significant intergroup differences were seen in intraoperative bleeding and in the number of cases requiring blood transfusions.

In humans, the confluence of the left and right hepatic ducts lies superiorly, the portal bifurcation is inferior to this bifurcation, and below is the proper hepatic arterial bifurcation. Therefore, it is convenient and safe to intraoperatively expose the proper hepatic artery and separate its left and right branches. Thus, surgeons can occlude the portal vein, bile duct, and occlusive-side artery branch in a single operation. BIOwHAC is convenient and safe as compared to Pringle maneuver. Our results showed that HVO required significantly longer operation time than BIOwHAC and Pringle maneuver (219.25 ± 58.09 min *vs* 151.84 ± 41.77 min and 158.50 ± 43.77 min) due to the net operation of vascular occlusion for 20-30 min. In addition, resection of the cholecyst is required in the right HVO, but not in BIOwHAC, which can satisfy the wish of the patients who want to conserve the cholecyst.

In the normal liver, 70%-75% of blood supply comes from the portal vein and 40%-60% of oxygen supply from arterial blood. Portal vein can not supply all parts of the liver with oxygen, and when the portal vein is completely occluded, the level of oxygen consumption in the liver remains the same as that before occlusion. This indicates that the hepatic artery alone is sufficient to meet the oxygen demand of the liver[17]. Our results showed that the patients in the BIOwHAC group had significantly lower serum AST and ALT levels than those in the Pringle maneuver group 1 d after operation, but no significant differences from that in the HVO group. This finding shows that hemihepatic artery conservation can provide enough oxygen to meet the demand of the intact hemiliver. In addition, no significant intergroup difference was noted in the postoperative serum albumin levels, which may be attributed to postoperative exogenous supplements.

Our results indicated no significant intergroup differences in the intraoperative bleeding and blood transfusion, liver function 3 and 7 d after operation, incidence of postoperative complications, and length of hospital stay. We recommend BIOwHAC because it is a convenient and safe technique similar to the Pringle maneuver and can protect the liver function injury as effectively as HVO.

In conclusion, among the various kinds of approaches for hepatic vascular occlusion available currently, the most suitable one should be selected on the basis of comprehensive preoperative examinations (CT or MRI imaging and liver function tests), intraoperative examinations (pathological examination and lesion location), examinations for invasion in the hepatic vein and inferior vena cava, cardiovascular status, as well as the experience and skill of surgeons and anesthesiologists.

COMMENTS

Background

Intraoperative bleeding occurs most commonly during hepatic resection. Hepatic inflow control plays an important role in constructing a bloodless surgical field.

Research frontiers

There are various techniques of hepatic vascular control, including Pringle maneuver, hemihepatic vascular occlusion (HVO), total hepatic vascular exclusion, liver hanging maneuver, *etc*.

Innovations and breakthroughs

Based on the differences between the distribution and oxygen content of the blood in the portal vein and that in the hepatic artery, hepatic blood inflow occlusion without hemihepatic artery control (BIOwHAC) was performed in this study.

Applications

BIOwHAC is convenient and safe similar to Pringle maneuver; this technique causes as slight hepatic ischemia reperfusion injury as HVO.

Terminology

BIOwHAC: the proper hepatic artery was surgically exposed, after which its left and right branches were separated. For the right and left hemihepatic occlusions, catheters were advanced and bypassed the portal vein, bile duct, and the respective branches of the hepatic artery before being tightened.

Peer review

This is a retrospective analysis on a single center series of different methods of inflow hepatic occlusion during liver resection for liver cancer. The study is well written and the methodology is correct.

Abstract

AIM: To investigate the relationship between human papillomavirus (HPV) infection and concurrent esophagus and gastric cardia cancer from the same patient (CC) and examine the significance of P16^{INK4A} protein expression.

METHODS: Polymerase chain reaction was used to detect the presence of HPV type16 (HPV16). The expression of P16^{INK4A} protein was detected using immunohistochemistry.

RESULTS: Among the CC specimens, HPV16-DNA was found in eight cases of esophageal squamous cell carcinoma (ESCC) and five cases of gastric cardia adenocarcinoma (GCA), respectively (47% *vs* 29%), and two of both ESCC and GCA. P16^{INK4A} was highly expressed in both ESCC and GCA. In the HPV-associated positive CC, higher P16^{INK4A} expression was observed in the GCA than in the ESCC (75% *vs* 25%, $P < 0.05$).

CONCLUSION: HPV16 as a correlated risk factor may play an important role in the development of ESCC and GCA. P16^{INK4A} may be a screening index in the HPV-associated carcinoma of gastric cardia.

Key words: Esophageal squamous cell carcinoma; Gastric cardia adenocarcinoma; Human papillomavirus; Polymerase chain reaction; Immunohistochemistry

INTRODUCTION

Esophageal carcinoma (EC) is one of the most common

malignant diseases worldwide. Linzhou (formerly known as Linxian) in Henan Province, northern China, has been recognized as the highest prevalence area of esophageal squamous cell carcinoma (ESCC) in the world[1]. In epidemiology, gastric cardia adenocarcinoma (GCA) in China is characterized by its striking geographic distribution and its concurrence with ESCC[2]. Similar phenomenon can be also observed in other esophageal cancer incidence areas worldwide[3]. At present, ESCC and GCA still are the main cause of tumor-related deaths in this area. Another interesting feature at the high prevalence area is that the primary cancers of the esophagus and gastric cardia are concurrent in the same patient in Henan, we named them concurrent carcinoma of the esophagus and gastric cardia in the same patient (CC), which is not uncommon in this area (0.4%-2.5%)[4]. The special pattern suggested that similar risk factors and mechanism might be involved in these two cancers.

Human papillomavirus (HPV) as one of the important tumor-related viruses has been firmly recognized in cervical cancer with HPV-DNA detected in > 99% specimens[5]. However, its oncogenic role in other tumors still remains controversial. As to its role in ESCC, it was firstly mentioned by Syrijanen twenty years ago[6]. Since then, many reports regarding this topic have been published, but the HPV infection rate in ESCC varied from zero to 90%[7,8] and in GCA from zero to 68%[9,10], depending on the specimens obtained from low- or high-risk areas and the methods used in each study[11]. In order to further investigate the prevalence of HPV infection in upper digestive tract tumor, the samples with concurrent ESCC and GCA from the same patient were tested for the existence of HPV type16 (HPV16)-DNA.

HPVs are small DNA viruses that can be classified as either high-risk or low-risk types. HPV-16 and 18 is most common in high-risk group, especially type 16 which is considered a risk factor for EC at a high prevalence area in Henan[8,12]. The E6 and E7 oncoproteins of the high-risk HPV types can efficiently destroy the cell cycle regulation and apoptotic pathways by binding to a number of host cell proteins, such as $P16^{INK4A}$ protein, which is an inhibitor of cyclin-dependent kinase. The HPV oncoproteins are able to alter the cell cycle and leaves them vulnerable to other genetic changes, ultimately resulting in malignant transformation[13,14]. However, the reports about HPV infection involved in the carcinogenesis of gastric cardia are very limited, and there has been no related study comparing the HPV detection rate and expression of $P16^{INK4A}$ protein in CC tissues. In our study, we investigated the HPV infection and changes of $P16^{INK4A}$ protein in the same concurrent cancer patient in the high-risk area of EC in Henan to understand the mechanism of esophagus/cardia carcinogenesis in this area, and further illustrate whether the two carcinomas have the similar pathogenesis.

MATERIALS AND METHODS

Clinical samples and diagnostic criteria of CC

A total of 23 cases of concurrent ESCC and GCA were obtained. Among them, DNAs from 17 ESCC and their corresponding GCA tissues were extracted from paraffin-embedded samples by conventional phenol-chloroform procedure. Six cases were from Linzhou Center Hospital, eight from Linzhou Yaocun Esophageal Cancer Hospital and three from Anyang City Cancer Hospital from September 2005 to June 2008. All the hospitals are located in the high incidence region of ESCC in Henan. There were twelve men and five women with an average age of 58 years. None of the patients received chemo- and radiotherapy before surgery.

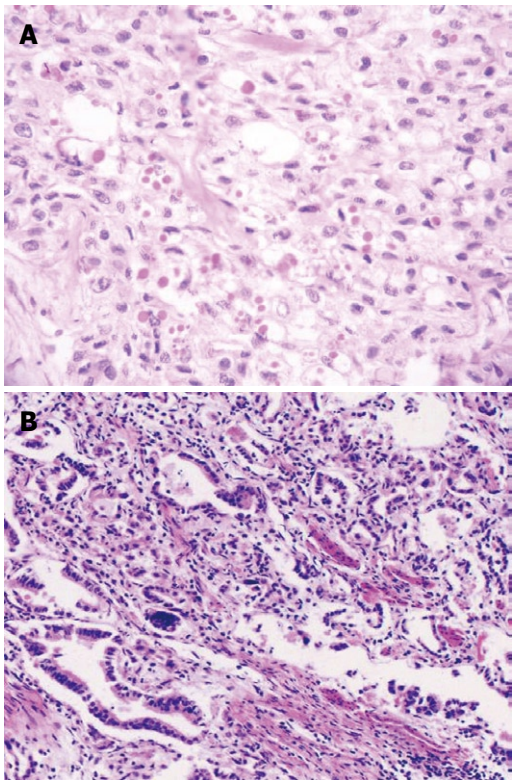

Figure 1 Hematoxylin and eosin staining in the concurrent esophageal and gastric cardia cancers tissue specimens. A: Esophageal squamous cell carcinoma tissue (× 100); B: Gastric cardia adenocarcinoma tissue (× 100).

The samples were immediately fixed by 10% formalin, dehydrated and paraffin-embedded, followed by pathological diagnosis and immunochemical analysis. The diagnosis of the CC was based on the following criteria: (1) All the tumors in the esophagus and cardia in the same patient are malignant; (2) All the tumors have defined pathological modality, i.e. concurrent esophageal squamous cell carcinomas and gastric cardia adenocarcinomas; and (3) None the tumors are metastatic (Figure 1). This study was approved by the Institutional Review Board of the School of Medicine, Zhengzhou University, China.

DNA extraction

The methods were used as described by Greer *et al*[15]. Briefly, each formalin-fixed and paraffin-embedded sample was cut into 10 μm thick sections, 5-10 slides were deparaffinized in xylene and graded alcohol, then the lysis buffer (300 mmol/L NaCl; 50 mmol/L Tris HCl pH 8.0; 0.2% SDS) was added into the tube with proteinase K

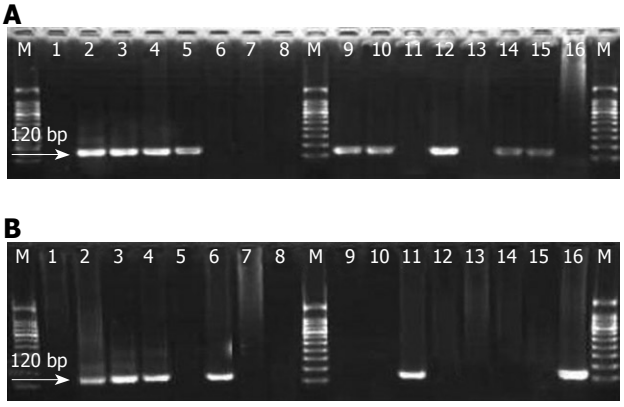

Figure 2 Amplification of human papillomavirus type 16-E6 gene fragment in the concurrent esophageal and gastric cardia cancers tissues. Polymerase chain reaction products were run in 3.0% agarose gel; Lane M: Molecular marker (100 bp ladder); Lane 1: Double water (negative control); Lane 2: Plasmid with human papillomavirus type 16 (HPV16)-E6 120 bp (positive control); Lanes 3-16: Represent positive and negative cases. A: HPV16-E6 gene fragment amplification in esophageal squamous cell carcinoma tissues; B: HPV16-E6 gene fragment in the corresponding gastric cardia adenocarcinoma tissue amplification.

(200 mg/L), and the solution was incubated at 55℃ overnight until it became clear. DNA was then extracted using conventional phenol-chloroform procedure, precipitated with cold alcohol and dissolved in ion-free water, and the concentration was determined based on its optical density. Quality of the extracted DNA was tested by polymerase chain reaction (PCR) with β-actin primer: 5'-TCACCCACACTGTGCCCATC-3' and 5'-GAACCGCTCATTGCCAATGG-3'. The DNA which was β-actin gene amplification positive was used to detect the presence of HPV16-DNA.

PCR and P16^{INK4A} protein immunostaining

The usable DNA went through PCR amplification using type-specific primer: 5'-TCAAAAGCCACTGTGTCCTG-3' and 5'-CGTGTTCTTGATGATCTGCA-3' targeting HPV16-E6 gene. Recombinant plasmid DNA HPV16$^{-pBR322}$ as positive control was obtained from Professor You-Lin Qiao, the Cancer Research Institute, Chinese Academy of Medical Sciences and double water was used as negative control in PCR. Reactions were set in 25 μL 1 × PCR buffer containing 10 mmol/L Tris HCl, pH8.4, 50 mmol/L KCl, 1.5 mmol/L $MgCl_2$, 4 mmol/L dNTP and 1.5 U Taq DNA polymerase (Promega). PCR conditions were as follows: an initial denaturation at 95℃ for 5 min followed by 5 cycles with cycling profile at 95℃ denaturing for 1 min, at 55℃ annealing for 1 min, and at 72℃ prolonging for 1 min, and then at 95℃ denaturing for 20 s, at 55℃ annealing for 30 s and at 72℃ prolonging for 30 s with 45 cycles[8]. The amplified products were revealed by electrophoresis on 3.0% agarose gels (Promega) containing 0.5% μg/mL of ethidium bromide in 1 × TAE buffer at 100 volts for 30 min. Samples were considered positive if a band of 120 bp was observed under the ultraviolet light (Figure 2). All the experiments from DNA extraction to HPV gene amplification were carried out at the Virus Research Institute, Chinese Academy of Preventive Medicine in Beijing, China by the same technician with the same protocol as established previously in Dr. Yi Zeng's laboratory. Positive control (plasmid with HPV16$^{-pBR322}$ DNA fragment) and negative control (double water) were set in each HPV-DNA amplification process. Each experimental step was taken following the previously established rules.

For immunohistochemistry, sections of paraffin-embedded tissue with a thickness of 3 μm were deparaffinized by passage through xylene. After the endogenous peroxidase activity was blocked with 0.3% H_2O_2, the slides were then rehydrated with 0.01 mol/L sodium phosphate/citrate buffer at pH 8.0 and heated in 0.01 mol/L-citrate buffer at pH 6.0, 95℃ for 30 min to retrieve the antigen. After rinsed in 0.01 mol/L phosphate-buffered saline (PBS) at pH 7.4, nonspecific antibody binding was reduced by incubating the sections with 10% fetal bovine serum in PBS for 30 min. The sections were incubated overnight at 4℃ with a mouse monoclonal antibody of p16^{INK4A} protein (1:200 dilution, PharMingen International). After washing thoroughly with PBS, the slides were incubated with biotinylated horse anti-mouse IgG for 30 min followed by 1:100 dilution of the Avidin-Biotin-Peroxidase Complex (Vectastain elite ABC kit, Vector Laboratories, Burlingame, CA) for an additional 30 min. The peroxidase signal was visualized by treatment with DAB substrate-chromogen system (DAKO) for 8 min. Finally, the sections were stained lightly with hematoxylin. In statistical analysis, those having less than 10% cells stained positive were classified as negative and the others were regarded as positive cases[16] (Figure 3).

Statistical analysis

Fisher's exact test was used to examine the association between HPV status and each clinicopathological factor including p16 expression. All the *P* values presented in the present study were two-sided. Experimental data were analyzed by statistical software SPSS 13.0.

RESULTS

The results of the PCR showed that, in the 17 CC, the detection rate of HPV16 in the ESCC was 47% (8/17), and 29% (5/17) in GCA. There was no significant difference between the two groups ($P > 0.05$). Two positive and six negative cases of ESCC and GCA were found in the HPV16-DNA simultaneously, illustrating the high consistency of HPV involved in the two kinds of tumors (47%) (Table 1).

In the 17 cases with CC, the positive ratio of P16^{INK4A} protein expression was 41% (7/17) in ESCC and 59% (10/17) in GCA, respectively. Twelve patients showed P16^{INK4A} protein changes (71%), among them, six patients were P16^{INK4A} immunoreaction positive (35%) in ESCC and GCA simultaneously.

According to the Fisher's Exact test, there was no significant difference between HPV infection and P16^{INK4A} protein expression in the ESCC and GCA specimens ($P > 0.05$). However, among the eight HPV positive ESCC

ESCC: Esophageal squamous cell carcinoma; GCA: Gastric cardia adenocarcinoma; HPV: Human papillomavirus; M: Moderately differentiated; H: Highly differentiated; L: Low differentiated.

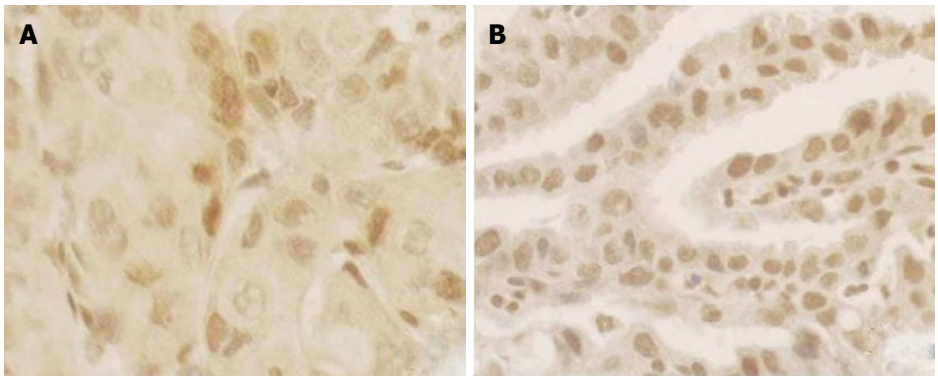

Figure 3 $P16^{INK4A}$ protein expression in the concurrent esophageal and gastric cardia cancers tissues by immunohistochemical staining Avidin-Biotin-Peroxidase Complex method (× 200). A: $P16^{INK4A}$ protein expression in esophageal squamous cell carcinoma; B: Expression of $P16^{INK4A}$ protein in gastric cardia adenocarcinoma.

specimens, only two expressed $P16^{INK4A}$, while four expressed $P16^{INK4A}$ in the HPV positive GCA tissues.

DISCUSSION

The present study demonstrates that both ESCC and GCA tissues from the same patient had HPV16-DNA infection, with an incidence of 47% and 29%, respectively. And HPV16 E6-DNA was observed in both ESCC and GCA tissues in two patients simultaneously. These results suggest that HPV16 might participate in the carcinogenesis of the ESCC and GCA.

In the Linzhou area in Henan, almost half of the ESCC patients have HPV16 infection, with a higher incidence than in GCA (47% *vs* 29%), but without a significant difference ($P > 0.05$). However, there were no correlations between HPV16 infection and gender, age, tumor size, depth of penetration, differentiation, lymph node metastasis and TNM stage (all $P > 0.05$). The difference and the mechanism of the affinity specificity of HPV16 to squamous epithelium and styloid glandular epithelium are still not clear[17]. Esophageal epithelium and cardia epithelium are under the same internal environment and heredity of the same organism, as well as exposure to the same environment and carcinogenic agents, which may be associated with the co-infection of the two different epithelial tissues for HPV. Recently, it has been reported that colonic epithelium and colon carcinoma have HPV infections[18-20], and further studies are still needed to confirm the biological significance and mechanisms for HPV invading the body.

Over the past 20 years, many reports regarding HPV infection in EC have been published, and the reported HPV detection rate in the literature varied largely. To explain these marked differences, different region, sampling methods, demographic and ethnic factor, disease status, and sensitivity of detection methods have been cited as potential causes of this inconsistency[11,21]. In the present

study, the same method was used to analyze the two kinds of neoplasms with different histological type in the same patient, which greatly reduced the disparity of the methodology and/or population.

CC is an ideal model for illustrating the environmental influence on both ESCC and GCA with the similar genobackground and comparability of environmental agents. The present study will deepen the understanding on the mechanism of esophageal/cardia carcinoma in this area. Although these results indicating the presence of HPV-DNA in esophagus and gastric cardia carcinoma tissues, suggest a possible role for HPV in upper digestive tract tumors, further studies are necessary for establishing a definite causative role.

$P16^{INK4A}$ gene is an important member of P53-Rb system, and its product $P16^{INK4A}$ protein can prevent the cell to enter S-phase from G1-phase, and suppress cell proliferation, through inhibition of the phosphorylation of the retinoblastoma (pRb)[22]. In this cascade regulation, pRb could negatively inhibit the expression of $P16^{INK4A}$ protein.

The studies of cervical cancer showed that the HPV-E6/E7 protein combined with pRb is deactivated, and removes the negative inhibition of the expression of $P16^{INK4A}$ protein, which causes the over-expression of $P16^{INK4A}$. In the present study, 7 (41%) cases showed the expression of $P16^{INK4A}$ protein in ESCC, and 10 (59%) in GCA, which is similar to the results in the adenocarcinoma of the uterine cervix by Ansari-Lari *et al*[23]. In the study of HPV-associated cervical cancer, expression of $P16^{INK4A}$ protein is higher in the adenocarcinoma than in the squamous cell carcinoma, and combined detection of HPV infection and $P16^{INK4A}$ protein expression would be helpful to the diagnosis of the primary adenocarcinoma of the uterine cervix[24]. In the present study, 2 of the 8 HPV-positive ESCC cases expressed $P16^{INK4A}$, while 4 of 5 HPV-positive GCA cases expressed $P16^{INK4A}$. These results suggested that in the HPV- associated CC, expression of $P16^{INK4A}$ protein in GCA is higher than in ESCC. It is obvious that it would be of great significance to further understand the molecular discrepancy of the HPV16 positive and negative patients, and explore the exact mechanisms of the role of HPV in the carcinogenesis of esophagus and cardia.

ACKNOWLEDGMENTS

We are grateful to Dr. Yan-Hong Zhang in Saint Louis University School of Medicine, Missouri, USA for carefully revising the manuscript and Professor You-Lin Qiao of the Cancer Research Institute, Chinese Academy of Medical Sciences who kindly donated HPV plasmid DNA.

COMMENTS

Background

Esophageal cancer (EC) is one of the most common malignant diseases, with a remarkable geographical distribution and poor prognosis. The five-year survival rate is only 10%. However, the five-year survival rate for the patients with the early EC is more than 90%. More than 85% of the EC patients are diagnosed at the late stage due to lack of early specific symptoms and unknown etiological factors, and the carcinogenesis remains the leading cause of late diagnosis for EC. Therefore, the current challenges in EC research are to obtain a better understanding of the exact etiological factors and molecular alteration in the esophageal carcinogenesis process to establish the strategies for prevention and early diagnosis of those with high risks.

Research frontiers

It has been well recognized that esophageal carcinogenesis is a progressive process involving multi-factors and multistage: tobacco, alcohol, fungal toxins, nutritional deficiencies, as well as infectious agents, are related to esophageal carcinogenesis. Among the infectious agents, human papillomavirus (HPV), a major cause of carcinoma of the cervix uteri throughout the world, is strongly implicated in the etiology of EC. HPV-16 and-18 are the most frequent genotypes, especially type-16 which is considered to be a risk factor for EC in the high prevalence area in Henan. On the other hand, oncoproteins of the high-risk HPV types can efficiently destroy the cell cycle and apoptotic pathways by binding to a number of host cell proteins, ultimately resulting in malignant transformation.

Innovations and breakthroughs

In this study, the authors found the HPV-16 DNA in 47% of esophageal squamous cell carcinomas (ESCC) and 29% of gastric cardiac adenocarcinomas (GCA) in concurrent cancers in the same patients (CC). Interestingly, HPV-16 DNA was detected in two cases of ESCC and GCA tissues simultaneously. These results suggested that HPV16 might participate in the carcinogenesis of the ESCC and GCA, and the two carcinomas might have similar risk of carcinogenesis. $P16^{INK4A}$ was highly expressed in both ESCC and GCA tissues. In the HPV-associated positive CC, higher $P16^{INK4A}$ expression was found in GCA than in ESCC (75% *vs* 25%, $P < 0.05$).

Applications

By knowing the prevalence and molecular alteration of high-risk HPV-associated EC, this study may contribute to the future strategies for prevention and early diagnosis of HPV-related malignancies, through the development of effective vaccines and biomarkers.

Terminology

HPVs are DNA viruses that infect basal skin and mucosal cells, and categorized according to their cervical oncogenicity-based risks.

Peer review

The manuscript is interesting, presenting data of HPV DNA detection in the concurrent esophageal squamous cell carcinoma and cardia adenocarcinoma and expression of p16 protein. Given the truth of these data, this would be a piece of evidence for involvement of HPV in esophageal carcinogenesis in man.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Reverse cholesterol transport was originally described as the high-density lipoprotein-mediated cholesterol flux from the periphery *via* the hepatobiliary tract to the intestinal lumen, leading to fecal excretion. Since the introduction of reverse cholesterol transport in the 1970s, this pathway has been intensively investigated. In this topic highlight, the classical reverse cholesterol transport concepts are discussed and the subject reverse cholesterol transport is revisited.

FROM THE EDITOR

Cholesterol is of vital importance for all vertebrates. It is an essential structural component of cell membranes. In addition, cholesterol is needed for the manufacture of bile salts, steroid hormones and vitamin D. However, too much cholesterol is harmful. A high level of serum cholesterol is a risk factor for certain cardiovascular diseases. Fortunately, the body possess a transport route in order to dispose cholesterol: reverse cholesterol transport, which is an interesting target for drug development aiming at the treatment/prevention of atherosclerotic and associated diseases. Since the introduction of reverse cholesterol transport in the 1970s, this pathway has been intensively investigated.

The thorough research on reverse cholesterol transport has led to a great understanding about the way cholesterol is disposed. However, new insights in cholesterol excretion were rendered as well. Insights make the classical view on reverse cholesterol transport questionable. In this topic highlight, the classical reverse cholesterol transport concepts are discussed and the subject reverse cholesterol transport is revisited[1-7].

Abstract

Cholesterol is of vital importance for the human body. It is a constituent for most biological membranes, it is needed for the formation of bile salts, and it is the precursor for steroid hormones and vitamin D. However, the presence of excess cholesterol in cells, and in particular in macrophages in the arterial vessel wall, might be harmful. The accumulation of cholesterol in arteries can lead to atherosclerosis, and in turn, to other cardiovascular diseases. The route that is primarily thought to be responsible for the disposal of cholesterol is called reverse cholesterol transport (RCT). Therefore, RCT is seen as an interesting target for the development of drugs aimed at the prevention of atherosclerosis. Research on RCT has taken off in recent years. In this review, the classical concepts about RCT are discussed, together with new insights about this topic.

Key words: Cholesterol; Excretion; Transport; Intestine; Liver

INTRODUCTION

In order to dispose of cholesterol, it is transported from the periphery to the liver and intestine, and is finally excreted *via* the feces. This pathway has been traditionally referred to as reverse cholesterol transport (RCT) or centripetal cholesterol flux. In this review, the term RCT is used. Research on RCT has taken off in recent years. This review starts with introduction of the term RCT in the early 1970s. This is followed by a discussion of research in the following years that led to the classical view on RCT: high-density lipoprotein (HDL)-mediated transport of cholesterol from the periphery to the liver, the subsequent uptake of HDL cholesterol by the liver, hepatobiliary cholesterol secretion, and finally, excretion *via* the feces (Figure 1). Both free cholesterol and the esterified form are involved in RCT. Cholesteryl esters are much less amphiphatic than free cholesterol and appear to be the preferred form for transport in the plasma and for storage. The transport proteins involved in RCT receive special attention in this review. Finally, new insights in cholesterol excretion are discussed, which make the current concept of RCT questionable.

THE BEGINNING

Glomset *et al*[1] introduced the term RCT in 1973, in a review that described the role of lecithin:cholesterol acyl

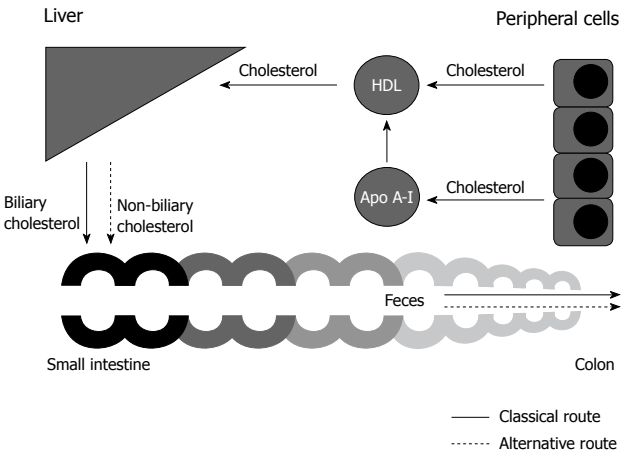

Figure 1 Cholesterol excretion routes. The filled arrows represent the classical route, and the dashed arrows represent the alternative route. In the classical view, apolipoprotein A-I (apo A-I) and high-density lipoprotein mediate cholesterol transport from the periphery towards the liver. Cholesterol is subsequently secreted into bile and is excreted *via* the feces. The alternative route describes the transport of non-biliary cholesterol towards the intestine for fecal excretion. How non-biliary cholesterol reaches the intestine is the subject of investigation.

transferase (LCAT) in metabolism. We nowadays know that LCAT is an enzyme that is synthesized in the liver and circulates in the blood plasma on the surface of lipoproteins, predominantly HDL. LCAT has the ability to catalyze the formation of cholesteryl esters on the surface of HDL by transferring fatty acids from phosphatidylcholine (PC, also known as lecithin) to the unesterified cholesterol[2]. It took several years after the discovery of LCAT before its physiological role was elucidated in more detail[3]. The *in vitro* testing of the possibility that LCAT plays a role in cholesterol transport was mainly hampered by the fact that most of the cholesterol of freshly prepared plasma lipoproteins is already esterified, that is, if the enzyme is able to alter the structure and physical properties of lipoproteins, most of the alterations have already occurred *in vivo*. The discovery of patients with familial LCAT deficiency[4-6] has provided a unique opportunity to circumvent these problems. By studying these patients, our knowledge about LCAT and cholesterol removal has increased.

CLASSICAL VIEW

Transport of cholesterol towards the liver

Although tissue culture studies had favored HDL[7,8] as the principal vehicle for cholesterol transport from the periphery to the liver, it took a decade before *in vivo* evidence was presented by Miller *et al*[9]. When cholesterol-loaded macrophages are incubated in medium that contains plasma, cholesterol moves from the cells to HDL and is subsequently esterified by LCAT[10]. The accumulation of cholesteryl esters in these particles increases their size and decreases their density; enrichment with apoprotein E also occurs, which decreases electrophoretic mobility[11,12]. Miller *et al*[9] have shown that similar changes were present in the circulating HDL of rabbits, when their peripheral tissues were loaded with cholesterol by intravenous injection of acetylated or native human low-density lipoproteins (LDLs).

Hepatic cholesterol uptake

Evidence for the existence of receptors that recognize HDL in plasma membranes of hepatocytes has been presented by several groups[13-15]. It appears that the rate of uptake of HDL cholesteryl esters by the liver in rats is several times greater than that of HDL apolipoprotein A-I (apo A-I), which suggests that cholesteryl esters dissociate from HDL particles at the surface of hepatocytes. This process might be facilitated by transient binding of HDL to the plasma membranes of such cells[16]. A similar process has been studied in cultures of human hepatoma cells[17]. The pathways for delivery of cholesteryl ester to the liver clearly cannot operate in patients with familial LCAT deficiency. Nevertheless, such patients do not accumulate large quantities of cholesterol in their plasma, as might be expected if the delivery of cholesteryl ester to the liver were hampered[18].

Hepatic processing of cholesterol

Once cholesterol has reached the liver, conversion into bile salts is the final destination for most of the cholesterol[19]. In contrast to cholesterol, bile salts are amphiphatic. Bile salts function as signaling molecules, and they act as physiological detergents: they emulsify droplets of dietary lipids in the intestine, which makes them available for absorption. Synthesis of bile salts involves the action of multiple different enzymes and can follow two major pathways, named the "classic" or neutral pathway and the alternative or acidic pathway. The classic pathway accounts for the majority of bile salt synthesis. In the enterohepatic circulation, intestinal bacteria modify bile acid structures, which yields secondary bile salts, for example, lithocholate and deoxycholate[20]. As about 95% of the bile salts reenter the enterohepatic circulation, the bile salt pool of the body consists of a mixture of primary and secondary bile salts. Only a small part of hepatic cholesterol is not converted to bile salts and is directly secreted into bile. The majority of this hepatobiliary secreted cholesterol will be re-absorbed in the small intestine[21].

Lipoproteins and lipid transfer

The first evidence that HDL is not a homogeneous set of molecules, but rather a mixture of heterogeneous subclasses, arose in 1979. Gebhardt *et al*[22] have described the existence of a pre-β migrating subclass of apo A-I-containing particles when studying human amniotic fluid. Similar particles have been demonstrated in peripheral lymph of dogs[23,24] and in human lymphedema fluid[25]. Castro *et al*[26] have found that, when radiolabeled cholesterol effluxes from cultured human fibroblasts into medium that contains human serum, almost all of it enters a minor component of HDL that is composed of very small apo A-I-containing particles. These particles differ from the majority of plasma HDL in having pre-β elec-

trophoretic mobility on agarose gel. It is rich in phospholipids, and contains little or no core lipid, and apo A-l as the only recognized apoprotein[26-28]. We know now that it is pre-β HDL cholesterol that is esterified by LCAT. After esterification, cholesteryl esters are sequestered into the core of the lipoprotein particle, eventually making spherical α-HDL. In this way, cholesterol is made ready for removal[2].

Some cholesteryl esters from HDL particles is transferred to LDL, very-low-density lipoproteins, or chylomicrons in exchange for triglycerides and phospholipids[29-35]. Triglyceride transfer is mediated by the cholesterol ester transfer protein (CETP) and phospholipid transfer is mediated by the phospholipid transfer protein (PLTP)[35,36]. Rodents do not express CETP, which might partly explain the high plasma HDL levels observed in these animals, in comparison to humans who express CETP. PLTP has not only been implicated in the transfer of phospholipids to HDL, but also in a process called HDL conversion[37]. In this process, PLTP mediates fusion of intermediate sized α-HDL particles to generate larger HDL particles with a concomitant release of lipid-poor apo A-I. These actions result in an enhanced capacity to take up cellular cholesterol.

Transport proteins

In the 1990s, several proteins and receptors involved in RCT were identified, which has given new insights in the mechanisms behind RCT.

ABCA1: Tangier disease was originally described and named on the basis of kindred living in Tangier Island in Chesapeake Bay, USA. Assmann *et al*[38] and Brook *et al*[39] have linked Tangier disease with abnormal HDL levels. The inheritance of the disease was already described in 1964[40]. However, it took until 1999 before it became clear that mutations in the ABC1 (nowadays in humans and rodents referred to as ABCA1) gene were responsible for the severe HDL deficiency in Tangier disease[41-43]. We now know that ABCA1 is involved in the first step of RCT. The mechanism by which ABCA1 mediates cholesterol efflux has been a matter of intense investigation. Two distinct mechanisms have been proposed to explain ABCA1-mediated cholesterol efflux from macrophages to apo A-I. These models are described below.

One model argues that apo A-I binds ABCA1 at the plasma membrane and is subsequently internalized and targeted to intracellular compartments, where lipidation of apo A-I occurs as part of a retroendocytosis pathway[44-46]. Hassan *et al*[47] have shown that two-thirds of apo A-I is bound to the plasma membrane and one-third is found in intracellular compartments. It appears that the C-terminal region of apo A-I is important in the ABCA1-mediated lipid efflux pathway. Apo A-I dissociated fourfold faster from the intracellular compartments than from the plasma membrane, which suggests an important contribution of ABCA1 in the endocytic pathway to apo A-I lipidation. In contrast, Faulkner *et al*[48] have shown, by studying ABCA1-mediated cholesterol efflux from macrophages, that the internalized apo A-I is re-secreted as a degraded protein. Furthermore, they have demonstrated that lipid-free apo-A-I-mediated cholesterol efflux from macrophages could be pharmacologically uncoupled from apo A-I internalization into cells, which raises doubts as to the significance of the endocytic pathway in efflux. In addition, confocal microscopy and efflux assays of apo A-I internalization and lipidation as a function of ABCA1 expression have indicated that apo A-I lipidation occurs at the cell surface, whereas ABCA1-dependent apo A-I internalization leads to its lysosomal targeting and degradation[49]. Data of Azuma *et al*[50] have suggested that the retroendocytosis pathway of ABCA1/apo A-I contributes to HDL formation when excess lipoprotein-derived cholesterol has accumulated in cells.

The other model argues that apo A-I forms complexes with phospholipids and cholesterol at the plasma membrane in a process that is promoted by ABCA1 activity. There is abundant evidence that ABCA1-mediated cholesterol efflux to apo A-I can occur at the plasma membrane[51-53]. It has been shown that optimal cholesterol efflux in macrophages requires binding of the C-terminal domain of apo A-I to a cell-surface-binding site, and the subsequent translocation of intracellular cholesterol to an efflux-competent pool[54]. By studying the binding of wild-type and mutant forms of human apo A-I to mouse J774 macrophages, it has been shown that ABCA1 activity creates two types of high affinity apo A-I binding sites at the cell surface. Only 10% of cell-surface-bound apo A-I interacts directly with ABCA1, whereas the rest is bound to lipid domains *via* the C-terminal domain. The low capacity site formed by direct apo A-I/ABCA1 interaction functions in a regulatory role, whereas the much higher capacity site generated by apo A-I/lipid interactions functions in lipidation[55]. Vedhachalam *et al*[53] have proposed an apo A-I/ABCA1 reaction scheme that involves three steps. First, there is binding of a small regulatory pool of apo A-I to ABCA1, thereby enhancing net phospholipid translocation to the plasma membrane exofacial leaflet; this leads to unequal lateral packing densities in the two leaflets of the phospholipid bilayer. Second, the resultant membrane strain is relieved by bending and by creation of exovesiculated lipid domains. The formation of highly curved membrane surface promotes high affinity binding of apo A-I to these domains. Third, this pool of bound apo A-I spontaneously solubilizes the exovesiculated domain to create discoidal nascent HDL particles. These particles contain 2-4 molecules of apo A-I and a complement of membrane phospholipid classes, together with some cholesterol. A key feature of this mechanism is that membrane bending induced by ABCA1 lipid translocase activity creates the conditions required for nascent HDL assembly by apo A-I. Overall, this mechanism is consistent with the known properties of ABCA1 and apo A-I and reconciles many of the apparently discrepant findings in the literature. Recently, it has been shown that sera with similar HDL cholesterol levels or apo A-I levels differ in

their ability to promote macrophage efflux due to the differences in the concentration of pre-β HDL[56].

ABCG1 and ABCG4: ABCA1 activity is needed for the predominant pathway for cholesterol efflux to apo A-I and the formation of pre-β HDL. However, it is doubtful whether ABCA1 operates alone in the formation of mature α-HDL. For example, HEK293 cells with ABCA1 overexpression, but without expression of HDL modifying factors like LCAT, PLTP, ABCG1, scavenger receptor class B type 1 (SR-BI), or apolipoprotein M, form pre-β HDL, but not α-HDL. In addition, it appears that the pre-β HDL that is formed is a poor substrate for subsequent lipidation by ABCA1, and presumably requires additional non-ABCA1-mediated lipidation for further maturation[57]. ABCG1 and ABCG4 or their heterodimers[58] might be good candidates for lipidation and maturation of HDL. Synergistic relationships between ABCA1 and ABCG1 and ABCG1/ABCG4 heterodimers have been demonstrated *in vitro*[59,60]. Wang *et al*[61] have shown that ABCG1 and ABCG4 mediate isotopic and net mass efflux of cellular cholesterol to HDL but not to lipid-poor apo A-I. In addition, mice with a targeted disruption of Abcg1 display impaired cholesterol efflux to mature HDL[62]. The exact mechanism behind ABCG1- and ABCG4-mediated cholesterol efflux is still a matter of debate.

SR-BI: SR-BI was identified as an HDL receptor (HDLR) in 1996. SR-BI is primarily expressed in liver and nonplacental steroidogenic tissues, and binds HDL with high affinity. The classic function of SR-BI is to mediate the selective uptake of HDL cholesterol by cells by a mechanism distinct from the classic LDL receptor (LDLR) pathway[63]. LDLR mediates endocytosis of the intact LDL particles *via* coated pits and vesicles, and their subsequent hydrolysis in lysosomes[64]. SR-BI mediates the selective uptake of HDL cholesterol by cells; primarily in the form of cholesteryl esters. This process involves the transfer of the cholesteryl esters from the hydrophobic core of the HDL particle to the cell, without transfer of the apolipoprotein at the surface of the particle. SR-BI-mediated selective lipid uptake appears to be a two-step process, in which high-affinity lipoprotein binding is followed by receptor-mediated transfer of lipids from the lipoprotein particle to the cell membrane. After lipid transfer, the lipid-depleted lipoprotein particle is released from the cells and re-enters the extracellular space[65]. SR-BI also mediates the bidirectional flux of unesterified cholesterol and phospholipids between HDL and cells[66].

Studies in genetically modified mice have revealed that SR-BI in the liver is particularly essential for RCT. In SR-BI$^{-/-}$ mice, plasma total cholesterol is elevated approximately twofold, and most of it circulates in abnormally large, heterogeneous, apolipoprotein-E-enriched HDL-like particles[67]. In addition, these mice exhibit impaired biliary cholesterol secretion, without concomitant changes in either biliary bile acid or phospholipid secretion[68]. Conversely, hepatic overexpression of SR-BI in mice results in the virtual disappearance of plasma HDL and a substantial increase in biliary cholesterol[69].

ABCG5 and ABCG8: At the beginning of the 21st century, two groups almost simultaneously identified mutations in genes ABCG5 and ABCG8, which underlie the disease sitosterolemia[70,71]. Sitosterolemia patients accumulate large amounts of plant sterols and exhibit complete abrogation of biliary plant sterol secretion. They also display increased cholesterol absorption and decreased biliary cholesterol secretion[72,73]. We now know that half-transporters ABCG5 and ABCG8 function as a heterodimer[70] in order to facilitate hepatobiliary cholesterol transport. Double knockout mice for Abcg5 and Abcg8 display extremely low biliary cholesterol concentrations in comparison to wild-type animals[74]. Overexpression of the human ABCG5 and ABCG8 in mice[75] and pharmacological induction of endogenous Abcg5 and Abcg8[76,77] both result in increased biliary cholesterol levels. Mice that lack either Abcg5[78], Abcg8[79], or both[74] do not show the same phenotype regarding physiology, which leaves room for discussion about the way these transporters function. Currently, two hypotheses exist. One argues that ABCG5/G8 act as a "flippase". In this case, the heterodimer shuttles cholesterol from the inner leaflet of the canalicular membrane through a chamber formed by the two half-transporters. This is followed by ATP binding and hydrolysis, which results in a conformational change of the complex. Cholesterol is thereby flipped into the outer membrane leaflet in a configuration that favors its release. Then, cholesterol is ready to be picked up by acceptors[80]. The other hypothesis argues that ABCG5/G8 act as a "liftase"[81]. In this case, the heterodimer promotes an activated state of cholesterol so that acceptors can easily pick up cholesterol. ABCG5/G8 could form a channel that binds cholesterol. Thereafter, the heterodimer might push cholesterol partly into the lumen when ATP is hydrolyzed (activation of cholesterol). Once cholesterol is activated, mixed micelles and PC vesicles are able to serve as an acceptor for cholesterol.

Summary

In summary, the classical view describes RCT as follows: the transport of cholesterol from the periphery to apo A-I and HDL by processes that are mediated by ABCA1, ABCG1 and/or ABCG4. The subsequent uptake of HDL cholesterol by the liver involves SR-BI. Thereafter, hepatobiliary cholesterol secretion is mediated by ABCG5/G8 and final excretion is *via* the feces.

NEW INSIGHTS

How solid is the classical definition of RCT? In recent years, new insights into RCT have been provided, which brings into question the current concept of RCT.

Classical route

Studies that try to pinpoint the rate-controlling step in RCT

often give rise to confusion. For example, Jolley *et al*[82] and Osono *et al*[83] has studied the importance of HDL in rate-control of RCT. They have used transgenic mice that expressed variable amounts of simian CETP in order to vary HDL levels. It appears that, in mice, neither the concentration of HDL cholesterol or apo A-I, nor the level of CETP activity dictate the magnitude of RCT[83]. Apo A-I$^{-/-}$ mice have very low HDL levels. When HDL is rate-controlling for RCT, then RCT should be hampered in apo A-I$^{-/-}$ mice. Nevertheless, Jolley *et al*[82] have demonstrated that the magnitude of the cholesterol flux from peripheral organs to the liver is virtually identical in mice that lacking apo A-I compared with control animals. They have suggested that the magnitude of RCT is probably ascribed to processes in peripheral organs. Although ABCA1 mediates cholesterol efflux from the periphery, it appears that Abca1$^{-/-}$ mice have unaltered hepatobiliary cholesterol secretion and fecal cholesterol excretion, while having virtually absent HDL levels[84]. Also, the proposed key player in the liver in HDL uptake, SR-BI, does not control RCT in mice[85]. Moreover, the exclusiveness of SR-BI as the sole high-affinity HDLR in the liver was compromised when Martinez *et al*[86] identified ecto-F1-ATPase as a high-affinity HDLR in hepatocytes. Furthermore, deficiency of Abcg5 and/or Abcg8 leads to mild[74,77] or no[78] decrease in fecal neutral sterol secretion in mice. This also questions the rate-controlling properties of these transporters on the magnitude of RCT. In addition, it has been shown that Abcg5/g8-independent, inducible routes exist that can significantly contribute to total hepatobiliary cholesterol output in mice[87]. Although most of the above-mentioned studies have been performed in mice and not in humans, it emphasizes the complexity of the mechanisms that underlie RCT.

Alternative route

In the classical concept of RCT, the liver plays a major role. When hepatobiliary cholesterol secretion is the primary route of cholesterol elimination, inhibition of ABCG5/G8, and hence, diminished hepatobiliary cholesterol secretion, should result in a drastic lowering of fecal neutral sterol excretion. Abcg5/Abcg8 double knockout mice do not show the expected low levels of fecal neutral sterol excretion[74]. In addition, Abcb4$^{-/-}$ mice, which also have almost no biliary cholesterol secretion, have the same fecal neutral sterol output as their wild-type littermates[88]. In addition, Kruit *et al*[88] have shown that, in these mice, intravenous radiolabeled cholesterol could be recovered in the feces. These findings indicate that hepatobiliary cholesterol secretion might not be the only route of cholesterol excretion. In mouse models with disturbed biliary secretion, there must be a direct transintestinal pathway for cholesterol excretion. In 2006, van der Velde *et al*[89] described significant direct intestinal cholesterol secretion in normal mice. This was later supported by van der Veen *et al*[90] who have measured cholesterol fluxes in mice. This route is nowadays referred to as transintestinal cholesterol efflux (TICE; see[91] for review) and continues to be elucidated[92-94]. Although quantitative cholesterol flux studies are warranted to quantify exactly the magnitude of TICE in humans, significant secretion of intestinal cholesterol in humans has been observed by Simmonds *et al*[21].

CONCLUSION

Although medical textbooks have taught us the classical view of RCT for several decades, it is desirable to open our eyes to the new insights into cholesterol excretion. Research on RCT has taken off in recent years. These new insights show us that the classical route for cholesterol excretion cannot be a strictly defined pathway. In addition, an alternative route for cholesterol disposal has come to light in the form of TICE (Figure 1). The new insights into RCT should make us question whether the classical view needs revision.

Abstract

Scavenger receptor class B type I (SR-BI) is an important member of the scavenger receptor family of integral membrane glycoproteins. This review highlights studies in SR-BI knockout mice, which concern the role of SR-BI in cholesterol and steroid metabolism. SR-BI in hepatocytes is the sole molecule involved in selective uptake of cholesteryl esters from high-density lipoprotein (HDL). SR-BI plays a physiological role in binding and uptake of native apolipoprotein B (apoB)-containing lipoproteins by hepatocytes, which identifies SR-BI as a multi-purpose player in lipid uptake from the blood circulation into hepatocytes in mice. In adrenocortical cells, SR-BI mediates the selective uptake of HDL-cholesteryl esters, which is efficiently coupled to the synthesis of glucocorticoids (i.e. corticosterone). SR-BI knockout mice suffer from adrenal glucocorticoid insufficiency, which suggests that functional SR-BI protein is necessary for optimal adrenal steroidogenesis in mice. SR-BI in macrophages plays a dual role in cholesterol metabolism as it is able to take up cholesterol associated with HDL and apoB-containing lipoproteins and can possibly facilitate cholesterol efflux to HDL. Absence of SR-BI is associated with thrombocytopenia and altered thrombosis susceptibility, which suggests a novel role for SR-BI in regulating platelet number and function in mice. Transgenic expression of cholesteryl ester transfer protein in humanized SR-BI knockout mice normalizes hepatic delivery of HDL-cholesteryl esters. However, other pathologies associated with SR-BI deficiency, i.e. increased atherosclerosis susceptibility, adrenal glucocorticoid insufficiency, and impaired platelet function are not normalized, which suggests an important role for SR-BI in cholesterol and steroid metabolism in man. In conclusion, generation of SR-BI knockout mice has significantly contributed to our knowledge of the physiological role of SR-BI. Studies using these mice have identified SR-BI as a multi-purpose player in cholesterol and steroid metabolism because it has distinct roles in reverse cholesterol transport, adrenal steroidogenesis, and platelet function.

INTRODUCTION

The scavenger receptor (SR) superfamily consists of integral membrane glycoproteins that are involved in recognition of polyanionic structures of either endogenous [e.g. oxidized low-density lipoprotein (LDL)] or exogenous [e.g. bacterial lipopolysaccharide (LPS)] origin. The SR family is structurally diverse and can be classified into eight different classes (A-H) based on the multi-domain structure of the individual members (reviewed by van Berkel *et al*[1]). The first SR to be cloned was the class A scavenger receptor SR-AI, which was originally identified as a receptor that recognizes acetylated LDL (acLDL). However, due to the limited relevance of acLDL in atherosclerosis, at that time it was primarily considered to be a receptor for negatively charged macromolecules[2]. Macrophage-expressed SR-As can bind many polyanionic molecules such as lipoteichoic acid from Gram-positive bacteria, and lipid IVA, a precursor of lipid A, from LPS of Gram-negative bacteria, as well as mediate uptake of bacteria by phagocytosis. In line with their ability to bind bacteria, class A scavenger receptors play prominent roles in the host response to infection[3,4]. In parallel with SR-As, SR class B type I (SR-BI), also known as CD36 and lysosomal integral membrane protein-Ⅱ analog-1 (CLA-1) in humans, has also been demonstrated to increase the uptake of both Gram-negative and Gram-positive bacteria *in vitro*[5,6].

As its name indicates, SR-BI belongs to the class B subfamily of SRs that also includes its splice variant SR-BII and CD36 (previously known as the OKM5 antigen, platelet glycoprotein Ⅳ, or GP88). The three class B SR proteins show a highly similar structure, which consists of a heavily N-linked glycosylated and fatty acylated protein backbone, which contains a large extracellular loop, two transmembrane domains, and short intracellular N-terminal and C-terminal domains (Figure 1). CD36 and SR-BI represent two distinct proteins that are derived from two different genes located on chromosome 5 in mice and 7 and 12 in humans. SR-BII, however, constitutes an isoform of the *SR-BI* gene, which represents around 40% of total SR-BI/BII mRNA[7]. The SR-BII protein differs from SR-BI only in the C-terminal cytoplasmic tail and contributes to only 12% of the immunodetectable SR-BI/BII protein in mouse liver[7].

Importantly, although SR-BI also modulates susceptibility to sepsis[8,9], it is predominantly known for its functions in lipoprotein metabolism. Since the generation of SR-BI knockout mice that lack a functional SR-BI protein by the group of Monty Krieger in 1997[10], it has become clear that SR-BI is a multi-purpose player in cholesterol and steroid metabolism. In this topic highlight, we review the data obtained from this widely used mouse model regarding the *in vivo* role of SR-BI in cholesterol and steroid metabolism within a wide variety of cells types in mice, including liver parenchymal cells (hepatocytes), adrenocortical cells, macrophages, and platelets. In addition, we discuss recent interesting findings from humanized SR-BI knockout mice that provide the first insight into an important contribution of SR-BI to steroid metabolism and (patho)physiology in humans.

LIVER PARENCHYMAL CELLS

Initial *in vitro* cloning and purification studies performed by the group of Krieger have shown that SR-BI, similar to CD36, displays a high affinity for acLDL, modified proteins (i.e. maleylated bovine serum albumin), and anionic lipids[11,12]. Not long after, it became clear that SR-BI, in addition to its ability to bind (modified) LDL and anionic lipids, can bind high-density lipoprotein (HDL) with a high affinity and saturability[13]. This provided the first evidence that SR-BI could be considered a functional HDL receptor. Immunoblotting on membranes of different murine tissues has revealed that SR-BI protein is highly expressed in liver[13]. The liver is the primary organ that is involved in removal of cholesterol from the body, therefore, much attention has been drawn to a possible role for SR-BI in hepatic lipid transport.

The liver consists of a wide variety of cells including parenchymal cells (hepatocytes), endothelial cells, and Kupffer cells, which represent the largest majority of all tissue macrophages found within the body. Expression profiling has indicated that SR-BI mRNA and protein are particularly high in parenchymal cells, the primary metabolic cell type of the liver[14,15]. However, SR-BI is also detected in Kupffer cells, albeit at a lower expression level[14,16]. In accordance with a role for SR-BI in hepatocyte HDL-cholesterol clearance, liver parenchymal cells are responsible for 88% of the hepatic uptake of cholesteryl esters from HDL in wild-type mice, when taking into account the contribution of these cells to liver mass[17]. Importantly, we have been able to show that SR-BI is responsible for the majority of the uptake of HDL-cholesteryl esters into the liver. Functional SR-BI deficiency in SR-BI knockout mice was associated with an 87% and 52% decrease in uptake of HDL-cholesteryl esters in liver parenchymal and Kupffer cells, respectively, compared with wild-type littermate controls[17]. *In vitro* association studies showed uptake of HDL-cholesteryl esters without whole particle internalization (selective uptake) in isolated liver parenchymal cells of wild-type mice, which was completely lost in those of SR-BI knockout mice. This suggests that, at least in mice, SR-BI is the sole molecule that is involved in the selective uptake of HDL-associated cholesteryl esters in hepatocytes[17]. In parallel with the major role of the liver in the clearance of HDL-associated cholesterol from the blood circulation, SR-BI knockout mice exhibit a marked increase in their plasma HDL-cholesterol levels. Already on a regular chow diet, in these mice an accumulation of larger, but not more, cholesteryl-ester-rich HDL particles can be observed[10], probably as a result of the diminished selective uptake of HDL-cholesteryl esters by SR-BI in the liver. In addition, SR-BI attenuated mice, with an SR-BI promoter mutation that resulted in 53% decreased expression of the receptor in the liver, displayed a lower hepatic selective HDL-cho-

Structural elements include a heavily N-glycosylated and fatty-acylated protein backbone that contains a large extracellular loop, two transmembrane domains, and short intracellular N-terminal and C-terminal domains.

lesteryl ester uptake and a higher plasma HDL-cholesterol level[18]. Furthermore, transgenic or adenoviral overexpression of SR-BI in hepatocytes is associated with virtual disappearance of HDL from the plasma compartment[19-22]. These findings convincingly show that SR-BI in mice is a functional HDL receptor in liver parenchymal cells.

SR-BI knockout mice also display a significant increase in the level of cholesterol associated with the plasma non-HDL fraction[10,23,24]. In parallel, transgenic mice that have liver-specific overexpression of SR-BI show a decrease in LDL- and very low density lipoprotein (VLDL)-cholesterol levels[20]. These observations suggest that SR-BI can also contribute to the clearance of apoB-containing lipoproteins *in vivo*. To verify this hypothesis, several groups have studied uptake of apoB100-containing LDL and VLDL lipoproteins, as well as apoB48-containing chylomicrons in hepatocytes from SR-BI knockout mice and their wild-type littermate controls. Rhainds *et al*[25] and Bourret *et al*[26] have detected a dose-dependent decrease in the selective uptake of cholesteryl esters associated with human LDL by liver parenchymal cells isolated from heterozygous (-45%) and homozygous (-87%) SR-BI knockout mice[25,26]. In parallel, the uptake of triglyceride-rich, chylomicron- remnant-like emulsion particles by liver parenchymal cells of homozygous SR-BI knockout mice is markedly lower compared to that of wild-type controls[27]. Furthermore, the association with and apparent uptake of β-VLDL is 1.6-2.2-fold decreased in hepatocytes isolated from SR-BI knockout mice *in vitro*[24], whereas the serum decay and hepatic uptake of β-VLDL is significantly diminished in response to SR-BI deficiency *in vivo*[24]. Moreover, SR-BI knockout mice show a higher postprandial triglyceride response to an intragastric fat load[27]. SR-BI deficiency, however, does not alter the ability of oxidized LDL to associate with liver parenchymal cells *in vitro*[26]. It thus seems that SR-BI also plays a physiological role in the binding and uptake of native, but not modified, apoB-containing lipoproteins by liver parenchymal cells *in vivo*. Combined with the fact that SR-BI is a functional HDL receptor *in vivo*, SR-BI can be considered a multi-purpose player in lipid uptake from the blood circulation into hepatocytes in mice.

ADRENOCORTICAL CELLS

Although SR-BI plays a widely recognized role in hepatic clearance of lipids, the highest protein expression of SR-BI is actually found in the adrenal glands[13]. More specifically, adrenocortical cells (i.e. Y1-BS1 murine adrenal cells) contain relatively high levels of SR-BI protein that are predominantly localized in cholesterol-rich caveolin-1-containing domains within the plasma membrane[28]. Cells within the adrenal cortex are involved in the synthesis of cholesterol-derived steroid hormones, including mineralocorticoids (i.e. aldosterone) and glucocorticoids (i.e. cortisol in humans and corticosterone in rodents). In the original 1997 study on the effect of the targeted mutation in the SR-BI gene on cholesterol metabolism *in vivo*, it was described that the adrenal cholesterol content was dose-dependently decreased in heterozygous (-42%) and homozygous (-72%) SR-BI knockout mice[10]. In accordance, the uptake of cholesteryl esters from HDL by the adrenals of SR-BI knockout mice is reduced[17]. Strikingly, however, in 2008, we and others were able to show that the impaired uptake of HDL-cholesteryl esters by the adrenal glands translates into functional changes in the adrenal steroidogenesis rate in SR-BI knockout mice. Adrenal SR-BI deficiency is associated with increased adrenal weight as a result of long-term overstimulation of adrenocortical cell proliferation by the pituitary-derived adrenocorticotropic hormone (ACTH)[10,29]. Under basal non-stressed conditions, plasma glucocorticoid levels (i.e. corticosterone) in SR-BI knockout mice are maintained within the normal range, probably as a result of the high level of circulating ACTH, a potent activator of adrenal steroidogenesis[8,29]. In contrast, SR-BI knockout mice are unable to increase plasma corticosterone levels upon a variety of stress triggers that activate the hypothalamus-pituitary-adrenal axis, which results in increased secretion of glucocorticoids by adrenocortical cells in the zona fasciculata. We have shown that the fasting-induced adrenal glucocorticoid response is significantly diminished in SR-BI knockout mice, resulting in a approximately 50% lower fasting plasma glucocorticoid level[29,30]. The adrenal cortex is virtually depleted of neutral lipids (i.e. cholesteryl esters) in SR-BI knockout mice under fasting stress conditions, which is associated with a visual change in the appearance of the adrenal glands (red/brownish color instead of

white)[10,29]. In parallel with fasting-induced glucocorticoid insufficiency, adrenals of SR-BI knockout mice are also unable to respond to a potent inflammatory stress trigger. Upon LPS exposure, wild-type mice show a significant increase in their plasma corticosterone levels. Plasma corticosterone levels, however, are not induced in SR-BI knockout mice challenged with LPS[8,30]. Glucocorticoids are important signaling molecules that through the action of their cognate nuclear receptor mediate downstream effects on energy homeostasis and the control of immune responses. In accordance, SR-BI knockout mice exhibit fasting hypoglycemia, which is paralleled by reduced expression of hepatic glucocorticoid targets involved in fatty acid utilization[29]. Furthermore, the LPS-induced cytokine (i.e. tumor necrosis factor-α and interleukin-6) response is enhanced, probably due to an impaired suppressive action of glucocorticoids on pro-inflammatory gene expression in macrophages and other immune cells, which leads to an overall higher LPS-induced mortality rate in SR-BI knockout mice[8]. In line with a prominent role for SR-BI in the generation of the substrate used for adrenal steroidogenesis under stress conditions, SR-BI expression in adrenocortical cells is tightly controlled by the steroidogenic activator ACTH *in vitro* and *in vivo*[31,32]. These findings suggest that functional SR-BI protein is necessary for optimal adrenal steroidogenesis in mice.

MACROPHAGES

Macrophages cannot limit the uptake of excess cholesterol and thus rely on active cholesterol efflux processes to maintain their intracellular cholesterol balance. As a result, disruption of the function of proteins crucially involved in macrophage cholesterol efflux is associated with the formation of so-called foam cells, which are large lipid-filled macrophages. The cholesterol transport protein ATP-binding cassette transporter A1 (ABCA1) has been shown to be a major player in macrophage cholesterol efflux. Ablation of ABCA1 function is associated with almost complete shutdown of cholesterol efflux from macrophages to apolipoprotein AI (apoAI), and enhanced foam cell formation *in vitro* and *in vivo*[33-35]. Lipidation of apoAI is the primary step in the formation of HDL, which executes the transport of cholesterol from peripheral cells (i.e. macrophages) back to the liver for subsequent excretion into the bile, a process also known as reverse cholesterol transport (reviewed by Van Eck *et al*[36]). SR-BI is a major player in the final step of reverse cholesterol transport because it, as discussed previously, mediates the selective uptake of HDL-cholesteryl esters into the liver.

Initial overexpression studies by Ji *et al*[37] have shown a clear correlation between the level of cellular cholesterol efflux to mature HDL and the expression levels of SR-BI protein *in vitro*, which suggests that SR-BI also mediates the primary step in reverse cholesterol transport *in vivo*. Follow-up studies have indicated that SR-BI does indeed mediate cholesterol efflux to HDL in cells that have been labeled with unesterified cholesterol[38]. Strikingly, however, SR-BI has been shown not to influence the efflux of cholesterol from macrophages that are loaded with cholesterol packaged in acLDL[38]. Furthermore, it actually decreases the efflux of cholesterol to apoAI *via* ABCA1 in RAW macrophages, which could be attributed the ability of SR-BI to re-uptake cholesterol after ABCA1-mediated efflux[38]. These studies were the first to show that SR-BI and ABCA1 have distinct and competing roles in mediating cholesterol flux between (pre-β) HDL and macrophages. In line with a role for SR-BI in cholesterol uptake, the association of β-VLDL and HDL in peritoneal macrophages is reduced in response to SR-BI deficiency[39]. Studies *in vitro*, however, have either shown that SR-BI does modulate cholesterol efflux[37] or have argued against a role for SR-BI in efflux in general[40-42]. To date, the quantitative role for SR-BI in macrophage cholesterol efflux has therefore been under discussion and this has contributed to the mystification of SR-BI as a player in cholesterol efflux from macrophages.

Thioglycolate-elicited peritoneal macrophages from SR-BI knockout mice loaded with unesterified cholesterol *in vivo* and subsequently subjected to cholesterol efflux *in vitro* displayed a 20% reduced efflux to mature HDL as compared to wild-type macrophages[39]. To study the quantitative role of different transport proteins in cholesterol efflux in mice, the group of Dan Rader has developed an experimental *in vivo* reverse cholesterol transport model. *In vitro* cholesterol-labeled bone marrow-derived or peritoneal macrophages from specific knockout mice are injected into recipient mice and subsequently the appearance of cholesterol in the plasma compartment, uptake by the liver, and the rate of sterol excretion into the feces are monitored. Using this experimental model, no effect of macrophage SR-BI deficiency on macrophage cholesterol efflux/reverse cholesterol transport was detected, because the cholesterol distribution in plasma as well as fecal tracer levels were no different upon injection of peritoneal or bone-marrow-derived macrophages from SR-BI knockout mice and their wild-type littermates into C57BL/6 recipient mice[43]. However, macrophages were cultured *in vitro* for at least 24 h before injection into recipient mice. *In-vitro*-cultured macrophages might display an altered expression of cholesterol transport proteins as compared to macrophages *in vivo*. In this respect, the absence of an effect of macrophage SR-BI deficiency in the described reverse cholesterol transport model might not necessarily imply that SR-BI does not affect the cholesterol efflux potential of macrophages *in vivo*.

In our opinion, too little knowledge is currently present about which type of macrophage and cholesterol acceptor combination *in vitro* best represents the *in vivo* situation. We anticipate that large-scale genomic and proteomic analysis on freshly isolated (tissue) macrophage foam cells, as well as peritoneal and bone-marrow-derived macrophages cultured under different loading conditions (i.e. unesterified cholesterol, acLDL, oxidized LDL) is needed to provide clues as to which setting might actually

be useful to study functional consequence of specified gene targets on cholesterol efflux *in vivo*. Although we appreciate an important role for SR-BI in cholesterol efflux, we encourage novel research into this interesting topic, which will unravel not only the contribution of SR-BI, but also clarify the interaction between the different cholesterol efflux pathways.

PLATELETS

Early evidence in several disease states in humans (e.g. familial hyperlipidemia) has suggested an interaction between cholesterol-containing lipoproteins and platelets[44,45]. As a consequence, the modulation of platelet functions by lipoproteins has been investigated intensively both in humans and animal models. Due to the large fluctuation in their plasma concentrations, the data on the influence of triglyceride-rich lipoproteins, such as chylomicrons and VLDL, are limited. In contrast, numerous studies have demonstrated a distinctive interaction of platelets with LDL and HDL (reviewed by Korporaal *et al*[46]).

Platelets are able bind to rapidly and reversibly to HDL in an activation-state- and temperature-independent manner with a Kd of 11-60 nmol/L[47,48]. The number of HDL binding sites expressed on the platelet surface ranges from 1200 to 3200 copies[47,48]. Koller *et al*[48,49] have observed that LDL interferes with the binding of HDL to platelets as a result of overlapping affinities for different receptors. In 1986, the same group described CD41 and CD61, the two constituents of integrin αⅡbβ3, as binding proteins for HDL on the platelet surface. An antibody directed against the integrin β3-subunit blocked the binding of HDL to integrin αⅡbβ3 on the platelet surface, thereby identifying αⅡbβ3 as the platelet receptor for HDL[49]. In contrast with these observations, others have reported that αⅡbβ3 is not involved in binding of HDL to platelets, because: (1) antibodies directed against integrin αⅡbβ3 have no effect; (2) HDL does not alter agonist-induced fibrinogen binding or platelet aggregation[50,51]; (3) HDL-induced platelet signaling is similar in control platelets and platelets from thrombasthenic patients with abnormal levels of αⅡbβ3 and fibrinogen[52]; (4) treatment of platelets with EDTA, which causes dissociation of the integrin complex and fully inhibits fibrinogen binding and platelet aggregation[53], does not inhibit the interaction between HDL and platelets[54]; and (5) αⅡbβ3 ligands like fibrinogen, fibronectin, vitronectin, and von Willebrand factor do not affect HDL binding[52]. It therefore remains unclear which receptor is the actual binding site for HDL in platelets.

In 2003, Imachi *et al*[55] identified SR-BI as being expressed on human platelets, which opened up the possibility that, as in the liver, adrenals, and macrophages, SR-BI acts as a functional HDL receptor in platelets. *In vitro* association studies by Valiyaveettil *et al*[56] have proved that oxidized HDL (oxHDL) binds to isolated platelets in an SR-BI-dependent manner. Binding of oxHDL could be diminished by pre-incubation of platelets with an SR-BI blocking antibody, whereas native HDL decreased oxHDL binding to human platelets[56]. In parallel, the oxHDL-induced repression of platelet aggregation *in vitro* was almost fully blocked by inhibiting SR-BI binding, which suggests that a direct interaction of HDL with SR-BI is necessary to alter normal platelet function[56]. To validate the functional role of SR-BI in platelets *in vivo*, the group of Monty Krieger has evaluated platelet function in SR-BI knockout mice and their littermate controls. SR-BI knockout mice suffer from thrombocytopenia, because their blood platelet counts are markedly reduced as a result of enhanced clearance of platelets by the reticuloendothelial system[57]. Probably as a compensatory response, splenic megakaryocyte (platelet precursor) counts are increased in SR-BI knockout mice[57]. Elegant crossover platelet infusion studies have shown that the increased turnover of platelets is not primarily due to genotype-induced changes in the platelets themselves, but rather is secondary to the high level of HDL-associated unesterified cholesterol that circulates in the plasma of SR-BI knockout mice. As unesterified cholesterol rapidly exchanges between the plasma compartment and blood cells, including platelets, SR-BI knockout platelets contain relative high cellular levels of cholesterol, which is associated with a functional impairment of the aggregation in response to ADP[57]. In parallel, we have shown that SR-BI deficiency and the dyslipidemia associated with it lead to thrombocytopenia and impaired platelet reactivity *ex vivo* as a result of the increased platelet cholesterol content[58]. In addition, SR-BI deficiency in mice is associated with enhanced thrombosis susceptibility[58]. However, platelet-specific deficiency of SR-BI is associated with resistance to hyper-reactivity induced by increased platelet cholesterol content[59], which suggests that SR-BI contributes to platelet function *in vivo*. In accordance, platelet-specific SR-BI modulates thrombosis susceptibility in SR-BI knockout mice[59]. These findings highlight an interesting novel role for SR-BI in regulating platelet number and function and thrombosis susceptibility in mice.

POTENTIAL FOR SR-BI IN CHOLESTEROL AND STEROID METABOLISM IN HUMANS: INSIGHTS FROM HUMANIZED SR-BI KNOCKOUT MICE

From the combined findings in SR-BI knockout mice it can be concluded that SR-BI is a multi-purpose player in cholesterol and steroid metabolism in mice. Several clinical studies have detected significant associations between several polymorphisms at the SR-BI locus and changes in plasma lipid levels and lipoprotein particle sizes[60-62]. Human subjects, in contrast to rodents, express cholesteryl ester transfer protein (CETP) that is able to transfer cholesteryl esters from HDL to the apoB-containing lipoproteins VLDL and LDL, in exchange for triglycerides. As a result, human subjects carry most of their cholesterol in the LDL fraction, whereas mice predominantly transport

their plasma lipids in HDL. The CETP→LDL→LDL receptor route provides an alternative for HDL-cholesteryl ester delivery from the blood circulation to the liver, which might be associated with a relatively limited uptake of HDL-cholesteryl esters *via* SR-BI into the liver in humans compared with mice. To date, no functional mutations in the *SR-BI* gene have been identified, therefore, the relative contribution of SR-BI to lipoprotein metabolism in humans is therefore still unclear.

To gain insight in the importance of SR-BI in the human situation, studies have been performed in humanized SR-BI knockout mice that express the *CETP* gene under the control of its natural regulatory elements. In these SR-BI knockout/CETP transgenic mice, similar to the human situation, relatively high mRNA expression levels of CETP can be detected in adipose tissue and macrophage-rich tissues such as the liver and spleen[30]. In accordance with the assumption that the CETP→LDL →LDL receptor route can provide an alternative for the delivery of HDL-associated cholesteryl esters to the liver in humans, transgenic expression of CETP is able to normalize almost fully the serum decay and hepatic uptake of HDL-cholesteryl esters in SR-BI knockout mice[63,64]. As a result, plasma total cholesterol levels are significantly lower in SR-BI knockout/CETP transgenic mice as compared to SR-BI knockout mice[30,63,64]. Importantly, plasma lipid levels as well as lipoprotein particle sizes are not fully restored. Plasma unesterified cholesterol levels, the unesterified cholesterol to total cholesterol ratio, and HDL particle size are only mildly decreased by CETP expression[63]. In parallel with previous findings of Dole *et al*[57], the increased unesterified cholesterol levels in SR-BI knockout mice with or without CETP expression are associated with a lower platelet count and reduced platelet aggregation[63]. CETP expression increases, but does not normalize, adrenal uptake of HDL-associated cholesteryl esters in SR-BI knockout mice. Strikingly, the stress-induced adrenal glucocorticoid insufficiency, however, is equally severe in SR-BI knockout mice with or without CETP expression[30]. Furthermore, the higher tissue oxidative status previously detected in SR-BI knockout mice[65] does not return to basal levels in mice that express the CETP transgene[63]. Changes in plasma lipid levels (i.e. an increase in apoB-containing lipoproteins or a decrease in HDL)[66], an increased adrenal steroidogenesis rate[67] as well as modified platelet function[68] underlie the process of atherothrombosis, the primary cause of cardiovascular disease mortality and morbidity. SR-BI deficiency in mice is associated with enhanced susceptibility to atherosclerotic lesion development[23]. This finding indicates that high HDL-cholesterol levels *per se* do not protect against atherosclerosis and underlines that other parameters regarding HDL function should be established and evaluated in the clinical setting. Expression of CETP also does not provide protection against atherosclerosis in SR-BI knockout mice[63]. Overall, it thus seems that, although CETP activity can restore the transport of HDL-cholesteryl esters to the liver in SR-BI knockout mice, it cannot normalize many other processes associated with disruption of the *SR-BI* gene in mice.

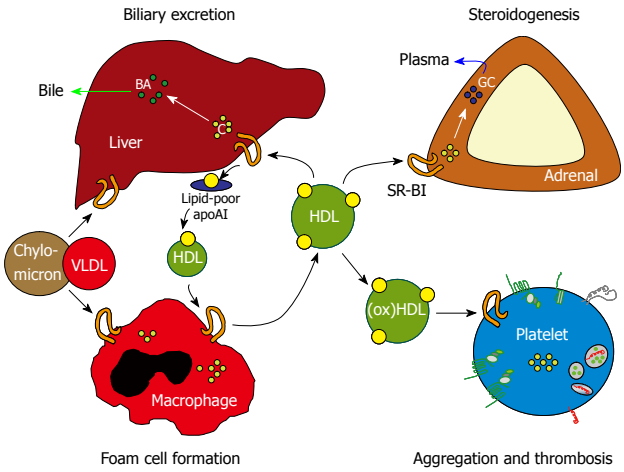

Figure 2 Overview of the diverse role of scavenger receptor class B type I in cholesterol and steroid metabolism in mice. (1) In liver, scavenger receptor class B type I (SR-BI) mediates the selective uptake of cholesterol (C; yellow) from high-density lipoprotein (HDL) that is subsequently converted to bile acids (BA; green) for biliary excretion; (2) HDL-associated cholesteryl esters are taken up *via* SR-BI in adrenocortical cells, which is efficiently coupled to the synthesis and subsequent secretion of glucocorticoids (GC; blue) into plasma; (3) SR-BI binds apolipoprotein (apo)B-containing lipoproteins, i.e. chylomicrons and very low density lipoprotein (VLDL), in liver and macrophages, which contributes to macrophage foam cell formation; (4) SR-BI is able to efflux cholesterol from macrophages to small HDL particles, which inhibits foam cell formation; and (5) HDL can interact with platelets, in part *via* the direct action of SR-BI, to modulate platelet aggregation and susceptibility to thrombosis.

CONCLUSION

The initial generation of the SR-BI knockout mice by the group of Monty Krieger has significantly contributed to our knowledge of the physiological role of SR-BI. Studies using these mice have identified SR-BI as a multi-purpose player in cholesterol and steroid metabolism, because it has distinct roles in reverse cholesterol transport, adrenal steroidogenesis, and platelet function (summarized in Figure 2). Recent studies have suggested a potential role for HDL and SR-BI in the control of endothelial cell[69-71] and stem and progenitor cell[72,73] physiology, and we are confident that upcoming research using SR-BI knockout mice will also reveal the importance of SR-BI in these additional cell systems.

Based upon the findings from humanized CETP transgenic SR-BI knockout mice, we anticipate that functional SR-BI mutations in humans who do naturally express CETP will be associated with various diseases (i.e. adrenal glucocorticoid insufficiency, impaired platelet function, and enhanced atherogenesis) similar to those observed in SR-BI knockout mice. We hope that functional mutations in the *SR-BI* gene will be identified in the near future as a result of large-scale DNA screening studies in human subjects that have relatively high plasma HDL-cholesterol levels. If changes in SR-BI function in humans are indeed associated with an increased susceptibility for atherosclerotic

rosis, this will further establish the importance of SR-BI as a therapeutic target for increasing HDL-mediated reverse cholesterol and lowering clinical atherosclerosis and the associated cardiovascular disease risk.

Abstract

Mitochondrial ATP synthase has been recently detected at the surface of different cell types, where it is a high affinity receptor for apoA-I, the major protein component in high density lipoproteins (HDL). Cell surface ATP synthase (namely ecto-F1-ATPase) expression is related to different biological effects, such as regulation of HDL uptake by hepatocytes, endothelial cell proliferation or antitumor activity of Vγ9/Vδ2 T lymphocytes. This paper reviews the recently discovered functions and regulations of ecto-F1-ATPase. Particularly, the role of the F1-ATPase pathway(s) in HDL-cholesterol uptake and apoA-I-mediated endothelial protection suggests its potential importance in reverse cholesterol transport and its regulation might represent a potential therapeutic target for HDL-related therapy for cardiovascular diseases. Therefore, it is timely for us to better understand how this ecto-enzyme and downstream pathways are regulated and to develop pharmacologic interventions.

Key words: F_1F_o ATP synthase; High density lipoproteins receptor; Apolipoprotein A-I; Purinergic receptor P2Y13; Adenylate kinase; Nucleotide; Endothelium; Antitumor immunity

INTRODUCTION

F_1F_o ATP synthase, the terminal enzyme of the oxidative phosphorylation pathway, is a complex molecular motor responsible for the large majority of ATP synthesis in all living beings, except in archaea which use a related enzyme to produce ATP, the A_1A_o ATP synthase[1]. It is

located in the inner membrane of mitochondria, in the thylakoid membrane of chloroplasts in plants, and in the plasma membrane (PM) of certain bacteria. ATP synthase is highly concentrated in inner membrane cristae, where it is part of the so-called "ATP synthasome", in association with an inorganic phosphate (Pi) carrier as well as the adenine nucleotide translocase (ANT) which exchanges ADP and ATP[2]. Experimental evidence also suggests that ATP synthase is organized in dimers[3], or even oligomers[4]. This supramolecular organization is involved in the generation of inner membrane cristae and depends on the e and g subunits[5].

Despite a few differences in subunit composition, the general structure of ATP synthase is highly conserved throughout evolution. In eukaryotic cells, it is composed of 16 unique subunits (α, β and c being present in multiple copies in the whole complex). It comprises the activity-bearing subunits (three αβ heterodimers), a rotor (subunits γ, δ, ε and the c ring) and a stator (subunits a, e, f, g, A6L, b, F6, d and OSCP) which holds the αβ heterodimers. It is organized into two major domains: a soluble F_1 domain (α, β, γ, δ, ε) and a membrane-associated F_o domain (Figure 1). The F_1 domain bears the catalytic activity while the F_o domain is a proton channel. The biogenesis of ATP synthase follows a complex and timed mechanism[6] which involves at least five assembly factors: Atp10p, Atp11p, Atp12p, Atp22p and Fmc1p[7-10]. So far only the human orthologs of Atp11p and Atp12p have been identified[11].

The F_o domain uses the proton gradient created by the four other complexes of the respiratory chain to drive the rotation of the central stalk, which will alternatively change the conformation of the three αβ heterodimers, leading to the synthesis of ATP from ADP and Pi. The rotation of ATP synthase was demonstrated by a remarkable experiment in which the αβ heterodimers were immobilized on a solid support while the γ chain was coupled to a fluorochrome-labeled actin filament, and visualized under a microscope after addition of ATP[12]. ATP synthesis and hydrolysis involve a binding-change mechanism[13,14] in which catalytic sites undergo conformational changes driven by the interactions with the γ chain. In the case of the eukaryotic ATP synthase, the translocation of 10 protons through the c ring will lead to a full turn, and the synthesis of 3 ATP molecules. However, the exact mechanism of catalysis is still debated, as experimental data support both a bi-site mechanism, in which one of the catalytic sites is empty at any given moment[15], or a tri-site mechanism where all sites are filled with nucleotides[16]. The F_1 domain also bears three non-catalytic sites which have been proposed to enhance ATP synthesis/hydrolysis upon binding of nucleotides[17].

In the absence of a proton gradient, or if the F_1 domain is isolated from the F_o domain, the enzyme behaves as an ATP hydrolase. This potential energy loss is tightly regulated by the inhibitor factor 1 (IF_1) protein when the proton gradient collapses, for instance in the case of hypoxia as the respiratory chain stops functioning. Under normal conditions, IF_1 exists as a homotetramer which turns into a homodimer when the pH in the matrix compartment decreases[18]. This allows it to tightly bind ATP synthase by interacting with both the αβ dimers and the central stalk, thereby blocking the rotation of the latter and preventing ATP hydrolysis[19]. This inhibitory mechanism has recently been shown to be highly dependent on the catalytic activity of the enzyme[20]. For extensive reviews on the structure and rotary mechanism of ATP synthase[21-23].

Given its essential role in ATP synthesis, defects in ATP synthase are involved in extremely severe and often lethal diseases because of the marked reduction in ATP production and concomitant accumulation of reactive oxygen species (ROS)[24,25]. Such pathologies are mostly linked to mutations in ATP synthase subunits, the most frequently described being mapped to the mitochondrial ATP6 gene (encoding for subunit a) which is responsible for the maternal-inherited NARP syndrome (Neurogenic muscle weakness, Ataxia, Retinitis Pigmentosa) or Leigh syndrome (severe and fatal encephalopathy), depending on the extent of heteroplasmic mutations. Defects in ATP synthase biogenesis, due to mutations in genes encoding its assembly factors for instance, have also been described[26]. Finally, abnormal accumulations of ATP synthase subunits have been found in various neurodegenerative diseases, such as subunit c accumulation in neuronal ceroid lipofuscinosis[27,28], or subunit α accumulation in Alzheimer's disease[29].

Over the past few years, various reports by many independent groups have described the presence, at the cell surface of mammalian cells, of various subunits of ATP synthase, which will also be referred to as ecto-F_1-ATPase throughout this review. The exact structure of this ectopically-expressed ATP synthase and whether it is exactly the same enzyme as the mitochondrial complex have not been definitely determined. Nevertheless, a number of pieces of experimental evidence suggest that it is a closely related entity. We will review here the various reports describing the unexpected cell surface expression of ATP synthase and its possible functions.

IS ECTO-F_1-ATPASE THE SAME ENTITY AS MITOCHONDRIAL ATP SYNTHASE?

Over the past few years, a growing number of reports, including our work[30,31], have described the presence of ATP synthase subunits at the surface of a wide variety of tumor as well as normal cells by fluorocytometry.

While most of these reports focused on the α and β subunits against which monoclonal antibodies are available[30-32], a few have described the presence of other subunits at the cell surface by using in-house manufactured polyclonal reagents analyzed by cytometry or confocal microscopy. Vantourout *et al*[33] have shown that high cell surface expression of major histocompatibility complex class I (MHC- I) antigens interferes with the detection

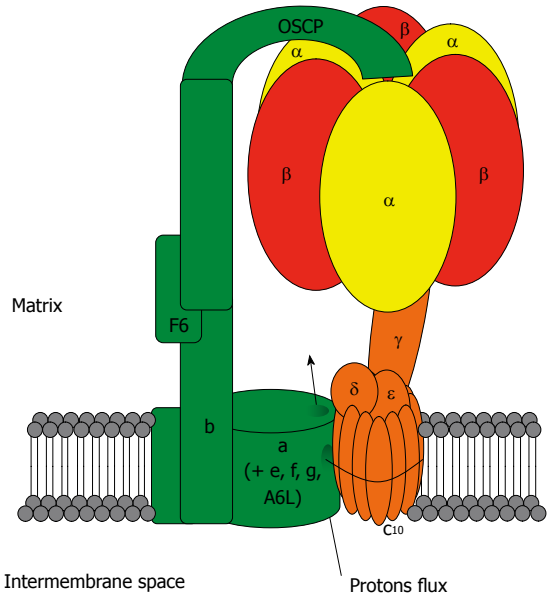

Figure 1 Mitochondrial ATP synthase. In eukaryotic cells, F_1F_o ATP synthase is a complex molecular motor composed of 16 unique subunits (α, β and c being present in multiple copies in the whole complex). It comprises the activity-bearing subunits (three αβ heterodimers), a rotor (in orange: subunits γ, δ, ε and the c ring) and a stator (in green: subunits a, e, f, g, A6L, b, F6, d and OSCP) which holds the αβ heterodimers. It is organized into two major domains: a soluble F_1 domain (α, β, γ, δ, ε) and a membrane-associated F_o domain. The F_1 domain bears the catalytic activity while the F_o domain is a proton channel. The F_o domain uses the proton gradient created by the four other complexes of the respiratory chain to drive the rotation of the central stalk, which will alternatively change the conformation of the three αβ heterodimers, leading to the synthesis of ATP from ADP and Pi. In the case of the eukaryotic ATP synthase, the translocation of 10 protons through the c ring will lead to a full turn, and the synthesis of 3 ATP molecules. In the absence of a proton gradient, or if the F_1 domain is isolated from the F_o domain, the enzyme behaves as an ATP hydrolase.

Table 1 Ecto-F_1-ATPase subunit detection in various cell types

Cells/tissues	Subunits	Methods	Ref.
K562, A549, Raji	β	B, FC, S	[38]
HUVEC	α, β, IF1	B, FC, CM	[35,39,40]
HepG2, IHH, Human hepatocytes	α, β	SPR, FC, CM	[30]
3T3-L1	α, β	B, CM	[41]
Jurkat	β	RP + MS	[42]
Rat hepatocytes	α, β, δ, γ, b, d, e, F6, OSCP	CM	[37]
HaCat, Human skin	β	RP + MS, CM	[43]
Daudi, RPMI-8226, U937, SK-NEP, G401, G402	α and/or β	FC	[31]
Awells, ST-Emo, HeLa, fibroblasts, Rma-S	α, β	B, CM, FC	[33]
Rat tonsils	β	PM	[44]
Neurons, neuroblastoma, astrocytoma	α	B, CM	[45]
Osteosarcoma	α, β, d	CM	[36]

Studies reporting a cell surface expression of ATP synthase subunits are summarized. The experimental approaches used in these studies are mentioned. B: Cell surface biotinylation; FC: Flow cytometry; S: Sequencing; CM: Confocal microscopy; SPR: Surface plasmon resonance (Biacore); RP + MS: Rafts purification and mass spectrometry; PM: Plasma membrane extraction. Cell lines/tissues are of human origin unless otherwise noted. K562: Erythroleukemia; A549: Lung adenocarcinoma; RPMI-8226: B myeloma; Raji, Daudi: Burkitt lymphomas; Jurkat: T lymphoma; HUVEC: Human umbilical vein endothelial cells; HepG2: Hepatocarcinoma; IHH: Immortalized human hepatocytes; 3T3-L1: Murine fibroblasts (differentiated into adipocytes); HaCat: Immortalized human keratinocytes; U937: Monocytic leukemia; SK-NEP, G401, G402: Renal cell carcinomas; Awells, ST-EMO: EBV-immortalized B cells (ST-EMO was derived from a major histocompatibility complex class I deficient patient); HeLa: Cervix carcinoma; Rma-S: Murine T lymphoma.

of the α and β subunits using some monoclonal reagents, probably through molecular hindrance. In a recent work, Mangiullo *et al*[34] described the presence of FoI-PVP (b subunit), γ and OSCP subunits at the cell surface of rat hepatocytes. The inhibitory protein IF_1 has also been shown to be present at the cell surface[35]. Recently, d and OSCP subunits were shown to be expressed on the surface of osteosarcoma cells[36]. In a number of studies, biochemical approaches have been used to confirm the presence of F_1-ATPase/ATP synthase in plasma membranes. Bae *et al*[37] have shown *via* a proteomics approach that multiple ATP synthase subunits are found in the lipid rafts of rat hepatocytes and $HepG_2$ cells, a human hepatocarcinoma cell line. F_1-ATPase components have been coprecipitated with cell surface proteins from hemopoietic tumors by Vantourout *et al*[33]. One could argue that pure plasma membrane preparations are extremely difficult to obtain and easily contaminated by membranes originating from different sub-cellular compartments. A very low amount of mitochondrial material could explain the presence of ATP synthase subunits in membrane preparations. Nevertheless, in some works using biochemical approaches[33,34] the absence of other mitochondrial proteins in samples has been carefully checked, ruling out a contamination by mitochondrial material. The observation of multiple components of F_1-ATPase by cytometry, and the identification of some of them by mass spectrometry and peptide sequencing[30,37,38], make very unlikely the hypothesis that ecto-F_1-ATPase detection could be due to cross-reactivity with other proteins bearing sequence similarities.

The presence of subunits other than α and β is also not completely unexpected. Indeed, since both these subunits do not have any membrane-anchoring domain, the cell surface expression of other subunits, especially from the F_o domain, would be required to allow such a localization of the complex.

To summarize, while definitive proof may still be lacking, it seems now highly probable that ecto-F_1-ATPase is a cell surface complex identical or closely related to the mitochondrial ATP synthase. The wide range of cellular types that have been shown to express ecto-F_1-ATPase (Table 1) certainly suggest that this ectopic expression is more likely to be a ubiquitous phenomenon rather than restricted to a few cell lines. Among all samples that we have analyzed for ecto-F_1-ATPase expression using different approaches, so far only one, namely 721.221 (an EBV-immortalized B cell line), seemed to not express ecto-F_1-ATPase, or at extremely low levels that are not detectable[33,46].

AN UNEXPECTED AND SO FAR UNEXPLAINED LOCALIZATION

While many proteins are now known to have multiple sub-cellular localizations, a cell surface expression of mitochondrial proteins is quite unusual and puzzling. To our knowledge, there is so far no experimental work precisely deciphering the mechanism used by ATP synthase to reach the plasma membrane (PM).

In our view, two main hypotheses are conceivable: (1) ATP synthase subunits are routed to the PM instead of the mitochondria. The concept of multiple localization of a given protein is quite established now and several mechanisms can be involved (see Karniely *et al*[47] for an extensive review). The first is that different mRNA isoforms of ATP synthase subunits could hold a cell-surface signal peptide rather than mitochondrial targeting signal. Bovine subunit c has been reported to have two isoforms (encoded by two different genes) with slightly different signal peptides[48]. However, to our knowledge, this is an isolated case so far, and there is no experimental evidence suggesting that these different peptides lead to different localizations. Another explanation is that the known signal peptides of ATP synthase subunits are ambiguous and could lead to a mitochondrial or cell surface expression. We have analyzed some of ATP synthase subunit leader peptides with the SignalP software[49] and some leader peptides of ATP synthase subunits may share some predicted similarities with PM-targeting sequences. Finally, some proteins use two targeting signals on the same polypeptide to reach different destinations, such as Catalase A in yeast[50]. This latter possibility seems unlikely since no PM signal can be identified in the sequences of ATP synthase subunits. Even if this first hypothesis cannot be definitely ruled out yet, it is in our opinion the less likely for a number of reasons. Firstly, it would imply that all subunits display ambiguous signals, or have different isoforms, and so far there is no formal proof of this. Secondly, two subunits (namely A6L and a) are encoded by the mitochondrial genome, and it seems unlikely that they would be targeted to the cell surface instead of staying in the mitochondria. Finally, the ATP synthase assembly factors would also have to be expressed elsewhere [such as the endoplasmic reticulum (ER)] to allow the expression of a complete and correctly assembled complex at the cell surface; and (2) The simpler and thus more tempting hypothesis is that once assembled into the mitochondria, ATP synthase then reaches the cell surface. As a direct rerouting of the whole complex *via* transporters is improbable in this case, given the size of ATP synthase (around 600 kDa and a dimension of 19 nm × 11 nm), it is suggested that the complex reaches the cell surface *via* vesicular transport or fusion of mitochondrial membranes with the PM.

In healthy cells, mitochondria form a dynamic network and constantly divide and fuse, a process which is believed to maintain the integrity and quality of the mitochondrial function and implicates several recently identified proteins such as mitofusins or Drp1[51,52]. A direct fusion of mitochondrial membranes with the PM, resulting in a cell surface expression of ATP synthase, seems difficult to imagine mostly because mitochondria have two membranes and ATP synthase is located in the inner one. Unless the fusion occurs between PM and mitochondrial contact sites, which are distinct structures playing an important role in the mitochondrial metabolism and apoptosis[53], this hypothesis is unlikely.

However, there are now several lines of evidence indicating that mitochondria communicate with other cellular compartments. A recent report by de Brito *et al*[54] has shown that mitofusin 2 is implicated in the interaction between ER and mitochondria, allowing the exchange of Ca^{2+} between those organelles. In another recent report, Neuspiel *et al*[55] identified a new outer membrane mitochondria-anchored protein ligase named MAPL (mitochondria-anchored protein ligase) and characterized the sorting of MAPL into mitochondria-derived vesicles which then fuse with peroxisomes. Interestingly, Neuspiel *et al*[55] have also identified distinct vesicles containing another mitochondrial protein, Tom20 (translocase of outer membrane 20, a member of the complex importing proteins encoded by the nuclear genome into mitochondria). These Tom20-containing vesicles do not fuse with peroxisomes and their fate is currently under investigation. In addition, Soltys *et al*[56] have shown that Hsp60, a mitochondrial chaperone, can be found in vesicles that are distinct from major organelles and may communicate with the PM. Interestingly, Hsp60 has also been shown to be expressed at the cell surface[57,58]. In both cases, these uncharacterized vesicles could thus be part of a shuttle system between mitochondria and PM, allowing the cell surface expression of selected mitochondrial proteins. In this context, Rab32 or endophilin B1, involved in mitochondrial dynamics and morphology, respectively[59,60], might also be involved in the biogenesis of mitochondria-derived vesicles and the trafficking towards the cell surface, raising the question of the existence of a new intracellular pathway from mitochondria to cell surface responsible for the targeting of the F_1-ATPase.

A recent report has shown that a deficiency in palmitoyl protein thioesterase 1 (Ppt1), responsible for the infantile neuronal ceroid lipofuscinosis syndrome, was linked with an increase in ecto-F_1-ATPase expression in neurons[61]. This suggests that Ppt1 might be involved in the regulation of the subcellular localization of ATP synthase. In addition, Schmidt *et al*[45] have immunoprecipitated F_1-ATPase α chain from the synaptic membranes of murine neural cells. Strikingly, they reported that this subunit was at least in part N-glycosylated and that this post-translational modification was abrogated by treating cells with the Golgi-disrupting drug brefeldin A. They also identified a unique N-glycosylation site which is absent in the human α-subunit sequence. This suggests that at least some components of the mitochondrial F_1-ATPase can transit through the Golgi apparatus, although the mechanism is still enigmatic.

Another question regarding the cell surface expres-

sion of ATP synthase is its sub-localization at the PM. Some of its subunits, as well as a few other mitochondrial proteins, have often been found in lipid rafts in proteomic studies[37,42]. However, a recent report by Zheng *et al*[62] suggested that mitochondrial proteins, including ATP synthase subunits, were the best contaminants of raft preparations, mostly based on the fact that they were resistant to cholesterol depletion by methyl-β-cyclodextrin, whereas raft-resident proteins usually are sensitive to this treatment. Detection of ecto-F_1-ATPase by confocal microscopy usually reveals a patchy pattern[30,33], which is reminiscent of several proteins residing in lipid rafts. We also have experimental evidence showing at least a partial co-localization of ecto-F_1-ATPase subunits with the raft markers cholera toxin (unpublished data). This may indicate that the presence of ecto-F_1-ATPase in lipid rafts is not exclusive. It may also vary with the cell line or conditions of culture. Similarly, its detection in isolated rafts may depend on raft purification procedures. Thus, more extensive studies are required to definitively answer this question.

A NEW LOCALIZATION FOR MANY NEW ROLES: ECTO-F_1-ATPASE AS A MOONLIGHTING PROTEIN

The term "moonlighting protein" was introduced in 1999 by Jeffery[63] to describe proteins that could perform several unrelated roles. Their different functions can depend on different localizations, expression in different cell lines, ligand concentration, or on many other mechanisms.

ATP synthase appears as a typical example of a moonlighting protein. Its α subunit, for instance, has been shown to be part of a complex importing cytosolic tRNAs into mitochondria in *Leishmania*[64]. Subunit F6 has also been shown to be present in plasma and involved in hypertension through its binding on ecto-F_1-ATPase expressed on endothelial cells[65]. It is also now clear that the whole complex expressed at the cell surface is implicated in many physiological roles, depending on the ligand and the cell type (Table 2). So far, the most documented roles of ecto-F_1-ATPase are its involvement in HDL endocytosis by hepatocytes, endothelial cell survival, and as an immunological ligand for a subset of non-conventional T lymphocytes (Figure 2).

Hepatic HDL-cholesterol uptake

Our work on high density lipoproteins (HDL) has identified ecto-F_1-ATPase as the receptor of apolipoprotein A-I (apoA-I), the major protein component of HDL. Indeed, binding of HDL on hepatocyte membranes displayed two binding sites with high and low affinities[68]. A high-affinity receptor for lipid-free apoA-I was purified by Biacore and identified as the β-chain of ATP synthase. As binding of lipid-free apoA-I to ecto-F_1-ATPase activated endocytosis of whole and fully lipidated HDL by the low-affinity binding sites, we have hypothesized that

Table 2 Ligands and roles of Ecto-F_1-ATPase

Cells/tissues	Ligands	Proposed roles	Ref.
K562, A549, Raji	?	NK/LAK-mediated tumor cell lysis	[38]
HUVEC	Angiostatin	Cell survival through ATP production	[40,60,66]
	HDL/apoA-I	Cell survival through purinergic receptor activation	
	FC6	Control of blood pressure	
Hepatocytes	HDL/apoA-I	HDL endocytosis	[30]
3T3-L1, HaCat	?	Cell survival	[41,43]
Tumor cells	Vγ9/Vδ2 TCR, apoA-I, MHC- I	Tumor cell recognition by Vγ9/Vδ2 T cells/presentation of phosphoantigens	[31,33,46,67]
Tonsils (mouse)	Enterostatin	Food intake regulation	[44]
Neurons	APP, Amyloid β-peptide	Synaptic plasticity regulation	[45]

Major roles of Ecto-F_1-ATPase described in the literature, as well as ligands involved, are summarized here. MHC- I : Major histocompatibility complex class I ; NK: Natural killer; LAK: Lymphokine activated killer; HDL: High density lipoprotein; apoA-I: Apolipoprotein A-I; FC6: Coupling factor 6; ATP: Adenosine triphosphate; APP: Amyloid precursor protein. Cells/tissues are of human origin unless otherwise noted. K562: Erythroleukemia; A549: Lung adenocarcinoma; Raji: Burkitt's lymphoma; HUVEC: Human umbilical vein endothelial cells; 3T3-L1: Murine fibroblasts (differentiated into adipocytes); HaCat: Immortalized human keratinocytes.

enzymatic activity of ecto-F_1-ATPase might play a role in this stimulatory process. Indeed, direct addition of ADP increased HDL endocytosis. We showed that binding of apoA-I on ecto-F_1-ATPase increased its hydrolase activity and led to an enhanced HDL endocytosis. Later, we identified the purinergic $P2Y_{13}$ receptor as the target of ADP produced by ecto-F_1-ATPase[69] and we have shown recently that the small GTPase RhoA and its effector ROCK I were activated downstream of $P2Y_{13}$[70]. We could demonstrate that this F_1-ATPase/$P2Y_{13}$-mediated HDL endocytosis pathway is controlled through cell surface adenylate kinase (AK) activity which consumes ADP generated upon activation of ecto-F_1-ATPase by apoA-I and therefore constitutively inhibits $P2Y_{13}$ and subsequent hepatic HDL endocytosis[71]. In addition, niacin (vitamin B3), which is well-known to increase plasma HDL levels in humans, has recently been shown to inhibit cell surface expression of ecto-F_1-ATPase in hepatocytes[72]. This study thus suggests the implication of ecto-F_1-ATPase in HDL metabolism.

Our recent work has confirmed the role of the $P2Y_{13}$ ADP-receptor in HDL-mediated reverse cholesterol transport (RCT) *in vivo*[73]. We showed that $P2Y_{13}$-deficient mice exhibited a decrease in hepatic HDL cholesterol uptake, hepatic cholesterol content, and biliary cholesterol output, although their plasma HDL and other lipid levels were normal. These changes translated into a substantial decrease in the rate of macrophage-to-feces RCT. Therefore, hallmark features of RCT are impaired in $P2Y_{13}$-deficient mice. Furthermore, cangrelor, a partial agonist of $P2Y_{13}$, stimulated hepatic HDL uptake and biliary lipid

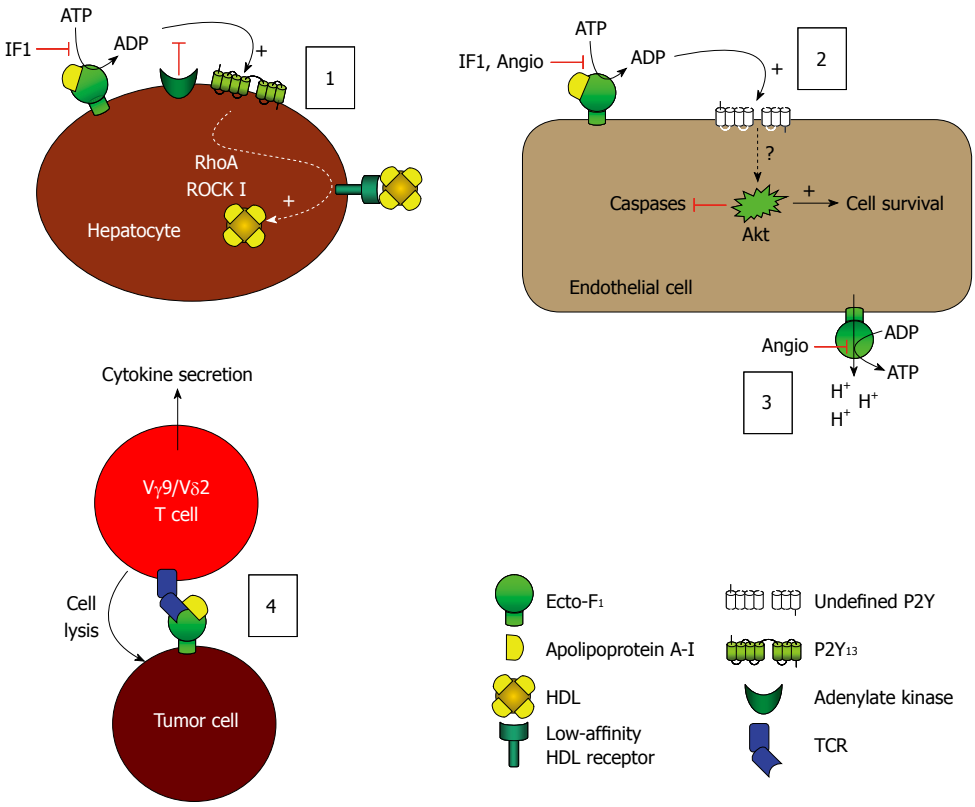

Figure 2 Model of the leading hypotheses regarding the distinct cellular events mediated by ecto-F$_1$-ATPase. (1) Model of F$_1$-ATPase/P2Y$_{13}$-mediated high density lipoproteins (HDL) endocytosis by hepatocytes. ApoA-I binding to ecto-F$_1$-ATPase stimulates extracellular ATP hydrolysis, and the ADP generated selectively activates the nucleotide receptor P2Y$_{13}$ and subsequent RhoA/ROCK I signaling that controls holo-HDL particle endocytosis. Conversely IF$_1$ inhibitor which inhibits ecto-F$_1$-ATPase activity or adenylate kinase (AK) activity which consumes ADP generated upon activation of ecto-F$_1$-ATPase, downregulates holo-HDL particle endocytosis. Thus, HDL endocytosis depends on the balance between the AK activity that removes extracellular ADP and the ecto-F$_1$-ATPase that synthesizes ADP. Activation of ADP synthesis by apoA-I unbalances the pathway and increases HDL endocytosis when required; (2), (3): Model of F$_1$-ATPase-mediated endothelial cell protection. (2): Hydrolytic activity of ecto-F$_1$-ATPase expressed on endothelial cells can be increased by apoA-I, stimulating cell proliferation. Conversely, inhibition by IF$_1$, angiostatin increases apoptosis and blocks proliferation both at the basal level and after stimulation by apoA-I. The downstream receptors and intracellular signaling are still not completely characterized, but ADP-sensitive receptors could be involved; (3): The anti-angiogenic activity of angiostatin is attributed to its ability to inhibit ATP production by ecto-F$_1$-ATPase, thus eliminating a significant source of energy and reducing proliferation. It is also proposed that this inhibition prevents the extrusion of protons by ecto-F$_1$-ATPase, thus lowering intracellular pH and hampering cell survival; and (4) Model of F$_1$-ATPase-mediated tumor cell recognition by Vγ9/Vδ2 T lymphocytes. Ecto-F$_1$-ATPase is found at the surface of tumor cells and plays a role in the presentation of adenylated derivatives of small phosphoantigens, which are classical inducers of cell lysis by Vγ9/Vδ2 T lymphocytes. Recognition of ecto-F$_1$-ATPase by the γ9/δ2 TCR is stimulated by apoA-I and requires a low expression of class I HLA-antigens, a situation commonly found in tumor cells.

secretions in normal mice and in mice with a targeted deletion of scavenger receptor class B type I (SR-BI) in liver [hypomSR-BI-knockout(liver)] but had no effect in P2Y$_{13}$ knockout mice, which indicate that the P2Y$_{13}$-mediated HDL uptake pathway is independent of SR-BI-mediated HDL selective cholesteryl ester uptake. Pharmacological activation of the P2Y$_{13}$ receptor might thus represent a new therapeutic approach to improve HDL-cholesterol removal and/or turnover, which could be an alternative way to prevent and treat atherosclerosis.

Endothelial cell survival

Ecto-F$_1$-ATPase has also been characterized by Moser *et al*[32] as the receptor of angiostatin, an inhibitor of angiogenesis originating from the proteolysis of plasminogen. Later work established that ecto-F$_1$-ATPase was able to synthesize ATP at the cell surface of endothelial cells. This ATP production would facilitate the proliferation of these cells, especially under hypoxic conditions which are known to impair cell survival through the inhibition of oxidative phosphorylation. The anti-angiogenic activity of angiostatin is attributed to its ability to inhibit ATP production by ecto-F$_1$-ATPase, thus eliminating a significant source of energy and reducing proliferation. It was also proposed that this inhibition prevents the extrusion of protons by ecto-F$_1$-ATPase, thus lowering intracellular pH and hampering cell survival[39,66].

It is well known that HDL and apoA-I have a protective effect against the development of endothelial dysfunction, one of the first events in the pathogenesis of atherosclerosis, by enhancing endothelial cell survival. The mechanisms mediating this atheroprotection are not well understood, but interactions between HDL and apoA-I with cell surface receptors have been proposed to be essential contributors. Considering that both HDL and apoA-I bind ecto-F$_1$-ATPase, we have evaluated the hypothesis that the protective effects of apoA-I on endothelial cells are dependent on ecto-F$_1$-ATPase activity. This hypothesis

is also supported by the anti-angiogenic effect of angiostatin.

As shown for hepatocytes[30], the hydrolytic activity of ecto-F_1-ATPase expressed on endothelial cells can be increased by apoA-I, stimulating cell proliferation and inhibiting apoptosis in a dose-dependent manner[40]. Conversely, inhibition by IF_1, angiostatin or antibodies directed against the β-chain of ecto-F_1-ATPase increases apoptosis and blocks proliferation both at the basal level and after stimulation by apoA-I. These results are in favor of a direct effect of the ecto-F_1-ATPase activity on endothelial cell survival through extracellular ADP production. The downstream receptors and intracellular signaling are still not completely characterized, but ADP-sensitive receptors could be involved.

This pathway thus provides a new mechanism of action of apoA-I in endothelial protection distinct from other HDL-mediated protective effects previously described[74]. Thus, depending on the cell type, distinct pathways seem to be involved downstream of F_1-ATPase activation by apoA-I and induce distinct cellular events such as stimulation of HDL uptake by hepatocytes or endothelial cell survival.

Tumor cell recognition

Vγ9/Vδ2 T lymphocytes are a non-conventional subpopulation of cytotoxic T cells unique to humans and higher primates. These cells are known to participate in the immune response against various intracellular pathogens as well as tumor cells, through the recognition of small alkyl diphosphate molecules termed phosphoantigens[75,76]. Experimental evidence suggests that recognition of these antigens requires a cell-cell contact, and thus may depend on a cell surface presentation molecule expressed on target cells but distinct from classical antigen presentation molecules such as major histocompatibility antigens and CD1[77]. This is confirmed by recent data showing that the recognition of phosphoantigens by a soluble recombinant Vγ9/Vδ2 T cell receptor (TCR) on the cell surface is dependent on a trypsin-sensitive structure[78]. We have initially identified apoA-I as an enhancer of the Vγ9/Vδ2 T cell response, and shown that these cells can actually recognize F_1-ATPase on the surface of tumor cells through their TCR[31]. We have also shown that ecto-F_1-ATPase interacts with MHC- I molecules on the cell surface of various cell lines, leading to a masking of epitopes which prevents the detection of ecto-F_1-ATPase by commercially available antibodies[33]. This suggests that cell surface expression of ATP synthase cannot be formally ruled out simply because it is not detected by flow cytometry or confocal microscopy. It is also of particular interest for the physiology of Vγ9/Vδ2 cells because, like natural killer cells, they express inhibitory receptors which bind MHC antigens and modulate TCR signaling and lymphocyte activation[79].

Our latest work has focused on the study of a novel ATP analog, ApppI [triphosphoric acid 1-adenosin-5'-yl ester 3-(3-methylbut-3-enyl) ester] in which the γ-phosphate of ATP is esterified with isopentenol. This metabolite has recently been identified in cells treated with aminobisphosphonate drugs which are known to potently sensitize cells to Vγ9/Vδ2 T cell cytotoxicity. As it is an ATP analog and has a structure reminiscent of nucleotidic phosphoantigens naturally produced by some bacteria, we thus used this molecule to explore the potential role of ecto-F_1-ATPase in phosphoantigen presentation to Vγ9/Vδ2 T cells. We found that classical targets of Vγ9/Vδ2 T cells can spontaneously produce ApppI[67]. Furthermore, it stably binds to purified ATP synthase and ApppI-loaded ATP-synthase efficiently activates Vγ9/Vδ2 T cells *in vitro*. Our current model proposes that phosphoantigens produced by tumor cells or intracellular pathogens are converted to nucleotidic derivatives, loaded onto ATP synthase, and presented to Vγ9/Vδ2 T cells when the complex is exported to the cell surface[46].

As ATP synthase is present at the cell surface of a number of normal cells, the potential self-reactivity of Vγ9/Vδ2 T cells is probably tightly controlled by the interaction between ecto-F_1-ATPase and MHC- I , as well as by phosphoantigen production by the target cell. Moreover, these observations suggest another beneficial role for apoA-I; as an immunomodulator in anti-tumor responses.

Since ecto-F_1-ATPase has already been detected in a wide variety of cells, with many different ligands, there is no doubt that it is probably implicated in many other cellular processes. In many instances, these roles seem to rely on the enzymatic activity of ATP synthase. While its hydrolase activity is undoubtedly possible since it does not need a proton flux nor requires a fully assembled F_1F_o complex, there are still conflicting reports regarding the ability of the cell surface complex to synthesize ATP.

TO SYNTHESIZE OR NOT TO SYNTHESIZE, THAT IS THE QUESTION

The first work showing that ecto-F_1-ATPase can synthesize ATP from ADP and Pi was reported in endothelial cells[39] and showed that angiostatin was able to inhibit both the synthase and hydrolase activities of ATP synthase. This was shown by bioluminescence measurement of ATP and a radioactive thin layer chromatography (TLC) assay using [^{3}H]ADP and ^{32}Pi. In later work, the authors have shown that ATP production was enhanced when extracellular pH was low, hypothesizing that concomitantly with ATP synthesis, ecto-F_1-ATPase would extrude protons from the cytoplasm. It was also proposed that this process improves the resistance of tumor and endothelial cells to low pH. Similarly, it would also improve cell survival in hypoxic conditions, a hallmark of tumoral microenvironment. Since then, a number of independent studies have reported a synthase activity in many different cell types, including keratinocytes, adipocytes, or hepatocytes, among others[34,43,41]. Most of these works have used a bioluminescence assay to measure the production of ATP after addition of ADP in the culture media and underlined

the importance of ecto-F_1-ATPase in this production through the use of oligomycin, a well known inhibitor of mitochondrial ATP synthase.

However, whether or not ecto-F_1-ATPase can synthesize ATP is still debated, as there are several conflicting reports. Several studies by our group and others seem to completely rule out a potential contribution of ecto-F_1-ATPase to extracellular conversion of ADP to ATP. Yegutkin *et al*[80] have shown that ATP production after addition of ADP to endothelial cells was not increased in the presence of Pi, which should be the case if ecto-F_1-ATPase was able to synthesize ATP. They concluded that ADP phosphorylation was mostly due to cell surface adenylate kinase (AK, which produces ATP and AMP from two ADP molecules) and/or nucleotide diphosphokinase (NDPK, which transfers terminal phosphate from a nucleotide triphosphate to a nucleotide diphosphate) enzymatic activities. This is in agreement with our results in hepatocytes as well as in endothelial cells. Indeed, we have observed that addition of [^{3}H]ADP and ^{32}Pi to the cell medium does not lead to production of dual-labeled ATP, but only [^{3}H]ATP[30,40,71], indicating that free inorganic phosphate is not used for ATP synthesis and excluding a role for ATP synthase in the process of ATP generation.

Most of the studies reporting a synthase activity have shown that oligomycin decreased extracellular ATP production after addition of ADP to culture media, thus suggesting that ecto-F_1-ATPase was indeed able to synthesize ATP. However, in our hands, oligomycin had no effect on ATP synthesis on the cell surface of human hepatocytes after addition of ADP[71]. The reason for these discrepancies is not clear. One should note that oligomycin has been shown to inhibit other enzymes, such as the non-gastric H,K-ATPase[81]. Thus it does not appear to be a strictly specific inhibitor of ATP synthase/F_1-ATPase and could act on other nucleotide-converting enzymes. One cannot exclude also that the activity of ecto-F_1-ATPase depends on particular experimental settings (culture conditions, cell type) and on the metabolic status of the cells. Nevertheless, in mitochondria, ATP production by ATP synthase is strictly dependent on the electrochemical proton gradient between the two sides of the inner mitochondrial membrane. This gives the chemical energy required for ATP synthesis. Whether a strong proton flux can occur at the cell surface and lead to ATP synthesis by ecto-F_1-ATPase is not certain and in the case of extracellular acidosis, the proton gradient would not be favorable for ATP synthesis. Mangiullo *et al*[34] have recently shown that ecto-F_1-ATPase was active in ATP synthesis and that it was correlated to an oligomycin-sensitive proton flux from the cytoplasm to the extracellular medium in the case of intracellular acidosis. Although, as discussed above, oligomycin might inhibit other proton pumps, this suggests that synthesis might occur in particular metabolic settings. It remains to be demonstrated whether these experimental conditions are relevant to physiological situations. Thus, the actual role of ecto-F_1-ATPase in proton transport across the PM remains arguable.

Accordingly, the synthase activity of ecto-F_1-ATPase is still an open issue, and there certainly is a need for reassessment of results obtained with the various techniques assessing ATP synthase activity as well as with the different inhibitors.

CONCLUSION

Over the past few years, data originating from many different groups have confirmed the cell surface expression of this mitochondrial enzyme. While this ectopic expression is now certainly widely accepted, there is still a need for a definitive characterization of its enzymatic activity, as well as new insights into the mechanism of its cell surface targeting.

In our opinion, the synthase activity of ecto-F_1-ATPase is still heavily challenged on both experimental and theoretical aspects. It is an important issue that requires additional work and may depend on the development of novel techniques which would be more specific and sensitive than those currently used. Nevertheless, the monitoring of dual-labeled ATP production from [^{3}H]ADP and ^{32}Pi by high-performance liquid chromatography (HPLC) is probably so far the most reliable method to determine whether ecto-F_1-ATPase is active in ATP synthesis, since ATP synthase is the only known enzyme able to generate ATP directly from ADP and inorganic free phosphate. Therefore, it should be the method of choice to study the enzymatic properties of ecto-F_1-ATPase.

Understanding how ecto-F_1-ATPase reaches the cell surface is a challenging but extremely important point. As the use of siRNAs targeting ATP synthase subunits is hardly conceivable since it will undoubtedly rapidly lead to cell death, inhibiting its cell surface expression might help to better characterize its roles. Further studies are definitely required to decipher this mechanism.

ATP synthase is a fascinating molecular machine and a perfect example of a nanomotor. It has been one of the most studied enzymes over the past 40 years and garnered Professor Boyer PD and Sir Walker JE the Nobel Prize in Chemistry in 1997 for their outstanding work on the comprehension of its structure and the ATP synthesis mechanism[82-84]. Its central role in energy production is fundamental, an active person synthesizing their own weight in ATP every day. This essential role is now enhanced by its new implication in various important cellular processes, achieved through this ectopic localization and interactions with diverse ligands. We are only beginning to decipher these new functions.

Abstract

Biliary cholesterol secretion is a process important for 2 major disease complexes, atherosclerotic cardiovascular disease and cholesterol gallstone disease. With respect to cardiovascular disease, biliary cholesterol secretion is regarded as the final step for the elimination of cholesterol originating from cholesterol-laden macrophage foam cells in the vessel wall in a pathway named reverse cholesterol transport. On the other hand, cholesterol hypersecretion into the bile is considered the main pathophysiological determinant of cholesterol gallstone formation. This review summarizes current knowledge on the origins of cholesterol secreted into the bile as well as the relevant processes and transporters involved. Next to the established ATP-binding cassette (ABC) transporters mediating the biliary secretion of bile acids (ABCB11), phospholipids (ABCB4) and cholesterol (ABCG5/G8), special attention is given to emerging proteins that modulate or mediate biliary cholesterol secretion. In this regard, the potential impact of the phosphatidylserine flippase ATPase class I type 8B member 1, the Niemann Pick C1-like protein 1 that mediates cholesterol absorption and the high density lipoprotein cholesterol uptake receptor, scavenger receptor class B type I, is discussed.

Key words: Cholesterol; Bile; Gallstone; Atherosclerosis; Reverse cholesterol transport; Lipoproteins; High density lipoprotein; Scavenger receptor class B type I

INTRODUCTION: WHAT IS THE IMPORTANCE OF BILIARY CHOLESTEROL SECRETION?

The liver plays a central role in cholesterol metabolism (Figure 1). Hepatocytes not only express a number of different lipoprotein receptors including low density lipoprotein receptor (LDLR), LDLR-related protein (LRP) and scavenger receptor class B type I (SR-BI), that enable them to take up cholesterol from virtually all lipoprotein subclasses, but cholesterol is also synthesized *de novo* within the liver in a regulated fashion[1]. In addition to these input pathways into the hepatic cholesterol pool, the liver is equipped to actively secrete cholesterol *via* 2 different routes: (1) within triglyceride-rich very low density lipoproteins (VLDL)[2,3], thereby supplying peripheral cells

with fatty acids, fat soluble vitamins and cholesterol; (2) by secretion into the bile either directly as free cholesterol or after conversion into bile acids, thereby providing a means of irreversible elimination of cholesterol from the body *via* the feces[4,5]. In general, the different hepatic cholesterol fluxes are interrelated, however, some are also markedly separated, as will be discussed later in this review.

Biliary cholesterol secretion itself is directly linked to 2 major disease complexes with a high relevance for health care systems worldwide, namely atherosclerotic cardiovascular disease (CVD) and gallstone disease. In atherosclerotic CVD, biliary cholesterol secretion is considered the final step in the completion of the reverse cholesterol transport (RCT) pathway[6,7]. The term RCT comprises the transport of peripheral cholesterol back to the liver for excretion into bile, most importantly cholesterol accumulating within macrophage foam cells in atherosclerotic lesions[8]. For RCT an enhanced biliary secretion of cholesterol originating from peripheral pools relevant for CVD is desirable. On the other hand, increased biliary cholesterol secretion is related to biliary cholesterol supersaturation, which is an important determinant for the formation of cholesterol gallstones that constitute more than 90% of all gallstones[9,10]. Notably, both CVD[11,12] and gallstone disease[13] also have a strong inflammatory component that plays an important role in the pathogenesis of these diseases. However, an in-depth understanding of the metabolic processes and transporters involved in the regulation of biliary cholesterol secretion is important and might conceivably reveal relevant targets for the treatment of CVD as well as cholesterol gallstone disease.

WHAT IS THE ORIGIN OF CHOLESTEROL SECRETED INTO BILE?

The most relevant source of cholesterol secreted into the bile is cholesterol derived from plasma lipoproteins, and a less relevant source is cholesterol originating from *de novo* synthesis or hydrolysis of stored cholesteryl ester[14]. High density lipoprotein (HDL) appears to be the preferential contributor for cholesterol secreted into bile[15]. In humans with a bile fistula, cholesterol originating from HDL appeared more rapidly in bile compared with LDL cholesterol[16]. Additional evidence for a more prominent role of HDL over LDL came from experiments demonstrating that biliary cholesterol secretion remained essentially unchanged when plasma LDL cholesterol levels specifically were reduced by 26% by means of LDL apheresis[17]. In contrast, reduction in plasma LDL cholesterol resulted in a consecutive decrease in biliary bile acid secretion[17], thereby lending further experimental evidence to older literature suggesting a metabolic compartmentalization of hepatic cholesterol pools with regard to bile acid synthesis *vs* direct biliary secretion[18,19]. However, definitive studies exploring the underlying metabolic pathways are still lacking.

It is, however, important to note, that modulation of plasma HDL cholesterol levels does not influence mass biliary cholesterol secretion, since ATP-binding cassette transporter A1 (ABCA1) knockout mice[20] as well as apolipoprotein-A-I (apoA-I) knockout mice[21,22] display unaltered biliary cholesterol secretion rates. These data indicate that specific intrahepatic metabolic and transport processes are most relevant and rate-limiting for biliary secretion of cholesterol.

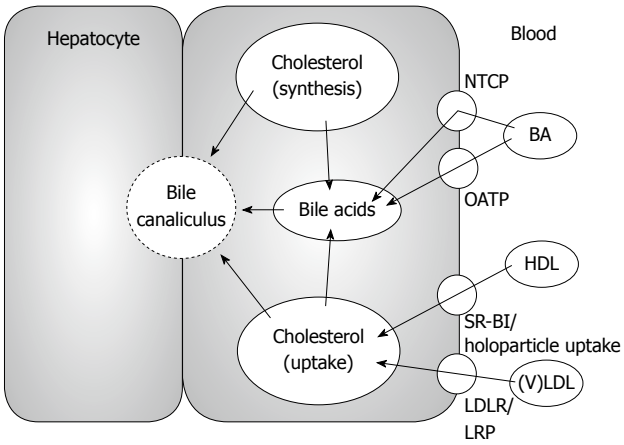

Figure 1 Overview of hepatic cholesterol metabolism in relation to biliary sterol secretion. HDL: High-density lipoprotein; BA: Bile acid; LDLR: Low-density lipoprotein receptor; LRP: LDLR-related protein; NTCP: Na^+ taurocholate co-transporting peptide; OATP: Organic anion transport polypeptides; SR-BI: Scavenger receptor class B type Ⅰ; (V)LDL: (Very) low-density lipoprotein.

HOW DOES CHOLESTEROL ORIGINATING FROM LIPOPROTEINS OR INTRACELLULAR SYNTHESIS REACH THE CANALICULAR MEMBRANE?

The hepatocyte is a polarized cell with a basolateral (sinusoidal) and an apical (canalicular) plasma membrane. Uptake of cholesterol from the plasma compartment occurs on the basolateral site (Figure 1), while biliary cholesterol secretion is an apical process (Figure 2). Hepatic cholesterol synthesis is carried out intracellularly. This polarization implies that a means of transport must exist for exogenous as well as endogenously synthesized cholesterol to reach the site where the biliary secretion process takes place.

Of note, cholesterol is also used for the synthesis of bile acids, and a number of factors modulating bile acid synthesis impact on hepatic cholesterol homeostasis. However, the regulation of bile acid synthesis will not be discussed, we refer to recent comprehensive reviews covering this topic[23,24].

The detailed mechanisms of intracellular cholesterol trafficking in hepatocytes are not understood thus far, especially how these relate to biliary cholesterol secretion. However, a few known transport proteins have been studied in more detail to test the effect of gain- or loss-of-function manipulations on biliary cholesterol secretion.

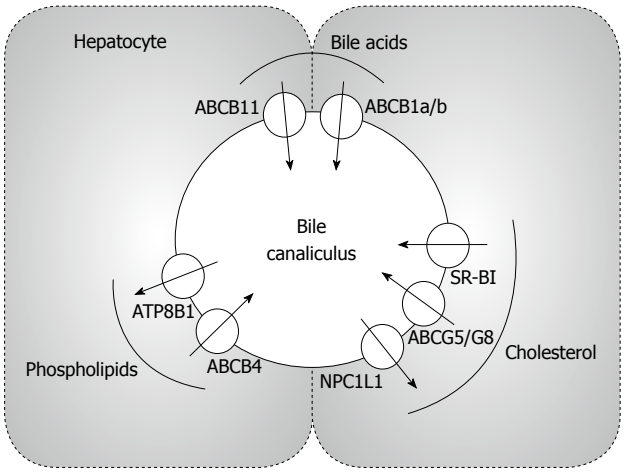

Figure 2 Overview of canalicular transporters/proteins that are involved in biliary bile acid, cholesterol and phospholipid secretion. ABC: ATP-binding cassette transporter; ATP8B1: ATPase class Ⅰ type 8B member 1; SR-BI: Scavenger receptor class B type Ⅰ; NPC1L1: Niemann-Pick C1-like protein 1.

A prominent example of such a protein is the Niemann-Pick type C protein 1 (NPC1) that plays a role in the intracellular trafficking of lipoprotein-derived cholesterol[25,26]. Specifically, NPC1 is involved in moving free cholesterol from the late endosomal/lysosomal compartment to the cytosol[25,26]. On a chow diet, mice lacking NPC1 expression had 37% higher biliary cholesterol secretion rates compared with controls[27]. However, when fed a 2% cholesterol-containing diet, biliary cholesterol secretion was significantly decreased in NPC1 knockout mice, while it increased 3.7-fold in wild-type controls[27]. These results indicated that NPC1 may become critical under conditions of high cholesterol intake. In turn, hepatic overexpression of NPC1 increased biliary cholesterol secretion by approximately 2-fold in chow-fed wild-type and high cholesterol diet-fed NPC1 knockout mice. However, no effect was observed in wild-type mice fed a 2% cholesterol diet[27]. The interpretation of this latter result is not straightforward, but other cholesterol metabolism pathways are also affected by NPC1, and changes in hepatic cholesterol content may play an additional role in explaining the observed phenotypes. Although more work is required to provide a detailed understanding of the role of NPC1, the presently available studies indicate that NPC1 is important in regulating the availability of cholesterol at the canalicular membrane for the biliary secretion process. Also NPC2, which plays a very similar role in intracellular cholesterol trafficking[28], is expressed in liver, is detectable in bile, and may be involved in the transport of cholesterol destined for biliary secretion. However, thus far no mechanistic studies have been performed, but a significant increase in hepatic NPC2 expression in gallstone-susceptible *vs* gallstone-resistant mouse strains has been reported[29]. Also the expression of another carrier protein, the sterol carrier protein-2 (SCP2), impacts biliary cholesterol secretion, with SCP2 overexpression increasing biliary secretion of cholesterol[30,31] and decreased SCP2 expression having the opposite effect[32]. Members of the steroidogenic acute regulatory (StAR) protein family of cholesterol transport molecules may also represent candidates to influence biliary cholesterol secretion[33,34]. However, thus far it has only been shown that StARD1 overexpression increases bile acid synthesis[35], while the absence of StARD3 in knockout mice had no impact on biliary sterol secretion[36]. In addition to intracellular cholesterol transport proteins, enzymes modulating the amount of free cholesterol present within a hepatocyte could also be expected to impact biliary cholesterol secretion. While this was shown to be the case for the neutral cholesteryl ester hydrolase[37], decreasing ACAT2 expression had no effect on biliary cholesterol output[38].

WHICH TRANSPORTERS ARE INVOLVED IN BILIARY CHOLESTEROL SECRETION?

On the apical membrane several transporters are directly involved in the biliary cholesterol secretion process. Transporter expression and activity is regulated by transcriptional as well as posttranscriptional mechanisms. Important transcriptional regulators are the nuclear hormone receptors liver X receptor (LXR; 2 isoforms LXRα, NR1H3, and LXRβ, NR1H2) and farnesoid X receptor (FXR, NR1H4), among others. For the specifics of LXR- and FXR-mediated gene regulation we refer to recent articles dealing with these topics[23,39-41]. In general, LXR is a nuclear receptor activated by oxysterols and functions as a sterol sensor exerting control on cholesterol metabolism[39,40]. As a general scheme, LXR activation stimulates metabolic processes favoring cholesterol elimination from the body, e.g. by increasing biliary cholesterol secretion *via* increased expression of ABCG5/G8[42] (see below) or by increasing the conversion of cholesterol to bile acids *via* increased expression of the cholesterol 7α-hydroxylase gene, at least in rodents[43].

On the other hand, FXR is the nuclear receptor activated by bile acids and orchestrates an adaptive response of the hepatocyte to altered bile acid levels[23,41]. In cholestatic conditions, FXR induces a downregulation of bile acid synthesis[23], a reduction in bile acid uptake into hepatocytes by decreasing the expression of the cellular uptake receptors[23] and an increased biliary secretion of bile acids by increasing the expression of specific transporters such as ABCB11[44] (see below).

In general, biliary bile acid secretion is the main driving force for the secretion of phospholipids and cholesterol[45]. Infusion of bile acids results in a dose-dependent increase in biliary cholesterol secretion[46]. However, cholesterol secretion into the bile also critically depends on functional biliary phospholipid secretion which is required for the formation of mixed micelles[46]. This is evidenced by the Abcb4 knockout mouse, that in the absence of this key biliary phospholipid transporter almost completely lacks biliary cholesterol secretion[47,48]. The following transporters are specifically involved in these processes:

ABCB4

ABCB4 has historically been named multi-drug resistance P-glycoprotein 2 (MDR2). ABCB4 functions as a phosphatidylcholine (PC) flippase translocating PC from the inner to the outer leaflet of the canalicular membrane[45]. Biliary cholesterol secretion is fully dependent on the functionality of ABCB4 and thereby biliary phospholipid secretion. In Abcb4-deficient animals, biliary cholesterol secretion is virtually absent[47,48]. Furthermore, PC decreases the toxic effects of bile acids on the canalicular membrane, and Abcb4 knockout mice as well as patients lacking this transporter develop a progressive liver disease[49,50].

ATPase class I type 8B member 1

ATPase class I type 8B member 1 (ATP8B1) is a P-type ATPase that flips phosphatidylserine (PS) from the outer to the inner leaflet of the canalicular membrane resulting in a reduction in the PS content and a consecutive increase in the sphingomyelin content of the outer canalicular leaflet[51,52]. In humans, mutations in *ATP8B1* cause severe chronic or periodic cholestatic liver disease[53,54]. A mutation resulting in severe liver disease is the glycine to valine substitution at amino acid 308 (G308V)[54]. In mice carrying the $Atp8b1^{G308V/G308V}$ mutation Atp8b1 is almost completely absent, which causes enhanced biliary excretion of PS and also cholesterol, mainly due to decreased rigidity of the outer canalicular leaflet (see below)[52,55].

ABCB11

ABCB11 is classically referred to as the bile salt export pump (BSEP; also known as sister of P-glycoprotein) and is mediating biliary secretion of bile acids[44,56]. A 2-fold increase in ABCB11 expression in transgenic mice resulted in increased biliary output of bile acids[57]. Notably, expression of other biliary transporters remained unaltered providing additional evidence that biliary bile acid secretion is the driving force for the secretion of the other lipid species into bile[57]. However, in Abcb11 knockout mice, there is still substantial residual biliary bile acid secretion and the expression of Mdr1a (Abcb1a) and Mdr1b (Abcb1b) was found to be upregulated indicating a potential compensation mechanism[58]. Subsequently, triple knockout mice lacking all 3 transporters have been generated to prove this concept, and indeed these mice develop an extreme cholestatic phenotype[59].

How do these transporters work together in the process of bile formation? First, the specific properties of the canalicular membrane need to be considered, since this has to fulfill 2 key functions: (1) withstand extremely high concentrations of bile acids, that are powerful detergents able to basically solubilize normal plasma membranes resulting in cell death; and (2) still allow for regulated secretion of the different bile components. The answer to these questions seems to lie in the asymmetry of the canalicular membrane with a high content of sphingomyelin and cholesterol in the outer leaflet[60]. In membranes composed of glycerophospholipids (PC, PS and phosphatidylethanolamine) lipids are loosely packed, the so-called "liquid disordered" phase[61,62]. Addition of sphingomyelin and cholesterol induces a more rigid membrane structure, the so-called "liquid ordered" phase that does not allow for the intercalation of detergents and thereby the membrane is rendered increasingly resistant against detergents[61,63,64]. The task of ATP8B1 in this model would be to preserve the rigid structure of the outer canalicular leaflet by inward flipping of PS. The amphipathic bile acids are actively excreted into the canalicular lumen by ABCB11, where they form simple micelles in the aqueous environment of the bile[9,46]. Phospholipids are translocated to the outer leaflet of the canalicular membrane by ABCB4 where they are added to the simple micelles resulting in mixed micelles[9,46]. However, the precise mechanism of how this occurs is still elusive. Subsequently, cholesterol is then taken up into these mixed micelles[9,46]. The authentic cholesterol transporters that play a role in this process are discussed below.

ABCG5/G8

The transport system contributing quantitatively the major amount of cholesterol secretion into the bile is the obligate heterodimer transporter pair ABCG5/ABCG8[65-67]. These are expressed almost exclusively in the liver and the intestine, and respective mutations have been identified as the disease substrate for sitosterolemia, a rare autosomal recessive disorder which is characterized by the accumulation of plant sterols in blood and tissues[68,69]. This accumulation is caused by increased sterol absorption from the diet and decreased biliary sterol secretion[70,71]. In the intestine, ABCG5/G8 secrete absorbed plant sterols back into the intestinal lumen, while on the bile canaliculus ABCG5/G8 mediate biliary plant sterol as well as cholesterol secretion into bile[70,71]. Since in healthy individuals, plasma plant sterol levels are very low, ABCG5/G8 represent, under physiological conditions, mainly a transport system for cholesterol. This is mirrored by the fact that biliary cholesterol secretion in ABCG5 and/or ABCG8 knockout mice is reduced by 75%[71-73]. In turn, transgenic overexpression of ABCG5/G8 resulted in an increase in biliary cholesterol secretion that was directly proportional to the copy numbers of the transgene over a wide range, indicating that under these conditions neither delivery of cholesterol to the transporters nor the level of cholesterol acceptors within the bile are rate-limiting[74]. In addition, ABCG5 and ABCG8 are targets of the nuclear hormone receptor LXRα and the increase in biliary cholesterol secretion observed upon LXR activation with endogenous or synthetic ligands depends largely on functional ABCG5/G8 expression[75]. Interestingly, also the increasing effects of cholate as well as diosgenin on biliary cholesterol secretion depend on the functional expression of ABCG5/G8 and subsequently are not seen in mice lacking either or both of the transporters[74,76]. Notably, there are as yet ill-defined ABCG5/G8-independent pathways of biliary cholesterol secretion[77] (see also below).

With relevance to atherosclerotic CVD, when human ABCG5/G8 transgenic mice overexpressing the transgene

in the liver as well as in the intestine were crossed into the atherosclerotic LDLR$^{-/-}$ genetic background, these mice developed significantly less atherosclerosis compared with wild-type controls[78]. On the other hand, only hepatic overexpression of ABCG5/G8 does not alter atherosclerosis in LDLR$^{-/-}$ as well as apoE$^{-/-}$ mice[79], unless intestinal cholesterol absorption is also reduced by ezetimibe[80]. With relevance to gallstone disease, recently specific mutations in ABCG5/G8, namely ABCG5 R50C and ABCG8 D19H, have been identified in humans and shown to increase the risk for cholesterol gallstone disease[81-83]. Since the role of ABCG5/G8 is to increase biliary cholesterol secretion, and cholesterol gallstone formation requires increased amounts of cholesterol within bile, these respective mutations are likely to constitute a gain-of-function phenotype. However, since these association data were obtained in human studies, this concept still requires verification in an experimental setting that allows determination of cause-effect relationships.

Although several studies have shown that the ABCG5/G8 heterodimer is a key component of biliary cholesterol secretion[70,71], the molecular mechanism by which this transporter pair mediates biliary cholesterol secretion at the canalicular membrane has not been yet elucidated. This lack of insight is mainly due to the unavailability of easy to study model systems such as polarized hepatocyte cell lines, or simple and reliable methods to isolate and characterize pure apical and basolateral membranes. However, the currently most accepted model suggests that ABCG5/ABCG8 act as a liftase elevating cholesterol just sufficiently outside of the outer leaflet of the canalicular membrane to be extracted by mixed micelles[84].

Niemann-Pick C1-like protein 1

The Niemann-Pick C1-like protein 1 (NPC1L1) was originally identified as a key regulator of intestinal cholesterol absorption and the molecular target of the cholesterol absorption inhibitor ezetimibe[85,86]. It is also highly expressed in human liver, but not in rodents[87]. In human hepatocytes, NPC1L1 is localized to the canalicular membrane[88]. Similar to its role in the intestine, hepatic NPC1L1 apparently facilitates the uptake of newly secreted biliary cholesterol[89]. In NPC1L1 transgenic mice with hepatic overexpression of the transgene, a more than 90% decrease in biliary cholesterol concentration is observed without any effect on biliary phospholipid and bile acid levels. Interestingly, treatment with ezetimibe normalizes biliary cholesterol concentrations in hNPC1L1 transgenic animals[89]. Therefore, particularly in humans, ezetimibe supposedly reduces plasma cholesterol levels by inhibiting both intestinal as well as hepatic NPC1L1 activity. However, the regulation of this important cholesterol transporter and modifier of hepatic cholesterol secretion is still incompletely understood.

SR-BI

SR-BI has been characterized as a receptor for HDL cholesterol, mediating bi-directional cholesterol flux, either efflux or selective uptake, depending on concentration gradients[90,91]. In contrast to ABC transporters, SR-BI apparently requires no energy consumption[91]. SR-BI is mainly expressed in the liver and in steroidogenic tissue[90,91]. In hepatocytes, SR-BI mediates the internalization of HDL cholesterol without the concomitant catabolism of HDL apolipoproteins[90,91]. SR-BI is detectable in hepatocytes *in vivo* at both the basolateral as well as the apical membrane[92,93]. Since HDL-derived cholesterol is a major source of sterols designated for biliary secretion[15], these properties of SR-BI suggest a potential involvement in biliary cholesterol secretion.

Cholesterol uptake from HDL *via* SR-BI can be increased in 2 different ways, by modulating the properties of the ligand, namely HDL, as well as by changing the expression level of SR-BI. HDL modification by phospholipases decreases its phospholipid content, destabilizes the particle and makes the HDL cholesterol ester more susceptible towards SR-BI-mediated selective uptake[94-97]. Overexpression of 2 phospholipases relevant for human physiology in mice, namely group IIA secretory phospholipase A2 (sPLA2)[98,99] and endothelial lipase (EL)[95,97,100] has 2 major metabolic effects: (1) in plasma, HDL cholesterol levels decrease significantly, and (2) hepatic cholesterol levels increase[94,101]. While SR-BI expression or membrane localization[94,101] was not affected, consecutive *in vitro* studies showed that SR-BI-mediated selective uptake from sPLA2- or EL-modified HDL was increased by 77%[94] and 129%[97], respectively, explaining the increased hepatic cholesterol uptake rates. However, despite this increased SR-BI-mediated hepatic cholesterol uptake, biliary cholesterol secretion in sPLA2 transgenic mice or mice with adenovirus-mediated EL overexpression was essentially unchanged compared with controls[94,101]. As a third example, the absence of hepatic lipase also did not affect biliary cholesterol secretion, although in this study actual SR-BI-mediated uptake of HDL cholesterol was not quantified[102]. Overall, these data demonstrate that biliary cholesterol secretion remains unaltered when only the ligand, HDL, but not SR-BI expression itself is modulated.

In contrast, changes in the hepatic expression level of SR-BI directly translate into altered biliary cholesterol secretion rates. SR-BI knockout mice have biliary cholesterol secretion rates reduced by 55%[103]. Consistent with these data, adenovirus-mediated SR-BI overexpression in the liver of wild-type mice increases gallbladder cholesterol content[92] as well as biliary cholesterol secretion rates[93]. Interestingly, with relevance to disease, hepatic SR-BI overexpression increases reverse cholesterol transport[104] and is protective against atherosclerotic CVD, even though plasma HDL cholesterol levels are decreased[105,106]. In gallstone-susceptible mice, hepatic SR-BI expression was higher and associated with biliary cholesterol hypersecretion[107]. In addition, hepatic mRNA as well as protein expression of SR-BI was higher in Chinese patients with cholesterol gallstone disease compared with controls and even correlated with an increased cholesterol saturation

index[108] suggesting that the link between SR-BI and biliary cholesterol secretion might be relevant for human pathophysiology as well. In this study, increased expression of LXRα was also noted in the livers of gallstone patients[108], and previous experimental work suggested that modulation of SR-BI expression results in altered expression of LXR target genes[109].

However, increased biliary cholesterol secretion in response to SR-BI overexpression was completely independent of LXR as evidenced by the use of knockout mice[93]. Surprisingly, this biological effect was also independent of functional expression of ABCG5/G8, since in ABCG5 knockout mice hepatic overexpression of SR-BI increased biliary cholesterol secretion rates to the levels of wild-type control mice and thereby normalized the cholesterol secretion deficit caused by absent ABCG5 expression[93]. To a certain extent canalicular SR-BI also acts independent of ABCB4, since hepatic overexpression of SR-BI in ABCB4 knockout mice resulted in significantly higher biliary cholesterol secretion, although in terms of mass secretion this effect was minor, indicating that cholesterol secreted *via* SR-BI still requires mixed micelles as acceptors[93]. Interestingly, SR-BI overexpression particularly augmented canalicular expression of the receptor[93]. Since, in SR-BI overexpression conditions, increased canalicular SR-BI localization was associated with an increased cholesterol content of the canalicular membrane and higher biliary cholesterol secretion rates[93], conceivably this biological effect was mediated by SR-BI. SR-BI requires a cholesterol gradient for transport[91], which is, however, constantly provided within the canaliculus by the direction of bile flow and the associated transport of cholesterol away from the hepatocyte. It would be interesting and physiologically relevant to explore whether SR-BI also contributes a significant part to the ABCG5/G8-independent biliary cholesterol secretion under steady-state conditions and not only has an effect in response to overexpression.

It is presently unclear how cholesterol secreted by SR-BI into the bile reaches the canalicular membrane. One possibility could be that SR-BI itself mediates this transport, since a transcytotic route of trafficking from the basolateral to the apical membrane has been proposed for SR-BI in a process that is dependent on microtubuli function[110]. However, even under conditions when microtubuli function and thereby transcytotic transport were efficiently abolished *in vivo*, SR-BI overexpression still significantly increased biliary cholesterol secretion[93]. These data indicate that microtubuli function is not required for the increasing effect of SR-BI on biliary cholesterol secretion. Other, as yet not characterized pathways, are therefore likely to contribute.

WHAT DIRECTIONS SHOULD FUTURE RESEARCH TAKE?

In our view, there are a number of interesting and relevant questions that are unresolved and should be addressed by future research in the field. The contribution of SR-BI to the ABCG5/G8-independent biliary cholesterol secretion under steady-state conditions would be important to know. Related to this, but also extending beyond SR-BI, more work appears to be required to identify and delineate the intracellular pathways for cholesterol transport that contribute to biliary cholesterol secretion. In addition to the selective uptake pathway for HDL cholesterol that is mediated by SR-BI, a holoparticle uptake pathway has also been characterized that is responsible for approximately a quarter of the total HDL cholesterol taken up into the liver[97,111-114]. However, whether this pathway contributes cholesterol for biliary secretion is currently unknown. Expanding this question, there also appears to be scope for assessing the differential contribution of apoB-containing lipoproteins *vs* HDL in bile acid synthesis and the respective biliary secretion of cholesterol and bile acids. Further research on these pathways would not only be relevant to increase our mechanistic insights into pathophysiology but also to define and characterize potential novel therapeutic targets for the treatment of atherosclerotic CVD and cholesterol gallstone disease.

CONCLUSION

Biliary cholesterol secretion is important for 2 major disease complexes, atherosclerotic CVD and cholesterol gallstone disease. Research thus far has provided valuable understanding of the regulation of biliary cholesterol secretion. With the identification of the ABC transporters mediating the biliary secretion of bile acids (ABCB11), phospholipids (ABCB4) and cholesterol (ABCG5/G8) the major transport proteins for the respective physiological processes have been delineated. However, more recently a number of proteins that modulate or mediate biliary cholesterol secretion such as the phosphatidylserine flippase ATP8B1, NPC1L1 and SR-BI have gained attention. Although several proteins are currently known that impact biliary cholesterol secretion, further research into the mechanisms determining their respective activities as well as the routes of intrahepatic cholesterol trafficking and the regulation of hepatic cholesterol pools is required.

Abstract

Reduction of low-density lipoprotein-cholesterol through statin therapy has only modestly decreased coronary heart disease (CHD)-associated mortality in developed countries, which has prompted the search for alternative therapeutic strategies for CHD. Major efforts are now focused on therapies that augment high-density lipoprotein (HDL)-mediated reverse cholesterol transport (RCT), and ultimately increase the fecal disposal of cholesterol. The process of RCT has long been thought to simply involve HDL-mediated delivery of peripheral cholesterol to the liver for biliary excretion out of the body. However, recent studies have revealed a novel pathway for RCT that does not rely on biliary secretion. This non-biliary pathway rather involves the direct excretion of cholesterol by the proximal small intestine. Compared to RCT therapies that augment biliary sterol loss, modulation of non-biliary fecal sterol loss through the intestine is a much more attractive therapeutic strategy, given that excessive biliary cholesterol secretion can promote gallstone formation. However, we are at an early stage in understanding the molecular mechanisms regulating the non-biliary pathway for RCT, and much additional work is required in order to effectively target this pathway for CHD prevention. The purpose of this review is to discuss our current understanding of biliary and non-biliary contributions to RCT with particular emphasis on the possibility of targeting the intestine as an inducible cholesterol secretory organ.

Key words: Cholesterol; Intestine; Bile; Lipoprotein; Reverse cholesterol transport

INTRODUCTION

Atherosclerosis is the disease process underlying the clinical complications of coronary heart disease (CHD), an epidemic that has taken more lives in the United States over the past century than the next four causes combined[1]. Atherosclerotic cardiovascular disease (ASCVD) was long thought to be a problem of developed Western societies, but it is now understood that this cholesterol-driven disease pervades throughout most of the world[2,3]. The most accurate predictor of ASCVD incidence is the plasma concentration of low-density lipoprotein cholesterol (LDLc). Hence, lowering LDLc has been the primary therapeutic goal for decades, and statins have been the main drug used to accomplish this. However, even with the substantial

LDLc lowering achieved with statin treatment, these drugs have been able to reduce CHD-associated mortality and morbidity by only approximately 30%[4]. Major pharmaceutical interest has thus shifted towards developing high-density lipoprotein cholesterol (HDLc)-elevating agents, since HDLc was shown to be an even stronger predictor than LDLc for CHD in the Framingham Heart Study[5]. There have been many mechanisms proposed as to how HDLc influences the development of CHD[6-8], but the most widely accepted is the idea that HDL directly facilitates the process of reverse cholesterol transport (RCT).

REVERSE CHOLESTEROL TRANSPORT: THE CLASSIC "BILIARY" MODEL REQUIRES RECONSIDERATION

Nearly forty years ago, Glomset *et al*[9,10] presented the seminal framework of HDL-driven RCT. This model for RCT was described as a process by which extrahepatic (peripheral) cholesterol is returned to the liver for excretion into bile for subsequent loss through the feces[9,10]. It is reasonable to assume that the process of RCT has primarily evolved to protect multiple peripheral tissues from the excess accumulation of unesterified cholesterol, which is known to be cytotoxic[11,12]. Importantly, in the context of ASCVD, RCT is thought to involve HDL-mediated efflux of cholesterol from the arterial wall, specifically from cholesterol-laden macrophages[13-15]. In the classic "biliary" view of RCT[9,10], HDL-mediated delivery of peripheral cholesterol to the liver directly results in biliary secretion[13-15]. Given this model, plasma HDLc levels should accurately predict both biliary sterol secretion and fecal sterol loss. However, there are now several examples where plasma HDLc levels do not predict the levels of cholesterol in bile or feces[16-18]. For example, in mice lacking ATP-binding cassette protein A1 (ABCA1) or apolipoprotein-AI, plasma HDLc is essentially at undetectable levels[16-18]. However, in the face of near complete absence of HDLc, biliary and fecal cholesterol levels are normal in these mice[16-18]. These studies quite convincingly demonstrate that plasma HDLc levels do not determine the amount of cholesterol ultimately excreted into the feces. These findings bring into question whether therapeutic strategies that simply raise HDLc will indeed promote fecal disposal of cholesterol. Ultimately, to effectively target RCT, a drug should show efficacy in promoting the fecal disposal of cholesterol, not simply raising HDLc.

Another problem with the classic model of RCT is that the levels of cholesterol secreted into bile do not accurately predict fecal disposal of cholesterol[19-24]. In support of this concept, it has been demonstrated in several mouse models where hepatobiliary cholesterol secretion is substantially diminished that fecal sterol loss is normal[19-23]. The first demonstration of this was seen in mice lacking the canalicular phospholipid transporter, multidrug resistance 2 (Mdr2)[19]. Mice lacking Mdr2 have the inability to secrete phospholipids into bile, and secondary to biliary phospholipid insufficiency these mice also have diminished biliary cholesterol secretion[19]. Quite strikingly, even with > 80% reduced levels of biliary cholesterol, Mdr2 null mice have normal or even increased fecal cholesterol loss compared to wild type mice[19,20]. Furthermore, activation of the liver X receptor (LXR) in Mdr2 null mice results in large increases in fecal sterol output, without increasing biliary cholesterol output, supporting the presence of an LXR-inducible non-biliary pathway for fecal sterol loss in these mice[20]. Our group has found strikingly similar results in another mouse model lacking the ability to secrete cholesterol into bile[21,22]. In order to characterize the role of Niemann-Pick C1-Like 1 (NPC1L1) in hepatobiliary sterol secretion, we previously generated mice transgenically overexpressing NPC1L1 in hepatocytes[21]. Interestingly, NPC1L1 overexpression in the liver results in a > 90% reduction in biliary cholesterol levels, yet mass fecal neutral sterol loss and macrophage RCT is normal in these mice[21,22]. In addition, LXR activation in NPC1L1-^{LiverTg} mice results in large increases in macrophage RCT and mass fecal neutral sterol loss[22], further supporting the existence of a non-biliary pathway in this model. In order to more definitively test whether bile is required for macrophage RCT, we set out to create a surgical model where there would be no biliary emptying into the small intestine, without obstructing bile flow. In order to do this we surgically diverted bile flow away from the small intestine and measured macrophage RCT. Importantly, mice surgically lacking biliary contributions to the intestine have normal LXR-inducible macrophage RCT[22]. Collectively, these studies in mice demonstrate that mass fecal sterol loss and macrophage RCT can proceed in the complete absence of biliary sterol secretion, challenging the obligate role of bile in RCT. Although the classic "biliary" model has been instrumental in providing a framework for our current understanding of RCT, we now understand that fecal sterol loss does not absolutely require circulating HDL[16-18] or biliary sterol secretion[19-22]. Paradigm shifting data such as these[16-23] strongly suggest that an alternative model for RCT is now appropriate. Based on our current understanding, fecal sterols originate from at least two distinct excretory routes: (1) the classic hepatobiliary sterol secretion route; and (2) the non-biliary liver to plasma lipoprotein to small intestine to feces route (Figure 1). Importantly, the major mechanisms regulating cholesterol secretion into bile have been recently defined[19,21,24-27], but almost no information exists regarding mediators of non-biliary cholesterol secretion by the intestine.

REVERSE CHOLESTEROL TRANSPORT: EARLY SUPPORT FOR AN ALTERNATIVE "NON-BILIARY" MODEL

Long before Glomset *et al*[9,10] proposed the "biliary" model for RCT, the existence of a "non-biliary" pathway for RCT was proposed by Sperry *et al*[28]. In 1927, Sperry's experiments demonstrated that in dogs that had undergone chronic biliary fistula surgery, fecal neutral sterol

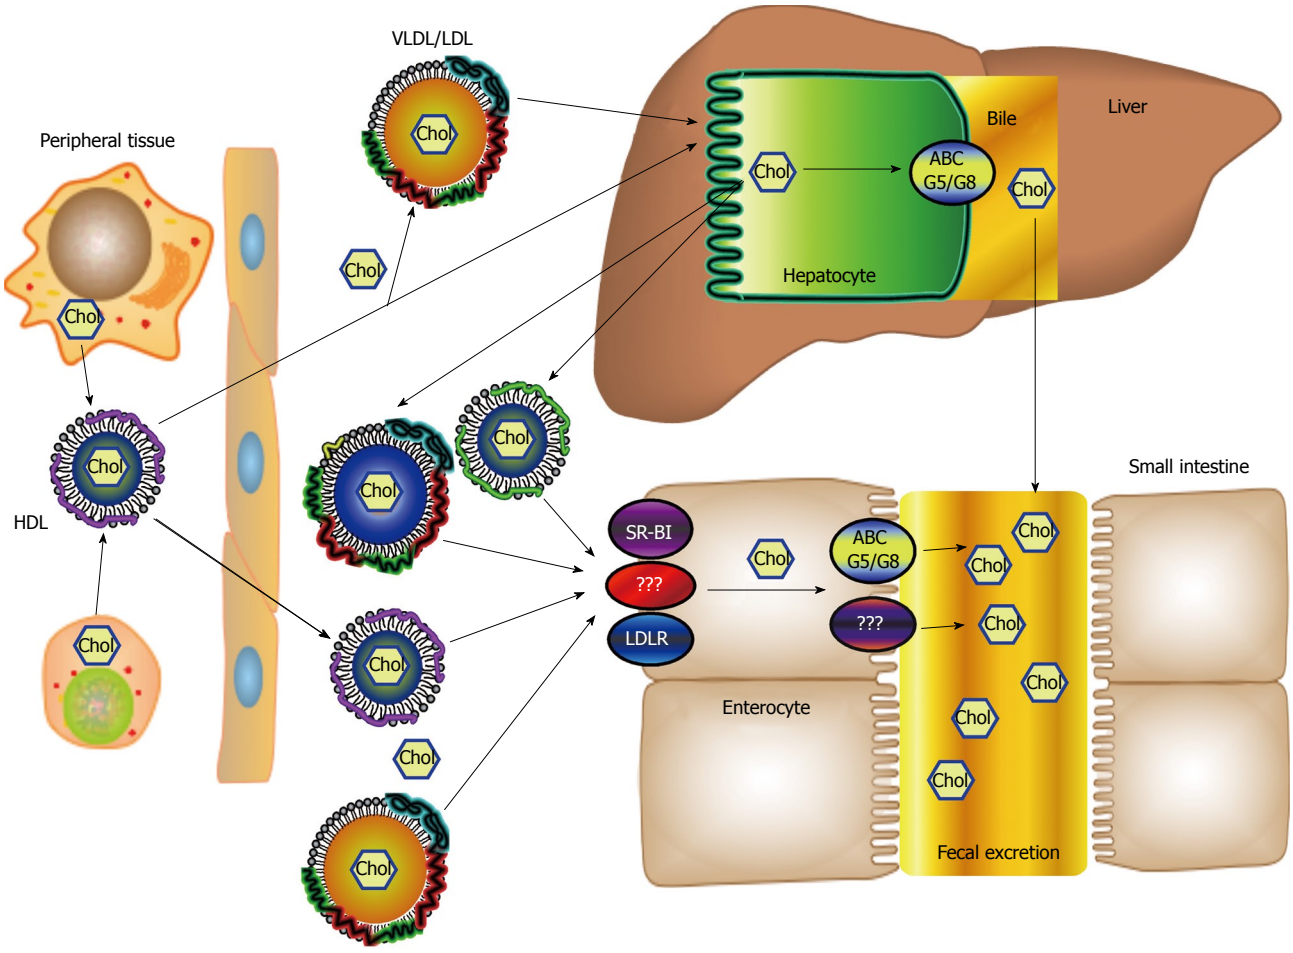

Figure 1 Biliary and non-biliary fecal cholesterol excretion. In this proposed model, cholesterol is effluxed from peripheral cells onto high-density lipoprotein (HDL) and then delivered to the liver or small intestine *via* HDL or very low density lipoprotein (VLDL)/low-density lipoprotein (LDL) following cholesterol ester transfer protein-mediated transfer. The cholesterol internalized or *de novo* synthesized by the liver is secreted into bile through the action of ABCG5/G8 and subsequently excreted in the feces. Alternatively, the liver secretes the cholesterol in apoB-containing lipoproteins or HDL containing apoAI or apoE, which are specifically targeted to the small intestine. After being internalized by scavenger receptor, class B, type I (SR-BI), LDL receptor (LDLR), or another lipoprotein receptor system, the cholesterol is trafficked across the enterocytes to the brush border membrane and effluxed into the intestinal lumen by ABCG5/G8 or a currently unidentified cholesterol transporter.

loss was paradoxically increased, compared to control bile intact dogs. Sperry's findings were largely ignored given that it was already well accepted in the 1920s that bile was the only source of fecal lipids. Nearly a half-century later, Pertsemlidis *et al*[29] confirmed the results of Sperry *et al*[28], by demonstrating surgical biliary diversion resulted in complete loss of fecal acidic sterol output, yet fecal neutral sterol output actually increased approximately 7-fold. These studies, along with elegant work done by Dietschy *et al*[30,31], have demonstrated that bile is absolutely required for the enterohepatic circulation of acidic sterols, but this is not the case for neutral sterols. Similar results have been seen in bile diverted rats[32] and familial hypercholesterolemic humans[33]. Actually, as early as 1959, it was suggested that non-dietary fecal cholesterol loss in humans consists of two distinct fractions: (1) the traditional fraction coming from hepatobiliary secretion; and (2) an elusive fraction directly secreted by the intestine[34]. Unfortunately, a major drawback of these early biliary diversion or obstruction models is the interruption of enterohepatic circulation of bile acids and other non-lipid components that are found in bile. Under bile-diverted conditions, the absence of bile salt delivery to the intestinal lumen compromises intestinal cholesterol absorption, and endogenous cholesterol synthesis is strongly upregulated locally in the intestine[30]. Given these limitations, these early studies have been largely ignored, and the theory that fecal neutral sterol loss derives only from a biliary origin has become dogma. However, we have recently demonstrated that biliary cholesterol secretion is not required for macrophage RCT in mice using both surgical and genetic models of biliary insufficiency[22]. Collectively, findings in animal models of bile diversion have clearly demonstrated the presence of a non-biliary component of RCT, yet the mechanisms underlying such a process are poorly understood.

RELATIVE CONTRIBUTION OF THE NON-BILIARY PATHWAY TO RCT

In addition to the classic RCT pathway involving choles-

terol secretion into the bile, there is mounting evidence that a non-biliary pathway quantitatively contributes to fecal cholesterol excretion. The non-biliary RCT pathway appears to involve the targeting of plasma cholesterol to the small intestine and the subsequent cellular secretion of the cholesterol into the lumen of this organ. Christened transintestinal cholesterol efflux (TICE) by Kuipers, Groen and their colleagues, the relative contribution of the non-biliary pathway to fecal cholesterol loss has not been fully defined. In normal chow-fed C57BL/6J mice, TICE accounts for 33% of total fecal neutral sterol loss[35], and roughly 20% of total fecal sterol loss in FVB mice[20]. However, it is important to point out that non-biliary fecal cholesterol loss is quite sensitive to pharmacological manipulation. To this end, LXR activation can dramatically augment non-biliary macrophage RCT[22], and increases mass fecal neutral sterol loss[20,22,35]. In fact, LXR activation in C57BL/6J increases the contribution of TICE to fecal cholesterol loss from 33% in vehicle treated mice to 63% in LXR agonist-treated mice[35]. Furthermore, activation of the peroxisome proliferator activated receptor δ (PPAR-δ) also promotes non-biliary neutral fecal sterol loss in mice[36]. Importantly, now in three independent genetically modified mouse models (ABCG5/G8$^{-/-}$, Mdr2$^{-/-}$, and NPC1L1-^{LiverTg}) that have severely diminished biliary cholesterol secretion, fecal neutral sterol loss is only modestly decreased[24] or not altered at all[20,22]. This clearly indicates that the non-biliary pathway must be able to adequately compensate for biliary insufficiency to maintain normal fecal cholesterol loss in rodents. Collectively, these data support the idea that fecal neutral sterol loss is a mixture of dietary, biliary, and intestinally-derived cholesterol, and the origins of the latter source likely originates from the plasma compartment[20,23,35]. Given the plasma source of intestinally derived fecal neutral sterols, and the central role of the liver in lipoprotein metabolism, it is tempting to speculate that the liver may serve as a potential site of organization for non-biliary fecal cholesterol loss.

ORIGINS OF NEUTRAL STEROLS FOR TRANSINTESTINAL CHOLESTEROL EFFLUX

In the classic view of RCT, the liver plays a central role in moving peripheral cholesterol out of the body[13-15]. In parallel, we believe that the liver also plays a central role in the non-biliary pathway by re-packaging peripheral cholesterol into liver-derived lipoproteins that are targeted for subsequent intestinal uptake[23]. In support of this concept, most of the mouse models where non-biliary fecal cholesterol loss has been described[20-23] represent conditions where free cholesterol could potentially accumulate in the liver due to defects in normal hepatic elimination pathways. It remains possible that under conditions where hepatic free cholesterol burden becomes too excessive for disposal through biliary secretion (i.e. Mdr2$^{-/-}$ mice[20], ACAT2 ASO treatment[22], or NPC1L1-$^{Liver\text{-}Tg}$ mice[22,23]), an alternative non-biliary plasma lipoprotein-based route for fecal cholesterol disposal is utilized. In previous work, we were able to show that the liver can secrete lipoprotein particles that preferentially deliver cholesterol to the proximal small intestine for fecal excretion[22]. However, whether these liver-derived lipoproteins represent nascent very low density lipoprotein (VLDL) particles, nascent HDL particles, or some novel lipoprotein remains to be addressed.

POSSIBLE COMPONENTS IN THE TRANSINTESTINAL CHOLESTEROL EFFLUX PATHWAY

Based upon their ability to transport mass amounts of cholesterol in the blood and deliver the cholesterol to specific cells within tissues and organs, lipoproteins are almost certainly involved in the TICE pathway. However, it is unclear which lipoprotein class or classes is involved and how the lipoprotein is targeted to the small intestine. Because of its role in the removal of excess cholesterol from peripheral tissues, HDL is a logical choice for the lipoprotein responsible for cholesterol trafficking to the small intestine. However, ABCA1 null mice, which have very low levels of HDL in plasma, have normal or increased fecal cholesterol excretion under basal conditions[16,18,37]. Furthermore, treatment with an LXR agonist, which stimulates TICE, causes fecal cholesterol excretion to increase to the same extent in both wild type and ABCA1 null mice[38]. Thus, at least in mice, HDL does not appear to be necessary for non-biliary RCT.

Apolipoprotein E (apoE)-rich HDL (HDL-E) could also be involved in delivering cholesterol to the small intestine for fecal excretion. HDL-E is found in the plasma of wild type mice[21] but its concentration is significantly increased in two mouse models with upregulated TICE, NPC1L1-^{LiverTg} and LXR agonist-treated wild type mice[21,39,40]. Compared to LDL and apoAI-rich HDL, HDL-E has an intermediate size and a higher ratio of free cholesterol to cholesteryl ester. The source of HDL-E is currently unknown, but it could be generated by hepatic ABCA1 effluxing cholesterol and phospholipid to lipid-poor apoE. Hepatic ABCA1 is increased in both NPC1L1-^{LiverTg} and LXR-agonist treated mice and it has been shown that hepatic overexpression of ABCA1 in mice increases the plasma concentration of HDL-E[41]. Humans and other species with high levels of cholesterol ester transfer protein activity have low concentrations of plasma HDL-E[42]. Thus, the contribution of HDL-E to the TICE pathway would presumably be much greater in mice than humans.

Evidence from our group also suggests that liver-derived apoB-containing lipoproteins can deliver cholesterol for TICE[23]. In order to study the hepatic function of the cholesterol esterifying enzyme ACAT2, we treated mice with an antisense oligonucleotide (ASO) which targets ACAT2 mRNA for degradation. Mice treated with ACAT2 ASO *vs* control ASO had no change in biliary cholesterol secretion but had a 2-fold increase in fecal cholesterol excretion. The increased fecal cholesterol excretion was concluded to be the result of TICE since

ACAT2 ASO-treated mice, unlike ACAT2 null mice, did not have a significant reduction in cholesterol absorption. To determine whether the liver was producing a lipoprotein that was targeted for clearance by the small intestine, isolated liver perfusion was conducted on mice that had been radiolabeled with [^{3}H]cholesterol and treated with control or ACAT2 ASO. The radiolabeled perfusate, which carried almost 100% of the cholesterol on VLDL, was then injected into control and ACAT2 ASO treated mice. After 6 h, 2-3 fold more [^{3}H]cholesterol from the ACAT2 ASO perfusate compared to the control ASO perfusate had accumulated in the lumen and wall of the proximal small intestine. One interpretation of this result was that the VLDL secreted from the ACAT2 ASO liver was preferentially targeted to the small intestine. It is also possible that following clearance of the perfusate VLDL by the liver, the [^{3}H]cholesterol was packaged into another lipoprotein that delivered the cholesterol to the intestine. However, hepatic production of this lipoprotein would likely be driven by some factor secreted exclusively into the ACAT2 ASO perfusate since intestinal accumulation of [^{3}H]cholesterol from ACAT2 ASO perfusate was similar in control and ACAT2 ASO-treated recipient mice.

Regardless of the lipoprotein class that delivers cholesterol to the small intestine, there must be receptors involved in the internalization or uptake of the lipoprotein cholesterol by the enterocytes. Scavenger receptor, class B, type I (SR-BI), which is expressed on the basolateral surface of enterocytes, is one receptor that could potentially play a role in TICE. SR-BI can bind VLDL, LDL, and HDL and subsequently mediates the selective uptake of the cholesteryl ester[43]. Intestinal expression of SR-BI also increases with LXR agonist treatment of mice[20,38]. However, when measured using an intestinal perfusion system, TICE was found to be significantly increased in SR-BI null mice[44]. Studies involving mice with intestine specific overexpression or deletion of SR-BI may aid in determining whether SR-BI plays a part in TICE.

If apoE-rich HDL or apoB-containing lipoproteins are involved in the TICE pathway then a member of the LDL receptor family may mediate the uptake of these particles by the enterocytes. The LDL receptor is expressed in the small intestine; however its expression at the protein level is downregulated in mice treated with LXR agonist[45]. Moreover, TICE appears to be stimulated in LDL receptor null mice treated with ACAT2 ASO compared to control ASO[23]. This data indicates that the LDL receptor is not necessary for TICE but does not exclude the possibility that other members of the LDL receptor family may compensate when the LDL receptor is absent.

Following delivery of lipoprotein cholesterol to the enterocytes, the ATP-binding cassette (ABC) transporters G5 and G8 appear to participate in pumping the cholesterol into the lumen of the small intestine. Expressed in the liver and small intestine[46], ABCG5/G8 functions as an obligate heterodimer and facilitates cholesterol excretion from the body by effluxing cholesterol from the apical surface of hepatocytes and enterocytes into bile and intestinal contents, respectively[24,25,46,47]. By employing stable isotope tracers, it was determined that the contribution of TICE to fecal cholesterol excretion decreased from 25% in wild type mice to 15% in ABCG5 null mice[35]. In addition, LXR agonist treatment of ABCG5/G8 null mice, unlike wild type mice, did not increase mass fecal neutral sterol loss[48] and macrophage reverse cholesterol transport[49]. Although this data indicates that ABCG5/8 plays a role in TICE, there appears to be multiple or redundant pathways for effluxing cholesterol from enterocytes into the intestinal lumen since TICE continues to function, albeit at lower efficiency, in the absence of ABCG5/G8.

METHODOLOGIES FOR MEASURING TRANSINTESTINAL CHOLESTEROL EFFLUX

Several different methodologies have been used to measure TICE or non-biliary excretion in mice. Taking into consideration dietary intake, biliary secretion, fractional absorption, and fecal excretion of cholesterol, it was calculated that under basal conditions in wild type mice, TICE contributed 20%-50% of the cholesterol in feces[20,50]. Using similar measurements, approximately 40% of fecal cholesterol excretion was attributed to TICE in wild type mice treated with LXR agonist[20]. By determining the kinetics of stable isotopically labeled cholesterol that was delivered orally and intravenously plus assessing the fate of *de novo* synthesized cholesterol that was isotopically labeled, it was determined that 33% and 63% of fecal cholesterol excretion in mice treated with vehicle or LXR agonist was the result of TICE[35].

Cholesterol secretion into the lumen of the small intestine was also observed when the intestine of wild type mice was perfused with bile acid; phospholipid micelles[36,44,50]. The rate of cholesterol secretion was found to be highest in the proximal third of the small intestine[50], and was dependent upon the concentration of the phospholipid in the micelles[44]. Since [^{14}C]cholesterol that was intravenously injected was found in the perfusate, a portion of the cholesterol secreted into the lumen was derived from the plasma. Moreover, the plasma cholesterol secreted in the lumen must have trafficked through and mixed with the cholesterol pool of the enterocytes since the specific activity of the cholesterol in the perfusate was similar to that of the mucosa but was 10-fold less than that of the serum[50]. Although these studies showed that bile salt:phospholipid micelles could mediate the efflux of cholesterol from the small intestine, the question remains whether TICE would occur if the micelles consisted of physiological concentrations of not only bile salt and phospholipid but also cholesterol.

DOES TICE PLAY A MAJOR ROLE IN HUMAN FECAL CHOLESTEROL EXCRETION?

Since most of the studies of the TICE pathway have been

conducted in mice, the question remains whether TICE contributes significantly to fecal cholesterol excretion in humans. Using an intestinal perfusion system, it was estimated that approximately 44% of total fecal cholesterol output originated from non-biliary sources in humans[51]. Yet, it cannot be determined from this data whether TICE was the source of the non-biliary sterol. The current methodologies used to measure TICE in murine models are invasive and therefore could not be implemented in humans. However, the procedures used to measure TICE in mice could be applied to non-human primates, whose lipoprotein and cholesterol metabolism closely resembles that of man. If in non-human primates TICE can be shown to play a significant part in fecal cholesterol excretion and to be amenable to pharmaceutical manipulation then future studies in humans could be warranted. Although our understanding of non-biliary fecal sterol excretion is still in its infancy, continued research surrounding this pathway has strong potential to lead to novel therapies for the prevention and/or treatment of ASCVD.

Abstract

The reverse cholesterol transport pathway (RCT) is the focus of many cholesterol-lowering therapies. By way of this pathway, excess cholesterol is collected from peripheral tissues and delivered back to the liver and gastrointestinal tract for excretion from the body. For a long time this removal *via* the hepatobiliary secretion was considered to be the sole route involved in the RCT. However, observations from early studies in animals and humans already pointed towards the possibility of another route. In the last few years it has become evident that a non-biliary cholesterol secretion pathway exists in which the intestine plays a central role. This transintestinal cholesterol efflux (TICE) pathway contributes significantly to the total fecal neutral sterol excretion. Moreover, recent studies have shown that TICE is also sensitive to stimulation. As a consequence, the direct role of cholesterol secretion from blood *via* TICE makes the intestine a suitable and approachable target for cholesterol removal from the body and possibly reduction of atherosclerosis. In this review, the discovery and recent findings contributing to understanding the mechanism of TICE will be discussed.

Key words: Cholesterol; Intestine; Transintestinal cholesterol efflux

INTRODUCTION

Since the introduction of statins about 25 years ago, therapeutic lowering of cholesterol levels has been proven successful in decreasing the incidence of cardiovascular diseases (CVDs)[1]. In fact, the reduction of low density lipoprotein (LDL) cholesterol levels in blood by the inhibition of cholesterol biosynthesis using these 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) reductase inhibitors is still the most potent cholesterol-lowering therapy to date[2]. However, while the reduction of LDL cholesterol levels in blood helps to prevent the development of atherosclerosis, the underlying process of CVD, it does not seem to be sufficient enough for the reversal of already existing atherosclerotic lesions[3,4]. With better understanding of cholesterol metabolism, new ideas for therapies to prevent CVD have emerged. One of the most prominent attempts in the last decade is stimulating reverse cholesterol transport (RCT)[5-7]. RCT describes the different stages of cholesterol transport, from efflux from peripheral tissues to fecal excretion[8]. Passage through liver and bile before subsequent entry into the intestinal lumen has long been considered to be the most important, if not the only, route in RCT. However recent findings have shown the existence of a cholesterol secretion pathway that is independent of this hepatobiliary tract[9,10].

REMOVAL OF CHOLESTEROL *VIA* ITS REVERSE TRANSPORT

Since the introduction of the term RCT in the early 1970s, our knowledge of this cholesterol removal pathway has advanced to a great extent[8]. In brief, the pathway starts with the efflux of cholesterol from peripheral cells, including from macrophages in the arterial wall, by cholesterol transporters adenosine triphosphate-binding cassette transporter protein (ABC) A1 and G1 (Figure 1)[6,7]. This cholesterol is transported *via* lipoproteins to the liver where it can be taken up by hepatocytes *via* specific lipoprotein receptors. The lipoprotein that mediates this transport is the high density lipoprotein (HDL). However, recent findings in transgenic mice also include a role for LDL *via* the activity of cholesteryl ester transfer protein[11]. After uptake at the basolateral side, the cholesterol can be transferred to the bile *via* secretion at the canalicular membrane of the hepatocyte. The cholesterol transport over the canalicular membrane is mainly facilitated by a heterodimer complex formed by ABCG5 and ABCG8[12]. Biliary cholesterol enters the intestinal lumen, from where a significant amount is re-absorbed by the enterocytes[13]. The remaining cholesterol leaves the body *via* fecal excretion.

This hepatobiliary pathway was considered to be the sole route for cholesterol secretion from the body. *In vivo* cholesterol balance studies in wild type and mouse models with abrogated biliary cholesterol secretion have, however, suggested the existence of an alternative direct cholesterol transport route from blood to the intestine.

TRANSINTESTINAL CHOLESTEROL TRANSPORT

If the fecal sterol output only depends on the hepatobiliary cholesterol transport, it should directly be affected by diminished biliary cholesterol secretion. Hence, fecal sterol excretion should be attenuated in mice lacking a functional ABCG5/ABCG8 or deficient for phospholipid transporter ABCG4. Interestingly, despite the very low to absent biliary cholesterol secretion in these mice their sterol output is similar to that of their wild type littermates[9,12,14]. The idea that the fecal sterol excretion might to a certain extent be independent of biliary cholesterol secretion is not confined to recent observations. Earlier findings going as far back as the beginning of the last century already suggested the existence of an additional source for cholesterol excretion. In 1927, Sperry[15] reported that he had measured more excreted cholesterol in the feces of dogs with bile fistula than he would have predicted based on the results obtained from control dogs; an observation which was confirmed 50 years later by Pertsemlidis *et al*[16]. It was also observed in rats that a large part of the cholesterol that ends up in the feces seems to originate from a source other than bile and diet[17,18].

To test the possibility that the intestine is not only responsible for the uptake of cholesterol but also is actively involved in the secretion of cholesterol, intestine perfusions were performed in mice[9]. In these experiments the bile duct was ligated and the bile itself was diverted *via* gallbladder cannulation. Subsequently, a section of the small intestine was perfused with a buffered solution containing a mixture of bile salts and phospholipids. This procedure allows a determination of the contribution of biliary cholesterol secretion, as well as that of transintestinal cholesterol secretion, to the total fecal neutral sterol output. This method demonstrated that a considerable amount of cholesterol is secreted by the small intestine. The secretion takes place over the entire length of the small intestine but it is most significant in the proximal part. The majority of this secreted cholesterol does not find its origin in the high turnover of enterocytes and does not correlate with cholesterol synthesis in the enterocytes. Moreover, intestine perfusions performed on mice that were intravenously injected with radiolabeled cholesterol established the direct secretion of cholesterol from blood through the intestinal wall into the intestinal lumen[9,19]. Surprisingly, these reports also showed that this transintestinal cholesterol efflux (TICE) pathway in mice plays a more prominent role in the excretion of cholesterol than the hepatobiliary route.

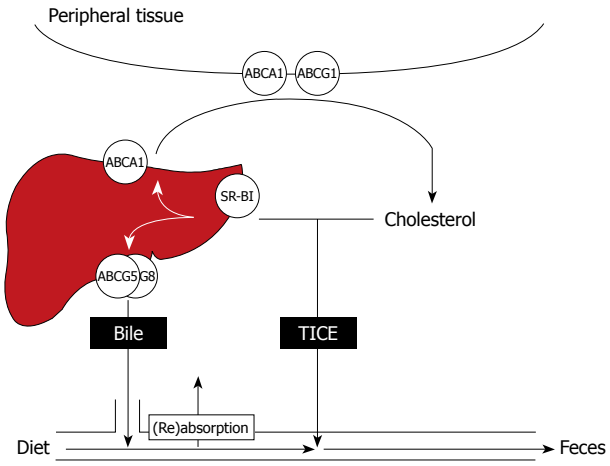

Figure 1 Schematic overview of the reverse cholesterol transport pathways. ABCA1: Adenosine triphosphate (ATP)-binding cassette transporter A1; ABCG1: ATP-binding cassette transporter G1; ABCG5: ATP-binding cassette transporter G5; ABCG8: ATP-binding cassette transporter G8; SR-BI: Scavenger receptor class B type I; TICE: Transintestinal cholesterol efflux.

While the intestine perfusions in mice showed for the first time the existence of TICE, a recent study by Brown *et al*[10] also unmistakingly showed the presence of a non-biliary route for cholesterol excretion. In their report, mice deficient for hepatic acyl-CoA: cholesterol O-acyltransferase 2 (ACAT2) had an increased fecal excretion of cholesterol without a changed biliary cholesterol secretion. Additionally, they also found intestinal cholesterol secretion to be the highest in the proximal small intestine.

With the evidence that the small intestine is not only involved in the uptake of cholesterol but also has the ability to actively secrete cholesterol, a new potentially attractive target for therapeutic lowering of cholesterol has emerged. However, more understanding of the mechanism of TICE is required.

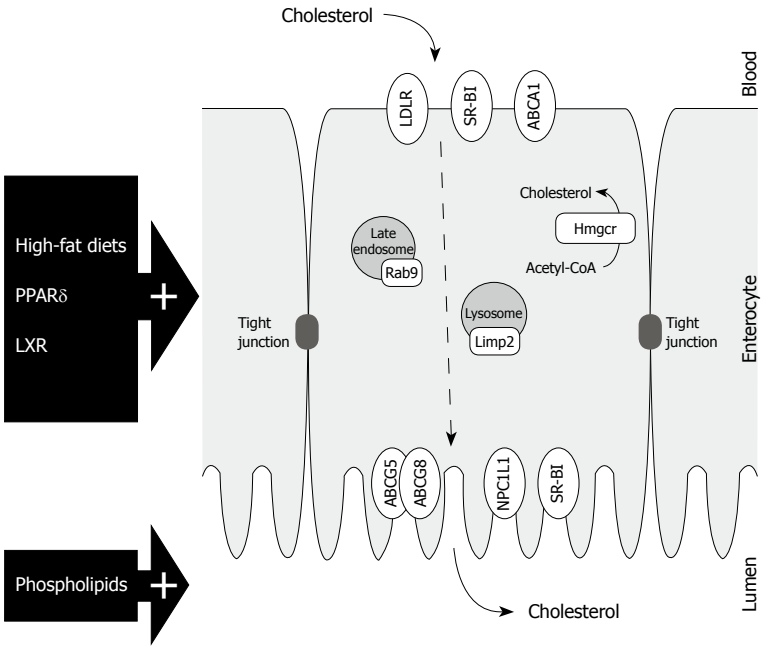

Figure 2 Enterocyte representation with a schematic overview of cholesterol transporters and potential transintestinal cholesterol efflux-related factors as discussed in this paper. PPARδ: Peroxisome proliferator-activated receptor δ; LXR: Liver X receptor; LDLR: Low density lipoprotein receptor; SR-BI: Scavenger receptor class B type I; ABCA1: Adenosine triphosphate (ATP)-binding cassette transporter A1; ABCG5: ATP-binding cassette transporter G5; ABCG8: ATP-binding cassette transporter G8; Hmgcr: 3-hydroxy-3-methyl-glutaryl-CoA reductase; Limp2: Lysosomal integral membrane protein 2; NPC1L1: Niemann-Pick C1-like 1 protein; TICE: Transintestinal cholesterol efflux.

IN VIVO STIMULATION OF THE TRANSINTESTINAL CHOLESTEROL EFFLUX PATHWAY

Several studies in mice have demonstrated that the activity of TICE can be stimulated. One of our earliest studies on TICE involved the sensitivity of this novel pathway to dietary manipulations. When mice are fed a high lipid diet, fecal neutral sterol excretion is increased[20-22]. Besides the higher input of cholesterol, this increase upon feeding with diets containing high cholesterol can be explained by reduced intestinal uptake of cholesterol and increased biliary cholesterol secretion. However, the increased fecal neutral sterol excretion seen in mice fed a high fat diet without cholesterol did not correlate with increased biliary cholesterol secretion. We studied the effect of high lipid diets on TICE and found that the secretion of cholesterol by the intestine is also increased in mice fed a western-type diet, containing high cholesterol and high fat[9]. Interestingly, a high cholesterol-only diet did not affect TICE suggesting that this secretion pathway is responsive to the fat content of the western-type diet[21]. This was confirmed in mice that were fed a high-fat diet without cholesterol. We also showed that activation of the peroxisome proliferator-activated receptor δ (PPARδ) caused an over two-fold increase in TICE[23]. This finding strengthened the link between TICE and fat metabolism since polyunsaturated fatty acids are natural ligands of this member of the nuclear receptor family[24].

Another nuclear receptor that is involved in the regulation of lipid-related metabolic processes, the liver X receptor (LXR), affects TICE as well[19,25]. In mice, activation of LXR increased fecal neutral sterol loss independent of biliary cholesterol secretion. However, the stimulation of TICE upon a high fat diet in LXRα knock-out mice suggests that LXR sensitivity of TICE occurs *via* a different pathway[22].

The effect of luminal modifications on TICE was investigated by means of introducing different combinations of bile salt-phospholipid[21]. Although the intraluminal presence of bile salts was crucial for TICE, an important finding was that, in contrast to biliary cholesterol secretion, TICE seemed to be insensitive to both the type of bile salt and bile salt concentration. The presence of intraluminal phospholipids was not essential for TICE. However, the addition of phospholipids did have a stimulatory effect on TICE.

POSSIBLE FACTORS INVOLVED IN TRANSINTESTINAL CHOLESTEROL EFFLUX

To gain better insight into this RCT pathway and identify key players in the intestine, the ability to stimulate the rate of TICE may be a helpful tool (Figure 2). Unfortunately, expression analysis of cholesterol-related genes in the small intestine from mice fed with a high-fat diet or treated with PPARδ agonist did not reveal many usual suspects[21,22]. The gene expression of the key factor in cholesterol synthesis, i.e. 3-hydroxy-3-methyl-glutaryl-CoA reductase (Hmgcr), was unaffected and the expression of most genes encoding cholesterol transporters was either unchanged or even decreased. One transporter that was upregulated in the small intestine of mice that received a high-fat diet was the scavenger receptor class B type I (SR-BI). Although it can mediate uptake from both LDL and HDL, SR-BI is mostly involved in the cellular cholesterol uptake from circulating HDL[26,27]. Considering their well accepted role in RCT *via* the hepatobiliary route, a comparable role for both SR-BI and HDL in TICE is plausible. However, a direct involvement of SR-BI has become debatable since TICE was also increased in mice deficient for SR-BI[21]. Also, *Sr-b1-/-* mice are characterized by elevated HDL-levels[28], but a possible relationship

between the physiologic concentration of HDL and the rate of TICE is questionable. In *Abca1-/-* mice, which are characterized by low HDL levels and unaltered biliary cholesterol secretion, no decrease in fecal neutral sterol excretion has been observed[29]. In addition, Briand *et al*[30] demonstrated in wild type mice that uptake of HDL by the intestine is significantly lower than the hepatic uptake. Taken together, these data dispute the direct involvement of the major players in the hepatobiliary route. How, and by which cholesterol donor, the cholesterol is transported to the intestine for TICE remains to be elucidated. However, the link that has been established between TICE and deficiency in hepatic cholesterol esterification due to liver-specific depletion of ACAT2 might help to shed some light on this part of the non-hepatobiliary cholesterol secretion route[10].

One important cholesterol transporter that was affected in both high-fat diet-fed and PPARδ agonist-treated mice, was the Niemann-Pick C1-like 1 protein (NPC1L1)[21,23]. Earlier reports could only partially explain the increased fecal neutral sterol output by the reduced cholesterol absorption caused by the attenuated expression of NPC1L1[22,31]. Despite the strong increase in fecal neutral sterol excretion in mice upon treatment with ezetimibe, the inhibitor of NPC1L1, we have shown that NPC1L1 plays no role in TICE[23].

Interestingly, gene expression analysis in the intestine of mice with an increased TICE did reveal two genes encoding proteins that have been associated with the intracellular transport of cholesterol[23]. Rab9 plays a role in cholesterol trafficking from late endosomes to the trans-Golgi network and it has been shown that overexpression of Rab9 can relieve cholesterol build up in Niemann-Pick type C cells, which is a manifestation of a lipid storage disorder[32,33].

The lysosomal integral membrane protein 2 (Limp2) is a lysosomal membrane protein that is known to bind to β-glucocerebrosidase and has specific functions in intracellular vesicular trafficking[34]. However, Limp2 is also the mouse ortholog of the human scavenger receptor class B type 2 (Scarb2) which has been shown to influence cholesterol homeostasis[35]. What the exact relationship between these two factors and TICE might be requires further studies.

Finally, a role for the heterodimer ABCG5/G8 in TICE cannot be ruled out. Despite being a likely candidate for mediating cholesterol secretion into the intestinal lumen in TICE, initial studies in mice lacking functional ABCG5/G8, as mentioned above, only helped in pointing out the existence of TICE. Since TICE was not reduced in *Abcg8-/-* mice, a possible function for ABCG5/G8 in TICE was questionable[9]. However, a more recent study from van der Veen *et al*[19] demonstrated that increase in TICE upon LXR agonist treatment was ABCG5/G8-dependent.

TRANSINTESTINAL CHOLESTEROL EFFLUX: A NEW THERAPEUTIC TARGET

Many cholesterol lowering therapies under development are aimed at increasing cholesterol excretion by stimulation of RCT. Recent studies in mice have now confirmed the presence of direct cholesterol secretion *via* the intestine. The contribution of TICE in mice to cholesterol excretion is even more prominent than that of the biliary cholesterol secretion. Of course, these observations do not constitute the existence and relevance of TICE in humans. However, by the late sixties Simmonds *et al*[36] had already observed cholesterol secretion in the small intestine after performing intestine perfusions in humans. Our group recently estimated that in humans TICE might amount to around one-third of biliary cholesterol secretion, based on average dietary cholesterol intake, biliary cholesterol secretion, and cholesterol excretion in humans[9]. Nonetheless, the exact contribution of TICE in humans still needs to be quantified. Interestingly, it has been documented that the identified and aforementioned stimulators of TICE in mice also have a positive effect on cholesterol excretion in humans. In mice, the secretion of cholesterol by the intestine could be induced by high fat diets and regulated by the phospholipid content in the intestinal lumen[21]. Several studies in men have shown that diets enriched with polyunsaturated fatty acids increase fecal sterol excretion[37-39]. Furthermore, the supplementation of phospholipids strongly stimulated the excretion of sterols in the feces in humans[40].

We are still challenged by a better understanding of the mechanistic details of this novel RCT pathway, but it is clear that TICE presents us with a therapeutic potential in the treatment of atherosclerosis. The direct role of the intestine in the reverse transport of cholesterol from "blood to gut" makes it a suitable and approachable target for cholesterol removal from the body and prevention of cardiovascular diseases.

Abstract

Reverse cholesterol transport (RCT) is a complex process which transfers cholesterol from peripheral cells to the liver for subsequent elimination from the body *via* feces. Thyroid hormones (THs) affect growth, development, and metabolism in almost all tissues. THs exert their actions by binding to thyroid hormone receptors (TRs). There are two major subtypes of TRs, TRα and TRβ, and several isoforms (e.g. TRα1, TRα2, TRβ1, and TRβ2). Activation of TRα1 affects heart rate, whereas activation of TRβ1 has positive effects on lipid and lipoprotein metabolism. Consequently, particular interest has been focused on the development of thyromimetic compounds targeting TRβ1, not only because of their ability to lower plasma cholesterol but also due their ability to stimulate RCT, at least in pre-clinical models. In this review we focus on THs, TRs, and on the effects of TRβ1-modulating thyromimetics on RCT in various animal models and in humans.

Key words: Cardiovascular disease; Cholesterol; Lipoprotein metabolism; Reverse cholesterol transport; Thyroid hormones; Thyroid hormone receptors

INTRODUCTION

Cardiovascular disease (CVD), resulting from the progression of atherosclerosis, is the leading cause of mortality and is no longer a disease limited to Western countries (for data and statistics visit the World Health Organization homepage at www.who.int). To date, the first treatment choice in the prevention and treatment of CVD are the 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, commonly known as statins[1]. These compounds lower hepatic cholesterol levels by activation of sterol regulatory element binding protein 2 (SREBP2). Activation of SREBP2 induces the expression of the low density lipoprotein (LDL) receptor (LDLR), which results in increased uptake of LDL-particles from plasma (see Figure 1 for a schematic representation of lipoprotein metabolism). Newer drugs such as ezetimibe, which acts by blocking intestinal cholesterol uptake, have recently been proposed as complements to statin therapy. Despite these new therapeutic approaches there is still a demand for improved treatment strategies, especially in light of the failure of some clinical trials[2]. A long debated approach is to promote reverse cholesterol transport (RCT)[3]. RCT is a complex process which transfers cholesterol from pe-

ripheral cells to the liver for subsequent elimination in the feces as bile acids and neutral steroids. RCT was originally proposed by Glomset[4] more than 40 years ago. Recently a non-biliary route for cholesterol elimination from the body has been described, named trans intestinal cholesterol excretion (TICE), in which cholesterol can be transported directly from blood across the enterocytes into the intestinal lumen[5].

THYROID HORMONES AND THYROID HORMONE METABOLITES

Thyroid hormones (THs) have prominent effects on growth, development, and metabolism in almost all tissues[6,7]. Thyroxine (T_4) and triiodothyronine (T_3) are synthesized by the thyroid gland and T_4 is the major secreted hormone. Yet, T_3 is classically considered as the active and more potent hormone since it binds to thyroid hormone receptors (TRs) with higher affinity than T_4. Selenoproteins known as deiodinases[8] convert T_4 to T_3 by 5' deiodination of the outer ring of molecules and regulate the local and systemic availability of T_3. Different types of deiodinases exist: type Ⅰ are present in peripheral tissues including the liver; type Ⅱ are mainly present in the pituitary gland, brain, and brown adipose tissue; and type Ⅲ are present in the placenta, brain, and skin. Whereas type Ⅰ deiodinases convert T_4 in the majority of circulating T_3, type Ⅱ deiodinases not only contribute to the circulating levels but also to the intracellular levels of T_3. Thus, type Ⅱ deiodinases confer to the tissues expressing this type of enzyme the ability to respond to circulating T_4 without being obligated to circulating T_3. Type Ⅲ deiodinases, together with type Ⅰ, convert T_4 into reverse T_3 (rT_3). rT_3 was regarded as an inactive metabolite, since no metabolic effects of rT_3 has been reported, however, the discovery of non-genomic actions of rT_3 on actin polymerization and microfilament organization in astrocytes and in the cerebellum[6,9] has shown that this molecule is active. In addition to deiodination, THs are metabolized by sulfation and glucuronidation[10]. These processes primarily occur in the liver, and to a lesser extent in the kidney, and results in relatively inactive metabolites with increased water solubility, which facilitate biliary and urinary secretion. When the activity of type Ⅰ deiodinases is low (e.g. in the fetus), T_3 sulfate may serve as a reservoir of inactive T_3 from which the active hormone can be generated by the action of tissue and intestinal bacterial sulfatases[11]. Similarly, iodothyronine glucuronides once excreted *via* the bile into the intestine can be substrates for the bacterial β-glucuronidases and the unconjugated THs generated can be reabsorbed into the body. Thus, THs undergo enterohepatic recirculation[12].

In the liver, oxidative deamination and decarboxylation of the alanine chain of T_3 and T_4 form triiodothyroacetic acid (Triac) and tetraiodothyroacetic acid (Tetrac), respectively. These so-called acetic acid analogues of THs are metabolically active. Tetrac has been evaluated in patients with myxedema and no major differences in efficacy were reported compared to T_4, except for the need for higher doses of Tetrac[13]. Also for Triac, the therapeutic doses to treat thyroid disorders are higher than those needed for T_4 in order to reach similar thyroid-stimulating hormone suppression[14]. Interestingly, Triac had bigger hepatic metabolic actions without enhanced thyromimetic activity specific to the pituitary gland[14]. The organ-selective effects of Triac are possibly explained by the higher affinity of this acetic acid analogue to TRβ (3.5-fold) and to TRα (1.5-fold) than T_3[15].

THYROID HORMONE RECEPTORS

TRs are members of the large superfamily of nuclear receptors (NRs) and can bind DNA as monomers, homodimers, or heterodimers mainly with the retinoic-X receptor α[16-18]. TRs are ligand-activated transcription factors and bind both THs and TH-response elements (TREs) classically located in the promoter regions of their target genes. TRs have the typical NR structure with a central DNA-binding domain containing two "zinc fingers" motifs which interact with the nucleotide of the TRE-sequences. The ligand-binding domain (LBD) is composed of twelve amphipathic helices, some of which specifically interact with co-activators and co-repressors[19-21]. Upon ligand-activation, TRs modify the conformation of their LBD region; a process that mainly involves helix 12 and results in release of co-repressors (e.g. NCoR and SMRT) and recruitment of co-activators (the steroid receptor co-activator complex[22] and the vitamin D receptor-interacting protein/TR associated protein complex[23]). Due to the interaction with co-repressors, TRs can decrease the transcriptional activity of the target genes, when not ligand-activated by THs. The interpretation of data generated in animal models in which TRs have been genetically depleted require caution when compared to conditions with low levels of circulating THs (e.g. after thyroidectomy, hypophysectomy, or in hypothyroidism). Under these conditions TRs are not ligand-activated and, being still present, may repress transcription. Apart from the genomic effect, which classically are mediated by activation of TRs bound to the promoter region of the target genes, THs may also regulate cells by non-transcriptional mechanisms[7].

The human TRs are encoded by the THRA and THRB genes, located on chromosome 17 and 3, respectively; the two TRα isoforms [TRα1, TRα2 (or c-erbAα2)] are generated by alternative splicing of the TRα mRNA whereas the two TRβ isoforms (TRβ1 and TRβ2) are generated by alternative promoter choice[16,24]. Both TRα1 and TRβ1 are expressed in almost all tissues[25], but the latter is the predominant TR isoform in the liver, brain, and kidney, whereas the former is predominantly expressed in muscle and brown adipose fat. TRβ2 is expressed in the hypothalamus, in the anterior pituitary gland, and in the developing brain[25-27].

LESSONS FROM STUDIES IN RODENTS

The generation of TR specific knock-out mice revealed that the T_3-induced cardiovascular liability is mediated by

TRα1[28,29], while the effect of T_3 on plasma cholesterol levels is mediated through TRβ1[30]. These findings raised interest in the development of thyromimetic compounds that specifically modulate TRβ1, either by selective hepatic uptake and/or by higher binding affinity to TRβ1, rather than TRα1. The first thyromimetic compound to be described was SK&F L-94901, which does not preferentially bind to either TRα or TRβ; instead the TRβ1 selective action is achieved by its liver-specific uptake[31]. L-94901 reduced plasma cholesterol levels, mainly in the LDL fraction, in cholesterol-fed hypothyroid and euthyroid rats[32]. Likewise, GC-1 (sobetirome) and KB-141 reduced plasma cholesterol levels in normal and hypothyroid mice and rats[33,34]. T-0681 decreased plasma apoB-containing lipoproteins and reduced atherosclerosis in cholesterol-fed rabbits[35], while MB07811 elicited a similar lipid-lowering effect in rats, as well as in obese mice[36].

The ability of thyromimetic compounds to reduce LDL-cholesterol can partly be explained by increased clearance through increased hepatic LDLR expression. KB-141, MB07811, and T-0681 induced hepatic LDLR expression in several mouse models[35,36], and T-0681 increased hepatic LDLR levels (approximate 2.5-fold) in hypercholesterolemic rabbits[35]. In accordance, LDLR expression was suggested to be crucial for the thyromimetic effect on lipid metabolism, since mice deficient in LDLR do not respond to treatment with either MB07811[36] or T-0681[35]. However, T_3 and sobetirome failed to induce hepatic LDLR mRNA expression and activity, despite reduced circulating levels of LDL-cholesterol in hyper-

cholesterolemic euthyroid mice[34]. Similarly, T-0681 had no effect on the hepatic LDLR protein expression in either C57BL/6 or apoE$^{-/-}$ mice[35]. Thus, the stimulation of LDLR by thyromimetics is not an obligatory finding.

In all animal models, the lipid-lowering effects were achieved at doses that did not affect the heart rate. For sobetirome and KB-141, the concentrations that produced tachycardia were almost 30-fold higher than the therapeutic concentrations in rats and even greater in non-human primates[33].

EFFECTS OF THYROID HORMONES AND THYROMIMETICS ON RCT IN RODENTS

Evidence from animal studies suggested that THs and thyromimetics have the capacity to promote RCT. Despite its complexity, the RCT pathway can be summarized in four major steps: (1) synthesis and lipidation of apolipoprotein AI (apoAI) to generate nascent high density lipoprotein (HDL); (2) efflux of excess cholesterol from peripheral cells (e.g. macrophages) to plasma HDL; (3) hepatic uptake of cholesterol from HDL *via* scavenger receptor class B type I (SRBI) and LDL *via* LDLR - the latter especially in the presence of cholesterol ester transfer protein (CETP); and (4) biliary secretion of cholesterol, as such, or after its conversion to bile acids, for final excretion from the body in feces.

Studies in rodents showed that T_3 and the thyromimetic compound CGS-23425 increased the levels of plasma apoAI[37,38], suggesting that TR stimulation may promote the synthesis of HDL and thus affect the initial step of RCT. Whether thyromimetic compounds stimulate cholesterol efflux to HDL by a direct action on peripheral cells (e.g. macrophages) is still unclear. Studies in rodents show that the ability of THs and thyromimetics to increase RCT is related to their capacity to stimulate the hepatic and final steps of this process by increasing the expression and activity of: (1) SRBI, responsible for the uptake of cholesterol-enriched HDL; (2) cholesterol 7α-hydroxylase (CYP7A1), which converts cholesterol into bile acids in the liver; and (3) ATP-binding cassette transporter G5 (ABCG5) and G8 (ABCG8), which promote biliary cholesterol excretion[30,34-36].

The regulation of bile acid synthesis by TRs and THs has been widely demonstrated in rodents[39-41]. In mice, TRβ has been identified as the primary mediator of the effect of T_3 on the stimulation of CYP7A1 expression and activity[30]. Also thyromimetic compounds such as MB07811, KB-141, T-0681, or sobetirome have been shown to increase the expression of hepatic CYP7A1[34-36]. In addition to the stimulation of bile acid synthesis, we were able to show that sobetirome increases the hepatic SRBI protein expression in normal and hypercholesterolemic euthyroid mice, leading to lower HDL-cholesterol levels and higher fecal bile acid excretion[34]. A limitation of our study was that a direct quantification of the *in vivo* RCT was not performed. RCT can be quantified *in vivo* by assessing the transport of [^{3}H]cholesterol from intraperitoneally injected macrophages to plasma, liver, and feces (called the macrophage-to-feces RCT)[42,43]. Recently, T-0681 was shown to stimulate the *in vivo* RCT in C57BL/6 mice[35] resulting in elevated fecal excretion of radiolabeled cholesterol, both as neutral sterols and as bile acids. This was paralleled by an increase in the hepatic expression of SRBI, CYP7A1, and ABCG5/G8[35].

Mice and rats have no plasma activity of CETP, which transfers cholesteryl esters from HDL to LDL. Thus, the RCT pathway in these rodent models does not properly resemble the human RCT, in which part of the cholesterol originally carried by HDL is delivered to the liver by LDL. Overexpression of human CETP in mice stimulates the *in vivo* RCT and, as expected, a considerable amount of the radiolabeled cholesterol effluxed from the macrophages was transferred from HDL to LDL for subsequent uptake by hepatic LDLR[44]. Surprisingly, T-0681 failed to stimulate *in vivo* RCT in mice overexpressing human CETP[35], despite the stimulation of hepatic SRBI and LDLR. In this mouse model, T-0681 did not affect hepatic ABCG5/G8 and CYP7A1 expression, as observed in wild-type mice[35]. Plasma CETP-mass was reduced and the authors suggested this was a possible cause of disturbed delivery of cholesterol to the liver[35]. Nevertheless, it is evident that it is difficult to draw any definite conclusions relevant to humans by studying mice overexpressing human CETP. In apoE knockout mice, treatment with T-0681 for 8 wk decreased plasma cholesterol levels and reduced the development of atherosclerosis, whereas treatment for 4 wk slightly increased small fatty streak lesions[35]. In line with the above observation, up-regulation of both hepatic ABCG5/G8 and CYP7A1 were only observed after 8 wk of treatment[35]. Recently, we treated (up to 25 wk) apoE-deficient mice with the new thyromimetic compound KB3495 (KaroBio AB). Reduced atherosclerosis and increased fecal excretion of neutral and acidic sterols were observed independently of the circulating levels of cholesterol in apoB-containing lipoproteins. This suggests that stimulation of RCT was *per se* sufficient to achieve the antiatherogenic effects[45]. Furthermore, no major effects on the hepatic expression of ABCG5/G8 mRNA were seen suggesting that TRβ1 modulation may increase RCT possibly by stimulation of TICE[5].

LESSONS FROM STUDIES IN HUMAN AND PRIMATES

It has been known since 1930 that hyperthyroidism is associated with reduced plasma cholesterol levels[46]. Also, studies have shown that hyperthyroid women have lower HDL-cholesterol and apoAI levels compared to healthy controls[47,48]. In addition, treatment with 1-thyroxine in patients with severe primary hypothyroidism significantly increased apoAI but modestly decreased HDL-cholesterol levels[49]. Interestingly, subjects with resistance to thyroid hormone, defined genetically by mutations in TRβ, have lower HDL-cholesterol levels compared to controls[50].

So far, no human or non-human primate studies that specifically aimed to investigate the role of thyromimetics in RCT have been performed. Rodents, unlike humans,

transport plasma cholesterol mainly in HDL-particles, lack CETP activity in plasma, and do not develop atherosclerosis. Also, the feed-forward response on Cyp7A1 activity by dietary cholesterol, which is mediated by activation of liver X receptor α (LXRα) in mice, is absent in humans, because functional LXRα response elements are not present within the human CYP7A1 promoter[51]. Hence, caution is required when extrapolating mechanisms in RCT from rodent studies to humans.

EFFECTS OF THYROMIMETICS ON BILE ACID SYNTHESIS IN HUMANS

Bile acid synthesis serves as the major elimination route of excess cholesterol, participating in maintenance of cholesterol homeostasis and in the hepatic part of RCT. In the liver, cholesterol is converted to 7α-hydroxycholesterol by the microsomal enzyme CYP7A1, the rate-limiting enzyme of the classic pathway, which is then converted to 7α-hydroxy-4 cholesten-3-one (C4). In humans, the classic pathway is responsible for the main part of bile acid synthesis[52]. Thus, it has been shown that plasma levels of C4 reflect bile acid synthesis and that plasma levels of C4 correlate with the enzymatic activity of CYP7A1 assayed in human hepatic microsomes[53-56].

Studies in human hepatoma cells and in primary human hepatocytes suggest that human CYP7A1 expression and promoter activity is actively repressed in response to THs[57,58], suggesting that THs and thyromimetic compounds would decrease bile acid synthesis. Nevertheless, treatment of moderately overweight and hypercholesterolemic subjects with eprotirome (KB2115), administered at 100 and 200 μg orally once daily for 2 wk, increased bile acid synthesis (C4) by approximate 50% and 100%, respectively. Since no effect on cholesterol synthesis in the body (indirectly measured as the ratio of lathosterol to cholesterol in plasma)[59] was observed it seems that eprotirome may induce a net cholesterol efflux from the body[59].

EFFECTS OF THYROMIMETICS ON HDL, apoAI, apoB AND LIPOPROTEIN (a) IN HUMANS AND NON-HUMAN PRIMATES

Measurement of apoAI, the major apolipoprotein in HDL, is as important as the measurement of HDL-cholesterol and the balance between apoB and apoAI (i.e. the apoB/apoAI ratio) indicates cardiovascular risk[60]. In a study by Ladenson *et al*[61], patients with hypercholesterolemia, who were already receiving simvastatin or atorvastatin, were administered 25, 50 or 100 μg eprotirome (KB2115) or placebo daily for 12 wk in addition to continued statin-therapy[61]. Serum total-, LDL-, and HDL-cholesterol, as well as apoB, apoAI, apoB/apoAI ratio, TG, and lipoprotein (a) [Lp(a)] decreased in the eprotirome-treated subjects[61] without adverse effects on heart or bones. In the study by Berkenstam *et al*[59], treatment with eprotirome was found to reduce serum total- and LDL-cholesterol levels as well as the apoB/apoAI ratio without detectable effects on the heart[59]. No significant changes in HDL-cholesterol, TG, Lp(a), or body weight were observed[59]. The discrepancies between these two studies with regard to HDL-cholesterol and apoAI, and whether the combination-therapy with statins and eprotirome[61] affects this, needs to be further investigated by studying CETP and lecithin cholesterol:acyltransferase (LCAT) activities, C4, hepatic gene expression (e.g. SRBI, CYP7A1, ABCG5/G8, ABCA1), and by studies on sterol fecal excretion.

Intestinal and hepatic ABCA1 regulates HDL levels[62,63]. Co-transfection experiments, performed in human embryonal kidney cells (HEK293) with the human ABCA1 promoter and an expression vector for TRβ, showed suppression of the ABCA1 promoter activity in the presence of T_3[64]. Whether TRβ1-modulators suppress the hepatic and intestinal ABCA1 transcription and expression *in vivo* in humans remains to be elucidated.

Lp(a) may contribute to the development of atherosclerosis, and extreme levels have been shown to increase the risk for myocardial infarction[65]. Cynomolgus monkeys have a lipoprotein cholesterol profile that resembles the human profile and express Lp(a). Sobetirome and KB141 reduce plasma levels of Lp(a) in this non-human primate model[33]. Eprotirome in combination with statin-treatment reduced the levels of Lp(a)[61] which was not observed in patients treated with eprotirome only[59], suggesting again that a possible synergism between statins and eprotirome may exist.

CONCLUSION

Compounds that specifically target TRβ1 have consistently been shown to stimulate RCT and decrease atherosclerosis in animal models, and may hypothetically be useful as a complement to statin therapy in the prevention of CVD. However, future studies evaluating the effects of these compounds on RCT in humans need to be performed. Clarification of the primary effect of TRβ1 modulation on human RCT is of great scientific value and strategic interest. The attractiveness of drugs able to promote RCT and lower LDL-cholesterol in humans - especially if not only acting *via* stimulation of LDLR - is immense.

Abstract

AIM: To develop a multiplex reverse transcription polymerase chain reaction (RT-PCR) method detecting circulating tumor cells in the peripheral blood of colorectal cancer (CRC) patients.

METHODS: Peripheral blood samples were collected from 88 CRC patients and 40 healthy individuals from the blood donors' clinic and subsequently analyzed by multiplex RT-RCR for the expression of carcinoembryonic antigen (CEA), cytokeratin 20 (CK20) and epidermal growth factor receptor (EGFR) mRNA. The analysis involved determining the detection rates of CEA, CK20 and EGFR transcripts *vs* disease stage and overall survival. Median follow-up period was 19 mo (range 8-28 mo).

RESULTS: Rates of CEA, CK20 and EGFR detection in CRC patients were 95.5%, 78.4% and 19.3%, respectively. CEA transcripts were detected in 3 healthy volunteer samples (7.5%), whereas all control samples were tested negative for CK20 and EGFR transcripts. The increasing number of positive detections for CEA, CK20 and EGFR transcripts in each blood sample was positively correlated with Astler-Coller disease stage ($P < 0.001$) and preoperative serum levels of CEA ($P = 0.029$) in CRC patients. Data analysis using Kaplan-Meier estimator documented significant differences in the overall survival of the different CRC patient groups as formed according to the increasing number of positivity for CEA, CK20 and EGFR transcripts.

CONCLUSION: These data suggest that multiplex RT-PCR assay can provide useful information concerning disease stage and overall survival of CRC patients.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies in the Western world. In Europe, CRC is the second most frequent cause of death from cancer, after lung cancer[1]. Although surgical resection followed by chemotherapy is the leading treatment option, approximately half of the patients eventually die due to distant metastases[2]. Overall survival is associated with the disease stage at the time of diagnosis, suggesting that early detection of disseminated disease may be of great significance[3]. Consequently, the development of new diagnostic methods that allow better definition of disease stage and better monitoring of disease progression is critical.

In the past years, various techniques have been used for the detection of circulating tumor cells (CTCs) derived from solid tumors in different body compartments, with variable results concerning their accuracy and clinical significance. Reverse transcription polymerase chain reaction (RT-PCR)-based methods have allowed the detection of CTCs in peripheral blood samples, which is characterized by great sensitivity compared to protein-based tumor marker estimations in serum[4]. However, controversial data have been reported, mainly associated with the choice of molecular tumor markers, cohort size and patient characteristics, as well as false-positive and false-negative results, caused by different PCR conditions and different sets of primers employed by different laboratories.

Among several molecular markers, cytokeratin 20 (CK20), carcinoembryonic antigen (CEA) and epidermal growth factor receptor (EGFR) are those more frequently used for CTC detection in CRC[5-7]. CK20 is a member of the intermediate filament protein family and a prominent component of the intestinal epithelium. CK20 expression is confined to gastrointestinal epithelium, urothelium, and Merkel cells of the epidermis, as well as malignancies that originate from the aforementioned sites[8-10]. Serum levels of CEA are commonly used in clinical practice for patient monitoring[11-14]. In addition, CEA and CK20 mRNA detection using RT-PCR methods have been widely investigated for the detection of CTCs in CRC patients[15-22]. Furthermore, EGFR has been suggested as a marker that is seldom expressed in hematopoietic cells[23-25], thus detection of EGFR over-expression in CRC patients has been correlated with the advanced clinical stages and disease progression in CRC patients[26-30].

The aim of the present study was to establish a multiplex PCR assay targeting the detection of CEA, CK20 and EGFR mRNAs in a single PCR reaction and to evaluate its possible clinical use in CRC patients.

MATERIALS AND METHODS

Subjects

Eighty eight patients (56 males and 32 females) with biopsy-proven primary CRC were enrolled in the study between June 2007 and June 2009. All patients underwent surgical resection for the primary tumor at the "Saint Savvas" Anticancer Hospital, the "G. Gennimatas" Athens General Hospital and the "Attikon" University Hospital, Athens, Greece. The mean age was 69 years (range 43-88 years). Peripheral blood samples were also collected from 40 healthy volunteers (20 men and 20 women), which were used as negative controls. Informed consent was obtained from all patients and healthy volunteers. The study was approved by the local Ethics Committee and conformed to the ethical standards of the Helsinki Declaration.

Cell lines and tissue samples

HT-29 CRC cells are known to express the 3 molecular markers used in our experiments and have been used in spiking experiments for the definition of the sensitivity of the assay[16,31-37]. HT-29 cells were maintained in Dulbecco's modified Eagle's medium/F-12 (Cambrex, Walkerville, MD, USA), supplemented with 10% heat-inactivated fetal bovine serum (Biochrom, Berlin, Germany) and 100 U/mL penicillin/streptomycin (Cambrex), at 37℃ in a humidified atmosphere of 5% CO_2.

CRC and matched normal adjacent tissue samples were obtained from 3 CRC patients during surgery, with the aim of confirming the expression of CEA, CK20 and EGFR mRNA in CRC specimens. The samples were collected in RNAlater solution (Ambion, Austin, TX) and subsequently homogenized (Ultra-Turrax T25; Thermo Fisher Scientific, Cheshire, UK) in 1 mL Tri Reagent TR-118 (MRC Inc. Cincinnati, OH, USA) at 500 *g*.

Blood sample preparation and RNA extraction

Three milliliters peripheral blood samples were taken preoperatively using a venous catheter into 3 mL EDTA-containing vacutainers (2 samples were obtained from each patient). All blood samples were processed within 4 h of collection. Each blood sample was added to 7.5 mL of Erythrocyte Lysis Buffer (ELB) (containing 155 mmol/L NH_4Cl, 10 mmol/L $KHCO_3$ and 0.1 mmol/L EDTA pH 7.4) and kept on ice for 45 min with occasional mixing by inversion every 5 min, so as to allow erythrocyte lysis. The samples were then centrifuged at 400 *g* for 10 min at 4℃ and the supernatant was discarded. The pellet of nuclear blood cells was resuspended in 5 mL of ELB and kept on ice for an additional 5 min period in order to remove the remaining red blood cells. Next, the pellet was centrifuged at 400 *g* for 10 min at 4℃. The pellet was then homog-

Table 1 Primer sequences used for reverse transcription polymerase chain reaction amplification of target transcripts

CEA: Carcinoembryonic antigen; CK20: Cytokeratin 20; EGFR: Epidermal growth factor receptor; PCR: Polymerase chain reaction.

enized in 1 mL Tri Reagent TR-118 (MRC Inc. Cincinnati, OH, USA) using a 5 mL syringe. Total cellular RNA was extracted using Tri Reagent TR-118, according to manufacturer instructions. The RNA pellet was diluted in diethylpyrocarbonate treated water; total RNA concentration and purity were determined by UV spectrophotometry (Biospec-nano, Shimadzu Biotech, Kyoto, Japan) and its quality was confirmed by amplification of cDNA for β-actin housekeeping gene.

RT-PCR

cDNA was synthesized using Moloney murine leukemia virus (M-MuLV) reverse transcriptase RNase H$^-$ (Finnzymes, Oy, Finland). Briefly, a mixture containing 1 μg of total RNA, 0.5 μg (25 μg/mL) oligo-dT$_{(18)}$ primer (Fermentas) and nuclease free water in a total volume of 15 μL was heated at 70℃ for 5 min and then chilled in ice for another 5 min. The mixture was supplemented with 0.5 mmol/L deoxynucleotides (HT Biotechnology LTD), reverse transcriptase buffer containing 50 mmol/L Tris-HCl (pH 8.3), 75 mmol/L KCl, 3 mmol/L $MgCl_2$, and 10 mmol/L DTT, 40 U Human Placental RNase inhibitor (HT Biotechnology LTD) and finally 200 U M-MuLV reverse transcriptase up to a final volume of 20 μL; it was subsequently incubated at 37℃ for 60 min. Table 1 presents the exact sets of primers used in our study. The sensitivity of the assay was determined in spiking experiments using serial dilutions of HT-29 CRC cells; 10^5, 10^4, 10^3, 10^2, 10, 1 and 0 cancer cells were added to different corresponding tubes, each containing 3 mL of blood taken from the same healthy subject. Spiking experiments were followed by erythrocyte lysis and RNA extraction, as described above.

PCR conditions

Primer pairs were chosen so that the sequences were located at different exons and their specificity was confirmed using NCBI Blast (Table 1). PCR reaction was performed using *Taq* DNA Polymerase (Qiagen, Hilden, Germany) in a final reaction volume of 25 μL containing 1 × CoralLoad PCR Buffer (contains 15 mmol/L $MgCl_2$), 1.67 mmol/L $MgCl_2$ (final concentration), 200 μmol/L each dNTP and 2.5 U *Taq* DNA Polymerase; cDNA volume and primer concentrations varied depending on the marker and the sample examined. For the amplification of tissue sample cDNAs, primer concentrations and cDNA volumes were 0.4 μmol/L and 2 μL, respectively for all markers, while cycling conditions were 94℃ for 3 min; 94℃ for 1 min, 52℃ for 1 min, 72℃ for 1 min (36 cycles); 72℃ for 10 min for CEA and CK20 cDNA amplifications then 94℃ for 3 min; 94℃ for 1 min, 57℃ for 1 min, 72℃ for 1 min (35 cycles); 72℃ for 10 min for the amplification of EGFR cDNA. The concentrations and the cycling conditions concerning PCR reactions in serial dilutions of HT-29 cells for each marker were as follows: for the amplification of CEA cDNA, 0.08 μmol/L of primers and 1 μL of cDNA were used, while the cycling conditions were 94℃ for 3 min, 94℃ for 30 s, 58℃ for 20 s, 72℃ for 30 s (40 cycles); 72℃ for 2 min; similarly, CK20 cDNA was amplified using 0.35 μmol/L of primers and 1 μL of cDNA, and PCR cycling conditions were 94℃ for 3 min; 94℃ for 30 s, 58℃ for 20 s, 72℃ for 30 s (36 cycles); 72℃ for 2 min; finally, the primer concentration used for EGFR assays was 0.4 μmol/L and 2 μL of cDNA added to the PCR mix, while amplification took place at 94℃ for 3 min; 94℃ for 1 min, 50℃ for 1 min, 72℃ for 1 min (39 cycles); 72℃ for 10 min. For the multiplex PCR reactions 2 μL of cDNA were used, adding primer concentrations as follows: CEA 0.06 μmol/L, CK20 0.15 μmol/L and EGFR 0.5 μmol/L. Cycling conditions were 94℃ for 15 min; 94℃ for 30 s, 58℃ for 20 s, 72℃ for 30 s (37 cycles); 72℃ for 10 min. PCR products were analyzed by electrophoresis on a 2% agarose gel followed by ethidium bromide staining and then captured under ultraviolet light in a Kodak EDAS 290 imaging system (Carestream Health, Rochester, NY, USA).

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences Predictive Analytics Software (SPSS PASW Statistics ver. 18.0) (SPSS Inc., Chicago, IL). The potential correlation between the molecular marker expression and the clinical and pathological characteristics of the patients was tested by Spearman's correlation. The overall survival rates were calculated using the Kaplan-Meier estimator and comparisons of survival curves between patient groups were carried out by the log-rank test. Overall survival was defined as the intermediate time interval between sampling and either death or last follow-up. To assess the independent prognostic significance of factors on overall survival, analysis was performed using the Cox proportional hazards regression analysis. A P value < 0.05 was considered to be statistically significant.

RESULTS

After CEA, CK20 and EGFR mRNA expression was

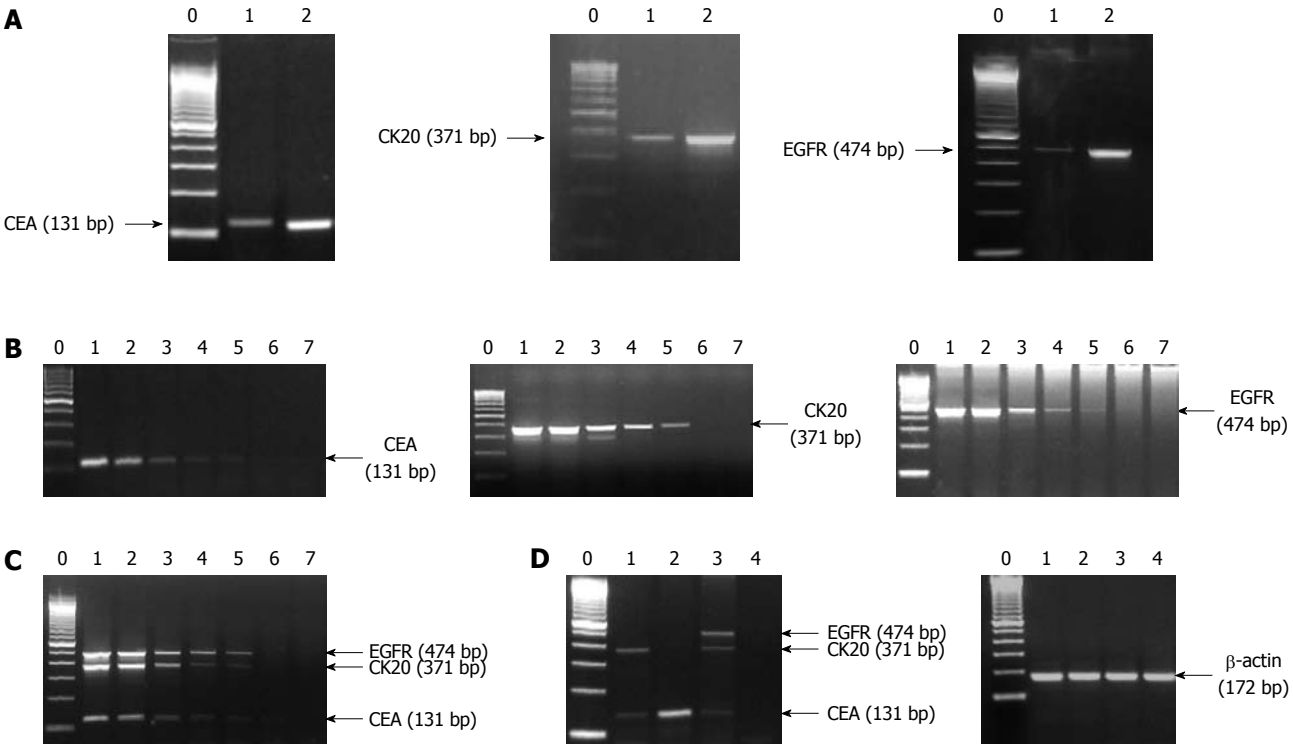

Figure 1 Detection of carcinoembryonic antigen, cytokeratin 20 and epidermal growth factor receptor mRNAs in colorectal cancer tissue samples, HT-29 colorectal cancer cells and colorectal cancer patient peripheral blood samples. A: Detection of carcinoembryonic antigen (CEA), cytokeratin 20 (CK20) and epidermal growth factor receptor (EGFR) mRNA in pairs of colorectal cancer (CRC) and normal adjacent tissue samples. Lane 0 = molecular weight marker (100 bp); lane 1 = normal tissue; lane 2 = CRC tissue; B: Assessment of the sensitivity of the reverse transcription polymerase chain reaction (RT-PCR) detections for CEA, CK20 and EGFR mRNA. Lane 0 = molecular weight marker (100 bp); lane 1 = 10^5 HT-29 cells in 3 mL of normal blood; lane 2 = 10^4 HT-29 cells in 3 mL of normal blood; lane 3 = 10^3 HT-29 cells in 3 mL of normal blood; lane 4 = 10^2 HT-29 cells in 3 mL of normal blood; lane 5 = 10 HT-29 cells in 3 mL of normal blood; lane 6 = 1 HT-29 cell in 3 mL of normal blood; lane 7 = normal blood; C: Assessment of the sensitivity of the multiplex RT-PCR detections for CEA (131 bp), CK20 (371 bp) and EGFR (474 bp) mRNA. Lane 0 = molecular weight marker (100 bp); lane 1 = 10^5 HT-29 cells in 3 mL of normal blood; lane 2 = 10^4 HT-29 cells in 3 mL of normal blood; lane 3 = 10^3 HT-29 cells in 3 mL of normal blood; lane 4 = 10^2 HT-29 cells in 3 mL of normal blood; lane 5 = 10 HT-29 cells in 3 mL of normal blood; lane 6 = 1 HT-29 cell in 3 mL of normal blood; lane 7 = normal blood; D: An example of multiplex RT-PCR-based detection pattern of tumor marker transcripts in the peripheral blood samples of CRC patients. Left: lane 0 = molecular weight marker (100 bp); lane 1 = patient sample positive for CEA (131 bp) and CK20 (371 bp) mRNA; lane 2 = patient sample positive for CEA (131 bp) mRNA; lane 3 = patient sample positive for CEA (131 bp), CK20 (371 bp) and EGFR (474 bp) mRNA; lane 4 = patient sample negative for all markers. Right: lane 0 = molecular weight marker (100 bp); lanes 1-4 = amplification of β-actin (172 bp) cDNA of the patient samples presented in the left side of this panel.

confirmed in pairs of CRC and normal adjacent tissue samples, spiking experiments with HT-29 cells were conducted for establishing the sensitivity of the assay when each marker was run independently (Figure 1). The assay conditions were then accordingly normalized so as to allow the reproducible detection of 10 HT-29 cells in 3 mL of normal blood for all 3 markers examined by multiplex PCR reaction (Figure 1). This cut-off limit has been shown to be of clinical significance in our studies with prostate cancer patients[41-43]. The detection of each marker both in HT-29 cells and in tissue samples (Figure 1, Panel A) was followed by digestion of the PCR product using restriction enzymes (initial development, data not shown). An example of various detection patterns of CEA, CK20 and EGFR transcripts is presented in panel D of Figure 1.

Out of the 40 healthy peripheral blood samples that were examined, 3 were positive for CEA transcripts, resulting in a specificity percentage of 92.5%. We were unable to correlate this finding with any particular clinical information on file of these volunteers. However, both CK20 and EGFR transcripts were absent from the analysis of healthy samples (specificity 100%). CRC patient characteristics are presented in Table 2.

Cox regression analysis was performed by grouping CRC patients according to the number of detected transcripts using our assay, with the aim of comparing the clinical significance of such detection patterns in CRC patients. Six groups of CRC patients were defined: group 0: no marker expression; group 1: positive only for CEA; group 2: positive for CEA and CK20; group 3: positive for all three markers; group 4: patients of groups 1 and 2 and group 5: patients of groups 2 and 3. Disease stage was found to be an independent prognostic factor for survival when comparisons were performed between group 1 and group 2 ($P = 0.005$), between group 2 and group 3 ($P = 0.005$), between group 3 and group 4 ($P = 0.003$) as well as between group 1 and group 5 ($P = 0.002$). When group 1 and group 3 were compared, tumor size was found to correlate significantly with survival ($P = 0.040$); however, the analysis showed a suggestive prognostic significance of other factors, such as lymph node involvement ($P = 0.088$), stage ($P = 0.066$), sex ($P = 0.062$) and the positivity for all transcripts detection ($P = 0.060$). Cox regression

Disease staging according to the modified Astler-Coller classification. A positive correlation was revealed using Spearman's test (Spearman's ρ = 0.396, $P < 0.001$). CRC: Colorectal cancer.

analysis could not be performed for the comparison of group 0 with the other groups, since all 4 patients with negative detection for all 3 markers were still alive at the time of analysis.

Our analysis revealed that 84 of 88 CRC patients (95.5%) were positive for CEA transcripts; 69 of 88 (78.4%) were positive for CK20 transcripts and 17 of 88 (19.3%) were positive for EGFR transcripts. In particular, 3 of 4 (75%) stage A; 23 of 26 (88.5%) stage B; 27 of 27 (100%) stage C and 31 of 31 (100%) stage D patients were positive for CEA transcripts. In addition, 1 of 4 (25%) stage A, 18 of 26 (69.2%) stage B, 21 of 27 (77.8%) stage C and 29 of 31 (93.5%) stage D CRC patients tested positive for CK20 transcripts. The EGFR transcripts were detected in 17 of 88 (19.3%) patients: in 2 of 26 (7.7%) stage B; in 4 of 27 (14.8%) stage C and in 11 of 31 (35.5%) stage D. No EGFR transcripts were detected in stage A CRC patients. The correlation of PCR detections to disease stage are presented in Table 3.

We documented that 84 CRC patients (95.5%) were positive by multiplex RT-PCR for at least one transcript (CEA); 69 (78.4%) were positive for at least two transcripts (CEA plus CK20), whereas 17 (19.3%) were positive for all 3 transcripts. Four (4.5%) patients showed no transcript detection. The association between clinical and pathological characteristics of patients with multiplex PCR-based detection of tumor markers was analyzed using Spearman's correlation (Table 4). This analysis revealed that any of the 3 transcript detections was positively correlated with Astler-Coller stage of the disease, when examined singly (CEA: Spearman's $\rho = 0.264$, $P = 0.013$; CK20: Spearman's $\rho = 0.306$, $P = 0.004$; EGFR: Spearman's $\rho = 0.305$, $P = 0.004$). In addition, positive detection of CK20 and CEA transcripts was positively correlated with serum CEA levels (CK20: Spearman's $\rho = 0.285$, $P = 0.014$; CEA: Spearman's $\rho = 0.228$, $P = 0.050$). Furthermore, a positive correlation was evident between positive detection of the three marker transcript panel and Astler-Coller stage (Spearman's $\rho = 0.396$, $P < 0.001$), as well as serum CEA levels (Spearman's $\rho = 0.253$, $P = 0.029$). Moreover, a suggestive (marginal) association was depicted when the positivity for all 3 transcript detections was analyzed *vs* lymph node involvement (Spearman's $\rho = 0.216$, $P = 0.055$) (Table 4).

Interestingly, all CRC patients who tested negative for all 3 tumor transcripts were alive at the time of verification. Of 15 patients who tested positive only for CEA, 14 were alive (93.3%) (follow-up from 9 to 26 mo). Thirty seven of 52 (71.2%) patients who tested positive for both CEA and CK20 were alive while 15 of them (28.8%) had died (follow-up from 1 to 28 mo). However, 10 of 17 patients who tested positive for all 3 transcripts had died (58.8%) and only 7 of them (41.2%) were alive (follow-up from 1 to 23 mo) at the time of analysis.

Kaplan-Meier plots comparing overall survival rates of groups 1, 2, 3, 4 and 5 are shown in Figure 2. Using log-rank test, such analysis revealed statistically significant differences between survival rates of CRC patient groups with different multiplex RT-PCR detection patterns. When patients with positive detection for only one marker (group 1) were compared to those positive for all three markers (group 3), a statistically significant difference in survival rates was observed ($P = 0.002$). Similarly, the comparison between the patient group with positive detections for two markers (group 2) and positive detections for all 3 markers (group 3) revealed significant differences in survival rates ($P = 0.007$). Likewise, significant survival differences were documented when survival of group 4 (groups 1 and 2) was compared to survival of group 3 ($P = 0.001$). In addition, significant differences in the survival of CRC patients were also found when group 1 was compared with group 5 (at least positive for 2 transcripts) ($P = 0.041$). No statistical significance was observed when group 1 was compared to group 2 ($P = 0.116$).

P-values were calculated by Spearman's test. [1]*P*-value calculation using data from 81 patients (7 missing values); [2]*P*-value calculation using data from 80 patients (8 missing values); [3]*P*-value calculation using data from 77 patients (11 missing values); [4]*P*-value calculation using data from 74 patients (14 missing values). CEA: Carcinoembryonic antigen.

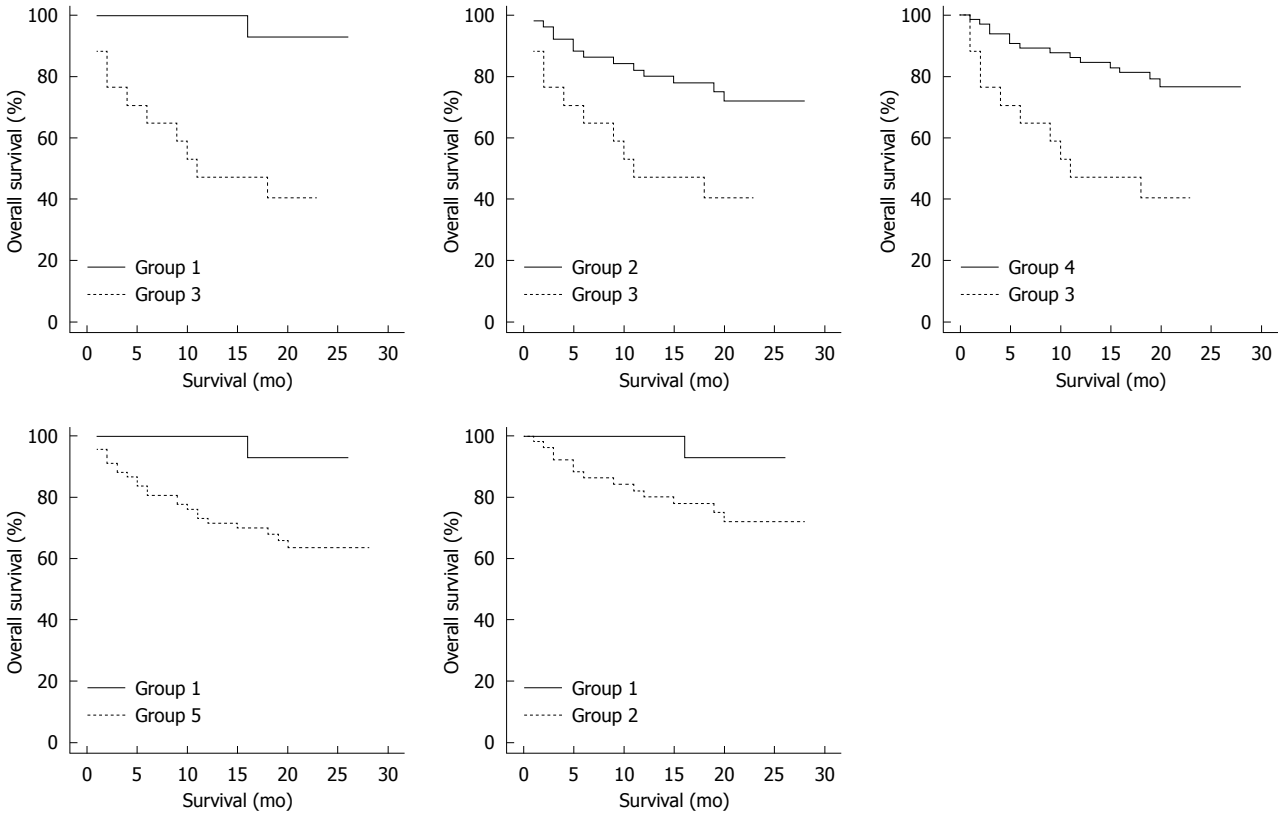

Figure 2 Kaplan-Meier analysis comparing the overall survival of patient groups as developed according to transcript detection patterns for carcinoembryonic antigen, cytokeratin 20 and epidermal growth factor receptor. Group 1: Carcinoembryonic antigen (CEA) positive; Group 2: Positive for 2 markers (CEA and cytokeratin 20); Group 3: Positive for all markers; Group 4: Combination of groups 1 and 2; Group 5: Combination of groups 2 and 3. Log Rank test *P* values were as follows: Groups 1 *vs* 3: *P* = 0.002; Groups 2 *vs* 3: *P* = 0.007; Groups 4 *vs* 3: *P* = 0.001; Groups 1 *vs* 5: *P* = 0.041; Groups 1 *vs* 2: *P* = 0.116.

DISCUSSION

The advantages of multi-marker use for CTC detection in CRC patients have been previously described[5,44-46]. Several studies have shown that the use of more than one marker independently increases the sensitivity and the specificity of CTC detection which correlates with disease stage in CRC patients[47-51]. However, the application of separate PCR reactions for each marker can be impractical, time-consuming and costly. Conversely, the implementation of multiplex RT-PCR which allows the examination of multiple marker expression in a single reaction could be advantageous. The employment of multiplex RT-PCR on peripheral blood samples represents an easily applied, non-invasive technique for the detection of CTCs in cancer patients[52].

The aim of the present study was to develop first and then to test the clinical significance of a multiplex RT-PCR-based detection of three markers (CEA, CK20 and EGFR) in CRC patients. Since we used a short follow-up period, our main analysis was based on overall survival and not on progression-free survival.

Our multiplex PCR-based detections of CEA, CK20 and EGFR transcripts were characterized by very good specificity, since none of the 40 healthy donor samples was found positive for the expression of CK20 or EGFR mRNA and only 3 control samples tested positive for CEA transcripts. This revealed that our assay was of higher specificity than that of previous studies[30,31,53,54]. The observed false positive results in control subjects could be attributed to illegitimate transcription of CEA in mononuclear blood cells. Indeed, it has been reported that CEA mRNA is detected in peripheral blood CD34+ progenitor cells[55]. Based on our data, CEA detection was the most sensitive (expressed in 95.5% of the CRC patients); the positivity rate was higher than that observed by Guadagni *et al*[22] or by Ferroni *et al*[56]. This, however, may be due to clinicopathological characteristics of the enrolled patients in this study and our experimental setting. Moreover, our data suggested that EGFR is possibly a marker for advanced stage in CRC (expressed in 19.3% of the patients and mostly in advanced disease). CK20 detection corresponded to a detection rate of 78.4%, higher than that reported previously by other groups[15,31,57,58]. Again, these detection rate discrepancies among studies using the same mRNA markers can be attributed to patient characteristics, as well as to the particular experimental conditions used by each research group.

Herein, our results revealed that the increasing number of the transcripts detected in this experimental setting could distinguish certain patient groups having significantly different overall survival. However, the detection of 1 (CEA) *vs* the detection of 2 markers (CEA plus CK20) did not show any statistically significant difference in overall survival ($P = 0.116$), which may be attributed to the short follow-up period. Notably, none of the CRC patients who tested negative for all 3 markers died during follow-up. These results are in concert with the results of Wang *et al*[48], who examined a membrane array-based detection of 4 mRNA markers, including CEA and CK20, in 157 CRC patients and found that the positive detection of all 4 markers (human telomerase reverse transcriptase, CK19, CK20, and CEA) was associated with poor overall survival. Similar results were reported by Uen *et al*[47], analyzing the detection of the same transcripts with progression-free survival in CRC patients.

In addition, Spearman's test revealed a positive correlation of positive detection for all 3 transcripts in our assay with higher disease stage and preoperative serum CEA levels. Furthermore, a suggestive correlation was also evident between positive detection of transcripts and higher level of lymph node involvement, suggesting that the higher number of tumor markers detected as positive by multiplex PCR assay is associated with higher levels of serum CEA and a larger amount of lymph node involvement, which are considered as indicators of advanced disease. This is in concert with the findings of Yeh *et al*[49]. Other studies have also examined the detection of CEA, CK20 or EGFR transcripts, however, using single PCR-based assays and reported that the higher number of positive detections correlated with disease stage[18,22,27,59] and serum CEA levels[38,60,61] or the presence of lymph node metastasis[58,62,63].

Herein, the increased number of positive multiplex PCR-based detections in each blood sample correlated with overall survival in CRC patients. Although the detection of the three marker panel was not found to be an independent prognostic factor of overall survival using Cox regression analysis, the log-rank test documented significant differences in overall survival rates among the patient groups formed according to the number of positive detections in each blood sample of CRC patients.

Nevertheless, our data suggested that our multiplex RT-PCR assay can provide useful information concerning CRC stage and overall survival. The combination of the mRNA markers in a single reaction could be of clinical value in the early detection of disseminated disease and monitoring of CRC patients, as it has been documented in other malignancies[5,41-45,64,65]. Future larger-scale studies and longer follow-up surveys would prove the clinical significance and prognostic importance of multiplex PCR-based detection of CTCs using CEA, CK20 and EGFR in CRC patients.

COMMENTS

Background

Colorectal cancer (CRC) is one of the most frequently diagnosed malignancies in both men and women. Overall survival is associated with the disease stage at the time of diagnosis, suggesting that early detection of disseminated disease may be of great significance. Detection of disseminated tumor cells in the peripheral blood of CRC patients could be promising for the early detection of disseminated disease and monitoring of CRC patients.

Research frontiers

Various techniques have been used for the detection of circulating tumor cells (CTCs) derived by solid tumors; among those, reverse transcription polymerase chain reaction (RT-PCR)-based methods have allowed the sensitive detection of CTCs in peripheral blood samples. Among several molecular markers, cytokeratin 20 (CK20), carcinoembryonic antigen (CEA) and epidermal growth fac-

tor receptor (EGFR) are those more frequently used for CTC detection in CRC using PCR-based methods.

Innovations and breakthroughs

Several studies have shown that the use of more than one marker independently increases the sensitivity and the specificity of the CTC detection in CRC patients. However, the application of separate PCR reactions for each marker can be impractical, while the implementation of multiplex RT-PCR allows the examination of multiple marker expression in a single reaction. The employment of multiplex RT-PCR in peripheral blood samples represents an easily applied, non-invasive technique for the detection of CTCs in cancer patients. The results showed that multiplex RT-PCR assay can provide useful information concerning CRC stage and overall survival.

Applications

The combination of mRNA markers in a single reaction could be of clinical value in the early detection of disseminated disease and monitoring of CRC patients. Future larger-scale studies and longer follow-up surveys would prove the clinical significance and prognostic importance of multiplex PCR-based detection of CTCs using CEA, CK20 and EGFR mRNA in CRC patients.

Terminology

CK20 is a member of the intermediate filament protein family and a prominent component of intestinal epithelium. CEA is a high molecular weight glycoprotein that plays a role in CRC metastasis. EGFR exerts control over normal cell growth and cancer pathogenesis in humans. Their mRNAs can be used as markers for the identification of CTCs in peripheral blood samples of CRC patients.

Peer review

This is a well written and produced paper with an important message. This original paper uses multiplex PCR assay for CK20, CEA and EGFR on blood samples to give information about CRC stage and prognosis. The authors have only studied small numbers of cases but the initial results are very encouraging.

Abstract

AIM: To investigate the correlation between cyclooxygenase-2 (COX-2) and cell cycle-regulatory proteins in patients with esophageal squamous cell carcinoma (ESCC).

METHODS: One hundred and two surgically obtained specimens of ESCC were randomly collected. All specimens were obtained from patients who had not received chemo- or radiotherapy prior to surgical resection. Twenty-eight specimens of normal squamous epithelium served as controls. The expression of COX-2, Ki-67, cyclin A and p27 was examined by immunohistochemistry. The Pearson test was used to analyze the relationship between groups.

RESULTS: The protein level of COX-2, Ki-67 and cyclin A was significantly higher in ESCC than in normal squamous epithelium (74.7 ± 61.2 *vs* 30.2 ± 43.4, 64.0 ± 51.6 *vs* 11.6 ± 2.3, 44.2 ± 32.2 *vs* 11.7 ± 5.0, respectively, all $P < 0.01$). In contrast, the protein level of p27 was significantly lower in ESCC than in normal squamous epithelium (182.0 ± 69.0 *vs* 266.4 ± 28.0, $P < 0.01$). In ESCC, COX-2 expression was correlated with T stage, the score of T1-T2 stage was lower than that of T3-T4 stage (55.0 ± 42.3 *vs* 83.0 ± 66.5, $P < 0.05$), and Ki-67, cyclin A and p27 expressions were correlated with the tumor differentiation (43.8 ± 31.7 *vs* 98.4 ± 84.8, 32.0 ± 19.0 *vs* 54.1 ± 53.7, 206.2 ± 61.5 *vs* 123.5 ± 68.3, respectively, all $P < 0.01$). COX-2 expression was positively correlated to Ki-67, cyclin A and negatively correlated to p27 expression in ESCC ($r = 0.270$, 0.233 and -0.311, respectively, all $P < 0.05$).

CONCLUSION: The expression of COX-2 is correlated with tumor cell invasion and is closely related to the cell proliferation in patients with ESCC.

INTRODUCTION

Esophageal cancer is one of the most frequently occurring malignancies and the seventh leading cause of cancer-related deaths in the world[1]. Esophageal squamous cell carcinoma (ESCC) remains the most common tumor histologically worldwide. A high incidence of ESCC has been observed in northern China, whereas adenocarcinoma of the esophagus is increasing in some areas of the United States and other Western countries. The prognosis for patients with locally advanced esophageal cancer treated with the standard approaches of surgery or radiotherapy is poor. Treatment failure is mainly due to both a high incidence of local-regional failure and early systemic dissemination of the disease[2].

Several studies have focused on molecular markers in this cancer to elucidate their relation to clinicopathologic features and prognosis of esophageal carcinoma[3-5]. Cyclooxygenase-2 (COX-2) may be involved in an early stage of squamous cell carcinogenesis of the esophagus and plays a non-redundant role in the regulation of cellular proliferation and tumorigenesis of esophageal epithelial cells[6], meanwhile, a significant correlation of COX-2 inhibitor nonsteroidal anti-inflammatory drugs was found with esophageal cancer[7]. COX-2 expression was also associated with the tumor volume response to radiotherapy in patients with cervical squamous cell carcinoma[8], and the use of COX-2 inhibitors could reduce the risk of bone metastases in stage Ⅱ-Ⅲ breast cancer[9].

Ki-67 is known as an indicator of cell proliferation, which is present in all phases of the cell cycle except in G_0. Moreover, Ki67 expression in localized prostate cancer could often predict postoperative progression[10]. In humans, several types of cyclin, including A-type, B-type, and C-type, have been isolated[11-15]. Cyclin A and B1-2 reach maximum levels in the S-phase and G2. Cyclin D1 over-expression indicated a poor prognosis of ESCC[16]. p27, one of the cell cycle-regulatory proteins, is a negative factor of cell proliferation, which is a cyclin-dependent kinase inhibitor[17,18]. Previously, we found that the p27 expression in the nuclei in well-differentiated ESCC was higher than in the other tumor types[19], and Miyabe *et al*[17] thought that p27 might be the most useful prognostic factor in mucoepidermoid carcinoma. Therefore, a molecular research into cancers has resulted in a better understanding of tumor biologic behavior, which has helped improve the survival of cancer patients, on the other hand, clinical application of immunohistochemical methodology may be cost-effective[20]. To our knowledge, the relationship between COX-2 expression and cell cycle-regulatory protein in ESCC has not been reported to date.

The aim of the present study was to investigate the correlation between COX-2 and cell cycle-regulatory proteins and explore the relationship between proliferative activity of cancer cells and COX-2 in patients with ESCC.

MATERIALS AND METHODS

Patients and specimens

We determined the expression of COX-2, Ki-67, cyclin A and p27 in 102 surgically resected ESCC specimens were formalin fixed and paraffin embedded and in 28 normal esophageal mucosa by immunohistochemical method. One hundred and two patients (86 males and 16 females) with ESCC were treated surgically at the Department of Thoracic Surgery, People's Hospital of Taizhou (Taizhou Medical School, Yangzhou and Nantong University) between August 2005 and September 2007. All the patients underwent subtotal or total esophagectomy and radical lymph node dissection.

Histopathological specimens were fixed in 10% buffered formalin, processed routinely, and embedded in paraffin. All specimens were obtained from patients who had not received chemo- or radiotherapy prior to surgery. All hematoxylin and eosin stained sections were reviewed and reexamined by pathologists. The grade of tumor differentiation was determined according to the classification of the World Health Organization[21], and staging according to the TNM classification of American Joint Committee on Cancer[22].

The patients were 35-76 years of age with a median age of 58.0 years. The location of the tumor was as follows: upper intra-thoracic esophagus in 11 cases (10.8%), middle intra-thoracic esophagus in 55 cases (53.9%), and lower intra-thoracic esophagus in 36 cases (35.3%). There were 32 (31.4%) well-differentiated cases, 50 (49%) moderately-differentiated cases (49%), and 20 (19.6%) poorly-differentiated cases. There were 5 stage Ⅰ cases, 47 stage Ⅱ, 33 stage Ⅲ and 17 stage Ⅳ cases. Normal esophageal mucosal samples were taken from the areas > 5 cm from the cancer, as non-tumor control samples.

Antibodies

The following antibodies were used in this study: rabbit monoclonal antibody anti-human COX-2 (Maixin Biotechnology Co., Ltd., Fuzhou, China); mouse monoclonal antibody anti-human Ki-67, p27 and PV-9000 test kit (Zhongshan Goldenbridge Biotechnology Co., Ltd., Beijing, China); mouse monoclonal antibody anti-human cyclin A (Thermo Fisher Scientific, CA). The final diluted concentration was 1:75.

Immunohistochemical staining

The specimens of adjacent non-cancerous esophageal mucosa were cut into 4-5-μm thick sections and mounted onto slides, deparaffinized with xylene, and re-hydrated with graded concentrations of ethanol. Endogenous peroxidase activity was blocked with hydrogen peroxide (H_2O_2) in deionized water for 10 min. The slides were

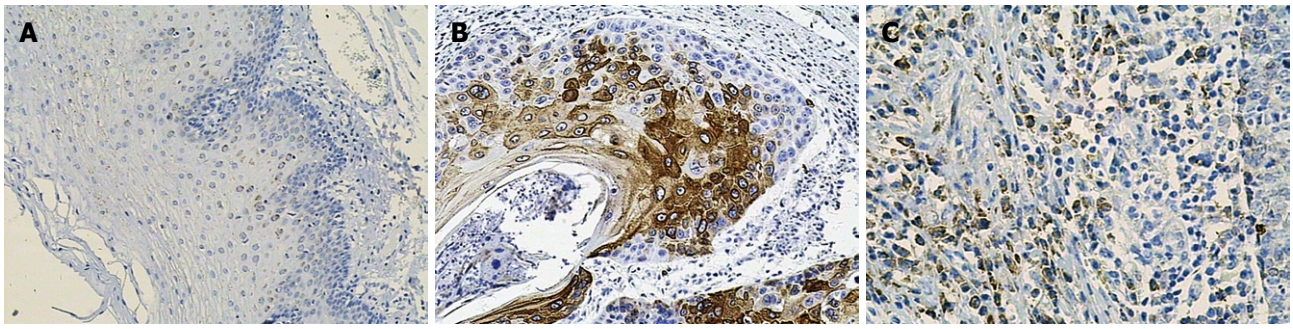

Figure 1 Expression of cyclooxygenase-2 in normal esophageal mucosa and esophageal squamous cell carcinoma. Positive staining in cytoplasm in normal mucosa (A), well-differentiated squamous cell carcinoma (SCC) (B) and poorly-differentiated SCC (C). Counterstaining with hematoxylin, × 200.

washed three times with Tris buffered saline (TBS) buffer (10 mmol/L Tris-HCl, 100 mmol/L NaCl, pH 7.5) for 2 min. An antigen retrieval technique was used before application of the primary antibody (10 mmol/L sodium citrate solution, pH 6.0 in a rice cooker, at 640 W for 30 min). After three washes with TBS, an aliquot of 100 μL of primary antibody was applied to each section and incubated at 4℃ overnight. After washing 3 times with TBS, agent one and then agent two (including the kit) were applied for 20 min at room temperature. Finally, the sections were washed 3 times with TBS, and the immunoreactions were visualized with 0.0067% diaminobenzidine as the substrate with 0.03% H_2O_2 in 100 mmol/L Tris-HCl buffer for 3 min. The sections were lightly counterstained in Haris hematoxylin solution for microscopic examination. Simultaneously, each section was incubated with TBS instead of the primary antibody as an internal negative control. The positive control included: gastric cancer tissue for COX-2, breast cancer tissue for Ki-67 and p27, carcinoma of tonsil for cyclin A.

The immunostained specimens were analysed by two independent pathologists. Cytoplasm and/or nuclear staining (brown reaction product) was regarded as a positive result for COX-2. The staining of Ki-67, p27, cyclin A (brown reaction product) was confined to the nuclei of the cells. Five fields in each tumor and non-tumor section were evaluated at high power (× 400) to determine the proportion of tumor cells and the staining intensity of the cytoplasm and/or nuclei in the entire sections. A score (0-300) was calculated for each marker by multiplying the intensity (none 0, weak 1, moderate 2, strong 3) by the percentage of expression (range 0-100), as reported previously[23]. At least five fields were observed, the average score in each tumor and non-tumor sections served as the result. To confirm the reproducibility of the results, all sections were scored twice, and the highest score from the two observers were thus reported.

Statistical analysis

The frequency of COX-2, Ki-67, cyclin A and p27 staining was expressed as mean ± SE. The correlations between the expression of these biologic molecular and clinicopathological factors were determined using *t* test (two groups had a same range of variance) and analysis of variance. The Pearson test was used to analyze the relationship between groups. SPSS 16.0 (SPSS Inc., USA) software package was used for statistical analysis, and *P* values less than 0.05 were considered statistically significant.

RESULTS

Expression pattern of COX-2 in normal human esophageal mucosa and ESCC

The mean of COX-2 staining in normal esophageal mucosa and ESCC was 30.2 and 74.7, respectively. This result suggested that the expression level of COX-2 in ESCC was higher than in normal human esophageal mucosa, with a significant difference ($t = 5.042$, $P < 0.01$, Figure 1).

Expression pattern of Ki-67, cyclin A and p27 in normal human esophageal mucosa and ESCC

Ki-67 and cyclin A were only expressed in base cells of normal esophageal mucosa. The mean staining rate of the two markers was significantly higher in ESCC (64.0 and 44.2) than in normal esophageal mucosa (11.6 and 11.7, $t = 5.272$ and $t = 5.021$, respectively, $P < 0.01$). The staining of Ki-67 was confined to the nuclei of the cells, while the staining of cyclin A was concentrated mainly in the nuclei of cells, and occasionally in the cytoplasm (Figures 2 and 3). In contrast, p27 staining was observed in all the cells except the base cells of normal esophageal mucosa, the mean staining rates in normal esophageal mucosa and in ESCC were 266.4 and 182, respectively (Figure 4). There was a significantly decreased p27 expression in ESCC ($t = 4.247$, $P < 0.01$).

COX-2, Ki-67, p27 and cyclin A staining and clinicopathological factors

The correlations between the expression of COX-2, Ki-67, p27 and cyclin A and the clinicopathologic features of ESCC are summarized in Table 1. Statistically, the expression of COX-2 was not associated significantly with the age of the patients, tumor size, lymph node metastasis and the TNM stage, but its expression level was significantly higher in T3-T4 than in T1-T2 ($t = 2.62$, $P < 0.05$). For the clinicopathologic features of Ki-67, p27 and cy-

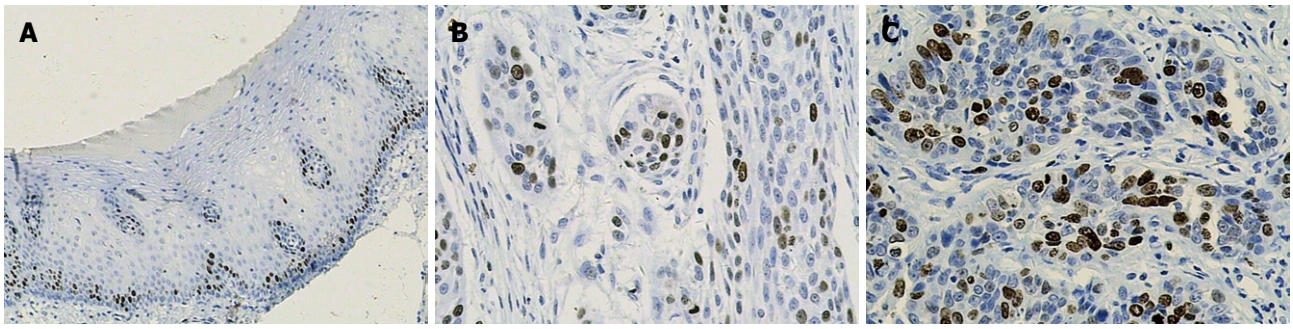

Figure 2 Expression of Ki-67 in normal esophageal mucosa and esophageal squamous cell carcinoma. Positive nuclei staining in normal esophageal mucosa (A, × 100), well-differentiated (B, × 200) and poorly-differentiated squamous cell carcinoma (C, × 200). Counterstaining with hematoxylin.

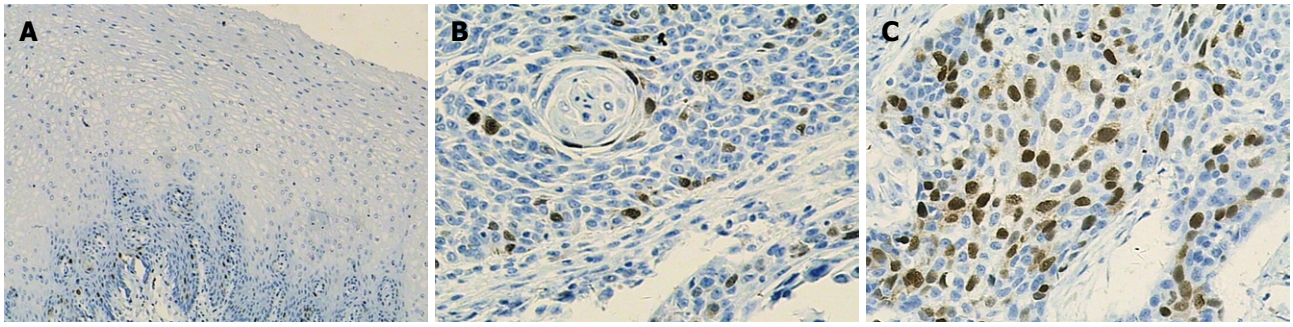

Figure 3 Expression of cyclin A in normal esophageal mucosa and esophageal squamous cell carcinoma. Positive nuclei staining in normal esophageal mucosa (A, × 100), well-differentiated (B, × 200) and poorly-differentiated squamous cell carcinoma (C, × 200). Counterstaining with hematoxylin.

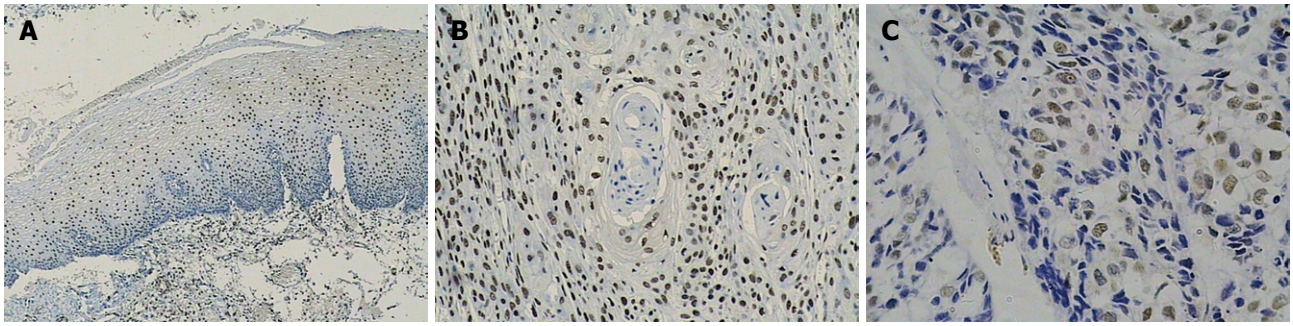

Figure 4 Expression of p27 in normal esophageal mucosa and esophageal squamous cell carcinoma. Sections stained with anti-p27 antibody showing nuclear staining (brown) in normal esophageal mucosa (A, × 100), well-differentiated (B, × 200) and poorly-differentiated squamous cell carcinoma (C, × 200). Counterstaining with hematoxylin.

clin A in ESCC, the expression levels of KI-67 and cyclin A were significantly higher in poorly-differentiated squamous cell carcinoma than in well-differentiated ESCC ($F = 7.839$, $P < 0.01$; $F = 3.519$, $P < 0.05$). The p27 positive immunostaining rate in the nuclei in well-differentiated ESCC was higher than in the other tumor types ($F = 5.49$, $P < 0.01$).

Correlation between COX-2 and cell cycle-regulatory proteins in ESCC

The correlations between the frequency of COX-2 and Ki-67, cyclin A and p27 in ESCC are summarized in Table 2. Positive correlations were observed between the staining frequency of COX-2 and Ki-67 and cyclin A ($r = 0.270$ and 0.233, $P < 0.01$), but negative correlations between the staining frequency of COX-2 and p27 in ESCC ($r = -0.311$, $P < 0.01$).

DISCUSSION

COX-2 expression gradually increased from normal human esophageal mucosa to ESCC. One of the molecular alterations in esophageal carcinomatous change is high COX-2 expression. The staining frequency of COX-2 increased with the tumorigenesis, and its upregulation in ESCC was significantly associated with tumor progression. These results gave additional information about the possibility that COX-2 may be involved in an early stage of squamous cell carcinogenesis of the esophagus[6]. Our study demonstrated that the staining frequency of COX-2

[a]Correlation is significant (2-tailed, $P = 0.05$); [b]Correlation is significant (2-tailed, $P = 0.01$). COX-2: Cyclooxygenase-2.

was significantly higher in ESCC than in normal esophageal mucosa ($P < 0.01$), suggesting that over-expression of COX-2 was one of the important phenotypes and characteristics in ESCC carcinomatous change.

Apart from the over-expression of COX-2 in patients with ESCC, the present study suggested that tumor with high COX-2 expression was easy to invade. Although there were different conclusions on the relationship between COX-2 and the clinicopathologic features in ESCC, many researchers found that over-expression of COX-2 was associated with infiltrating field of tumor. Nozoe *et al*[24] reported that the prognosis of ESCC patients with a strong COX-2 expression was significantly poorer than that of ESCC patients with a weak COX-2 expression. Based on the data from Liu *et al*[25], the expression of COX-2 was not significantly correlated with gender or age, but increased expression of COX-2 was correlated with invasion and lymph node metastasis statistically. These studies have helped understand the molecular mechanisms of carcinogenesis and progression of ESCC. Yu *et al*[26] suggested that elevated COX-2 expression was not associated with clinicopathological features including age, sex, tumor size, histological grade, lymph node metastasis, and TNM stage. Our study found that expression of COX-2 was associated with T stage (tumor invasion) in ESCC patients, and there was a significantly lower expression in T1-T2 than in T3-T4 ($P < 0.05$)[24,25].

The levels of expression of Ki-67, cyclin A and p27 may suggest the proliferative activity of cancer cells in patients with ESCC. Ki-67, cyclin A over-expression and low p27 expression were associated with poorly-differentiated ESCC, compared with ESCC which had low Ki-67 and cyclin A expression and high p27 expression[3].

Previous studies had revealed the following mechanisms of COX-2 promoting cell proliferation: (1) COX-2 can contribute to inhibition of apoptosis and proliferation, increased angiogenesis, adhesion and invasion and modulation of inflammation; and (2) COX-2 may be involved in an early stage of squamous cell carcinogenesis of the esophagus and plays a non-redundant role in the regulation of cell proliferation and tumorigenesis of esophageal epithelial cells[6,27]. However, these findings are obtained from animal or *in vitro*, and the relationship between COX-2 and tumor cell proliferation in patients with cancer has not been completely elucidated. In this study, the samples were obtained from ESCC patients, and the expression of COX-2 was positively correlated to Ki-67 and cyclin A, which promotes cell proliferation, and was negatively correlated to p27 expression, which is a cell-proliferating suppressor in ESCC. This indicated the higher expression of COX-2 and the stronger tumor cell proliferation in ESCC, and also supported the theory that COX-2 is an important regulatory enzyme in cell proliferation.

In conclusion, our results showed that COX-2 over-expression not only was common in ESCC, but also correlated to tumor cell invasion, and COX-2 had the potential to become a molecular target in the treatment of ESCC. We will investigate the relationship between expression of COX-2 and curative effect of chemotherapy and survival rate of ESCC patients in the future studies. Ki-67 and cyclin A staining was positively correlated while p27 staining was negatively correlated with COX-2 expressions, which suggested that the over-expression of COX-2 was closely related to the cell proliferation in patients with ESCC.

COMMENTS

Background

Esophageal cancer is one of the most frequently occurring malignancies and the seventh leading cause of cancer-related deaths in the world. Treatment failure results from both a high incidence of local-regional failure and early systemic dissemination of the disease. Cyclooxygenase-2 (COX-2) may be involved in an early stage of squamous cell carcinogenesis of the esophagus and plays a non-redundant role in the regulation of cellular proliferation and tumorigenesis of esophageal epithelial cells. The relationship between COX-2 expression and cell cycle-regulatory protein in esophageal squamous cell carcinoma (ESCC) has not been reported to date.

Research frontiers

COX-2 plays a non-redundant role in the regulation of cellular proliferation and tumorigenesis of esophageal epithelial cells. Ki-67 is known to be an indicator of cell proliferation. Cyclin A reaches maximum levels in the S-phase and G2. p27 is a negative factor of cell proliferation. This study investigated the correlation between COX-2 and cell cycle-regulatory proteins and explore the relationship between the proliferative activity of cancer cells and COX-2 in patients with ESCC.

Innovations and breakthroughs

Many studies have shown recently that not only there was a significant correlation between COX-2 inhibitor nonsteroidal anti-inflammatory drugs (NSAIDs) and esophageal cancer, but also a correlation between the COX-2 expression and the tumor volume response to radiotherapy. Moreover, Ki67 expression, cyclin D1 and p27 might be the most useful prognostic factor in different carcinomas. This study reported that COX-2 expression was positively correlated to Ki-67 and cyclin A and negatively correlated to p27 expression in ESCC. The results may help reveal the molecular feature of ESCC.

Applications

By better understanding tumor biologic behavior, the survival of cancer patients can be improved. COX-2 over-expression not only was common in ESCC, but also correlated to tumor cell invasion, and COX-2 had the potential to become a molecular target in the treatment of ESCC.

Peer review

The authors analyzed the correlation between COX-2 and cell cycle-regulatory proteins in patients with ESCC using immunohistochemistry. They found that COX-2 expression had a significant correlation with T stage and was positively correlated to Ki-67, cyclin A and negatively correlated to p27 expression in ESCC. Considering the samples were from patients, the results are interesting and may help to reveal the molecular feature of ESCC.

Abstract

AIM: To determine whether the association of β-blockers with endoscopic treatment is superior to endoscopic treatment alone for the secondary prophylaxis of oesophageal variceal bleeding.

METHODS: Randomised controlled trials comparing sclerotherapy (SCL) with SCL plus β-blockers (BB) or banding ligation (BL) with BL plus BB were identified. Main outcomes were overall and 6, 12 and 24 mo rebleeding rates, as well as overall and 6, 12 and 24 mo mortality. Two statistical methods were used: Yusuf-Peto, and Der Simonian and Laird. Inter-trial heterogeneity was systematically taken into account.

RESULTS: Seventeen randomised controlled trials were included, 14 with SCL and 3 with BL. Combination β-blocker and endoscopic treatment significantly reduced rebleeding rates at 6, 12 and 24 mo and overall [odds ratio (OR): 2.20, 95% confidence interval (CI): 1.69-2.85, $P < 0.0001$] compared to endoscopic treatment alone. Mortality at 24 mo was significantly lower for the combined treatment group (OR: 1.83, 95% CI: 1.16-2.90, $P = 0.009$), as well as overall mortality (OR: 1.43, 95% CI: 1.03-1.98, $P = 0.03$).

CONCLUSION: Combination therapy should thus be recommended as the first line treatment for secondary prophylaxis of oesophageal variceal bleeding.

Key words: Oesophageal varices; Portal hypertension; Cirrhosis; Secondary prevention; β-blockers; Banding ligation

INTRODUCTION

Upper gastrointestinal bleeding from ruptured oesophageal varices is the main complication of portal hypertension and is one of the leading causes of death in patients with cirrhosis. It is estimated that 70% of patients who have survived a first episode of variceal bleeding subsequently rebleed[1]. Secondary prophylaxis of variceal bleeding is thus of utmost importance for these patients.

The use of β-blockers alone has been shown to decrease the risk of recurrent bleeding in cirrhotic patients[2-4]. Endoscopic treatments [sclerotherapy (SCL) and banding ligation (BL)] are also effective in preventing rebleeding in patients with portal hypertension. It has been demonstrated that sclerotherapy decreases the risk of recurrent bleeding and improves survival in cirrhotic patients compared to placebo[5,6]. Banding ligation is currently the endoscopic therapy of choice as it has been shown to be safer and more effective in preventing rebleeding than sclerotherapy[7-10]. However, sclerotherapy continues to be routinely used in a certain number of countries. Combining pharmacological and endoscopic treatment may be more effective than either treatment alone as they act through different mechanisms, thus enhancing each other's therapeutic effect. Many randomised controlled trials have been undertaken to determine whether β-blockers have an additional beneficial role when combined with sclerotherapy or banding ligation to prevent rebleeding. The results of these studies are controversial. Sørensen[11] suggested that β-blockers and sclerotherapy had no additive effect in the prevention of variceal rebleeding, whereas a number of trials have reported favourable results when banding ligation is combined with β-blockers[12,13]. The recommendations of the American College of Gastroenterology[14] state that combined endoscopic and pharmacological therapy is the most effective for secondary prophylaxis, whereas the Baveno IV Consensus conference[15] recommends either β-blockers, banding ligation or both; the authors add that combined therapy is probably the best treatment, but that more trials are needed to prove this. The aim of this meta-analysis is therefore to determine whether the association of β-blockers with endoscopic treatment (sclerotherapy or banding ligation) leads to decreased rebleeding rates and improved survival in patients with portal hypertension compared to endoscopic treatment alone.

MATERIALS AND METHODS

Source of trials

All randomised controlled trials comparing endoscopic treatment alone (sclerotherapy or banding ligation) with a combination of endoscopic treatment associated with β-blockers for the prevention of variceal rebleeding were identified. Trial were retrieved using MEDLINE (1950 to October 2009) and Web of Science (1900 to October 2009), by using the terms "secondary prophylaxis variceal bleeding, endoscopic therapy, β-blockers, sclerotherapy and variceal rebleeding". Conference abstracts from the American Association for the Study of the Liver, European Association for the Study of the Liver, the Digestive Disease Week, the United European Gastroenterology Week and the French National Society of Gastro-enterology between 1980 and 2009 were manually searched. The list of published articles or abstracts was verified and completed through an in depth study of the references quoted in each article. All trials included were peer-reviewed (full articles published in peer reviewed journals or abstracts selected by a peer committee). The final search was performed on April 30, 2010.

Study selection

The trials selected for this meta-analysis met the following criteria: (1) randomised controlled trials published as abstracts, letters to the editor or peer-reviewed articles; (2) patient population: patients presenting portal hypertension (with or without cirrhosis) and oesophageal varices which had previously bled and had not received prior β-blocker or endoscopic treatment; and (3) interventions: treatment with sclerotherapy or banding ligation alone or concomitant treatment with β-blockers (administered from the start of endoscopic treatment) and sclerotherapy or banding ligation; in parallel treatment groups. We chose to exclude studies which associated β-blockers with nitrates or studies in which β-blockers were commenced only after completion of endoscopic therapy. No language restrictions were applied.

Data extraction and quality assessment

Data extraction and quality assessment were performed by three independent reviewers (Ségalas-Largey F, Oberti F and Blanc P). Discrepancies were resolved through discussion before analyses. Trial quality was evaluated using criteria established by Poynard[16] and Nicolucci *et al*[17], simplified and adapted for portal hypertension by Pagliaro *et al*[18]. For each trial, two separate scores were calculated using Poynard's and Pagliaro's criteria; each score was expressed as a percentage of the highest score possible. In addition, we noted for each trial randomisation, investigator blinding, estimation of sample size and intention-to-treat analysis.

Data synthesis and analysis

Primary end-points were all-cause rebleeding rates and mortality at 6, 12 and 24 mo, as well as overall rebleeding and mortality rates as reported at end of follow-up. All-cause rebleeding was defined as upper gastrointestinal bleeding of any source. We chose this as the primary outcome as endoscopic treatment of oesophageal varices may induce bleeding related to oesophageal ulcers. Results were determined at different time points in order to take into account variations in follow-up duration between trials. For each time point, raw data was extracted from studies when available using Kaplan-Meier survival curves.

A meta-analysis including all trials (sclerotherapy and banding ligation) was performed, as well as subgroup analyses of trials using sclerotherapy and trials using banding ligation.

Statistical methods

All results were expressed as odds ratio (OR), with a 95% confidence interval (CI). Results were first calculated using a fixed-effect model (Collins *et al*[19]). Heterogeneity was calculated using Breslow-Day's test. When significant heterogeneity was found, both the OR and *P*-heterogeneity were subsequently calculated using a random-effect model (DerSimonian *et al*[20]). This model takes into account heterogeneity by providing a more conservative estimate of treatment effect with wider confidence intervals in order to adjust for inter-trial variability. *P*-heterogeneity was initially considered significant if < 0.05; however, when *P*-heterogeneity tended towards significance (i.e. between 0.05 and 0.10), we preferred to take the precaution of calculating results using the random-effect model. The percentage of variability beyond chance was estimated using the I^2 statistic[21]. Publication bias was assessed using the Egger Test[22] and represented graphically using funnel plots[23] plotting the natural log of the OR *vs* its standard error. The Trim and Fill analysis for publication bias was performed using Duval and Tweedie's methods[24]. Additionally, the failsafe number according to Orwin's formula[25] was calculated, which represents the number of non-significant studies which would be necessary to reduce the effect size to a non-significant value. All analyses were performed using Comprehensive Meta-analysis software (version 2.2.048 New Jersey, USA, 2008).

RESULTS

Study identification and selection

Our search identified 229 potentially relevant references. Two hundred and six reports were excluded when it was obvious they did not meet inclusion criteria. A total of 23 reports were considered for detailed analysis. Four studies were excluded as they associated β-blockers with nitrates[26-29]. Two studies were excluded as they started β-blocker therapy after completion of endoscopic therapy[30,31]. Seventeen studies were included in the meta-analysis.

Study characteristics

Study characteristics are reported in Table 1. Fourteen trials[32-45] comparing sclerotherapy with combination sclerotherapy plus β-blockers were included with a total of 925 patients. Among these 925 patients, 887 were analysed: 435 were treated by sclerotherapy alone and 452 by sclerotherapy plus β-blocker. Thirty-eight patients from the trial of Elsayed *et al*[34] were not included as they were excluded from the study after randomisation for various reasons (non compliance, loss to follow up, shunt surgery). Ten studies were published as full articles[33-37,40-44], three in abstract form[32,39,45] and one as a letter to the editor[38]. One study was published in Spanish[33].

Three articles comparing banding ligation with combined banding ligation and β-blocker therapy were included, with a total of 256 patients[12,13,46]. Among these 256 patients, 252 were analysed. Four patients from the trial of de la Peña *et al*[13] were excluded after randomisation due to withdrawal (3 patients) or diagnosis of lymphoma (one patient). One hundred and twenty-five were treated with banding ligation alone and 128 with banding ligation plus β-blockers. Two trials were published as full articles[12,13] and one in abstract form[46].

Patient characteristics are shown in Table 2. Chronic liver disease was the most common cause of portal hypertension in all studies and was mainly due to alcohol abuse in 9 trials[12,33,36-41,44], to viral infection in 3 trials[12,42,43] and to schistosomiasis in 2 trials[34,35]. The aetiology of liver disease was not reported in three studies[32,45,46]. In 8 studies, only patients with cirrhosis were included[32,33,37,39-41,43,45]. Most patients had mild or severe liver disease in 9 studies[12,13,34-38,40,44]. However, in the study by Avgerinos *et al*[43], the majority of patients were Child's class A, whereas in 3 trials Child's class C patients were not included[33,39,42]. Severity of liver disease was either incompletely reported

or not mentioned at all in 5 studies[32,39,41,45,46]. Variceal size was medium or large for the majority of patients in 11 trials[12,13,33,35-38,41-44] and was not reported in 5 others[32,34,39,40,45]. Sclerotherapy was performed with polidocanol in 5 studies[37,38,40-42], ethanolamine in 6 studies[33-36,43,44] and aetoxisclerol in one study[45]. The sclerosing agent was not reported in 2 trials[32,39]. Banding ligation was performed with multi-band ligators at intervals varying from 10 to 21 d, until complete variceal eradication was achieved. Propranolol was the β-blocker used in 12 trials[32,34-37,40-46] and nadolol in 5 trials[12,13,33,38,39]. The time to eradication of oesophageal varices was reported in 13 trials[12,13,33-38,40-44]. In the sclerotherapy plus β-blocker group the mean time to eradication of varices was slightly shorter (166 d-5.7 sessions) than in the sclerotherapy group (171 d-6 sessions). For patients treated with banding ligation, eradication was achieved in 44 d (3.3 sessions) *vs* 42 d (3.15 sessions) in the banding ligation plus β-blocker group. β-blockers were administered from the start of sclerotherapy until eradication in 7 studies[35-41], whereas in 5 studies[32-34,42,44], β-blockers were given both during and following variceal eradication. Follow-up duration for sclerotherapy studies ranged from 2 to 39 mo (mean 16.6 mo). Follow-up duration for banding ligation studies ranged from < 3 to

16 mo (mean 10.3 mo). Overall follow-up duration ranged from 2 to 39 mo (mean 15.4 mo).

Quality assessment

Variables defining study quality are presented in Table 3. All trials were correctly randomised. Three trials were double-blinded[12,37,42] and six trials were single-blinded[13,35,38,40,43,44]. Sample size was calculated in six trials. Six studies[12,40-44] were performed on intention-to-treat basis. The quality scores determined by Poynard's criteria and by Pagliaro's criteria were strongly correlated.

Outcome measures

All-cause rebleeding: The all-cause rebleeding rate was reported in all studies except for the trial of Lundell *et al*[40]. For sclerotherapy trials, 162 patients rebleed in the sclerotherapy group (39.2%) whereas 110 patients (25.4%) rebleed in the sclerotherapy plus β-blocker group. Four sclerotherapy trials[32,34,37,41] found rebleeding rates to be significantly lower in the sclerotherapy plus β-blocker group; the difference was not significant for the remaining 10 studies. For banding ligation studies, 49 patients bled in the banding ligation only group (39.5%), whereas 22 patients bled in the banding ligation plus β-blocker group (17.2%). Two banding ligation studies found rebleeding rates to be significantly lower in the banding ligation plus β-blocker group[12,13]. The third study[46] also found bleeding rates to be lower in this group, without specifying whether the difference was significant or not. When sclerotherapy and banding ligation studies were pooled, a total of 211 patients (39.3%) bled in the endoscopic therapy only group, and 132 (23.5%) bled in the endoscopic therapy plus β-blocker group.

When sclerotherapy and banding ligation trials were pooled for meta-analysis (Table 4), rebleeding rates were significantly lower in the endoscopic therapy plus β-blocker group at 6 and 12 mo, and for overall end-of-follow-up bleeding rates (at 6 mo, OR: 1.70, 95% CI: 1.24-2.34, $P = 0.01$; at 12 mo, OR: 2.22, 95% CI: 1.25-3.99, $P = 0.007$; overall OR: 2.20, 95% CI: 1.69-2.85, $P < 0.0001$). At 24 mo, the decrease in rebleeding in favour of the endoscopic plus β-blocker group was at the limit of significance (OR: 1.67, 95% CI: 0.99-2.81, $P = 0.05$). All funnel plots were symmetrical; the failsafe numbers were 8, 16 and 33, respectively, for bleeding rates at 6 and 12 mo and overall. The Egger tests were negative for publication bias ($P = 0.47$, $P = 0.31$, $P = 0.39$, respectively). Forest plots for 12 mo and overall rebleeding rates are shown in Figure 1A and B.

Mortality: Mortality was reported in all studies except for the trial of Kanazawa *et al*[32]. In sclerotherapy trials, 71 patients died in the sclerotherapy group (17.2%), whereas 59 deaths occurred in the sclerotherapy plus β-blocker group (13.7%). In banding ligation trials, 27 patients died in the banding ligation group (21.8%), whereas 17 patients died in the banding ligation plus β-blocker group (13.3%). None of the sclerotherapy or banding ligation trials reported a significant difference in mortality between the two treatment arms. When sclerotherapy and banding ligation studies were taken together, a total of 98 patients died in the endoscopic therapy group (18.3%) and 76 died in the endoscopic therapy plus β-blocker group (13.6%).

No significant difference in mortality rates was present at 6 and 12 mo. However, at 24 mo a significant difference in mortality in favour of the combination therapy (endoscopy plus β-blocker) group appeared (OR: 1.83, 95% CI: 1.16-2.90, $P = 0.009$). Overall mortality rates were also significantly decreased in the combination therapy group (OR: 1.43, 95% CI: 1.03-1.98, $P = 0.03$), as shown in Table 4. Funnel plots seemed symmetrical, and the failsafe number for both mortality at 24 mo and overall mortality was 2. The Egger test did not find evidence of publication bias ($P = 0.17$ and $P = 0.34$, respectively). Forest plots for overall and 24 mo mortality are shown in Figure 1C and D.

Subgroup analyses

Sclerotherapy trials: A subgroup analysis was performed including sclerotherapy trials only. The rebleeding rates at 6, 12 and 24 mo were lower in the sclerotherapy plus β-blocker group, but the difference was not significant (Table 5). When overall end-of-follow-up rebleeding rates were taken into account, the difference was significantly lower in favour of the sclerotherapy plus β-blocker group (OR: 2.00, 95% CI: 1.49-2.69, $P < 0.0001$). The failsafe number was 54, the funnel plot seemed symmetrical and

the Egger test did not indicate publication bias ($P = 0.46$). No significant difference in mortality rates was present at 6, 12, 24 mo or with overall end-of-follow-up mortality (Table 5).

Banding ligation trials: A subgroup analysis was performed including the three banding ligation trials (Table 6). Outcomes were significantly in favour of banding ligation plus β-blockers concerning overall bleeding rates (OR: 3.16, 95% CI: 1.76-5.34, $P < 0.0001$). The failsafe number was at 4, and the Egger test did not indicate publication bias ($P = 0.47$). No significant difference was present for mortality. Analyses at different time-points were not performed due to insufficient data.

DISCUSSION

The results of this meta-analysis show that the association of endoscopic treatment with β-blockers is more effective in secondary prophylaxis of oesophageal variceal bleeding than endoscopic treatment alone, with a significant decrease in rebleeding rates overall and at all time points (6, 12 and 24 mo). We have shown for the first time a significant decrease in mortality rates with combined β-blocker and endoscopic treatment over endoscopic treatment alone, with significantly decreased overall and 24 mo mortality rates. Banding ligation is currently the preferred endoscopic treatment for oesophageal varices as it has been shown to be superior to due to less recurrent bleeding, fewer complications, and lower mortality rates[7,9,10,47-49]. However, we chose to include studies using sclerotherapy in our meta-analysis, as it continues to be widely used in the developing world, where schistosomiasis, one of the leading causes of portal hypertension worldwide[50], and viral B cirrhosis are prevalent.

The superiority of combination β-blocker and endoscopic treatment in reducing rebleeding rates may be explained by their synergistic action, with β-blockers reduc-

ing portal hypertension, while sclerotherapy and banding ligation act focally on the oesophagus. Although overall rebleeding rates are significantly in favour of combination therapy for sclerotherapy trials alone, when studies using banding ligation are added to those using sclerotherapy, the decrease in rebleeding rates in the combination therapy group becomes significant at 6, 12 and 24 mo, and remains significant overall. These results are robust as the failsafe numbers (i.e. number of medium sized non significant studies needed to reduce the effect size to a non significant value) are relatively high (8, 16 and 33 for 6 mo, 12 mo and overall bleeding rates, respectively). This may be due to the fact that all the banding ligation studies were in favour of combination therapy concerning rebleeding rates[12,13]. Indeed, the subgroup analysis including banding ligation studies only was strongly in favour of combined treatment concerning bleeding rates ($P < 0.0001$). However, we are aware that the number of studies using banding ligation included in this meta-analysis is relatively low ($n = 3$) compared to the number of studies using sclerotherapy ($n = 14$). This difference is due to the fact that sclerotherapy is an older and more widespread technique compared to banding ligation, and that the highly significant results in favour of combined therapy in the three banding ligation studies would not have been conducive to the completion of further similar studies. Kumar *et al*[28] suggested that the pooling of sclerotherapy and banding ligation studies as in the meta-analysis of Gonzalez *et al*[51] would lead to inferior results for endoscopic therapy as sclerotherapy is known to be inferior to banding ligation for the treatment of variceal bleeding. We therefore decided to perform a subgroup analysis including only banding ligation trials as suggested by a recent editorial[52], which showed a significant decrease in rebleeding rates for banding ligation associated with β-blockers. Although only three studies were concerned, this result is relatively robust as four additional medium-sized non significant studies would be needed to render the result insignificant.

As with bleeding rates, a significant difference in mortality in favour of the combination β-blocker and endoscopic therapy group appeared when sclerotherapy and banding ligation studies were pooled. A significant difference was present overall and at 24 mo, perhaps due to the fact that the numbers of deaths at 6 and 12 mo were too low to reveal any significant statistical difference [at 6 mo: 39/309 (12.6%) for the endoscopic therapy group and 33/319 (10.3%) for the combined therapy group; at 12 mo 33/246 (13.4%) and 30/259 (11.6%), respectively]. It could be hypothesised that this decrease in mortality may be due to reduced bleeding rates, but one must keep in mind that although mortality rates are a standard end-point of all clinical trials and meta-analyses concerning variceal bleeding, it is difficult to attribute decreased mortality to decreased bleeding rates in a cirrhotic population prone to various life-threatening complications. β-blockers could have a beneficial effect on survival independent of their preventative effect on variceal bleeding as they act globally by reducing portal hypertension, and it has been suggested that they may reduce the frequency of complications of cirrhosis such as ascites, hepato-renal syndrome, portal hypertensive gastropathy[53,54] and spontaneous bacterial peritonitis[55,56]. However, the results concerning decreased mortality in the combination endoscopic and β-blocker therapy group must be interpreted with caution as the fail-safe number is relatively low: only two additional medium-sized non significant studies would be necessary in order to render the results insignificant. Additional studies with long term follow-up, preferably using banding ligation, are necessary in order to confirm these results.

Three meta-analyses have been previously published concerning combination therapy. The meta-analyses of Gonzalez *et al*[51] and Ravipati *et al*[57] compared combination treatment with endoscopic treatment (sclerotherapy or banding ligation) alone, and found a significant difference in rebleeding rates in favour of combination therapy, whereas results were non-significant for mortality. The meta-analysis of Ravipati *et al*[57] included 11 sclerotherapy trials, compared to 14 trials (148 additional patients) in our meta-analysis. Cheung *et al*[58] performed a small meta-analysis including four trials comparing banding ligation with banding ligation plus β-blockers, and did not find any significant difference for either mortality or bleeding rates. The meta-analysis of Gonzalez *et al*[51] included 23 trials. However, in contrast to our meta-analysis, these three meta-analyses[51,57,58] included studies associating β-blockers with nitrates, as well as studies in which β-blockers were introduced only at the end of variceal eradication. We decided not to include these studies for both medical and methodological reasons. Firstly, there is no proof in current literature that the association of nitrates with β-blockers is superior to β-blockers alone concerning bleeding rates and mortality. One non-blinded trial found a significantly lower bleeding rate for patients treated with nadolol plus isosorbide mononitrate[59]; however, two larger, more recent double-blinded placebo controlled trials[60,61] were unable to confirm these results, with a greater number of side effects noted in the nitrate group[60]. This association, which is poorly tolerated in certain patients, has therefore not yet been recommended by either the Baveno IV Consensus[15], or the American College of Gastroenterology[14]. Secondly, optimal combination therapy would entail introducing β-blockers at the beginning of endoscopic treatment as they would protect against bleeding recurrence before complete eradication, by reducing portal hypertension. We therefore chose not to include studies which started β-blocker treatment after eradication. However, we included all studies which started β-blockers at the beginning of eradication regardless of whether β-blocker treatment was continued after eradication or discontinued at the end of the eradication programme, as so far no studies have shown a difference in superiority between these two treatment protocols. Thirdly, including studies in which β-blockers are associated with nitrates or started only after eradication may considerably increase intertrial heterogeneity due to differences in treatment protocols. This methodological aspect has been an object of criticism in a recent editorial concerning a previous meta-analysis[52]. We therefore did not include studies associating β-blockers

with nitrates. Our stricter study inclusion criteria may lead to more precise conclusions concerning optimal treatment modalities.

The results of clinical trials and meta-analyses especially should always be interpreted with caution. A recent trial comparing banding ligation alone with banding ligation associated with drug therapy[28] did not find any significant difference in bleeding rates or mortality. However, in this trial drug therapy consisted of β-blockers associated with nitrates, as opposed to β-blockers alone, as in the trials included in the present meta-analysis. Our meta-analysis was limited by variations in quality of the studies included, and by lack of data concerning studies published as abstracts or letters, for which trial and patient characteristics were incomplete. The time over which data was included in this study was relatively large (1986-2005), which may contribute to inter-trial heterogeneity as improvements in patient care over time would affect bleeding and mortality outcomes. Data was insufficient to determine the effect of the date of trials on outcome. Likewise, subgroup analyses according to criteria such as Child's class, origin of cirrhosis or variceal size were not performed due to incomplete data. We nonetheless decided to include abstracts and letters in our meta-analysis in order to ensure optimal data analysis (246 additional patients). Adverse events were difficult to evaluate as the quality of reporting varied and most trials did not distinguish serious from non serious events. Nine studies did not perform intention-to-treat analysis whereas 2 did not state whether this was the case or not, which may lead to overestimation of treatment effect. Calculation of outcome measures at different time points reduced heterogeneity due to varying follow-up durations, but these results were limited by the fact that not all studies expressed outcome measures according to follow-up time. Ideally, a meta-analysis would include individual patient data with updated follow-up, but in our case these data were not available and we therefore had to rely on group data provided by each study. Nevertheless, we aimed to ensure the robustness of our meta-analysis results by calculating the failsafe number for each significant result, which was not estimated in previous meta-analyses[51,57,58].

In conclusion, we show that combination endoscopic and β-blocker therapy is more effective than endoscopic therapy alone in secondary prophylaxis of variceal bleeding, with a significant decrease in bleeding rates and mortality. With banding ligation becoming more and more widespread, we believe that combination β-blocker and banding ligation therapy should be recommended as first line prophylactic treatment in cirrhotic patients who have already bled from oesophageal varices.

COMMENTS

Background

Upper gastro-intestinal bleeding from ruptured oesophageal varices is a frequent and serious complication of cirrhosis. It has been estimated that 70% of patients who survive a first variceal bleeding episode subsequently rebleed. Secondary prophylaxis of variceal bleeding is therefore crucial in the management of these patients.

Research frontiers

Both β-blockers and endoscopic treatment (alone or in combination) have been used to prevent variceal rebleeding. However, there is currently no consensus as to which treatments are the most effective in secondary prophylaxis of variceal bleeding.

Innovations and breakthroughs

This meta-analysis shows for the first time that mortality is significantly decreased when β-blockers are associated with either sclerotherapy or banding ligation compared to endoscopic therapy alone. Bleeding rates are also decreased with combination β-blocker and endoscopic therapy.

Applications

The results suggest that combination β-blocker and endoscopic therapy should be recommended as the first line treatment for the secondary prophylaxis of oesophageal variceal bleeding. Additional studies with long-term follow-up are needed to confirm the results concerning mortality.

Peer review

This topic is important and there is still a considerable difference of opinion in the literature. The authors have done an exacting job of describing the conditions of their meta-analysis so that the readers can easily put the findings into the context of their own practice.

Abstract

AIM: To asses the value of computed tomography (CT)-perfusion in the detection of residual hepatocellular carcinoma (HCC) vascularization after transarterial chemoembolization (TACE).

METHODS: Thirty-two consecutive patients were prospectively included in this study. All patients had liver cirrhosis and a confirmed HCC lesion which was treated with TACE. One month after treatment, perfusion measurements of treated lesions were carried out. The CT-perfusion (CT-p) protocol was performed with 16 slice multidetector computed tomography which included the following parameters: 8 dynamic slices/scan per 40 scans after iv injection of 50 mL of iodinated contrast (350 mg/mL) at a flow rate of 6 mL/s. Treated lesions were evaluated using dedicated perfusion software, which generated a quantitative colour map of perfusion. The following parameters were considered: hepatic perfusion (HP), arterial perfusion (AP), blood volume (BV), hepatic perfusion index (HPI), and time to peak (TTP). Perfusion parameters were described with quartile values of their distribution and statistically analyzed.

RESULTS: Perfusion parameters of the treated lesions could be quantitatively assessed using CT-p analysis. The presence of residual tumor tissue was observed in 13 of the 32 patients. The values of the perfusion parameters measured within the relapse tissue were: HP (mL/100 g per minute): median = 44.4 (1^{st}qt = 31.3, 3^{rd}qt = 55.8); BV (mL/100 g): median = 18.7 (1^{st}qt = 11.5, 3^{rd}qt = 22.5); AP (mL/min): median = 39.0 (1^{st}qt = 36.5, 3^{rd}qt = 61.3); HPI (%): median = 34.0 (1^{st}qt = 30.4, 3^{rd}qt = 38.9); TTP (s): median = 17.3 (1^{st}qt = 15.8, 3^{rd}qt = 26.5). With the use of the univariate paired Wilcoxon signed rank test, HP, AP and HPI were shown to be significantly higher ($P < 0.001$) in the relapse site than in the primary lesion. The BV and TTP parameters showed a tendency to be greater and lower, respectively, in the relapse site than in the primary lesion.

CONCLUSION: In patients with HCC treated with TACE, CT-p provides measurement of flow parameters related to residual arterial structures in viable tumor, thus helping in the assessment of therapeutic response.

INTRODUCTION

The prognosis of patients with untreated hepatocellular carcinoma (HCC) is poor, with a median survival of less than 6 mo after diagnosis. Although surgery remains the only hope for cure, very few patients (10%-15%) are candidates[1]. For large HCCs (> 3 cm), transarterial chemoembolization (TACE) remains the sole approach to inhibit cancer growth in most patients, and has been used extensively to treat unresectable HCCs[2]. The rationale for chemoembolization stems from the observation that unlike normal liver tissue, HCC receives most of its blood supply from the hepatic artery, therefore, it is logical to use the hepatic artery as a means to target the tumor while preserving normal liver[1]. The goal of TACE is to determine tumor necrosis and control tumor growth while preserving as much functional liver tissue as possible[1], therefore, the early detection of residual or recurrent tumor after TACE is a critical point and can facilitate successful retreatment at an early stage. Usually the presence of residual viable tumor or recurrence after TACE is assessed using multiphasic multidetector computed tomography (MDCT) scanning, but this technique can be affected by artefacts produced by high concentrations of lipiodol, making it difficult to evaluate the characteristics of the lesion. Response may be better assessed by noting alterations in vascular tumor perfusion rather than size, and therefore functional measurements may be an appropriate method to assess tumor response.

Perfusion computed tomography (CT) is a technique that enables depiction of tumor vascular physiology, being, also, non-invasive and fast; perfusion-CT can be repeated sequentially to assess temporal changes in tumor blood flow, which is of clinical importance for monitoring tumor response to antiangiogenic agents and other treatments[3].

The utility of hepatic perfusion characterization relies on the resolution of each component of its dual blood supply-the portal vein and the hepatic artery-because contributions from each are altered predictably in many diseases and could be used in monitoring therapeutic effectiveness[4]. TACE is a liver-directed therapy that takes advantage of the relatively selective vascularization of hepatic arterial tumors. HCCs can derive approximately 80% to 85% of their blood supply from the hepatic artery, whereas the portal vein as well as the hepatic artery supplies the normal hepatic parenchyma[4].

Quantitative measurement of hepatic perfusion has the potential to provide important information about tumor vascularization, useful in the assessment and management of various liver diseases and in the determination of their treatment outcome[5].

The purpose of this study was to determine the value of functional CT with perfusion imaging in the quantitative assessment of blood flow changes related to the effects of TACE treatment in patients with HCC lesions.

MATERIALS AND METHODS

Patients

According to the Barcelona staging classification[6] TACE was performed in 35 consecutive cirrhotic patients with otherwise untreatable HCC, and included 28 men and 7 women (mean age, 65 years; range, 45-76 years). The cause of cirrhosis was hepatitis infection in 24 patients (hepatitis B in 7 patients, hepatitis C in 17 patients), alcohol related in 4 patients, and both hepatitis C and alcohol related in 7 patients.

To be included in the study, patients had to meet the following criteria: (1) be older than 18 years; (2) Child-Pugh class A or B; (3) have focal or multifocal HCC; and (4) not have any contraindications to CT imaging. Excluded from the study were patients who had: (1) a life expectancy of less than 6 mo; (2) Child-Pugh class C; (3) uncorrectable coagulopathy (international normalized ratio > 1.5); (4) thrombosis of the main portal vein branches (portal venous thrombosis was excluded prior to TACE by means of Doppler US); (5) a total bilirubin level higher than 4.0 mg/dL; (6) a serum creatinine level higher than 1.7 mg/dL; and (7) thrombocytopenia (platelet count < 50000/μL). The diagnosis of HCC was established with FNAB or on the basis of the presence of a tumor larger than 2 cm in diameter with typical imaging findings[6] in the setting of cirrhosis.

Before being enrolled, all subjects gave their informed consent after the nature of the procedure had been fully explained, in accordance with the regulations of the institutional review board that approved our study.

According to the current literature[7-9], CT is commonly used as the standard imaging technique for evaluating the therapeutic response in patients with HCC after TACE[8], and was performed 4 wk after TACE treatment, in order to assess the intralesional deposition of iodized oil and evaluate the presence of the residual viable portion of the treated lesion[6,8].

All patients underwent CT-perfusion 1 d after the MDCT study and subsequently a selective conventional

DSA study to correlate the angiographic findings with those of the CT-perfusion examination.

TACE treatment

After initial mapping, visceral conventional DSA with a selective 5-F visceral catheter [either: Simmons (Cook, Bloomington, IN, USA) or Cobra (Terumo Medical, Somerset, NJ, USA) catheters were used], mesenteric arteriography was performed to check for presence of the right hepatic artery. Indirect portography was performed next to outline the portal circulation in the venous phase. Depending on the size, location, and arterial supply of the tumor and its satellites, the tip of the catheter was advanced further into segmental arteries for selective embolization, typically we coaxially inserted a 2.8-F microcatheter (Renegade Hi-Flow; Boston Scientific, Natick, MA, USA) over a 0.016-inch-diameter guidewire (Headliner; Terumo, Tokyo, Japan) to super select the hepatic lobar or segmental hepatic artery supplying the targeted tumor. We performed conventional DSA following an injection of Iobitridol (Xenetix 350; Guerbet, Aulnay, France).

Once the operator selected the final catheter position for TACE, intraarterial chemotherapy was performed by injection of 10-12 mL of iodized oil (Lipiodol Ultra Fluide; Laboratoire Guerbet, Roissy, France) mixed with an emulsion of 40 mg of doxorubicin hydrochloride into the hepatic artery. Embolization was performed by means of a mixture of Iobitridol (Xenetix 350; Guerbet, Aulnay, France) and 1-mm-diameter absorbable gelatin sponge particles (Spongostan; Ferrosan, Søborg, Denmark).

Under direct radiographic monitoring, we injected the solution (mean dose, 9.4 mL; range, 2-18 mL) until some slowing of antegrade blood flow to the targeted tumor was identified with conventional fluoroscopy. The amount of injected chemoembolic material was chosen at the discretion of the attending interventional radiologist. After the TACE procedure, the patients recovered with 20-24 h bed rest.

Perfusion CT technique

Perfusion-CT was performed using a multi-detector 16-slice CT scanner (Brilliance, Philips Medical Systems, Eindhoven, The Netherlands). For selection of the appropriate transverse level, an unenhanced CT scan of the liver, performed during a single breath hold, was obtained before initiation of perfusion CT scanning. The perfusion study of the selected area (maximal tumor diameter) was performed in a single breath hold at the end of expiration. Single location (2.4 cm width) cine CT scanning (40 scans; eight slices/scan) was obtained using the following parameters: 120 kV, 120 mA, 512 × 512 matrix, 3-mm slice thickness, and 1-s scan time. The radiation dose delivered to each patient with our CT perfusion technique was 8 mSv. Oxygen inhalation (4 mL/min) was given to help the patients hold their breath during the examination. Scanning was initiated after a 7-s delay from the start of the intravenous bolus injection of 50 mL of non-ionic iodinated contrast agent (Xenetix 350; Guerbet, Aulnay, France) at a flow rate of 6 mL/s, using an 18-gauge catheter positioned in the antecubital vein. Dynamic CT images were acquired for a total duration of 40 s.

To avoid motion artefacts, patients were clearly informed of a possible flushing sensation commonly associated with a rapid bolus of iodinated contrast agent. Moreover, as image quality may be degraded in patients breathing deeply during acquisition resulting in inaccurate perfusion parameters values, a band compressing the abdomen that limited breath-related liver excursions was used.

Image analysis and quantification of perfusion parameters

The functional computed tomographic images were then transferred to an image workstation, and the data were analyzed using dedicated perfusion software (Philips Brilliance Workspace 2.0; Philips Medical Systems), which generated a quantitative map of liver perfusion displayed on the monitor using a colour scale. The parametric map images were created using the highest spatial resolution pixel-by-pixel calculation technique. Perfusion was assessed by the dedicated computed tomographic software based on the maximum slope model: perfusion was therefore calculated as the average slope of the tissue enhancement divided by the peak enhancement in the aorta, as described initially by Miles and Griffiths[4,10].

The region of interest (ROI) was hand drawn in a selected portion of the treated lesion where a hypervascular area had been detected on the colour map (Figures 1 and 2); another ROI was positioned within the intralesional deposition of iodized oil (Figures 1 and 2); further ROIs were also placed in definite areas of the surrounding cirrhotic liver parenchyma (Figures 1 and 2). In those patients in whom the presence of a focal hypervascular area, suspected as residual HCC, had not been seen at the CT-perfusion study, ROI was positioned only on the site of deposition of iodized oil and in the surrounding liver parenchyma, and the perfusion parameters were calculated. The resulting temporal changes in contrast enhancement were then analyzed to quantify a range of parameters that reflected the functional status of tissue perfusion.

The absolute values of the following five perfusion parameters were calculated for treated HCC, and for cirrhotic liver parenchyma: (1) Hepatic perfusion (HP), mL/100 g per minute), which is the blood flow per unit volume/mass of tissue per minute; (2) Blood volume (BV, mL/100 g), which is the blood volume contained in 100 g of tissue; (3) Arterial perfusion (AP, mL/min), which is the arterial fractional blood flow; (4) Hepatic perfusion index (HPI, %), which represents, of the total blood liver flow [arterial perfusion (AP) + portal perfusion (PP)], the percentage of arterial origin (AP/AP + PP); and (5) Time to peak (TTP, s) which is the time to reach the maximum value of contrast material concentration.

In only three of 35 patients, the perfusion study was not performed due to the fact that the tumor and portal trunk, or main portal branches, were not on the same transverse plane.

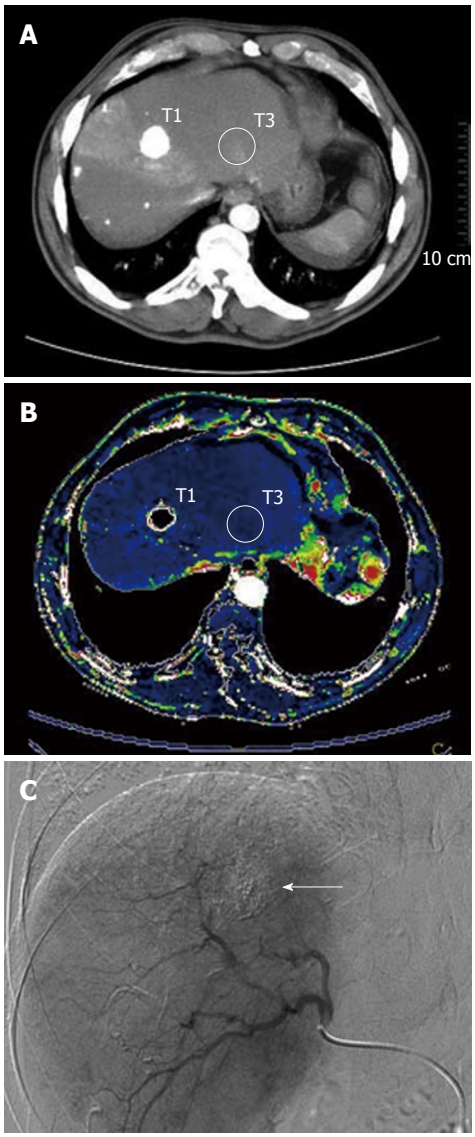

Figure 1 A 69-year-old man with Child A liver cirrhosis and 12 mm lesion of hepatocellular carcinoma, treated with transarterial chemoembolization, in the seventh segment of the liver that underwent computed tomography-perfusion study. A: Multiphasic multidetector computed tomography scan image shows two hand drawn regions of interest (ROIs): T1 positioned on the successfully treated tumor contouring the treated area; T3 positioned on the surrounding liver parenchyma avoiding vessel structures, in order to obtain the quantitative perfusion data of the regions; B: Functional arterial perfusion colour map shows an homogenous distribution of perfusion area, with decreased perfusion range of colors compared with the background liver parenchyma; ROIs were positioned at the same level, on the successfully treated tumor (T1) and on the surrounding liver parenchyma (T3); C: Post chemoembolization digital fluoroscopic image obtained in the same patient shows excellent distribution of the lipiodol-chemotherapy mixture (arrow).

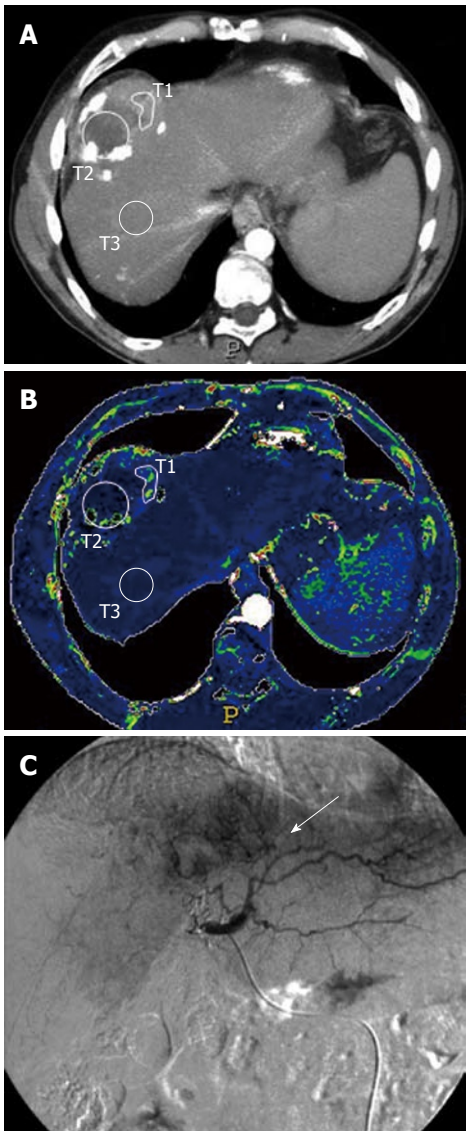

Figure 2 A 57-year-old man with Child B liver cirrhosis and 42 mm lesion of hepatocellular carcinoma in the fourth segment of the liver that underwent computed tomography-perfusion study. A: Transverse data raw multiphasic multidetector computed tomography scan image shows regions of interest (ROIs) positioned on the periphery of lesion (T2), and on the primary lesion without relapse (T1) and on the surrounding liver parenchyma (T3) avoiding vessel structures, in order to obtain the quantitative perfusion data of the regions; B: Functional arterial perfusion colour map shows that the distribution of perfusion in the treated lesion is heterogeneous, with a different range of colours of residual disease (T1) compared with primary lesion without relapse (T2) that reveal the unsuccessful treatment of transarterial chemoembolization; ROIs were also positioned at the same level in surrounding liver parenchyma (T3); C: Post chemoembolization digital fluoroscopic image obtained in the same patient shows disomogeneous distribution of the iodized lipiodol-chemotherapy mixture, with presence of hypervascular region (arrow) at the periphery of treated lesion, demonstrating the viable portion of tumour.

Statistical analysis of perfusion parameters

The perfusion parameters HP, BV, AP, HPI, TTP were described by the quartile values of their distribution and calculated: for the ROI in the area of iodized oil deposition (T1) in all patients (with or without residual disease); for the ROI in the hypervascular area (T2) at the colour map in 13 patients who presented residual neoplastic disease; for the ROI placed in the surrounding liver parenchyma (T3) in all patients.

The distributions of the differences in the parameters between the residual disease, deposition of iodized oil and surrounding cirrhotic liver tissue were graphically represented by means of box-plot representations (Figure 3).

The univariate unpaired Wilcoxon signed rank test was used to assess whether there were differential expressions of each single perfusion parameter in the area of deposition of iodized oil between both groups of pa-

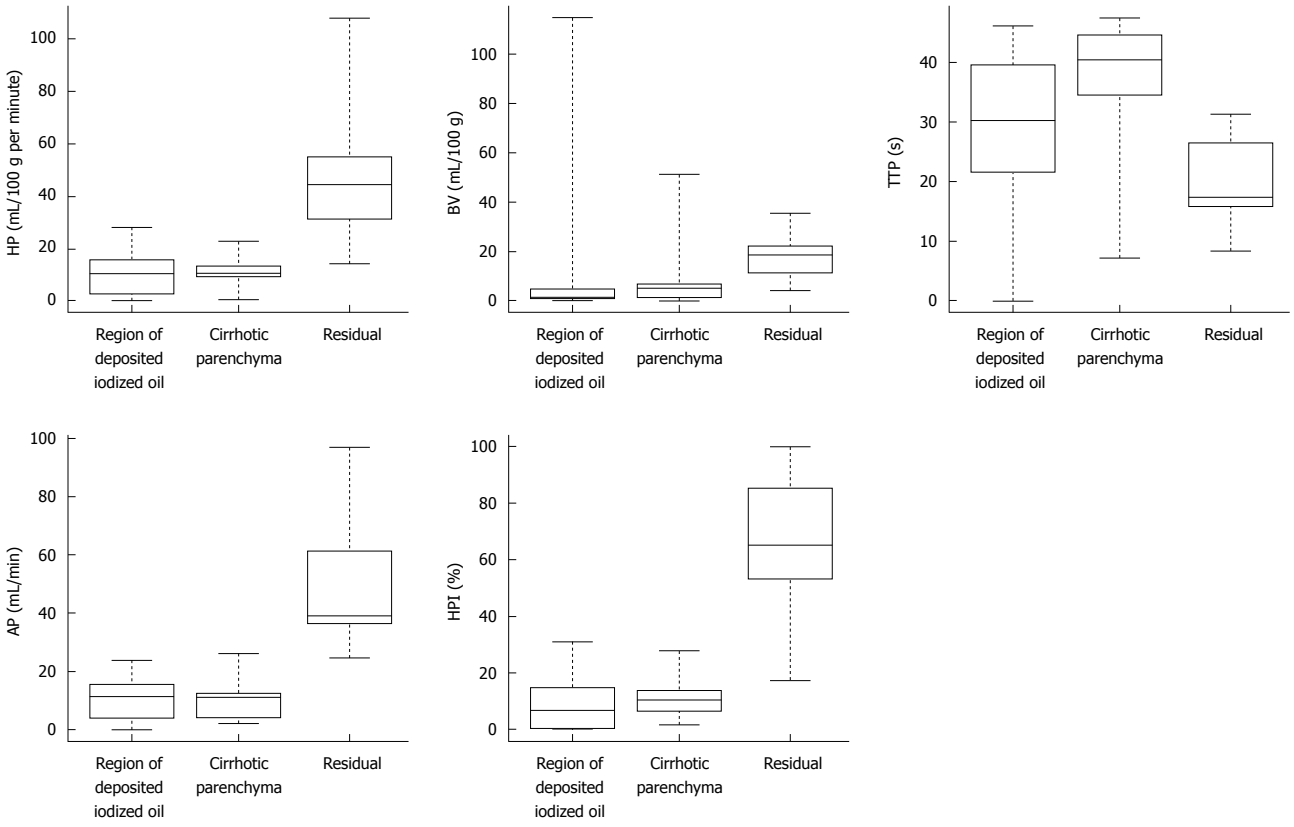

Figure 3 Box plots of the differences in perfusion parameters (hepatic perfusion, tissue blood volume, hepatic perfusion index, arterial perfusion, and time to peak). The lower boundary of the boxes indicates the 25th percentile, line within the boxes marks the median, and the higher boundary of the boxes indicates the 75th percentile. Error bars below and above the boxes indicate minimum and maximum values. HP: Hepatic perfusion; BV: Blood volume; HPI: Hepatic perfusion index; AP: Arterial perfusion; TTP: Time to peak.

tients (those who did and did not present residual HCC). While, the paired version of the Wilcoxon test was used to assess whether, in patients who had residual disease, there were differential expressions of the perfusion parameters between the area of deposition of iodized oil and the residual site.

Bonferroni correction was used to take multiple comparisons into account, considering *P*-values less or equal to 0.05/10 were indicative of a statistically significant difference[11].

In the comparison between the area of deposition of iodized oil and the residual site for patients who had residual disease, the alternative hypothesis postulated a greater value for, HP, BV, AP and HPI in the residual disease than in the area of deposition of iodized oil or cirrhotic parenchyma, due to the presence of residual arterial vascular structures. For TTP, the alternative hypothesis postulated a lower value for the residual disease site than the primary lesion, due to a possible increase in the arterial flow within the tumor.

The statistical analysis was performed using the R statistical package (http://cran.r-project.org).

RESULTS

A total of 32 lesions (mean size: 4.1 ± 1.6 cm), located on both hepatic lobes were evaluated with the CT-Perfusion (CTp) technique.

For all patients, the descriptive analysis of perfusion parameters measured within the treated tumor tissue with deposition of iodized oil (T1) showed the following results.

HP (mL/100 g per minute): median = 10.5 (1^{st}qt = 9.3, 3^{rd}qt = 13.7); BV (mL/100 g): median = 5.2 (1^{st}qt = 1.3, 3^{rd}qt = 6.7); AP (mL/min): median = 11.2 (1^{st}qt = 4.0, 3^{rd}qt = 12.5); HPI (%): median = 10.7 (1^{st}qt = 6.4, 3^{rd}qt = 13.7); TTP (s): median = 40.3 (1^{st}qt = 34.6, 3^{rd}qt = 44.6) (Table 1, Figure 3).

In the 13 patients who presented residual disease, the same descriptive analysis of perfusion parameters was performed within the residual tumor tissue (T2) and showed the following results: HP (mL/100 g per minute): median = 44.4 (1^{st}qt = 31.3, 3^{rd}qt = 55.8); BV (mL/100 g): median = 18.7 (1^{st}qt = 11.5, 3^{rd}qt = 22.5); AP (mL/min): median = 39.0 (1^{st}qt = 36.5, 3^{rd}qt = 61.3); HPI (%): median = 65.0 (1^{st}qt = 53.2, 3^{rd}qt = 85.0); TTP (s): median = 17.3 (1^{st}qt = 15.8, 3^{rd}qt = 26.5) (Table 1, Figure 3).

The corresponding perfusion values calculated also in the cirrhotic liver parenchyma surrounding the treated HCC lesion were: HP (mL/100 g per minute): median = 10.4 (1^{st}qt = 9.3, 3^{rd}qt = 13.2); BV (mL/100 g): median = 11.7 (1^{st}qt = 9.5, 3^{rd}qt = 11.9); HPI (%): median = 16.4 (1^{st}qt = 13.8, 3^{rd}qt =18.3); AP (mL/min): median = 10.4 (1^{st}qt = 9.5, 3^{rd}qt = 11.9); TTP (s): median = 44.6, (1^{st}qt = 40.3, 3^{rd}qt = 51.8) (Table 1, Figure 3).

Table 1 Descriptive characteristics of analyzed perfusion parameters

Parameter	Primary treated lesion site in region of deposited iodized oil			Background cirrhotic liver parenchyma			Residual hepatocellular carcinoma		
	Median	1st qt	3rd qt	Median	1st qt	3rd qt	Median	1st qt	3rd qt
HP (mL/100 g per minute)	10.5	9.3	13.7	10.4	9.3	13.2	44.4	31.3	55.8
BV (mL/100 g)	5.2	1.3	6.7	11.7	9.5	11.9	18.7	11.5	22.5
HPI (%)	10.7	0.3	14.9	16.4	13.8	18.3	65	53.2	85.0
AP (mL/s)	11.2	4	12.5	10.4	9.5	11.9	39	36.5	61.3
TTP (s)	40.3	34.6	44.6	44.6	40.3	51.8	17.3	15.8	26.5

HP: Hepatic perfusion; BV: Blood volume; HPI: Hepatic perfusion index; AP: Arterial perfusion; TTP: Time to peak.

With the use of the univariate paired Wilcoxon signed rank test, HP, AP and HPI were shown to be significantly higher ($P < 0.001$) in the site of residual disease than in the region with iodized oil deposition (Figure 3). The BV parameter showed a tendency to be greater in the residual site than in the region of iodized oil deposition, but significance according to the Bonferroni correction was not reached ($P = 0.03$) (Figure 3). The TTP values showed a tendency to be lower in the site of residual disease than in the region of iodized oil deposition, but again significance according to the Bonferroni correction was not reached $P = 0.01$) (Figure 3).

Use of the univariate unpaired Wilcoxon signed rank test showed that no significant differences were found for each parameter, calculated in the region of the lesion with deposition of iodized oil, between the two groups of patients with or without relapse of HCC (Figure 3).

In our series no significant correlation was found between CT perfusion parameters in cirrhotic parenchyma and in the successfully treated lesion, although in lesions with deposition of iodized oil mean BV value was moderately lower than those in the surrounding cirrhotic parenchyma.

The survival rate at 6, 12 and 18 mo was 94% (30/32), 82% (26/32) and 72% (23/32), respectively.

DISCUSSION

TACE is the most widely used therapy in patients with HCC who are considered unsuitable candidates for surgery, and should be considered not only the best possible therapeutic approach in patients with advanced HCC but also an appropriate step before surgical resection or liver transplantation[12].

The mixture of chemotherapeutic agents and iodized oil is almost completely retained in neoplastic nodules and can remain in HCC tissue for a long time. Subsequent mechanical embolization of the artery feeding the neoplasm causes ischemic damage to the tumor and prolongs the duration of the effects of chemotherapeutic agents[13].

For a definite assessment of the therapeutic efficacy of interventional procedures, histological examination using percutaneous needle biopsy may be the most definite assessment of the therapeutic efficacy of interventional therapy. However, it is an invasive procedure, and the specimen retrieved does not always represent the entire lesion owing to sampling errors.

Similar to the findings in most previously reported investigations[7,8], the presence of residual viable tumor or recurrence after TACE is assessed using multiphasic MDCT scanning, which represents the standard imaging technique for monitoring the effectiveness of TACE.

Generally, HCC tends to recur at the site adjacent to the original tumor, however, after TACE treatment it can be difficult to evaluate contrast enhancement in a tumor with partial retention of iodized oil on contrast-enhanced CT due to beam hardening artefacts produced by the high attenuation of iodized oil[12].

In general, the viable portion of malignant tumors exhibits increased perfusion, and in the primary tumors, therefore, the radiologic estimation of perfusion in liver tumors is useful for both diagnosis and selection of the therapeutic strategy[14].

After TACE, tumor response may be better assessed by alterations in vascular perfusion rather than tumor size, and functional measurements may therefore be more appropriate[15].

In this regard, perfusion-CT could be considered suitable for monitoring tumor response after treatment.

Perfusion CT techniques typically require a baseline image acquisition without contrast enhancement followed by a series of images acquired over time after an intravenous bolus of conventional iodinated contrast material. The resulting temporal changes in contrast enhancement are subsequently analyzed to quantify a range of parameters that reflect the functional status of the vascular system[16].

In the current study, we investigated the value of several tissue perfusion parameters obtained by functional CT, with the perfusion technique, for the quantitative assessment of HCC-related residual vascularization after TACE treatment.

Our results show that the values of the perfusion parameters calculated were significantly different in residual tumor compared to the area of iodized oil deposition, in particular, HP, AP, BV and HPI were found to be higher ($P < 0.001$) in HCC than in the surrounding cirrhotic liver tissue, due to tumor-associated neovascularization, whereas TTP values were lower in areas of HCC relapse. In the assessment of residual neovascularization related to tumor regrowth, AP - which represents the arterial fractional blood flow - may be considered the most rel-

evant perfusion parameter, as it can specifically demonstrate the presence of new arterial blood vessels in partial or incomplete treated lesions. Also, the higher HPI values could explain the reduction of portal perfusion inflow in residual HCC disease, with a simultaneous increase in arterial fractional inflow.

Findings in the current work are also in line with those recently reported in experimental studies where perfusion CT was used for assessing tumor response to treatment by evaluating perfusion changes[17-19]. Those studies validated the idea that functional CT can provide quantification of residual viable tumor perfusion. In an animal model, Kan *et al*[17] found that functional CT enabled accurate quantification of changes in liver tumor perfusion during and after an embolization procedure thus helping optimize therapeutic outcomes. In another study[18], the same researchers reported on the ability of functional CT to assess changes in liver tumor perfusion in response to antiangiogenic treatment.

In our study, we found that the zone of increased perfusion appeared as a hypervascular area on the colour map, representing an area in which the arterial blood continued to sustain tumor growth.

Our findings are in line with a previous study by Chen *et al*[19] who correlated the changes of CT-perfusion parameters to different responses of tumors to TACE, supporting the idea that CT-perfusion could be used in the assessment of TACE efficacy, by evaluating quantitative parameters before and after chemoembolization.

Our data confirmed the recent experimental work of Sabir *et al*[15], who demonstrated in a murine xenograft tumor model receiving antiangiogenic therapy, that perfusion MDCT was able to identify changes in tumor blood flow, and therefore indicate the early reversal of tumor responsiveness to antiangiogenetic therapy. This also demonstrated, therefore, that perfusion MDCT is able to identify focal areas of new tumor perfusion before clinically measurable changes in tumor size.

Our study findings are consistent with those of Li *et al*[20] who demonstrated that CT perfusion parameters can be reliable indicators for evaluating tumor necrosis and angiogenesis, relating the dynamic contrast-enhanced measures with outcome of histopathologic (microvessel density) studies in lung carcinoma. Evaluating the CT perfusion parameters of the necrotic lung carcinomas, they found that necrotic tumors exhibited significantly lower perfusion.

The main limitation of the present study is related to the fact that a liver tissue section of only 2.4 cm in thickness could be examined in each patient. This limitation, however, could be overcome by the use of multi-detector CT scanners enabling the acquisition of 64 or more sections which can produce isotropic spatial resolution, while simultaneously delivering exceptional temporal resolution with excellent z-axis coverage (4-8 cm)[21]. A further limitation was that CT perfusion parameters were not compared with established markers of tumor vascularity, such as histologic examination, which is the most reliable method for assessing therapeutic efficacy of the TACE procedure. Such a method, however, is invasive and the specimen retrieved does not always represent the entire lesion owing to sampling errors[6].

In conclusion, our preliminary study in humans has shown that perfusion CT may be helpful in monitoring the outcome of TACE in cirrhotic patients with HCC. We believe that perfusion-CT provides non-invasive, reliable information on residual tumor vascularization and could be part of the current CT protocols aimed at following-up such patients.

COMMENTS

Background

Transcatheter arterial chemoembolization (TACE) is the most widely used therapy in patients with hepatocellular carcinoma (HCC) who are considered unsuitable candidates for surgery. Chemoembolization involves delivery of chemotherapy combined with arterial embolization to destroy tumor cells. Such a treatment makes use of the hypervascular nature of HCC: antineoplastic agents are directly injected into the hepatic artery allowing high intratumoral concentrations of drugs and thereby reducing systemic side effects. After TACE, tumor response may be better assessed by alterations in vascular perfusion rather than tumor size, and functional measurements may therefore be more appropriate. Thus, quantitative measurement of hepatic perfusion has the potential to provide important information in the assessment and management of HCC lesions and in the determination of their outcome.

Research frontiers

Perfusion computed tomography is a recent technique that allows depiction of tumor vascular physiology and has the ability to detect regional and global alterations in organ blood flow, in addition to being non-invasive and fast; perfusion computed tomography (CT) can be repeated sequentially to assess temporal changes in tumor blood flow, which is of clinical importance for monitoring tumor response to antiangiogenic agents and other treatments like TACE.

Innovations and breakthroughs

This new technique may better define the assessment of therapeutic efficacy of interventional procedures without using histological examination, evaluate tumor progression and monitor response to treatment providing a quantitative measurement of flow parameters related to residual arterial structures in viable tumor. As it is a relatively simple imaging technique, perfusion CT could be integrated into the current computed tomographic protocols, providing an *in vivo* marker of tumor-related angiogenesis.

Applications

This preliminary study in humans has shown that perfusion CT may be used to successfully monitor therapeutic response after TACE in cirrhotic patients with HCC lesions. In addition, the follow-up protocol along with conventional multi-detector computed tomography may include a CT-perfusion protocol in order to better depict residual tumor after TACE treatment, by providing quantitative information about tumor vascularization.

Peer review

The authors assess the value of CT-perfusion technique in detection of residual HCC vascularization after TACE. It's a nice imaging clinical study to follow up patients with HCC.

Abstract

AIM: To characterize the prevalence of subpopulations of $CD4^+$ cells along with that of major inhibitor or stimulator cell types in therapy-naïve childhood Crohn's disease (CD) and to test whether abnormalities of immune phenotype are normalized with the improvement of clinical signs and symptoms of disease.

METHODS: We enrolled 26 pediatric patients with CD. 14 therapy-naïve CD children; of those, 10 children remitted on conventional therapy and formed the remission group. We also tested another group of 12 children who relapsed with conventional therapy and were given infliximab; and 15 healthy children who served as controls. The prevalence of Th1 and Th2, naïve and memory, activated and regulatory T cells, along with the members of innate immunity such as natural killer (NK), NK-T, myeloid and plasmocytoid dendritic cells (DCs), monocytes and Toll-like receptor (TLR)-2 and TLR-4 expression were determined in peripheral blood samples.

RESULTS: Children with therapy-naïve CD and those in relapse showed a decrease in Th1 cell prevalence. Simultaneously, an increased prevalence of memory and activated lymphocytes along with that of DCs and monocytes was observed. In addition, the ratio of myeloid /plasmocytoid DCs and the prevalence of TLR-2 or TLR-4 positive DCs and monocytes were also higher in therapy-naïve CD than in controls. The majority of alterations diminished in remitted CD irrespective of whether remission was obtained by conventional or biological therapy.

CONCLUSION: The finding that immune phenotype is normalized in remission suggests a link between immune phenotype and disease activity in childhood CD. Our observations support the involvement of members of the adaptive and innate immune systems in childhood CD.

Key words: Crohn's disease; Dendritic cell; Infliximab; Lymphocyte; Monocyte; Regulatory T cell; Relapse; Remission; Therapy-naïve; Toll-like receptor

phenotype in children with therapy-naïve remitted and relapsed Crohn's disease. *World J Gastroenterol* 2010; 16(47): 6001-6009 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i47/6001.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i47.6001

INTRODUCTION

Crohn's disease (CD) is a chronic gastrointestinal disease characterized by segmental inflammation of the intestinal mucosa associated with a dysregulated action of the mucosal immune system to the otherwise innocuous luminal antigens in a genetically susceptible host. About 10%-15% of patients with CD are diagnosed before 18 years of age[1]. Certain features are unique to pediatric CD in comparison to adult onset disease such as different disease location, altered response to immunosuppressive therapy and different genetic and immune phenotype[2,3]. Different characteristics may suggest differences in the pathomechanism of CD in children compared to that in adults. Theories regarding CD pathomechanism include malfunctioning of the immune system. Indeed, several studies carried out in adult CD indicate the involvement of either adaptive or innate immunity[4-7].

In adult CD, peripheral Treg prevalence is diminished in therapy-naïve patients and in the active state of disease or relapses and is increased with therapy or in remission[8-10], while intestinal Treg prevalence is increased in active CD[9-11]. Simultaneously, the prevalence of effector T cells[12-14] and activated T cells[15-17] is increased in the periphery in active CD. The shift of T lymphocytes toward Th1 commitment in peripheral blood and biopsy specimens is a widely observed phenomenon in CD[18].

In addition, the prevalence of antigen presenting cells (APCs) including dendritic cells (DCs) decrease in remission, and even more so in relapses at the periphery, but is increased in tissues, simultaneously with an increased expression of Toll-like receptor (TLR)-2 and 4 in therapy-naïve and treated CD adults[19-21]. Monocytes/macrophages, another group of APCs, are comparable at the periphery but increased in biopsies and showed upregulation of TLR-2 and TLR-4 in the active state and in remission of CD[22-25]. Other cell types of innate immunity such as natural killer (NK) and natural killer T (NKT) cells are less prevalent in active CD[17,26-28].

There have been a limited number of studies specifically performed to investigate alterations of the immune system in children with CD. In addition, the majority of available data are on treated CD children. While in untreated CD children some alterations in adaptive immunity have been reported, such as the skewness of the Th1/Th2 ratio to Th2 (this finding is in contrast with that observed in adult CD)[29-32], recent data suggest that the disturbance of innate immune functions is also a major factor contributing to CD in children. Indeed, in untreated children the central macrophage prevalence is increased[33], and TLR-2 and 4 receptor expression is also enhanced[34]. The role of innate immune system in the pathomechanism of CD may be inversely associated with age at disease onset[2].

The immune dysregulation in CD is affected by ongoing therapy. Aminosalicylates and steroids, as well as immunosuppressive drugs used as first-line therapy in CD have strong immunomodulatory effects[35]. In addition, biological therapy including the tumor necrosis factor α inhibitor infliximab (IFX)[36] also has substantial effects on immune cell functions [many of the data are from patients with rheumatoid arthritis (RA)] as it may increase the prevalence of peripheral and central Tregs[8,37], effector and activated[38,39] and Th1 committed T cells[39,40]. IFX also decreases the prevalence of NK cells[38], DCs[41,42] and monocytes[43,44], as well as TLR-2 and TLR-4 expression in peripheral cells[45]. The immunological impact of conventional or IFX therapy on peripheral immune phenotype is, however, known exclusively for adult CD patients and has not been explored fully in CD children.

In this prospective study we aimed to explore the major cell prevalence of the adaptive and innate immune systems in therapy-naïve CD children and its alteration with the improvement of CD obtained by conventional therapy or IFX treatment.

MATERIALS AND METHODS

We enrolled the following patient groups into our study: (1) 14 therapy-naïve CD children. No drug was prescribed for these patients at the time of CD diagnosis. The diagnosis of CD was established by means of "The Porto criteria"[46]; disease activity was determined according to the Pediatric Crohn's disease activity index (PCDAI)[47]; (2) During conventional treatment [steroid, azathioprine (AZT) and 5-aminosalicylate (5-ASA)], 10 children responded forming the remission group. Clinical remission was defined as a PCDAI < 10; (3) IFX therapy (5 mg/kg IFX at weeks 0, 2, and 6) was started in 12 CD children who failed to respond to conventional therapy forming the "relapsed group". Non-responsiveness was defined as moderately increased PCDAI (PCDAI > 30) in patients under conventional therapy; and (4) Fifteen age- and gender-matched children with functional abdominal pain served as controls. All patients and controls were diagnosed, treated and followed up in the Outpatient Clinic of the First Department of Pediatrics, Semmelweis University between September 2007 and August 2009. The Institutional Ethical Committee approved our study; written parental informed consent was obtained.

The patients' clinical characteristics are shown in Table 1. Small and large bowel was involved in 11 of 14 treatment naïve CD patients, according to the literature (L3 localization, Montreal criteria[48]). Therapy-naïve CD patients and CD patients with relapse had lower body mass index than controls. Lower body weight and body mass index is a common presenting sign in pediatric patients with CD[49]. Reduced food intake, postprandial abdominal cramps, systemic release of cytokines and malabsorptive diarrhea were listed as factors responsible for this phenomenon[50].

IFX: Infliximab; PCDAI: Pediatric Crohn's disease activity index; L1: Small bowel; L2: Large bowel; L3: Small bowel and large bowel localization according to Montreal criteria[48].

Together with other routine blood sampling 6 mL of lithium-heparin anticoagulated blood was taken from therapy-naïve patients at the time of diagnosis, at the time of first remission in the remission group and at the initiation of IFX therapy, and then 2 and 6 wk later in the relapsed groups. From peripheral blood mononuclear cells (PBMCs), the identification of markers (6B11, CCR4, CD3, CD4, CD8, CD11c, CD14, CD25, CD45RA, CD45RO, CD123; CD161, CXCR3, HLA-DR and Lin-1 BD Biosciences Pharmingen, San Diego, CA, USA; TLR-2 and TLR-4 eBioscience, San Diego, CA, USA) and FoxP3 assay (eBioscience, San Diego, CA, USA) were performed with a BD FACS Aria (BD Biosciences Pharmingen, San Diego, CA, USA)[51]. Briefly, from whole blood, PBMCs were separated with gradient centrifugation using Ficoll-Paque (GE Healthcare Life Sciences, Pittsburgh, PA, USA). The isolated PBMCs were washed twice with Phosphate Buffered Saline pH 7.4 (PBS, Central Pharmacy of Semmelweis University, Budapest, Hungary) and were stained with the appropriate fluorescent antibodies according to the manufacturers' instructions. For intracellular staining, cells were incubated first with Fixation/Permeabilization Buffer (eBioscience, San Diego, CA, USA), then washed twice with Permeabilization Buffer (eBioscience, San Diego, CA, USA) and stained by FoxP3 and isotype control. At the end of staining, cells were washed twice with PBS and with Permeabilization Buffer for the detection of cell surface markers and FoxP3, respectively. Samples were resuspended in PBS and were measured within 1 h recording at least 50 000 events in the lymphocyte gate.

Our data did not follow normal distribution, therefore non-parametric statistical tests and median and interquartile ranges were used. Mann-Whitney and Friedman tests with Dunn's post hoc comparison and Spearman's correlation were used for statistical analysis, the level of significance was 5% ($P < 0.05$). All data are expressed as median (interquartile range). Statistical analysis was performed with Statistica 8 (Statsoft, Tulsa, OK, USA).

RESULTS

Major clinical characteristics and laboratory data are summarized in Table 1. The investigated cell prevalence values and cell ratios of the adaptive and innate immune systems are summarized in Tables 2 and 3, respectively. We also highlighted the most important alterations in Figures 1 and 2.

First, we compared the immune phenotype in therapy-naïve CD patients with that of healthy controls. In CD children, the prevalence of activated T cells (i.e. $CD4^+CD25^+$ cells) increased. At the same time, the prevalence of T cells with Th1 commitment (i.e. $CD4^+CXCR3^+$ cells) decreased resulting in a skewness of Th1/Th2 to Th2. The prevalence of memory (i.e. $CD4^+CD45RO^+$) cells increased and, therefore, a shift in the naïve/memory ratio toward memory cells was observed. The prevalence of regulatory T (i.e. $CD4^+CD25^{hi}FoxP3^+$) cells was comparable between the two groups.

Striking differences in cell prevalence values of innate immunity were obtained between therapy-naïve CD and healthy children. The occurrence of NK and NKT cells (marked as $CD3^-CD161^+$ and $CD3^+6b11^+$, respectively) was lower in CD children. Interestingly, the prevalence of the APCs investigated differed largely between CD and healthy children. DCs (i.e. those with $Lin1^-HLADR^+$ expression) were more prevalent and, within DC cells, the myeloid DCs (mDCs, i.e. $CD11c^+$ cells) were more prevalent, while plasmocytoid DCs (pDCs, i.e. $CD123^+$ cells) were less frequent in CD than in healthy children. This leads to skewness of mDCs in the mDC/pDC ratio. The prevalence of peripheral monocytes (i.e. $CD14^+$ cells) also increased in therapy-naïve CD patients. In addition, the prevalence of DC cells and monocytes expressing TLR-2 and TLR-4 receptors was also increased in CD. Of note,

Table 2 Prevalence and ratios of cellular members of adaptive immunity

Cell prevalence in parent population	Control	Therapy-naïve (before conventional therapy)	First remission (with conventional therapy)	Relapse (before IFX therapy)	IFX therapy (before 2nd infusion)	IFX therapy (before 3rd infusion)

[a]$P < 0.05$, [b]$P < 0.01$, [d]$P < 0.001$ *vs* control; [c]$P < 0.05$, [f]$P < 0.01$ *vs* therapy-naïve; [e]$P < 0.05$ *vs* first remission; [g]$P < 0.05$ *vs* relapse. Data are expressed as median (interquartile range). IFX: Infliximab; PBMC: Peripheral blood mononuclear cell; NK: Natural killer, $CD3^-CD161^+$; NKT: Natural killer T, $CD3^+6b11^+$; DC: Dendritic cell, Lin1-HLA-DR^+; mDC: Myeloid dendritic cell, $CD11c^+$; pDC: Plasmocytoid dendritic cell, $CD123^+$; Monocyte ($CD14^+$); TLR: Toll-like receptor.

4 of the 14 therapy-naïve CD children did not respond to conventional therapy. Their immune phenotype at the therapy-naïve phase did not differ from those children who responded to conventional therapy (data not shown).

In the second phase of our study, we prospectively tested the alteration in cell prevalence values during therapy. At the time of first remission with conventional therapy, the Th1/Th2 ratio shifted to Th1 and normalized along with activated T cell prevalence. Memory T cells remained elevated, while all the other cell types of adaptive immunity were comparable to that measured before therapy. For innate immune cells, NK and NK-T remained lower than normal and total DC prevalence remained higher than the control. However, mDC and pDC ratios, total monocyte prevalence and cells expressing TLR-2/TLR-4 receptor values (including monocytes and DCs) were normal.

In children who relapsed with conventional therapy, immune phenotype again became comparable to that in therapy-naïve CD. Therefore, we measured lower Th1, increased activated T, higher DC and higher macrophage prevalence as well as higher TLR-2 and TLR-4 expression in comparison to controls. In addition, the prevalence of mDCs, simultaneously with TLR-2 and TLR-4 expressing DCs was higher in relapsed than in remitted CD. During IFX therapy, immune cell prevalence was measured at two time points (i.e. 2 and 6 wk after the initiation of therapy). Th1, activated T and Treg prevalence increased significantly by week 6 of therapy. Total DC, mDC, pDC, total monocyte, along with TLR-2 and TLR-4 expressing DC and macrophage prevalence were normal at this time. Of note, although no significant alteration was observed at week 2, some tendencies were already present (Figures 1 and 2).

DISCUSSION

In our study we investigated the major components of adaptive and innate immunity in a simultaneous manner in CD children. While CD4 numbers in therapy-naïve CD children were normal as in early studies with adult patients[52,53], we noticed a shift to the Th2 direction in Th1/Th2 committed T lymphocytes. This finding is in line with other reports on blood[29,30,32] or biopsy specimens of therapy-naïve CD children[31]. Similar to adults, we also found a higher than normal prevalence of activated $CD4^+$ cells and effector memory cells and a decrease in effector cell/naïve CD4 cell ratios[12-17]. We tested the idea that this was

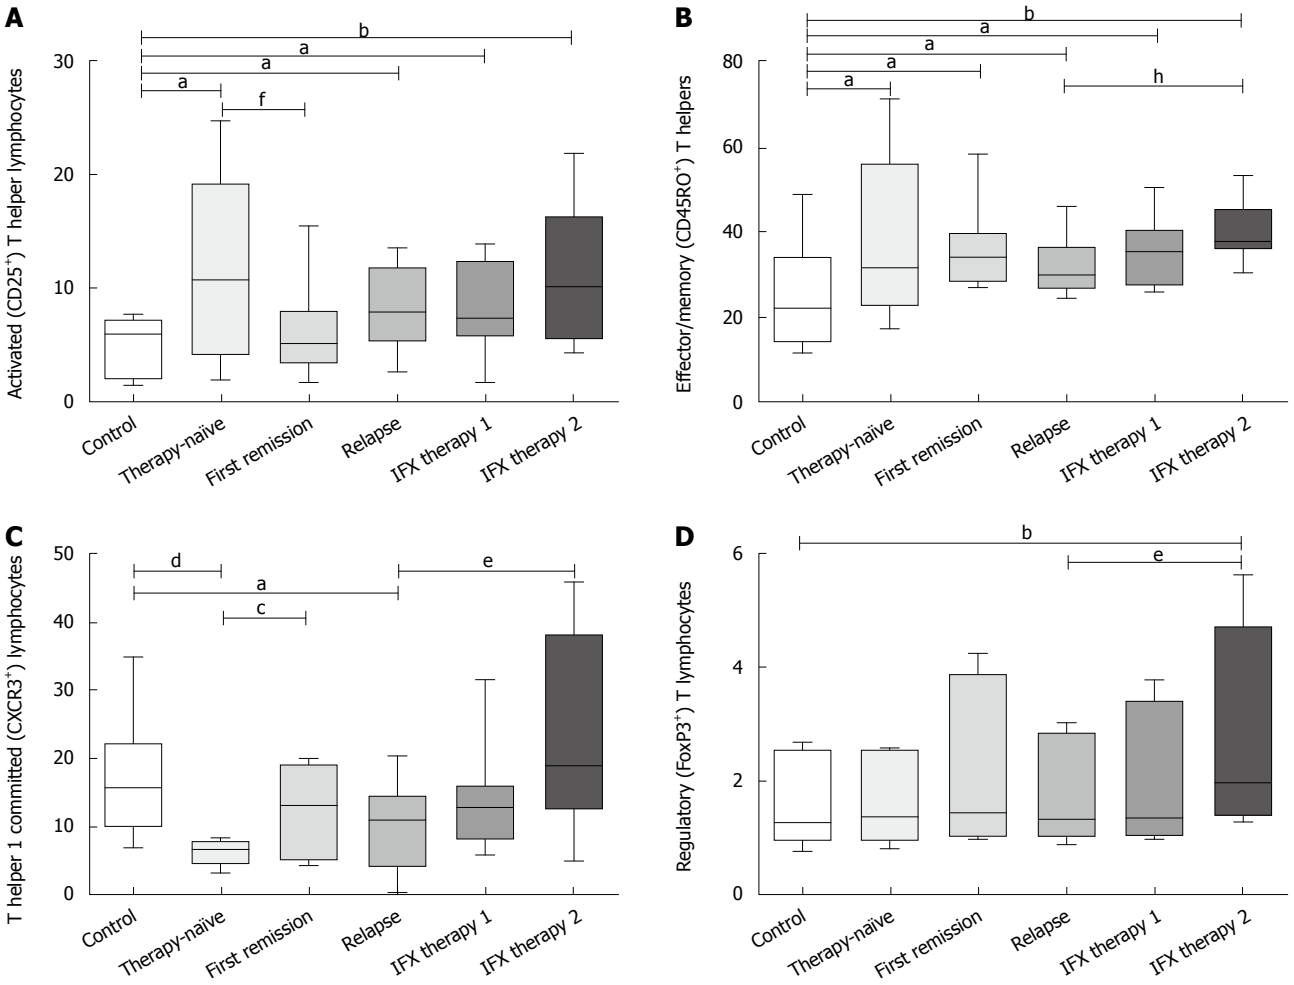

Figure 1 Prevalence of cellular members of adaptive immunity. The prevalence of activated (i.e. $CD4^+CD25^+$) (A), effector or memory (i.e. $CD4^+CXCR3^+$) (B), Th1 committed (i.e. $CD4^+CXCR3^+$) (C) and regulatory T (i.e. $CD4^+CD25hiFoxP3^+$) cells (D). $^aP < 0.05$, $^bP < 0.01$, $^dP < 0.001$ *vs* control; $^cP < 0.05$, $^fP < 0.01$ *vs* therapy-naïve; $^eP < 0.05$, $^hP < 0.01$ *vs* relapse.

due to low Treg numbers, but our data showing a normal prevalence of FoxP3 expressing CD4 cells do not support this notion. This finding is in contrast with that suggesting a diminution of Treg cells in untreated CD adults. However, in an earlier study Tregs were identified according to $CD4^+CD25^{high}$ positivity[8] currently not regarded as a sensitive marker for this cell type.

Our study provides novel information on the possible contribution of the innate immune system to a Th2 shift in therapy-naïve CD children. While some authors suggested that altered NK and NKT function may be a component in adult CD[17,26-28], our data are the first to show lower than normal NK and NKT prevalence in therapy-naïve CD children. In addition, we also observed a marked increase in monocyte and DC prevalence with an increase in the mDC/pDC ratio. These cell populations are major triggers of immune response and may be linked with the increase in memory T cell prevalence. As recent studies emphasized, mDC and pDC have distinct regulatory properties as mDC may shift the immune response not only toward Th1, but also in the Th2 direction[54], while pDC can induce Tregs[55]. Therefore, an increase in the mDC/pDC ratio in our patients may contribute to a lower Th1/Th2 ratio. Furthermore, we also measured an increased prevalence of TLR-2 and TLR-4 expressing monocytes and DCs that may also play a role in the activation of immune cells. This finding is in accordance with our previous observation of high TLR-2 and TLR-4 expression in the colonic mucosa of therapy-naïve CD children[34].

We tested prospectively the link between immune phenotype and disease activity index in our patients. The majority of immune system alterations in therapy-naïve CD are normalized with the normalization of PCDAI. While Th1 prevalence significantly increased compared to the therapy-naïve state and almost normalized during therapy, Th1/Th2 was still in the normal range at first remission suggesting a difference in CD immune phenotype between adults and children[4-7].

In remitted patients, NK and NKT prevalence increased and the difference between therapy-naïve CD and healthy controls disappeared. This finding does not support previous reports on decreased NK and NKT numbers in treated CD adults[17,26-28]. We also observed that the mDC/pDC ratio, prevalence of monocytes and that of TLR-2 and TLR-4 expressing DCs and monocytes were also normalized. This may suggest that normalization of immune phe-

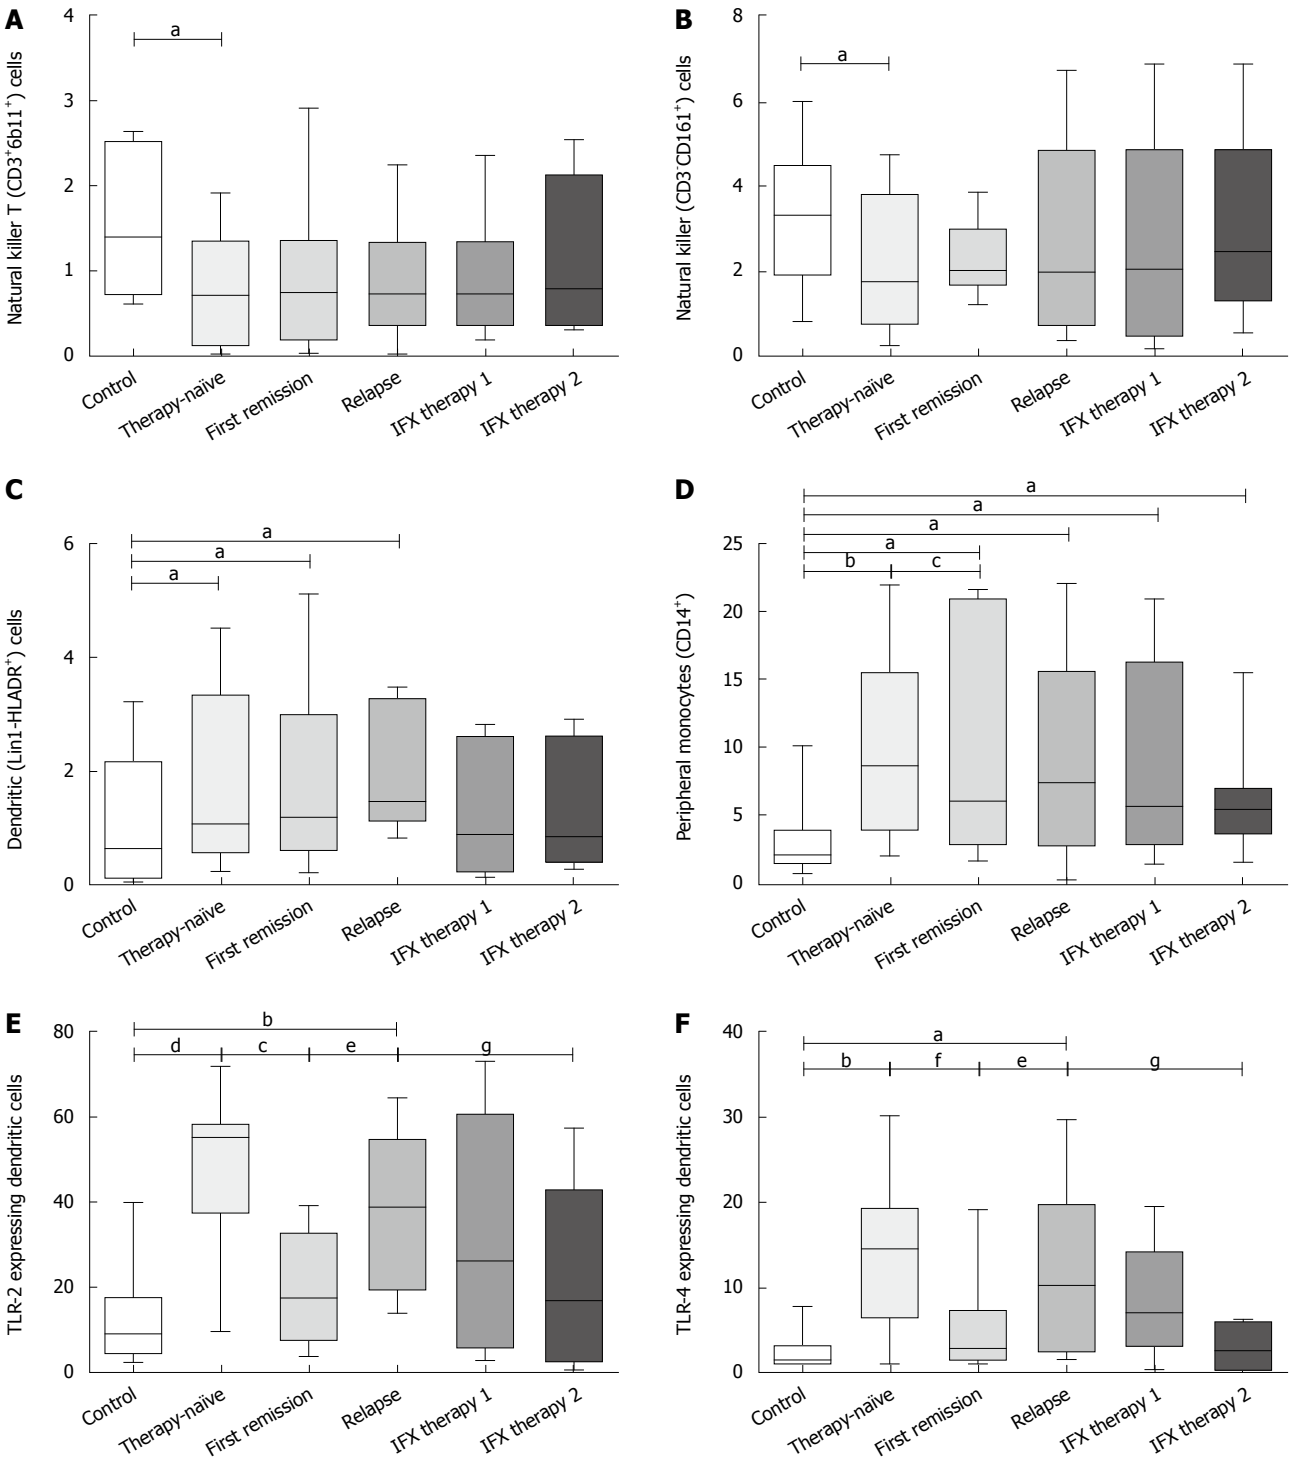

Figure 2 Prevalence of cellular members of innate immunity. The prevalence of natural killer T (i.e. $CD3^+6b11^+$) (A), natural killer (i.e. $CD3^-CD161^+$) (B), dendritic cell (i.e. $Lin1\text{-}HLA\text{-}DR^+$) (C), peripheral monocyte (i.e. $CD14^+$) (D), Toll-like receptor 2 expressing dendritic cell (E) and Toll-like receptor 4 expressing dendritic cell (F). $^aP < 0.05$, $^bP < 0.01$, $^dP < 0.001$ *vs* control; $^cP < 0.05$, $^fP < 0.01$ *vs* therapy-naïve; $^eP < 0.05$ *vs* first remission; $^gP < 0.05$ *vs* relapse.

notype is linked to an improvement in PCDAI. This may be a specific feature in childhood CD as a number of studies reported a higher than normal prevalence of activated and effector T lymphocytes even in treated CD adults[12-17]. Tregs probably do not play a role in this normalization as their prevalence was not altered in remission.

We performed another prospective study in 12 CD children who relapsed with conventional therapy and were treated with IFX. In these CD children, the immune phenotype was similar to that observed in therapy-naïve CD children (with the only exception of normal prevalence of NK and NKT cells). During IFX therapy, however, marked changes occurred in the 6th wk of IFX treatment and the prevalence of Th1 cells and the APCs investigated were normalized. Interestingly, the prevalence of activated T cells, memory cells and Treg cells were elevated further.

Recently, increased numbers of Th1 cells and high blood levels of Th1-type cytokines were found in adult patients with rheumatoid arthritis (RA) after IFX treatment[39,40]. Others also found an increase in effector and activated T cells with IFX[38,39]. While the explanation for this is still unclear, an attractive hypothesis may be that IFX inhibits the homing of Th1 and activated T cells to the inflammation site and transiently increases their peripheral occurrence[38,40].

Theoretically, this immune phenotype may refer to an increased risk for infections. However, our patients did not exhibit major clinical signs and symptoms of infection during IFX therapy. Interestingly, simultaneously with these changes, IFX therapy also increased the prevalence of peripheral Treg cells. This phenomenon - which may be due to a resistance of Tregs to IFX-induced apoptosis - was also demonstrated previously in the peripheral blood of adult CD patients[8], and in colonic samples from CD children[37].

In our patients, the prevalence of monocytes, mDCs, mDC/pDC ratio and TLR-2 and TLR-4 expressing DCs normalized during IFX therapy indicating the possible impact of biological therapy on innate immunity. This is in line with the observation of others investigating RA and CD patients[41,43-45].

Our study has three major limitations. First, although we did correct for multiplicity when performing pairwise comparisons, the study was not powered for the multitude of statistical tests we performed, thus some significances could occur by chance alone. Second, peripheral cell prevalence values do not necessarily reflect the intestinal phenotype. Third, our results may have been affected by ageing of the patients during the follow-up period. The short duration of our prospective study (i.e. about 10 mo until the first remission or 6 wk from the beginning of IFX therapy), however, makes this bias less likely.

CD exhibits several abnormalities in adaptive immunity (such as a decrease in Th1 cell and an increase in memory and activated T cell prevalence) and innate immunity (such as an increase in DC, monocyte and TLR-2 and TLR-4 exhibiting APC prevalence). The majority of the observed alterations of the innate immune system are normalized with the improvement of clinical signs and symptoms of CD, irrespective of whether this is obtained by conventional therapy or add-on IFX therapy. This finding suggests a link between immune phenotype and disease activity in childhood CD.

If these results are reinforced by other groups, the observations may raise the possibility that immune phenotype is a potential biomarker for clinical response in CD children.

COMMENTS

Background

About 10%-15% of patients with Crohn's disease (CD) are diagnosed before 18 years of age. Pediatric CD is a unique subtype of CD due to different location, altered responsiveness to therapy and different susceptibility factors compared with those in adult CD.

Research frontiers

Several studies indicate both the malfunction of adaptive and innate immunity in adulthood CD. Fewer data are available for CD children. The alteration of immune phenotype with treatment is also unclear in this population.

Innovations and breakthroughs

In this prospective study, the authors demonstrated marked alterations in both adaptive and innate immunity in childhood CD. These abnormalities were resolved in infants responding to conventional therapy but not in non-responding children. Immune phenotype depends on disease activity.

Applications

These observations support the involvement of members of the adaptive and innate immune systems in childhood CD. They also identify immune phenotype as a possible biomarker for the follow-up of therapeutic success.

Peer review

In this study, the authors prospectively investigated the major components of adaptive and innate immunity in CD children. The authors showed several abnormalities in adaptive and innate immunity in CD children. They also showed that the majority of observed alterations were normalized in remission stage and suggest a link between immune phenotype and disease activity in childhood CD. Although the number of CD patients enrolled to this study was small, this prospective study demonstrated clinically interesting results in CD children.

Abstract

AIM: To investigate two distinct clinical phenotypes of reflux esophagitis and intra-hernial ulcer (Cameron lesions) in patients with large hiatal hernias.

METHODS: A case series study was performed with 16831 patients who underwent diagnostic esophagogastroduodenoscopy for 2 years at an academic referral center. A hiatus diameter ⩾ 4 cm was defined as a large hernia. A sharp fold that surrounded the cardia was designated as an intact gastroesophageal flap valve (GEFV), and a loose fold or disappearance of the fold was classified as an impaired GEFV. We studied the associations between large hiatal hernias and the distinct clinical phenotypes (reflux esophagitis and Cameron lesions), and analyzed factors that distinguished the clinical phenotypes.

RESULTS: Large hiatal hernias were found in 49 (0.3%) of 16831 patients. Cameron lesions and reflux esophagitis were observed in 10% and 47% of these patients, and 0% and 8% of the patients without large hiatal hernias, which indicated significant associations between large hiatal hernias and these diseases. However, there was no coincidence of the two distinct disorders. Univariate analysis demonstrated significant associations between Cameron lesions and the clinico-endoscopic factors such as nonsteroidal anti-inflammatory drug (NSAID) intake (80% in Cameron lesion cases *vs* 18% in non-Cameron lesion cases, $P = 0.015$) and intact GEFV (100% in Cameron lesion cases *vs* 18% in non-Cameron lesion cases, $P = 0.0007$). In contrast, reflux esophagitis was linked with impaired GEFV (44% in reflux esophagitis cases *vs* 8% in non-reflux esophagitis cases, $P = 0.01$). Multivariate regression analysis confirmed these significant associations.

CONCLUSION: GEFV status and NSAID intake distinguish clinical phenotypes of large hiatal hernias. Cameron lesions are associated with intact GEFV and NSAID intake.

Key words: Large hiatal hernia; Reflux esophagitis; Cameron lesion; Gastroesophageal flap valve; Nonsteroidal anti-inflammatory drug

INTRODUCTION

Hiatal hernia promotes gastric acid access to the esophagus and impairs its clearance. The overall consequence of increased esophageal acid exposure is reflux esophagitis. Larger hiatal hernias impair the normal anti-reflux mechanisms to a greater extent than do smaller hernias. Esophagitis severity and esophageal acid exposure increase significantly for hernias > 3 cm in length, as measured endoscopically[1]. The size of a hiatal hernia and the degree of lower sphincter hypotension are the most significant independent predictors of esophagitis presence and severity[2].

Gastric erosions or ulcers located on or near the neck of a large hiatal hernia sac, collectively referred to as Cameron lesions, cause gastrointestinal bleeding and anemia[3]. The prevalence of Cameron lesions is known to be dependent upon hiatal hernia size, with higher prevalence corresponding to larger hiatal hernia size[4].

There is convincing evidence that large hiatal hernias involve each of the two distinct disorders reflux esophagitis and Cameron lesions. However, the relationships between large hiatal hernias and these two disorders have not been clarified. We aimed to elucidate these relationships and to clarify the key factors that differentiate the clinical phenotypes of large hiatal hernias into reflux esophagitis and/or Cameron lesions.

MATERIALS AND METHODS

Patients and methods

From January 2005 to January 2007, 16 831 patients were referred for diagnostic esophagogastroduodenoscopy (EGD) to the Department of Endoscopy at Jikei University Hospital. Patients with the diagnosis of hiatal hernia were identified using databases of endoscopic and medical records. Endoscopic images of these patients were retrieved from the endoscopic filing system (Olympus Medical Systems, Tokyo, Japan), to confirm the presence of Cameron lesions and/or reflux esophagitis, as well as the presence and size of the hiatal hernia.

Cameron lesions were defined as gastric erosions or ulcers located on or near the neck of the hiatal hernia sac. Although Cameron lesions were originally described as linear erosions[3], various lesion shapes, namely, linear, oblong or round, have been reported[4]. Therefore, the shapes of the erosions or ulcers were not taken into account as long as the lesions were located on or near the neck of the hiatal hernia sac. Long linear erosions that extended from the neck to the lower or middle gastric body were excluded from this definition.

The standard endoscopic recording of diagnostic EGD comprised 40 still images, including two images of the gastric cardia from the retroflex views of the so-called U-turn and J-turn, and two images of the esophagogastric junction from the esophageal antegrade view. Additional still images were obtained with no limitation as to image numbers when abnormal findings, such as esophagitis and ulceration, were noted. Hiatal hernia size was defined as the diameter of the neck of the hernia sac in the still images of the retroflex views of the gastric cardia. For example, if the diameter of the neck was three times that of the endoscope shaft (the diameters of the endoscopes used ranged from 8.9 mm to 10.4 mm; GIF-Q260, GIF-XQ260, GIF-H260, GIF-Q240, GIF-XQ240; Olympus Medical Systems), the size of the hiatal hernia was recorded as 3 cm (Figure 1). The measurements were made at 0.5 cm intervals. A large hiatal hernia was tentatively defined as having a diameter ⩾ 4 cm.

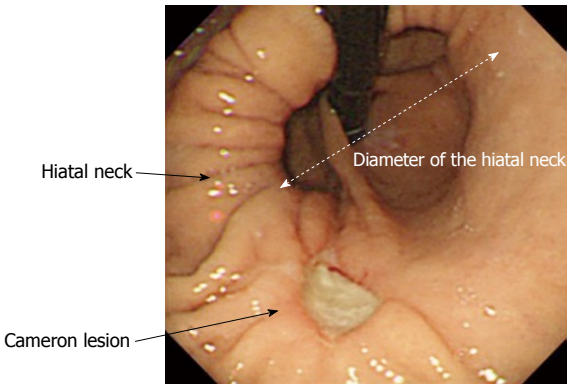

Figure 1 Representative image of the retroflex view of the gastric cardia in a patient with a large hiatal hernia and Cameron lesions.

A fold or ridge that surrounded the gastric cardia was designated as a gastroesophageal flap valve (GEFV). GEFV status was assessed using the still images of the retroflex views of the gastric cardia. A GEFV composed of a sharp fold that firmly surrounded the cardia was defined as an intact GEFV, which corresponded to grade I in Hill's classification[5,6]. A loose and dull fold or disappearance of the fold was classified as an impaired GEFV, which corresponded to grade Ⅱ-Ⅵ (Figure 2).

Reflux esophagitis was evaluated using the Los Angeles classification[7]. Patients with mucosal breaks were defined as having reflux esophagitis (grade A-D). The status of gastric mucosal atrophy was assessed using the Kimura-Takemoto classification[8]. The closed and open types were defined according to the presence of gastric mucosal atrophy.

GEFV status, hernia size, and the existence of reflux esophagitis and Cameron lesions were evaluated separately by three endoscopists, who were blinded to the clinical information. When there was a lack of consensus among the three endoscopists regarding the results obtained for the endoscopic factors, the matching results (if available) from two of the three endoscopists were adopted. If there were no matched results between the three endoscopists, they re-examined together the endoscopic still images and reached a consensus.

Statistical analysis

The parameters of age, sex, hiatus diameter, GEFV status, long-term nonsteroidal anti-inflammatory drug (NSAID) intake, gastric atrophy, and hemoglobin level were examined for associations with Cameron lesions and reflux esophagitis. Long-term NSAID intake was defined as the

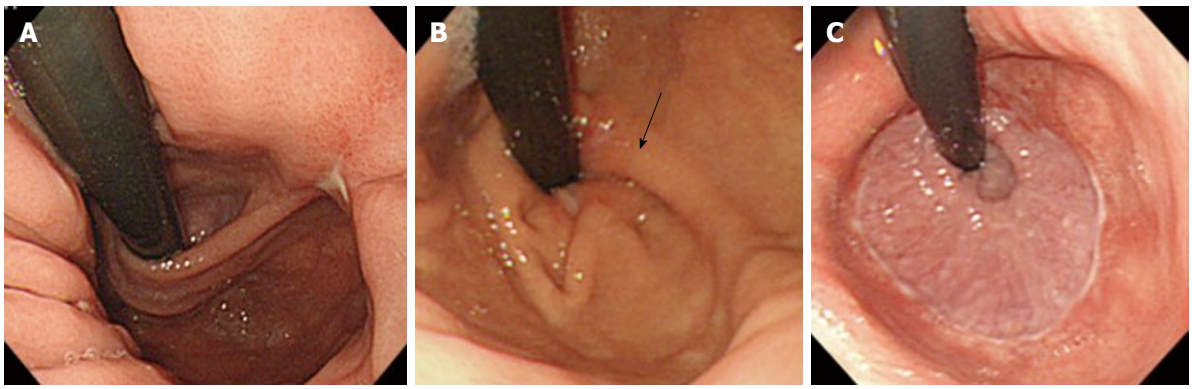

Figure 2 Representative endoscopic images of an intact gastroesophageal flap valve (A) and an impaired gastroesophageal flap valve (B, C). A loose and dull fold was classified as an impaired gastroesophageal flap valve (arrow in B).

use of any NSAID, including low-dose aspirin, for at least 3 d a week in the previous month. The associations were evaluated by univariate and multivariate logistic regression analyses. When the *P*-value was less than 0.05, the difference was considered to be statistically significant. All analyses were performed using the STATA 8.0 software (STATA Inc., College Station, TX, USA).

RESULTS

Associations between large hiatal hernias and the two clinical phenotypes

Of the 16 831 patients who underwent EGD, 4658 (27.7%) were identified as having hiatal hernias, and 49 (0.3%; 24 male and 25 female) met the criteria for large hiatal hernias. The mean age of the patients with large hiatal hernias was 69.8 years (range: 41-90 years). The indications for EGD for the 49 patients were as follows: epigastralgia (n = 12), heartburn (n = 11), anemia (n = 6), melena or hematemesis (n = 4), dysphagia (n = 2), vomiting (n = 2), and others (n = 12).

Cameron lesions and reflux esophagitis were found in five (10%) and 24 (49%) of the patients with large hiatal hernias, respectively. In contrast, Cameron lesions and reflux esophagitis were found in 0 (0%) and 1253 (8.4%) of the patients without large hiatal hernias, which indicated significant associations between large hiatal hernias and these two disorders. However, Cameron lesions concomitant with reflux esophagitis were not detected in any of the patients with large hiatal hernias.

Univariate and multivariate regression analyses of the associations between Cameron lesions and clinico-endoscopic factors

The results are shown in Table 1. Univariate analysis demonstrated significant associations between Cameron lesions and the clinico-endoscopic factors of NSAID intake, intact GEFV, and hemoglobin level in the 49 patients with large hiatal hernias. Although reflux esophagitis was found in 54.5% of the patients without Cameron lesions, it was not found in any of the patients with such lesions. Multivariate regression analysis showed a significant association between the presence of Cameron lesions and NSAID intake. As all of the patients with Cameron lesions showed intact GEFV, the association between Cameron lesions and GEFV status could not be evaluated adequately in the multivariate regression analysis.

Table 1 Univariate regression analysis and multivariate logistic regression analysis on the linkage between Cameron lesion and clinico-endoscopic factors

Univariate and multivariate regression analyses of the associations between reflux esophagitis and clinico-endoscopic factors

The results are shown in Table 2. Univariate analysis demonstrated significant associations between reflux esophagitis and the clinico-endoscopic factors of sex and intact GEFV. Reflux esophagitis was frequently observed in male patients and in patients without intact GEFV. Multivariate regression analysis showed a significant reverse association between reflux esophagitis and intact GEFV.

Endoscopic features of Cameron lesions

The results are shown in Figure 3. Five patients with large hiatal hernias presented with Cameron lesions. Two of

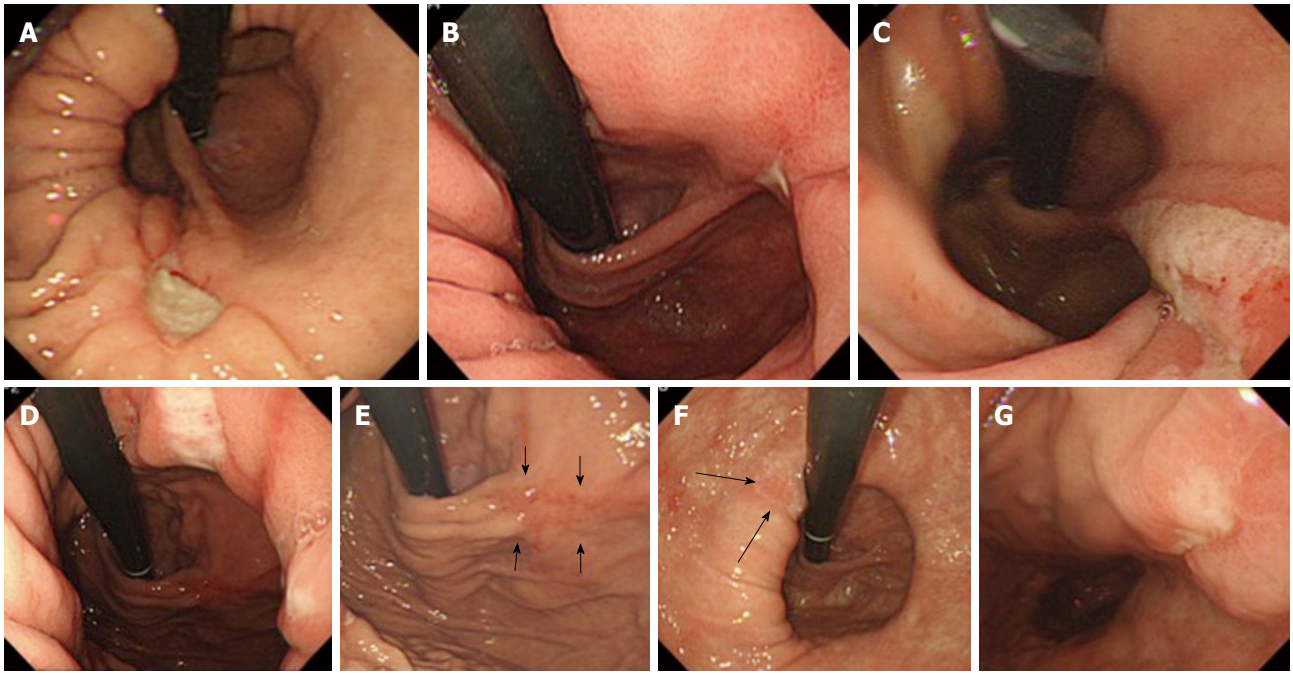

Figure 3 Representative endoscopic images of five patients with Cameron lesions. A: Case #1 (no nonsteroidal anti-inflammatory drug, Hb5.4); B: Case #2 (loxoprofen + low dose aspirin, Hb5.3); C: Case #3 (diclofenac, Hb6.3); D, E: Case #4 (low dose aspirin, Hb8.0); F, G: Case #5 (low dose aspirin, Hb10.3). An ulceration scar was noted at the point at which the gastroesophageal flap valve fold diverged from the anterior stomach wall (arrows in E and F).

these patients (#3 and #4) showed multiple linear erosions or ulcers that resembled the lesions described by Cameron *et al*[3]. In contrast, three of the patients showed solitary, non-linear lesions. In three patients (#1-#3) the lesions were localized to the crossing of the hiatal neck and the extension of the GEFV fold on the anterior gastric wall. In patient #4, there was no open ulcer at the crossing of the hiatal neck and the extension of the GEFV fold, although an ulceration scar was noted at the point at which the GEFV fold diverged from the anterior stomach wall (arrows in Figure 3).

DISCUSSION

Large hiatal hernias were identified in 0.3% of the patients referred to an academic referral center for diagnostic EGD. For this population, we found significant associations between the presence of large hiatal hernias and Cameron lesions or reflux esophagitis. These two disorders, which individually are linked with large hiatal hernias, were not detected concomitantly in any patient. GEFV status clearly differentiated the clinical phenotypes of large hiatal hernias into Cameron lesions or reflux esophagitis. Although the Cameron lesions were found exclusively in patients with intact GEFV, reflux esophagitis was frequently found in those with impaired GEFV.

GEFV contributes to the barrier functions against gastroesophageal reflux. The sling fibers of the stomach, which are located below the lower esophageal sphincter, are associated with a valve mechanism through which the pressure in the gastric fundus creates a flap that presses against the lower end of the esophagus[9]. GEFV status has been proposed as a useful predictor of gastroesophageal reflux disease[5,10,11]. In the present study, we have demonstrated that the anti-reflux mechanism of GEFV functions effectively, even in patients with large hiatal hernias, who are generally considered to have impaired barrier functions against gastroesophageal reflux.

All of the patients with Cameron lesions had intact GEFV, and 80% of the lesions were located at the point where the intact and sharp fold of the GEFV diverged from the stomach wall, especially on the anterior wall. As shown in Figure 1, the fold of the GEFV is speculated to be stretched excessively at the points where the fold

diverges from the stomach wall. Although the mechanisms that underlie the onset of Cameron lesions remain unclear, mucosal ischemia might result from the accumulation of excessive loads at a point on the hiatus neck and/or the extension of the GEFV. Mucosal injury might be exacerbated by the combination of mechanical loading and NSAID intake, which has been significantly linked with Cameron lesions.

Although *Helicobacter pylori* (*H. pylori*) is one of the main causes of gastric ulcer, the status was not examined systemically in this case series. We tested *H. pylori* status in four of five patients with Cameron lesions. Three and one of these four patients were negative and positive for *H. pylori*, respectively. Since the *H. pylori*-positive rate of the tested patients with Cameron lesions is lower than the rate (60%-80%) in elderly Japanese patients, *H. pylori* infection might not be the major ulcerogenic factor in Cameron lesions. One of the limitations in the present study is that we could not obtain the information on anti-secretory drug intake in all patients. Therefore, it is difficult to evaluate the association between anti-secretory drug intake and the clinical phenotypes seen in large hiatal hernia.

Cameron *et al*[3] have described multiple linear erosions on the gastric folds of the hiatus neck as a distinct entity. However, lesions of various shapes (i.e. linear, oblong or round) have been reported[4]. For three of the cases in the present study, the lesions were solitary and non-linear, and appeared to be different from the lesions demonstrated in the original article. Gastric erosions or ulcers located on the hiatus neck might have different etiologies. For example, multiple linear erosions or red streaks are often observed in other disorders, such as alkaline reflux gastritis, or in the antrum of the *H. pylori*-negative stomach[12]. Further studies with larger populations of patients with Cameron lesions might increase our understanding of the various etiologies of this disorder.

Endoscopic diagnosis of a hiatal hernia is not easy, and accurate measurement of hernial size is difficult[11,13]. Most investigators define hernial size as the distance between the Z-line and diaphragmatic crus using the length markings on the endoscope (most of the markings are at 5-cm intervals). This application of endoscopy has been shown to be unreliable owing to the large inter-observer variability[14]. It is also difficult to ensure that the tip of the endoscope is located precisely at the Z-line or diaphragmatic crus, as the circumferential distance from these landmarks to the incisors can vary. In cases of paraesophageal hernias without sliding hernias (type Ⅱ hiatus hernias)[15], measurements of this distance are not valid for assessing the size of an esophageal hernia. In the present study, which included type Ⅱ hiatus hernias, hernial size was defined as the diameter of the neck of the hernia sac in images taken of the retroflex views of the gastric cardia. The measurement of hiatus diameter by comparison with the endoscope shaft is relatively objective, and hiatus diameter might be valid for assessing the size of a type Ⅱ hiatus hernia. However, the hiatus diameter does not necessarily reflect the distance between the Z-line and diaphragmatic crus, even if these two parameters show strong correlation. Therefore, our definition of large hiatal hernias as having hiatus diameter $\geqslant$ 4 cm is tentative, and confirmation of the results obtained in the present study in prospective studies using both types of measurement is required.

In conclusion, GEFV status and NSAID intake differentiate the clinical phenotypes of patients with large hiatal hernias. Cameron lesions are found exclusively in patients with intact GEFV, and reflux esophagitis is frequently found in patients with impaired GEFV. NSAID intake and mechanical loading could contribute to the onset of Cameron lesions.

COMMENTS

Background

Gastric erosions or ulcers, located on or near the neck of a large hiatal hernia sac, are designated as Cameron lesions. Large hiatal hernias are involved in reflux esophagitis and Cameron lesions.

Research frontiers

Cameron lesions and reflux esophagitis are mutually exclusive lesions that can be distinguished by the status of gastroesophageal flap valve (GEFV). Nonsteroidal anti-inflammatory drug (NSAID) intake is linked to the presence of Cameron lesions.

Innovations and breakthroughs

The authors have demonstrated that the anti-reflux mechanism of GEFV functions effectively even in a large hiatal hernia. Further investigations with manometer and pH monitoring might confirm the barrier function of GEFV and the etiology of Cameron lesions.

Applications

It is known that Cameron lesions recur frequently and cause chronic anemia. Conservative treatment such as anti-secretory drug and iron drug intake are effective for Cameron lesions. Sometimes blood transfusion might be necessary for treatment.

Peer review

This is an interesting paper about the association between hiatal hernia and pathological changes in esophageal and gastric mucosa represented by esophagitis and Cameron lesions. The authors also evaluated the effect of treatment with NSAID on the development of these mucosal changes. In addition, they have presented an alternative method for estimation of hiatal hernia size.

Abstract

AIM: To assess the benefits and limits of surgery for primary hepatic lymphoma (PHL), and probability of survival after postoperative chemotherapy.

METHODS: A retrospective analysis was undertaken to determine the results of surgical treatment of PHL over the past 8 years. Only nine patients underwent such treatment. The detailed data of diagnosis, treatment, and prognosis were carefully studied.

RESULTS: All patients were mistaken as having α-fetoprotein-negative hepatic cancer before pathological diagnosis. The mean delay time between initial symptoms and final diagnosis was 26.8 d (range: 14-47 d). Hepatitis B virus infection was noted in 33.3% of these patients. Most of the lesions were found to be restricted to a solitary hepatic mass. The surgical procedure performed was left hepatectomy in five cases, including left lateral segmentectomy in three. Right hepatectomy was performed in three cases and combined procedures in one. One patient died on the eighth day after surgery, secondary to hepatic insufficiency. The cumulative 6-mo, 1-year, and 2-year survival rates after hepatic surgery were, respectively, 85.7%, 71.4%, and 47.6%. One patient survived for > 5 years after surgery without any signs of recurrence until latest follow-up, who received routine postoperative chemotherapy every month for 2 years and then regular follow-up. By univariate analysis, postoperative chemotherapy was a significant prognostic factor that influenced survival (P = 0.006).

CONCLUSION: PHL is a rare entity that is often misdiagnosed, and has a potential association with chronic hepatitis B infection. The prognosis is variable, with good response to early surgery combined with postoperative chemotherapy in strictly selected patients.

Key words: Primary hepatic lymphoma; Diagnosis; Surgery; Survival

INTRODUCTION

Primary hepatic lymphoma (PHL) is confined to the liver with no evidence of lymphomatous involvement in the spleen, lymph nodes, bone marrow, or other lymphoid structures[1]. PHL is a very rare malignancy, and constitutes about 0.016% of all cases of non-Hodgkin's lymphoma[1]. Most patients are treated with chemotherapy, with some physicians employing a multimodality approach[2]. However, the optimal therapy is still unclear and the outcomes

are uncertain. The purpose of this short report is to define the correct management of PHL with the help of nine clinical cases observed in the past 8 years.

MATERIALS AND METHODS

Patients

In view of the policy to try to resect hepatic lymphoma completely whenever possible, the charts of all patients operated upon for this condition from January 2002 to March 2010 were reviewed retrospectively. The diagnosis of PHL was defined[3]: (1) at the time of disease presentation, the patient's symptoms were caused mainly by the liver involvement; (2) there was an absence of palpable lymphadenopathy, and no radiological evidence of distant lymphadenopathy; and (3) there was an absence of leukemic blood involvement in the peripheral blood smear. Thus, patients with splenic, lymph node, or bone marrow involvement were excluded. During this period, only nine patients met these criteria. The analyses included sex, age, information concerning PHL, the type of liver surgery performed, postoperative therapy, the associated morbidity and mortality, and overall survival. The follow-up was complete for all nine patients.

Statistical analysis

The clinicopathological factors were analyzed for prognostic significance using a Kaplan-Meier product-limit method with a log-rank test. Significance was established at $P < 0.05$. Statistical calculations were performed by a statistical analysis program package (SPSS Inc., Chicago, IL, USA).

RESULTS

Clinicopathological data

The clinicopathological characteristics of the patients are depicted in Table 1. PHL commonly presents at 51 years of age (range: 28-78 years), with a male to female ratio of 0.8:1. The most common presenting symptom is abdominal pain or discomfort, which occurs in 55.6% of patients. Clinical examination revealed the presence of palpable abdominal masses in 22.2% of cases. All patients were misdiagnosed before pathological diagnosis. The mean delay time between initial symptoms and final pathological diagnosis was 26.8 d (range: 14-47 d). Diffuse large B-cell lymphomas were the most common type of PHL (66.7% of cases). The next most common type was mucosa-associated B-cell lymphoma, found in 22.2% of cases, followed by peripheral T-cell lymphoma (11.1%).

PHL: Primary hepatic lymphoma.

Laboratory findings

Liver function tests, including transaminases, alkaline phosphatase, lactate dehydrogenase and bilirubin were abnormal in 33.3% of patients. As the bone marrow was not involved, blood counts were within the normal range in most patients, except for three with marked splenomegaly related to liver dysfunction. Tests for human immunodeficiency virus, hepatitis B virus (HBV), and hepatitis C virus (HCV) were also carried out. In all patients, α-fetoprotein (AFP) and carcinoembryonic antigen were not significantly elevated. Hypercalcemia and coagulation abnormalities were not found in any of our patients. HBV infection was noted in 33.3% of these patients and hepatitis C in 11.1%.

Imaging studies

The most common presentation was a solitary lesion, which occurred in about 77.8% of cases, followed by multiple lesions in about 22.2% of patients. Ultrasound was performed in all the patients and usually demonstrated hypoechoic lesions to the surrounding normal liver parenchyma in 88.9% of cases.

On computed tomography, PHL lesions usually appear as hypoattenuating lesions, which might have a central area of low intensity that indicates necrosis (Figure 1A). Following the administration of intravenous contrast agent, PHL lesions might show slight enhancement (Figure 1B). Most magnetic resonance imaging (MRI) findings in PHL were described as hypointense on T1-weighted images, and hyperintense on T2-weighted images in our patients.

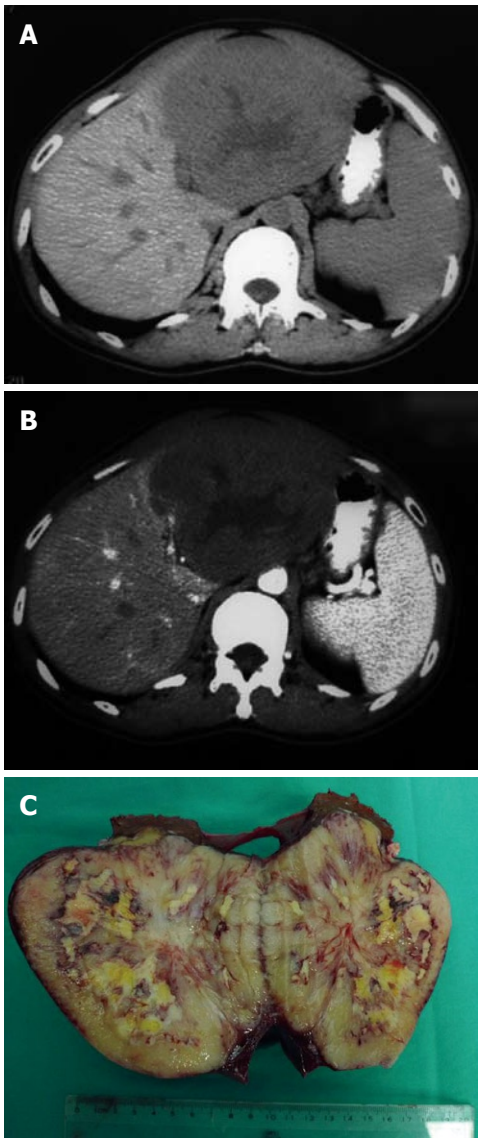

Figure 1 The preoperative imaging and surgical specimen in primary hepatic lymphoma. A: By computed tomography, primary hepatic lymphoma (PHL) appeared as a solitary hypoattenuating lesion with a central area of low intensity; B: PHL lesion was slightly enhanced following the administration of intravenous contrast agent; C: Pathological features revealed that the PHL lesion was an encapsulated, hypovascular tumor with central necrosis.

Operative details and perioperative outcome

Liver resection was performed in all cases. In eight patients, the resection was classified as curative, whereas one patient had palliative resection with a portal lymph-node-positive biopsy. The distribution of surgical procedures was left hepatectomy in five patients (55.6%), right hepatectomy in three (33.3%), and combined procedure in one (11.1%). In the postoperative course, one patient died on the eighth day after surgery, secondary to hepatic insufficiency. Postoperative chemotherapy was administered to five patients.

Survival and prognostic factors

The cumulative 6-mo, 1-year and 2-year survival rate was 77.8%, 66.7%, and 55.6%, respectively, with a median survival of 23 mo. One patient was also alive and tumor-free for > 5 years after resection. Among the factors considered, postoperative chemotherapy ($P = 0.006$) was the only significant prognostic factor for survival (Figure 2).

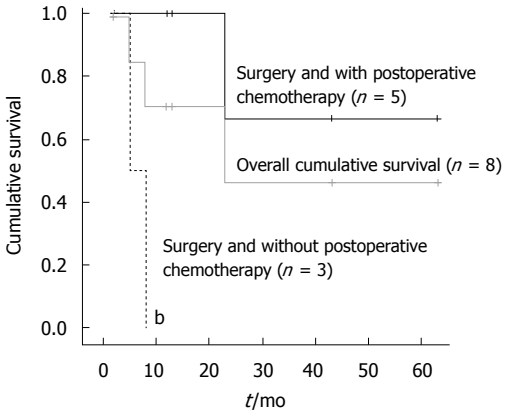

Figure 2 Survival among patients undergoing hepatic resection for primary hepatic lymphoma, with or without postoperative chemotherapy, and the overall cumulative survival of all patients (except for one who died perioperatively). $^{b}P < 0.01$ *vs* hepatic resection for primary hepatic lymphoma with postoperative chemotherapy (log rank test).

DISCUSSION

We suggest that our patients had PHL because we found only liver tumor and no lymphadenopathy or bone marrow lesions. Although the liver contains lymphoid tissue, host factors can make the liver a poor environment for the development of malignant lymphoma[4]. Therefore, PHL is rare. In our study, PHL in men was less frequent than in women, which did not accord with the previously reported trend towards male predominance[1-5].

The etiology of PHL is unknown, although several possible factors such as hepatitis, cirrhosis, and immunosuppressive drugs have been proposed[3]. There appeared to be a strong association between PHL and HBV in our patients. Hepatitis B was found in 33.3% of patients. In contrast, the prevalence of hepatitis C was very low, with only one patient having the infection. However, some authors have revealed a variety of possible associations between PHL and chronic HCV infection[6-8].

Conflicting theories exist on the association of HBV infection and PHL[3,9-11]. Aozasa *et al*[9] have reported a 20% prevalence of hepatitis B surface antigen positivity in a series of 69 patients with PHL, in which 52 patients were from western countries and 17 from Japan. Chronic antigenic stimulation by HBV has been postulated to play a role in the development of PHL[10]. Based on all these data, it is likely that some association between PHL and HBV does in fact exist. However, the high prevalence of HBV infection in the present study perhaps corresponded to the high HBV seropositivity in China of 10% in the general population[12].

Although it remains uncertain to what extent HBV contributes to the development of PHL, a host environment with impaired immunity might play an important role[6,7,13]. Therefore, we hypothesize that chronic HBV infection, as with our three patients, could have impaired

host immunity, which subsequently led to accelerated development of PHL. If this hypothesis is confirmed, suppression from HBV infection or from complications related to chronic viral infections could be crucial steps in preventing carcinogenesis of PHL.

Due to the rarity of this disease entity, the non-specific clinical presentation, and laboratory and radiological features, PHL can be confused with focal nodular hyperplasia, primary hepatic tumors, carcinoma with hepatic metastases, and systemic lymphoma with secondary hepatic involvement[10]. In the present study, all patients were mistaken as having AFP-negative hepatic cancer before pathological diagnosis. We retrospectively performed imaging studies to discriminate between these possibilities. As in our patients, most PHL is usually hypoechoic by sonography and shows hypointensity on T1-weighted and hyperintensity on T2-weighted MRI.

The optimal therapy for PHL is still unclear and the outcomes are uncertain[5]. Most patients with PHL present with poor prognostic features. One large review of 72 patients has shown the median survival to be 15.3 mo (range: 0-123.6 mo)[14]. In our study, the median overall survival for all nine patients was 23 mo. These results are better than those previously reported and could have been due to strict patient selection and the use of postoperative chemotherapy in most patients.

Our univariate analysis revealed that postoperative chemotherapy was the only significant prognostic factor that influenced survival. In a previous study, one patient treated with surgery followed by chemotherapy and radiation was reported to be alive at 5 years following initial diagnosis[2]. Page *et al*[15] have stratified several pretreatment risk factors after a retrospective cohort review. Lei has proposed that, in patients with localized disease, surgery followed by adjuvant chemotherapy should be considered to prevent disease recurrence[3]. Therefore, we advise that good prognosis of PHL can be obtained by early surgery combined with chemotherapy in strictly selected patients.

The primary limitation of this study was the small sample size and its retrospective nature, even though this study population represents a relatively large sample in surgical management of PHL in one single center. A larger prospective series could enable us to draw more substantive conclusions with regard to the roles of postoperative chemotherapy and HBV infection in the surgical setting of PHL.

COMMENTS

Background

Primary hepatic lymphoma (PHL) is a rare malignancy. The rarity of the disease causes problems in diagnosis and management. The optimal therapy is still unclear and the outcomes are uncertain.

Peer review

The authors reported their experience of surgical management of PHL. Satisfactory survival can be achieved by early surgery combined with postoperative chemotherapy in strictly selected patients.

Abstract

AIM: To evaluate whether alcohol dehydrogenase-1B (ADH1B) His47Arg and aldehyde dehydrogenase-2 (ALDH2) Glu487Lys polymorphism is involved in the esophageal squamous cell carcinoma (ESCC) risk in Chinese Han population.

METHODS: Seven studies of ADH1B and ALDH2 genotypes in Chinese Han population in 1450 cases and 2459 controls were included for meta-analysis. Stratified analyses were carried out to determine the gene-alcohol and gene-gene interaction with ESCC risk. Potential sources of heterogeneity between studies were explored, and publication bias was also evaluated.

RESULTS: Individuals with ADH1B arginine (Arg)/Arg genotype showed 3.95-fold increased ESCC risk in the recessive genetic model [Arg/Arg *vs* Arg/histidine (His) + His/His: odds ratio (OR) = 3.95, 95% confidence interval (CI): 2.76-5.67]. Significant association was found in the dominant model for ALDH2 lysine (Lys) allele [glutamate (Glu)/Lys + Lys/Lys *vs* Glu/Glu: OR = 2.00, 95% CI: 1.54-2.61]. Compared with the non-alcoholics, Arg/Arg (OR = 25.20, 95% CI: 10.87-53.44) and Glu/Lys + Lys/Lys (OR = 21.47, 95% CI: 6.44-71.59) were found to interact with alcohol drinking to increase the ESCC risk. ADH1B Arg+ and ALDH2 Lys+ had a higher risk for ESCC (OR = 7.09, 95% CI: 2.16-23.33).

CONCLUSION: The genetic variations of ADH1B His47Arg and ALDH2 Glu487Lys are susceptible loci for ESCC in Chinese Han population and interact substantially with alcohol consumption. The individuals carrying both risky genotypes have a higher baseline risk of ESCC.

INTRODUCTION

Esophageal carcinoma (EC) ranked as the eighth most common malignancy and the seventh leading cause of cancer death worldwide characterized by remarkable diversity according to geographical distribution. It is known that Asian countries, in particular China, Iran and Japan, have the highest incidence rates of EC in the world, and the esophageal squamous cell carcinoma (ESCC) is a predominant histological type. For example, in China, the age-standardized incidence rates of ESCC in males and females were 72-150/100000 and 26-64/100000, re-

spectively, from 1995 to 2004 in a southern population[1]. ESCC is a complex disease influenced by environmental as well as genetic factors[2]. Behavioral factors include alcohol drinking which is common to all "high-risk populations"[3]. Odds ratio for ESCC was 50.1 for those who were both heavy drinkers and smokers in comparison with those who neither drank nor smoked[4]. Alcohol is not a carcinogen, and acetaldehyde is the most toxic alcohol metabolite in alcohol-associated carcinogenesis[2].

Efficiency in the conversion of ethanol to acetaldehyde and subsequent oxidation to acetate depends mainly on the alcohol dehydrogenase-1B (ADH1B) and the aldehyde dehydrogenase-2 (ALDH2) activities. Upon consumption of an alcoholic beverage, ethanol is first catalytically oxidized into acetaldehyde, occurring mainly through ADH1B. It is subsequently metabolized into harmless acetate, chiefly by ALDH2. Thus, genetic variants that result in functional differences in enzyme activity, lead to differences in acetaldehyde exposure among drinkers. A polymorphism in the *ADH1B* gene, resulting in an amino acid transition from arginine (Arg) to histidine (His) at codon 47 (Arg47His) in exon 3, bestows the super-active "fast" metabolic character on ethanol. About a 40-times greater maximum velocity has been identified for the ADH1B fast His allele than that for the less active Arg/Arg form[5,6]. In contrast, ALDH2 has a polymorphism, which results from the substitution of glutamate (Glu) to lysine (Lys) at residue 487 (also recognized as Glu504Lys) encodes a catalytically inactive subunit of ALDH2, whose ALDH2 Glu/Lys genotype has only 6.25% of the normal ALDH2 Glu protein[7].

In China, the ADH1B 47His allele frequency decreases dramatically from 90% to 10% from East China to West China, and its geographic distribution is consistent with the unearthed culture relic sites of rice domestication in China[8,9]. The ALDH2 487Lys allele is essentially absent in all parts of the world except East Asia and has the highest frequency in China, and is high in south coast and east coast of China, and decreased gradually toward inland China, west, northwest and north China. The origin of ALDH2 487Lys could be traced back to ancient Pai-Yuei tribe in south China[10]. Combined with the demographic history, the ADH1B 47His and ALDH2 487Lys are carried by Han Chinese as they spread throughout East Asia[11]. One effect of the ALDH2 487Lys mutation is the "Asian flush" - the red face, nausea, and rapid heartbeat that many people with East Asian ancestry experience when they drink alcohol. The alcohol flushing response (Asian Glow) is a biomarker for ALDH2 487Lys allele[12].

Various studies have focused on ADH1B and ALDH2 polymorphisms and the risk of ESCC in Chinese Han population[13-19]. These studies also suggested a gene-gene and gene-alcohol interaction for ESCC risk[18]. For example, the risk for ADH1B Arg/Arg carriers was significantly increased from 1.2 to 74 times in non-drinkers and drinkers, respectively, compared with non-drinkers who carried the ADH1B His/His genotype[15]. A meta-analysis of seven Asian (Chinese, Japanese, and Thailand) studies found that 487Lys allele was risky for ESCC susceptibility[20]. However, there was only one Chinese population for the meta-analysis. Meta-analysis can provide an opportunity to help identify genetic associations by overcoming the coalescent issues[21]. We performed a meta-analysis among all eligible studies to clarify the effect of ADH1B Arg47His and ALDH2 Glu487Lys polymorphism alone and interactively on ESCC risk in Chinese Han population.

MATERIALS AND METHODS

Selection criteria and identification of eligible studies

Eligible studies were identified by searching the database of PubMed for relevant articles in English. The latest searches were undertaken in January 2010. The following search terms: "esophageal cancer" or "esophageal cancer" and "ADH2" or "aldehyde dehydrogenase" or "ADH1B" or "ALDH2" "aldehyde dehydrogenase 2" "polymorphism" were used in isolation and combination with one another. Searches were limited to the studies involving human subjects and Chinese population. All population-based case-control studies focusing on the associations between the ADH1B Arg47His, ALDH2 Glu487Lys variants and ESCC risk were eligible for inclusion. Review articles, case reports, esophageal adenocarcinoma and repeated literatures were excluded. When overlapping articles were found, we only included the publication that reported the most extensive information.

The full-text of the candidate articles were examined carefully to determine whether they accorded with the inclusion criteria for the meta-analysis. A total of seven published studies with full-text articles examined the association of polymorphisms ADH1B Arg48His and ALDH2 Glu487Lys, and 3 of the seven were about the interaction between *ADH1B* and *ALDH2* gene.

Data extraction

Data were extracted independently by Zhang GH and Mai RQ. We extracted the following information from each manuscript: author, year of publication, region, selection and characteristics of cancer cases and controls, and genotyping information.

Meta-analysis

The risk of ESCC associated with the ADH1B Arg47His and ALDH2 Glu487Lys variants were estimated for each study by odds ratio (OR) with 95% confidence intervals (CI) using comprehensive meta-analysis software version 2.0. For all studies, we evaluated the risk of the variant genotypes Arg/Arg or Arg/His, Lys/Lys or Glu/Lys and compared with the His/His and Glu/Glu genotypes. We then calculated the OR of the polymorphisms with dominant and recessive model. Between-study heterogeneity was estimated using the Cochran's Q and χ^2. Heterogeneity was considered statistically significant when $P < 0.05$. Point estimates and 95% CI were computed with both random effect and fixed effect models. If heterogeneity existed, point estimates and 95% CI were estimated on the basis of random effect model, Otherwise the fixed effect model was used. For the analysis of gene-gene interaction between ADH1B Arg47His and ALDH2 Glu487Lys, the His/His

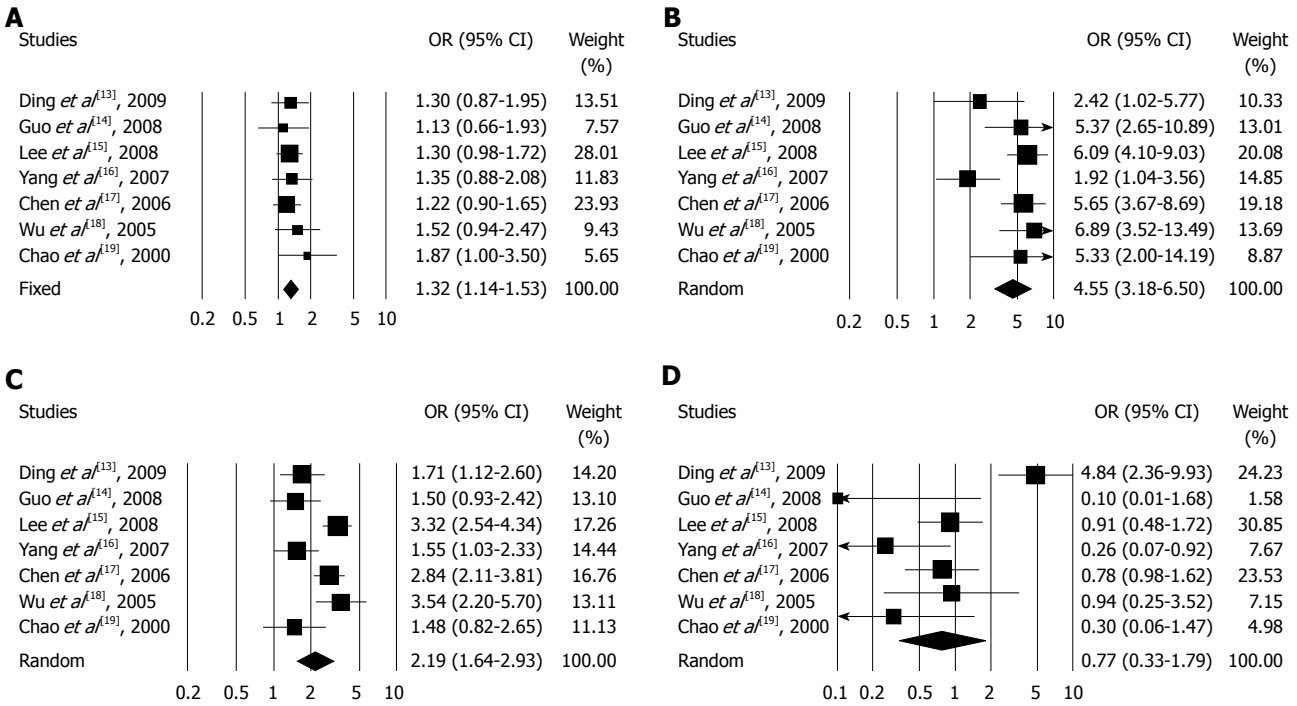

Figure 1 Forest plot shows the odds ratios and confidence intervals of the association. A: Between arginine (Arg)/histidine (His) and His/His genotype of alcohol dehydrogenase-1B (ADH1B) His47Arg polymorphism; B: Between Arg/Arg and His/His genotype of ADH1B gene His47Arg polymorphism; C: Between glutamate (Glu)/lysine (Lys) and Gly/Glu genotype of aldehyde dehydrogenase-2 (ALDH2) Glu487Lys polymorphism; D: Between Lys/Lys and Glu/Glu genotype of ALDH2 Glu487Lys polymorphism. OR: Odds ratio; CI: Confidence interval.

and Glu/Glu was considered as the reference genotype. For the gene-environment interaction, non-drinkers carrying the His/His genotype were set as compared subjects. Publication bias was assessed using funnel plots and Egger's test. $P < 0.05$ was considered statistically significant. χ^2 test was performed to examine the Hardy-Weinberg equilibrium (HWE) when genotype data were available.

RESULTS

Eligible studies and meta-analysis databases

Table 1 presents the characteristics of all the studies that were included in the meta-analyses. Seven studies published until July 2010 were about ADH1B Arg47His, ALDH2 Glu/Lys polymorphism and risk of ESCC, with a total number of 1450 cases and 2459 controls (Table 1). The genotype distribution in the control groups in each study did not depart from the HWE with $P > 0.05$.

Meta-analysis results

ADH1B Arg47His polymorphism: When the Arg/His and homozygote Arg/Arg were compared with the homozygous His/His genotype, the pooled ORs for all the 7 studies were 1.32 (95% CI: 1.14-1.53, $P < 0.001$, $P_{hetero} = 0.905$) in the fixed model and 4.55 (95% CI: 3.18-6.50, $P < 0.001$, $P_{hetero} = 0.029$) in the random model, respectively (Figure 1A and B). Similarly, increased associations were found in the dominant model, Arg/Arg + Arg/His *vs* His/His genotype, pooled OR was 1.62 (95% CI: 1.41-1.85, $P < 0.001$, $P_{hetero} = 0.206$). Arg/Arg *vs* Arg/His + His/His genotype, pooled OR was 3.95 (95% CI: 2.76-5.67, $P < 0.001$, $P_{hetero} = 0.014$) in the recessive model.

HWE: Hardy-Weinberg equilibrium.

ALDH2 Glu487lys polymorphism: The variant heterozygous genotype Glu/Lys carriers have a significant increased risk of ESCC compared with those carrying Glu/Glu genotype (OR = 2.19, 95% CI: 1.64-2.93, $P < 0.001$, $P_{hetero} < 0.001$). But the homozygous genotype Lys/Lys did not show a significantly increased risk of ESCC (OR = 0.77, 95% CI: 0.33-1.79, $P = 0.537$, $P_{hetero} < 0.001$) (Figure 1C and D). Similarly, no associations were found in the recessive model (Lys/Lys *vs* Glu/Lys + Glu/Glu: OR = 0.48, 95% CI 0.19-1.20, $P = 0.118$, $P_{hetero} < 0.001$). Combining the homozygous Lys/Lys and heterozygous Glu/Lys genotypes, the pooled OR for the dominant model was 2.00 (Lys/Lys + Glu/Lys *vs* Glu/Glu: 95% CI: 1.54-2.61, $P < 0.001$, $P_{hetero} = 0.001$).

Gene-environmental interactions: The joint associations of the ADH1B, ALDH2 polymorphism and alcohol drinking with the risk of ESCC were observed when the analysis was stratified by alcohol drinking status. Among

non-drinkers, there was no evidence for an increased risk for ADH1B Arg/His *vs* His/His genotype of individuals (OR = 1.06, 95% CI: 0.75-1.50). However, compared with non-drinkers carrying ADH1B His/His genotype, drinkers carrying Arg/Arg and Arg/His genotype (OR = 6.97, 95% CI: 1.70-28.56) showed a significantly higher risk of ESCC, and the risk of homozygote Arg/Arg was highest (OR = 20.69, 95% CI: 5.09-84.13) among the subgroups of the three studies[13,15,17]. In the recessive model, when the drinking factor was integrated, statistically significantly elevated risks were found (Arg/Arg *vs* Arg/His + His/His: OR = 25.20, 95% CI: 10.87-53.44) (Table 2).

Odds ratios for the ALDH2 genotypes and the risk of ESCC were stratified by the alcohol consumption. Risk of ESCC was particularly high for drinkers with ALDH2 Glu/Lys genotype compared with non-drinkers having ALDH2 Glu/Glu genotype (OR = 23.83, 95% CI 3.75-151.05, $P < 0.001$) in the subgroups of five studies[13-15,17,18]. Furthermore, the homozygous Lys/Lys was found to interact with alcohol drinking to increase the ESCC risk (OR = 16.33, 95% CI: 5.21-51.17). In the dominant model, the OR risk was increased from 2.00 of null model to 21.47 of the interaction model.

Gene-gene interactions: Table 3 shows the interaction of ADH1B and ALDH2 genotypes on ESCC risk. Compared with subjects having ADH1B His/His with ALDH2 Glu/Glu, OR for those with ALDH2 Glu/Glu and ADH1B Arg+, ALDH2 Lys+ and ADH1B His/His, and ALDH2 Lys+ and ADH1B Arg+ was 3.66-13.46. The significantly increased risk for ESCC (OR = 7.09, 95% CI: 2.16-23.33, $P < 0.001$) was noted in individuals with ADH1B Arg+ and ALDH2 Lys+. Individuals carrying two risky alleles had an additional risk compared to those with only one risky allele.

Publication bias

Funnel plot and Egger's test were performed to assess the publication bias. No influence of publication bias was found in our study using Egger's test $P = 0.202$ for the ADH1B, Egger's test $P = 0.085$ for the ALDH2, as indicated by the funnel plot (Figure 2).

DISCUSSION

Several studies have demonstrated that the ADH1B and ALDH2 genotypes would be expected to result in exposure to high acetaldehyde concentrations[22]. A recent genome-wide association study showed that ADH1B Arg47His and ALDH2 Glu487Lys are associated with ESCC in a Japanese population[23]. The proportion of individuals carrying "susceptible genotypes of alcohol-related diseases" in Chinese Han healthy population was 68.16%[24]. In this meta-analysis, the pooled OR of ADH1B Arg47His polymorphism was 1.32 (95% CI: 1.14-1.53, $P < 0.001$, $P_{hetero} = 0.905$) and 4.55 (95% CI: 3.18-6.50, $P < 0.001$, $P_{hetero} = 0.029$) for Arg/His and homozygote Arg/Arg genotype in Chinese Han population, respectively. We also observed that ALDH2 Glu/Lys had independent and statistically significant effects on ESCC. Although there was no statistically significant increase of ESCC risk in the recessive model (OR = 0.48, 95% CI: 0.19-1.20, $P = 0.118$, $P_{hetero} < 0.001$) and Lys/Lys genotype (OR = 0.77, 95% CI: 0.33-1.79, $P = 0.537$, $P_{hetero} < 0.001$), the highest pooled OR was found in the Glu/Lys genotype (OR = 2.19, 95% CI: 1.64-2.93, $P < 0.001$, $P_{hetero} < 0.001$). Our meta-analysis confirmed a positive association between the polymorphisms of ADH1B, ALDH2 and susceptibility to ESCC. The study by Zhou *et al*[25] found that Glu/Lys genotype was a risk factor for esophageal squamous cell dysplasia. Combining with our results, ALDH2 may be a candidate biomarker to screen early ESCC.

ADH1B and ALDH2 polymorphism was considered as risk-conferring factor for alcohol dependence[26], and many studies have indicated that the synergistic interaction between ADH1B and ALDH2 polymorphism and alcohol drinking are involved in the risk of ESCC[14,17,18]. Taking alcohol consumption and genetic vulnerability into con-

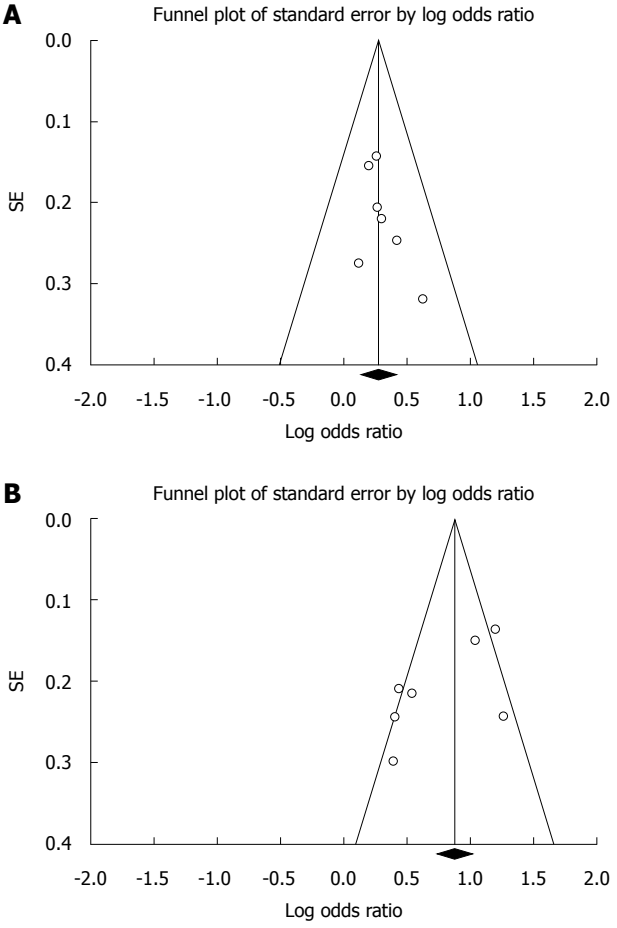

Figure 2 Funnel plot of alcohol dehydrogenase-1B His47Arg (A) and aldehyde dehydrogenase-2 Glu487Lys (B) polymorphisms and esophageal squamous cell carcinoma risk for publication bias.

sideration, this meta-analysis further identified an alcohol-genotype-dependent increase in ESCC risk for alcohol consumers. In this meta-analysis, the risk of individuals with ADH1B Arg/His genotype and alcohol drinking increased ESCC risk by 6.97 times (95% CI: 1.70-28.56). However, among non-drinkers, there is no strong evidence of an increased risk (OR = 1.06, 95% CI: 0.75-1.50). The magnitude of effect of ALDH2 Lys/Lys genotype was significant in alcohol drinkers (OR = 16.33, 95% CI: 5.21-51.17). Alcohol drinkers carrying ALDH2 Glu/Lys (OR = 23.83, 95% CI: 3.75-151.05) or ADH1B Arg/Arg (OR = 20.69, 95% CI: 5.09-84.13) had a higher risk of ESCC. These results might suggest that both the ADH1B Arg and ALDH2 Lys allele indicate a longer exposure to alcohol and highly-concentrated acetaldehyde, thus greatly increasing the susceptibility to ESCC. Alcohol has been intensified by the genetic modulation of ADH1B and ALDH2, which should make it more powerful. Furthermore, alcohol drinking with a combined genotype of ADH1B Arg/Arg and ALDH2 Glu/Lys was associated with increased DNA damage[27]. Avoidance of alcohol may be an important way to prevent ESCC among ADH1B Arg and ALDH2 Lys allele carriers.

There are many studies to explore the interaction between the ADH1B Arg/His and ALDH2 Glu487Lys polymorphism[14,15,18]. In this meta-analysis, we further found there was a highly significant gene-gene interactive effect between the two polymorphisms and ESCC risk. The risk effect of the interaction between ADH1B and ALDH2 was strongest in Arg+ and Lys+ carriers (OR: 7.09, 95% CI: 2.16-23.33), followed by Glu/Glu and Arg+ (OR = 3.66, 95% CI: 1.66-6.74) and Lys+ and His/His (OR = 2.72, 95% CI: 1.34-5.51) carriers. The results indicate that combined roles of the two genes and alcohol consumption should be considered to define the individual with ESCC risk.

We observed that the Arg/Arg and Glu/Lys genotypes were associated with increased risk for ESCC, but pooled OR was higher in carriers of the Arg/Arg (4.55) than in Glu/Lys carriers (2.00). Furthermore, the interactive risk of Glu/Glu and Arg+ (OR, 3.66) was higher than Lys+ and His/His (OR, 2.72). These results might suggest that the ADH1B has a predominant role in determining the risk of ESCC when the general population is considered.

Limitations

Although our primary result of this meta-analysis is suggestive, some limitations still exist. Firstly, we still lack more genotype data from the multiple highest incidence area, such as the Taihang Mountain in central China, Xinjiang and Chaoshan populations. Secondly, the number of studies included in this article was insufficient and the sample size of individual studies was also small. It is undoubted that larger studies should be done for confirming these findings, because our results are based on a limited sample size. Lastly, OR value was obtained without correction. More accurate OR should be corrected by age, gender and other environmental factors. A more precise analysis should be conducted if more detailed individual data are available, which would allow for an adjusted estimate. Adjusted covariates might help explain the association between ADH1B Arg47His and ALDH2 Glu/Lys polymorphism and susceptibility to ESCC.

In conclusion, this meta-analysis of seven case-control studies provided evidence that ADH1B Arg/His and ALDH2 Glu/Lys polymorphism was significantly associated with increased risk of ESCC. Gene-gene and gene-environment interactions are warranted to confirm the real contribution of these polymorphisms to ESCC susceptibility. Further studies in different high incidence areas of ESCC in China are also necessary to clarify the correlation between ADH1B Arg47His and ALDH2 Glu487Lys polymorphisms and ESCC risk.

COMMENTS

Background

Esophageal squamous cell carcinoma (ESCC) is the fourth most frequent cause of cancer-related deaths in China. Alcohol intake is positively associated with the risk of ESCC. The activity of alcohol dehydrogenase 1B (ADH1B) and acetaldehyde dehydrogenase 2 (ALDH2) is primarily responsible for the oxidative detoxification, and polymorphism His47Arg in ADH1B and Glu487Lys in ALDH2 modulate the conversion rate of acetaldehyde. These polymorphisms are most prevalent in East Asia and they have highest frequencies in Chinese Han population.

Research frontiers

Many case-control studies have been performed to evaluate the ADH1B and ALDH2 polymorphisms for esophageal cancer risk in Chinese Han population,

including the role of gene-gene and gene-environment interaction in esophageal cancer risk. However, the evidence is insufficient with the small sample size.

Innovations and breakthroughs

This is the first meta-analysis which systemically studied the association between ADH1B and ALDH2 polymorphisms and esophageal cancer susceptibility in Chinese Han population, and suggested that ADH1B His47Arg and ALDH2 Glu487Lys are susceptible loci for ESCC and interact substantially with alcohol consumption. The individuals carrying the both genotypes have a higher baseline risk of ESCC.

Applications

This study provided a potential biomarker to identify high-risk individuals for esophageal cancer in Chinese Han population, specially among the alcohol drinkers.

Terminology

ADH1B: A member of the alcohol dehydrogenase family and the major enzyme that catalyzes alcohol to acetaldehyde in liver. ALDH2: A member of aldehyde dehydrogenases, and is the second enzyme of the major oxidative pathway of alcohol metabolism.

Peer review

The data and their interpretations are reasonable. This paper has a certain value in this research field because previous studies had a low statistical power because of the small sample size.

Abstract

AIM: To investigate the prognostic value of chromosome 18q microsatellite alterations (MA) in stage Ⅱ colon cancer.

METHODS: One hundred and six patients with sporadic stage Ⅱ colon cancer were enrolled in this study. DNA was extracted from formalin-fixed, paraffin-embedded tumor and adjacent normal mucosal tissue samples. MA, including loss of heterozygosity (LOH) and microsatellite instability (MSI), was analyzed by polymerase chain reaction, polyacrylamide gel-electrophoresis and DNA sequencing at 5 microsatellite loci on chromosome 18q (D18S474, D18S55, D18S58, D18S61 and D18S64).

RESULTS: Among the 102 patients eligible for MA information, the overall frequencies of LOH, high and low frequency MSI/microsatellite stable were 49.0%, 17.6% and 82.4%, respectively. The high frequency of 18q-LOH was significantly associated with the poor 5-year overall survival (OS) (P = 0.008) and disease free survival (P = 0.006). High levels of MSI were significantly associated with a longer 5-year OS (P = 0.045) while the higher frequency of 18q-LOH at the loci of D18S474 and D18S61 was significantly associated with a poorer 5-year OS (P = 0.010 and 0.005, respectively). But multivariate analysis showed that only the frequency of 18q-LOH was significantly associated with the prognosis of the disease.

CONCLUSION: High frequency of 18q-LOH is an independent prognostic factor indicating poor prognosis of the patients with stage Ⅱ colon cancer.

Key words: Chromosome 18q; Loss of heterozygosity; Microsatellite instability; Stage Ⅱ colon cancer; Prognosis

INTRODUCTION

Colorectal cancer (CRC) is the third most common ma-

lignant cancer worldwide, with an estimate of one million new cases and a half million deaths annually[1]. Although the clinicopathological stage is currently the gold standard for prognosis, the molecular biological factors that determine the outcome of patients exhibiting the same clinicopathological stage are poorly understood, especially for stage Ⅱ and Ⅲ patients.

In recent years, multiple tumor-related biomarkers have been proposed as prognostic factors for CRC, but their predictive value has not been consistently demonstrated. Rapid advances in the molecular genetics of CRC have stimulated attempts to evaluate the prognostic significance of specific genetic alterations in this tumor type. The American Society of Clinical Oncology (ASCO) has published evidence-based clinical practice guidelines for the use of tumor markers in CRC bi-annually from 1996 to 2006[2]. Similarly, the European Group on Tumor Markers revised its recommendations for the use of tumor marker tests in the prevention, screening, treatment and surveillance of CRC in 2007[3]. These recommendations described new tumor markers, such as microsatellite instability (MSI), loss of heterozygosity (LOH) at chromosome 18q, as well as the traditional markers such as carcinoembryonic antigen (CEA), CA19-9, p53, Ras, and DNA ploidy.

It has been shown that CRC arises through at least two distinct pathways of genetic instability pathways of microsatellite alteration (MA): one involving chromosomal instability presenting as LOH, and the other involving MSI[4-6]. Although most studies have proven the prognostic value of LOH at chromosome 18q (18qLOH) in CRC, the outcomes are controversial. To further define the clinical effect of molecular genetic alterations on clinicopathological features and prognosis, we analyzed LOH and MSI at chromosome 18q in 106 patients retrospectively with stage Ⅱ colon cancer.

MATERIALS AND METHODS

This study consisted of randomly selected 106 consecutive patients who had undergone curative colon resection for sporadic stage Ⅱ colon cancer between 1996 and 2001. All cases were deemed sporadic, based on the absence of relevant family history in the initial patient interview records. None of the patients had additional synchronous colon cancers or other evidence of a heritable form of CRC.

A curative operation was defined as one in which no macroscopic tumor remained after surgery and histopathological examination showed radical resection margins were free of tumor at lines of the operative specimen. The methods used to exclude distant metastases at the time of resection included preoperative liver ultrasonography, abdominal and pelvic CT scan, chest X-ray, and intraoperative exploration. The right colon was defined as the large bowel proximal to the right half of the transverse colon; the left colon was defined as the large bowel between the right colon and the rectosigmoid junction. All specimens were histopathologically reviewed by a single gastrointestinal pathologist who was unaware of the results of molecular genetic testing. In accordance with the classification of tumors by the World Health Organization[7], we defined tumors as mucinous if 50% or more of the tumors displayed mucinous differentiation and as undifferentiated if features of tumor cell differentiation were absent. Other tumors were classified as adenocarcinomas.

Twelve lymph nodes on average were examined per case. Tumors were staged according to the TNM classification system and based on pathological findings after operation. Adjuvant chemotherapy was administered to patients with (1) clinicopathological factors with emergent presentation and associated with high risk of recurrence (i.e. bowel perforation or occlusion); (2) poorly differentiated tumors (histological grade); (3) deep tumor invasion and adjacent organ involvement (T4); (4) venous invasion; and (5) peritoneal involvement. The drug regimen for chemotherapy was 5-fluorouracil-based adjuvant chemotherapy for nearly 6 mo.

Patients were observed after the completion of therapy every 3 mo for 2 years, every 6 mo for the next 3 years, and then annually, or until relapse. History and physical examination, complete blood cell and platelet count, blood biochemistries, ultrasound, CEA and CA19-9 measurements were performed at each visit. The chest X-ray, colonoscopy, and CT scan were performed at least once a year.

The overall survival (OS) time was calculated from the date of surgery to the time of the last visit or death. The disease-free survival time was calculated from the date of resection to the time of relapse.

DNA extraction, LOH and MSI analysis

DNA extraction: Three to four 8 μm-thick sections were obtained from archival blocks of formalin-fixed, paraffin-embedded tumor and adjacent normal mucosal tissues. One 8 μm-thick section of each tumor sample was stained with HE, and the percentage of tumor cells was estimated by visual examination by a pathologist. Representative tumor samples contained a minimum of 80% of tumor cells. Microdissection of regions representing tumor and matching normal tissues was performed. Samples were selected and collected into Eppendorf tubes. The tissue samples were de-paraffinized with xylene, and the DNA was extracted by incubating the samples overnight at 56℃ in lysis buffer [10 mmol/L Tris-Cl (pH 8.0), 2.5 mmol/L $MgCl_2$, 50 mmol/L KCl, 0.5% Tween 20] containing 0.2 mg/mL proteinase K (Invitrogen Inc., Carlsbad, CA). Digested products were boiled for 8 min at 95℃ to inactivate enzymes, centrifuged, and cooled on ice. The supernatant was used directly for polymerase chain reaction (PCR).

PCR: A panel of five polymorphic microsatellite markers located in chromosomal regions potentially involved in colon carcinoma development and progression were interrogated. These regions were D18S474 (18q21.1),

D18S55 (18q23), D18S58 (18q23), D18S61 (18q22.2), and D18S64 (18q21.3). The primer sets were obtained from published sequences and purchased from Invitrogen Inc. (Carlsbad, CA). The target sequences in normal and tumor DNA were amplified by PCR in a 50 μL reaction mixture containing 5 μL of DNA sample, 10 × buffer (10 mmol/L Tris-HCl pH 9.0, 50 mmol/L KCl, 0.1% Triton X-100), 3 mmol/L $MgCl_2$, 5 U *Taq* Polymerase, 10 mmol/L of each dNTP, and 10 mmol/L of each primer. Each forward primer was coupled with the fluorescent dye TET (4,7,2',7'-tetrachloro-6-carboxyfluorescein; Invitrogen Inc., Carlsbad, CA). The reactions were submitted to 35 cycles of amplification in a PTC-100™ thermal cycler (Bio-Rad Inc., America) at the following annealing temperatures: 55℃ for D18S474, 57℃ for D18S55, 61℃ for D18S58, 55℃ for D18S61, and 59℃ for D18S64. The presence and correct size of all amplicons were determined using 2% agarose gel electrophoresis (Biowest Inc., CA).

Fragment analysis: Amplicons were separated in a 6% polyacrylamide denaturing gel (Bio-Rad Inc., CA) using the ABI 377 DNA Sequencer (ABI Inc., CA). A total of 0.5 μL PCR product was mixed with 0.5 μL blue dextran loading solution (Bio-Rad Inc., CA). After 5 min of denaturation at 95℃, the sample was loaded onto the gel and subsequently run for two h at 2750 V, 125 W, and 50℃. After electrophoresis, the fluorescent signals were automatically collected by a gene scanner. Analysis of these signals with the Genotyper (Version 2.0) image analysis software (ABI Inc., CA) generated electropherograms, which displayed alleles as peaks. The height and area of the peaks calculated by the software were proportional to the concentration of the alleles in the sample.

LOH: The presence of two distinctly sized alleles in normal tissues was the necessary condition for evaluation of allelic losses. Cases in which the normal DNA sample was homozygous were classified as non-informative. The ratio of allele peak areas calculated for each tumor sample was divided by the allele peak area ratio of the normal matching control. If this quotient was greater than 1.00, the quotient was converted to give a result ranging from 0.00 to 1.00. Ratios below 0.6, indicating at least a 40% reduction of a tumor allele, were indicative of LOH[8,9].

MSI: The unique appearance of one or more alleles in the tumor DNA but not in its paired normal DNA, such as new peaks in the electropherogram, indicated the MSI[10]. To ensure the reproducibility of the results, DNA analysis of the first 20 samples was repeated and 99% concordance was recorded. Tumors were classified as demonstrating a high frequency of MSI (MSI-H) if instability was detected in more than two loci of the five interpretable microsatellite markers investigated. Tumors were deemed as low frequency MSI (MSI-L) if instability was found in one of the five markers according to the international criteria. Tumors without MSI were considered to be microsatellite stable (MSS)[11]. In our study, MSI-L and MSS tumors were considered as a single group in comparison with MSI-H tumors. However, further studies of the significance of MSI-L[12] are needed, which may represent a biologically and clinically distinct entity[13,14] (Figure 1).

Statistical analysis

Statistical analysis was performed using the SPSS 12.0 package. The main factors compared in this study were frequency of MA and survival. Contingency tables and the χ^2 test were used to evaluate differences between percentages. The association of disease-free and OS with prognostic factors was evaluated by means of multivariate logistic regression.

Disease-free intervals in patients with recurrence were measured as the interval between the date of resection and the date of diagnosis of recurrence. Duration of survival was measured from the date of resection until the date of death from any cause or until the censoring date of June 30, 2008. In the survival analysis, deaths caused by postoperative complications within 30 d were excluded. Survival curves were drawn according to the Kaplan-Meier method, and differences in disease-free and OS were evaluated by means of log-rank test. The simultaneous effects of more than one prognostic factors were estimated by the Cox's proportional hazards regression model. Mortality rate ratios were used to assess the difference in deaths caused by colon cancer. The significance level was set at 0.05; the confidence interval was 95%; and all *P* values reported were two-sided.

RESULTS

We investigated 66 male and 40 female patients. The mean age of this group was 57 years (range, 19-84 years). Of the 106 primary tumors, 47 were located in the right colon and 59 were located in the left colon. A total of 88 (83.0%) patients with the high recurrent clinicopathological factors mentioned above underwent adjuvant chemotherapy (Table 1).

Microsatellite alteration

The number of tumors that could be evaluated for microsatellites (MA) varied in region because the polymorphic markers were non-informative for some patients. 18qLOH was observed in 50 (49%) of the 102 patients. The incidence of 18qLOH was 30.2% (26 of 86), 23.4% (18 of 77), 28.6% (20 of 70), 35.0% (28 of 80), and 20.8% (15 of 72) at D18S474, D18S55, D18S58, D18S61 and D18S64, respectively. Of the 102 tumor specimens evaluated for MSI, 42 (41.2%) cases were identified as MSI in at least one locus. Furthermore, seven cases were MSI at three loci, 11 cases at two loci, and 24 cases at one locus. According to the criteria mentioned above, 18 cases (17.6%) that showed MSI in at least two loci were defined as MSI-H. The remaining 84 cases (82.4%) were defined as MSI-L/MSS (Table 2).

Poorly differentiated ($P = 0.023$) nonmucinous ($P = 0.005$) tumors located in the left colon ($P = 0.023$) more

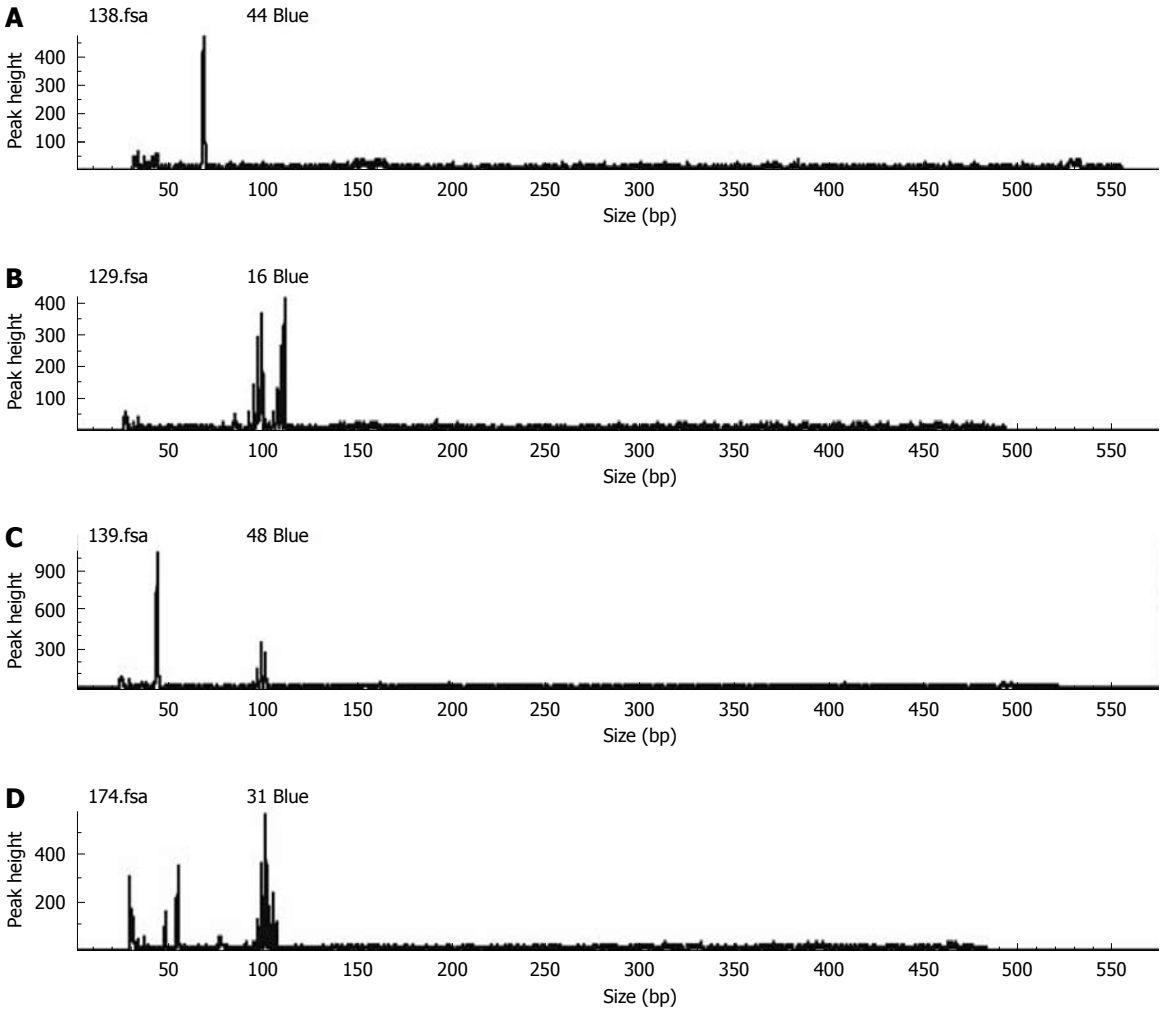

Figure 1 Representative examples showing homozygosity and heterozygosity in normal tissues and loss of heterozygosity and microsatellite instability in tumor tissues. A: Normal sample shows homozygosity; B: Normal sample shows heterozygosity; C: Tumor sample shows loss of heterozygosity; D: Tumor sample shows microsatellite instability.

likely displayed chromosome 18qLOH. No association was found between 18qLOH, age, and gender. MSI-H was more likely to be displayed by well/moderately differentiated ($P = 0.047$) mucinous ($P = 0.004$) tumors located in the right colon ($P < 0.001$). No association was found between MSI-H, age and gender (Table 3).

Survival analysis

Of the molecular markers tested, 18qLOH was significantly associated with a reduced 5-year OS ($P = 0.019$) and a disease-free survival ($P = 0.010$) during the follow-up period. High levels of MSI were moderately associated with an improved 5-year OS during the follow-up period ($P = 0.045$). However, the rates of disease-free survival were not significantly different between patients with MSI-H and MSI-L/MSS tumors (Table 4, Figure 2). When the status of chromosome 18q was evaluated according to each microsatellite locus, the D18S474 and D18S61 loci were associated with a poor 5-year OS ($P = 0.010$ and 0.005, respectively) (Table 5, Figure 3).

Cox's proportional hazards regression model was adjusted for gender, age, T stage and chemotherapy, and multiple markers were analyzed. Only 18qLOH was independently associated with the OS rate (RR = 2.679, $P = 0.021$). However, when 18qLOH was excluded from the proportional hazards regression model, MSI-H status was found to be associated with the OS (RR = 3.149, $P = 0.039$) (Tables 6 and 7).

DISCUSSION

In 2006, the ASCO published evidence-based clinical practice guidelines for the use of tumor markers in CRC to update the recommendations for the use of tumor marker tests in the prevention, screening, treatment, and surveillance of gastrointestinal cancers. As part of the update, 18q-LOH and MSI were mentioned in CRC for the first time[2]. In this publication, there were 16 series focusing on the LOH at 18q in the prognosis of early-stage CRC[15-30]. Of the 16 studies, 8 found that CRC patients with harbored LOH at 18q had a significantly lower survival than those who were heterozygous[15,19,20,22,25,28-30]. Four of the eight positive series also found that 18qLOH tumors had a significantly worse prognosis in a

LOH: Loss of heterozygosity; MSI: Microsatellite instability.

multivariate analysis with hazard ratios for death of 2.0, 2.75 and 7.30[19,22,25], or for recurrence of 9.60[15]. Three reports did not find 18qLOH to be independently prognostic[20,28,30] and one did not perform multivariate analysis[29]. In two studies where 18qLOH was not found to be prognostic in a univariate or multivariate analysis[20,21], LOH at 18q did yield a poor prognosis in stage Ⅱ disease.

As for MSI, 17 series focusing on MSI in the prognosis of early stage CRC were considered in this review[15-17,19,31-43]. Six of the series were analyzed in patients on randomized therapeutic trials[16,17,19,31,40,41]. The remaining studies selected patients treated in defined time periods. Interestingly, 11 of the 17 series found that patients with MSI-H colon or rectal cancers had a significantly better survival than those with MSI-L/MSS[15,17,31,33-40,43]. Two series found no association of MSI-H with a better survival from randomized trials of adjuvant chemotherapy[16,19]. One study did find a statistically significant association of MSI-H status with a better disease-free survival[19]. Of the 11 positive series, six also found that MSI-H tumors had a significantly better prognosis in a multivariate analysis[17,33,37,38,40,43]. However, four did not find MSI-H to be independently prognostic[15,31,34,39]. Multivariate analysis was not done in one series[35].

Although there is evidence suggesting an association of 18qLOH and MSI with the prognosis of CRC, the ASCO expert panel determined that the data was insufficient and controversial to recommend using the two tumor markers as independent prognostic tests in the clinic.

Our study in patients with stage Ⅱ colon cancer confirms some previous findings of a lower survival in patients with 18qLOH and a longer survival in patients with MSI-H to some extent. Our present study showed that stage Ⅱ sporadic colon cancer patients with 18qLOH were associated with a significantly shorter OS and a disease-free survival as compared with 18qLOH-negative patients. This association was independent of other clinicopathological variables. According to other investigators, tumors with 18qLOH were more frequently located in the left colon. This observation, together with that of the worse prognosis of colon cancers with 18qLOH, may account for the findings that patients with tumors in the left side of the colon have a worse prognosis than those in the right side.

The reasons why some studies did not find that 18qLOH can predict survival in stage Ⅱ CRC may have several explanations. First, different loci and number of 18q markers were used by various investigators. Second, variation in surgical techniques, regimens of chemotherapy or radiotherapy, and methods of histopathologic analysis of the tumor (i.e. electrophoresis or DNA sequencing directly) could create significant differences. Third, differ-

LOH: Loss of heterozygosity.

ences in TNM stage (stage Ⅱ or stage Ⅲ), T stage (T3 or T4), or tumor location (colon or rectum) could also contribute to the controversial results. For these reasons, our study selected a relatively small range of tumor locations (colon cancer) and TNM stage (stage Ⅱ) to investigate the frequency of 18qLOH and its prognostic value.

In contrast to the unfavorable prognosis associated with 18qLOH, MSI-H is associated with a favorable prognosis. Patients with tumors exhibiting MSI-H had a better OS than patients with MSS tumors. The correlation between the MSI-H genotype and disease-free survival was not significant ($P = 0.155$). However, we hypothesize that this association lacks significance only as a result of the small sample size examined. The favorable effect of MSI on survival, however, resulted as being independent only when multivariate analysis did not consider 18qLOH. The survival advantage of patients with MSI-H tumors compared to those with MSS tumors is not unanimously accepted. Thus, the outcome referred to this phenotype is controversial. In our study, the National Institute of Health consensus definition of MSI has been used.

The chromosome 18q contains several genes with potential importance in colon cancer pathogenesis and progression. Deletion of portions of 18q has been implicated

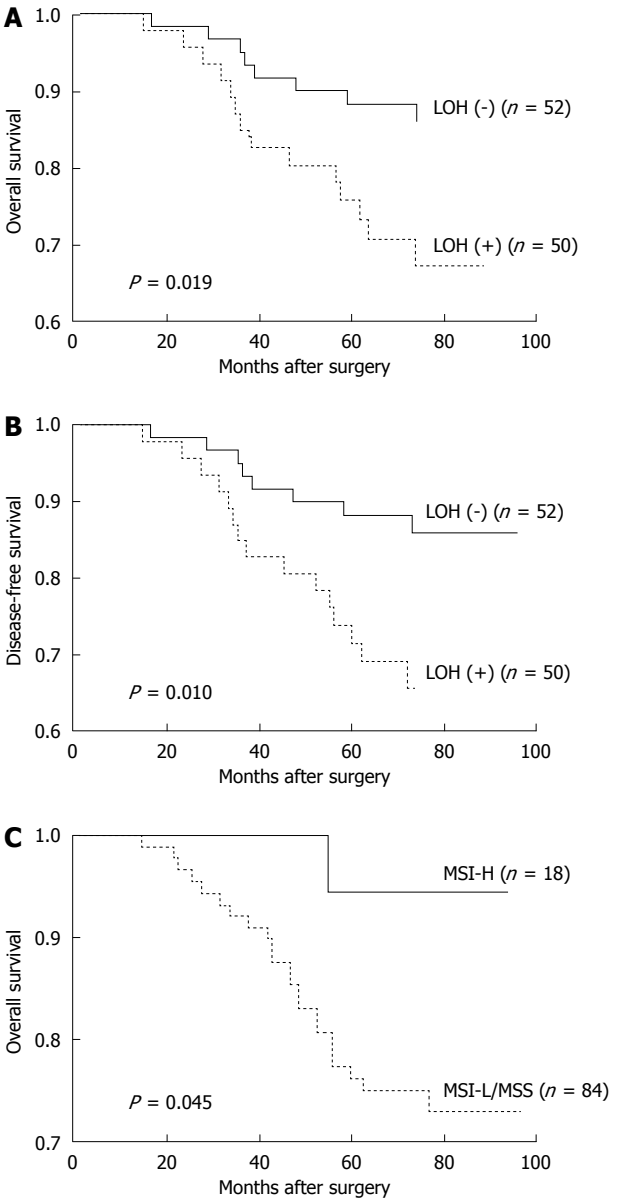

Figure 2 Kaplan-Meier estimates of overall survival and disease-free survival among patients with stage Ⅱ colon cancer according to microsatellite alteration. In our study, 18qLOH was significantly associated with reduced 5-year overall survival (P = 0.019) (A) and disease-free survival (P = 0.010) (B). High levels of microsatellite instability was moderately associated with improved 5-year overall survival during the follow-up period (P = 0.045) (C). LOH: Loss of heterozygosity; MSI-L: Low frequency microsatellite instability; MSI-H: High frequency of microsatellite instability; MSS: Microsatellite stable.

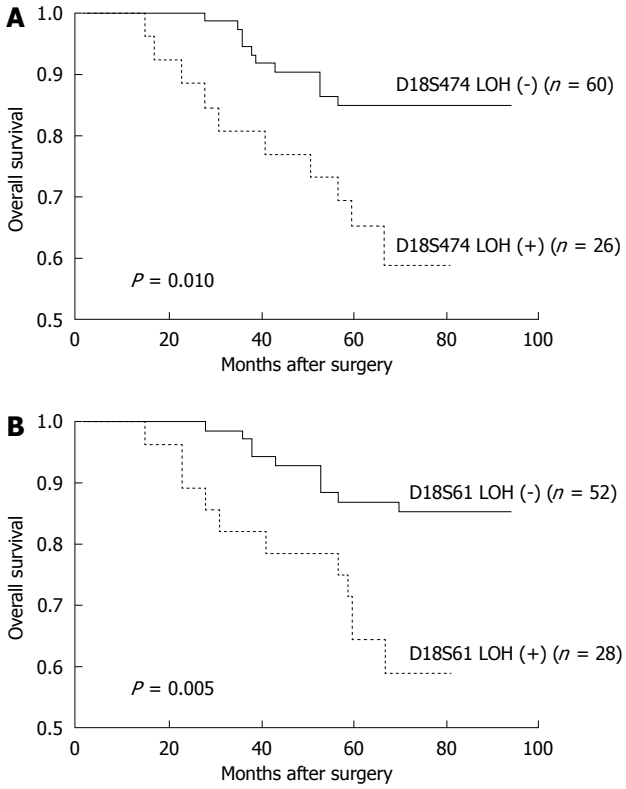

Figure 3 Kaplan-Meier estimates of overall survival among patients with stage Ⅱ colon cancer at microsatellite loci, D18S474 and D18S61. When the status of chromosome 18q was evaluated according to each microsatellite loci, the D18S474 (A) and D18S61 (B) loci were associated with worse 5-year overall survival (P = 0.010 and 0.005, respectively). LOH: Loss of heterozygosity.

as an important step in the development of many CRCs. Among the genes located on 18q are the *DCC* gene that codes for a neutrin-1 receptor important in apoptosis, cell adhesion, and tumor suppression. *SMAD-4* gene, which codes for a nuclear transcription factor in transforming growth factor-β1 signaling, is involved in tumor suppression and the *SMAD22* gene is involved in endodermal differentiation[44].

MSI is a measure of the inability of the DNA nucleotide mismatch repair system to correct errors that commonly occur during the replication of DNA. It is characterized by the accumulation of single nucleotide mutations and length alterations in repetitive microsatellite nucleotide sequences. It is an alternative pathway to chromosomal instability with LOH in the pathogenesis of colon cancer[11].

In conclusion, the results of this study support the opinion that in colon cancer, genetic approaches may delineate subgroups of patients who would benefit most from specific treatment or other investigative therapies. We found that 18qLOH is a very informative prognostic genetic marker that could lead to the identification of patients who should be subjected to different adjuvant therapy plans. In addition, our study demonstrated that MSI-H in colon cancer is a potentially favorable prognostic genetic marker. This lends support to the hypothesis that MSI-H is an index of a less aggressive type of tumor growth and a heightened immunologic response. Although these results suggest that 18qLOH and MSI are prognostic genetic markers, the final verdict should depend on large-scale prospective randomized control trials.

COMMENTS

Background

It has been shown that colorectal cancer (CRC) arises through at least two distinct genetic pathways of microsatellite alteration (MA): one involving chromosome instability presented as loss of heterozygosity (LOH), and the other involving microsatellite instability (MSI). Although many studies have proven the prognostic value of MA at chromosome 18q in CRC, the outcomes are controversial.

Research frontiers

To further define the clinical effect of molecular genetic alterations on clinicopathological features and prognosis, the authors analyzed 106 patients retrospectively with stage Ⅱ colon cancer for LOH and MSI at chromosome 18q.

Innovations and breakthroughs

In order to minimize the bias, the authors selected a relatively small range of tumor locations (colon cancer) and TNM stage (stage Ⅱ) to analyze expression of LOH and MSI focusing on five microsatellite loci at chromosome 18q.

Applications

This study found LOH at chromosome 18q to be a very informative prognostic genetic marker that could identify patients who should be subjected to different adjuvant therapy plans.

Peer review

The manuscript presented data of LOH and MSI assays on more than 100 cases of stage Ⅱ colonic adenocarcinomas. The results showed the preferential occurrence of allelic imbalance on 18q in more aggressive lesions, indicating the clinical significance of these markers.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Long term hepatitis B virus (HBV) infection is a major risk factor in pathogenesis of chronic liver diseases, including hepatocellular carcinoma (HCC). The HBV encoded proteins, hepatitis B virus X protein and preS, appear to contribute importantly to the pathogenesis of HCC. Both are associated with oxidative stress, which can damage cellular molecules like lipids, proteins, and DNA during chronic infection. Chronic alcohol use is another important factor that contributes to oxidative stress in the liver. Previous studies reported that treatment with antioxidants, such as curcumin, silymarin, green tea, and vitamins C and E, can protect DNA from damage and regulate liver pathogenesis-related cascades by reducing reactive oxygen species. This review summarizes some of the relationships between oxidative stress and liver pathogenesis, focusing upon HBV and alcohol, and suggests antioxidant therapeutic approaches.

Key words: Hepatitis B virus; Hepatitis B virus X protein; Alcohol; Chronic liver disease; Oxidative stress; Antioxidant

Peer reviewer: Thomas Bock, PhD, Professor, Department of Molecular Pathology, Institute of Pathology, University Hospital of Tuebingen, D-72076 Tuebingen, Germany

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most frequent tumor types worldwide. It is the fifth most common cancer and the third leading cause of cancer death[1]. There are multiple etiological agents that are associated with the development of HCC, the most frequent being chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections, and long-term exposure to the mycotoxin, aflatoxin B1.

HBV is recognized as a major etiological factor in the development of such diseases as fatty liver (steatosis), cirrhosis, hepatocellular adenoma, and HCC[2,3]. The risk of HCC in chronic HBV carriers is more than 100 times greater than in uninfected individuals. In the year 2000, worldwide new cases of HCC had increased to 564 300[4]. More than 80% of these cases occur in developing countries, especially Southeast Asia and sub-Saharan Africa. Some 80%-90% of HCCs develop in cirrhotic liver[5]. After 20-30 years of chronic infection, 20%-30% of patients develop liver cirrhosis. HCC develops at an annual rate of 3%-8% in HBV-infected cirrhotic patients[6].

In the course of chronic infection, fragments of HBV

DNA integrate randomly into host DNA. Many of these integrated species encode the hepatitis B virus X protein (HBx) and truncated preS polypeptides, which contribute major steps in hepatocarcinogenesis. HBx binds to the DDB1 subunit of a UV-damaged DNA binding protein[7], the latter of which appears to be important for maintaining the integrity of DNA repair[8]. HBx has also been shown to bind to and functionally inactivate p53[9,10].

Therefore, the HBx and HBs proteins represent the two potential candidate proteins involved in HBV-related hepatocarcinogenesis[11-16]. HCC is also a common complication of alcoholic cirrhosis, although ethanol appears to not be directly carcinogenic[17].

OXIDATIVE STRESS

Oxidative stress is a disturbance in the oxidant-antioxidant balance leading to potential cellular damage. Most cells can tolerate a mild degree of oxidative stress, because they have sufficient antioxidant defense capacity and repair systems, which recognize and remove molecules damaged by oxidation. The imbalance can result from a lack of antioxidant capacity caused by disturbances in production and distribution, or by an overabundance of reactive oxygen species (ROS) from other factors. ROS are potential carcinogens because of their roles in mutagenesis, tumor promotion, and progression[18]. If not regulated properly, the excess ROS can damage lipids, protein or DNA, inhibiting normal function[19]. ROS alterations in different signaling pathways may modulate gene expression, cell adhesion, cell metabolism, cell cycle and cell death. These events may induce oxidative DNA damage, which in turn increases chromosomal aberrations associated with cell transformation[20]. ROS may also activate cellular signal pathways, such as those mediated by mitogen-activated protein kinase (MAPK), nuclear factor-κB (NF-κB), phosphatidylinositol 3-kinase (PI3K), p53, β-catenin/Wnt and associated with angiogenesis[21-23]. Importantly, HBx stimulates the activities of MAPK, NF-κB, PI3K, and β-catenin (as well as other pathways) that are thought to contribute importantly to the development of HCC. Perhaps this is why carriers with chronic liver disease (CLD) develop a high incidence of HCC, while asymptomatic carriers do not.

OXIDATIVE STRESS EFFECT ON CHRONIC LIVER DISEASE AND LIVER FIBROSIS

Several *in vitro* and *in vivo* observations suggest that oxidative stress and associated damage could represent a common link between different forms of chronic liver injury and hepatic fibrosis. For example, oxidative stress contributing to lipid peroxidation is one of the critical factors involved in the genesis and the progression of nonalcoholic steatohepatitis and liver cancer[24,25]. Viral infection or alcohol abuse greatly increased the highly variable miscoding etheno-modified DNA like epsilondA [1,N(6)-etheno-2'-deoxyadenosine] levels by triggering lipid peroxidation. Patients with chronic hepatitis, liver cirrhosis, and HCC due to HBV infection had more than 20 times higher urinary epsilondA levels[25] compared to uninfected individuals with no liver disease.

Among the mechanisms involved in mediating the process of liver fibrosis, an important role is played by ROS[26]. During the progression of liver injury, hepatic stellate cells (HSCs) become activated, which produce extracellular matrix such as collagen I [27]. Collagen I gene regulation has revealed a complex process involving ROS as a key mediator[28-30]. ROS-sensitive cytokines contribute to HSC activation during inflammation through paracrine signals released from immune cells[31]. The activated HSCs become responsive to platelet-derived growth factor (PDGF) and transforming growth factor (TGF)-β. PDGF facilitates the progression of hepatic fibrosis in human CLD. It increased the accumulation of hydrogen peroxide in HSCs. Specifically PDGF-induced increases in collagen deposition and liver fibrosis is markedly reduced by treatment with the anti-oxidant drug Mn-TBAP[32,33]. TGF-β increases ROS production and decreases the concentration of glutathione (GSH)[34]. In this context, it is important to note that HBx trans-activation activity is stimulated by ROS. Given that HBx is also associated with the development of HCC in both human carriers and in transgenic mice, and that HCC is associated with chronic inflammation, this underscores the importance of inflammation in the context of chronic HBV infection to hepatocarcinogenesis.

HBV INFECTION AND OXIDATIVE STRESS

Many groups have shown that HBV can induce oxidative stress using HBV transgenic mice or HBV DNA transfection of cells *in vitro*, while oxidative stress is also common among HBV infected patients with CLD[35-41]. Oxidative stress also precedes the development of HCC in transgenic mice that overproduce and accumulate intracellular HBsAg. Several studies have found that the total peroxide level, a parameter of oxidative stress, is significantly higher in patients with chronic hepatitis compared to asymptomatic carriers, and positively correlated with alanine aminotransferase (ALT) levels, suggesting that oxidative stress plays a critical role in hepatic injury. Oxidative stress is also associated with the severity of the disease. Lipid peroxidation and oxidative DNA damage are enhanced in patients with HBV infection.

Mitochondria are a major source of ROS. ROS can form through electron leakage from the mitochondrial respiratory chain[42]. HBx itself targets mitochondria and directly interacts with voltage-dependent anion channel 3. It alters the mitochondrial membrane potential and increases the endogenous ROS level[43-46]. HBx expression also induces oxidative stress through calcium signaling and activates cellular kinases, leading to the activation of transcription factors NF-κB, signal transducer and activator of transcription 3, and others *via* phosphorylation[47,48]. It is observed that HBV-induced oxidative stress also stimu-

lates the translocation of mitogen-activated protein kinase Raf-1 to mitochondria. This activation involves both the Src- and the PAK-mediated phosphorylation of the Raf-1 activation domain[49]. HBx also induces lipid peroxidation *via* down-regulation of SeP expression, resulting in increased expression of tumor necrosis factor-α in the human hepatoblastoma cell line, HepG2[50].

Activity of the anti-oxidant enzymes CuZn-SOD and GSH-Px was found to be the lowest in chronically infected patients compared with other groups[51,52]. Detection of an increase in MDA levels, which is a product of lipid peroxidation in HBV infected groups, indicates that oxidative stress is increased in HBV infection[52,53]. After treatment with interferon-α and lamivudine, however, there was a decrease in the products of lipid peroxidation and an increase in the antioxidant enzymes, such as CuZn-SOD and GSH-Px, compared with pretreatment[53].

The marker 8-hydroxydeoxyguanosine (8-OHdG) is useful in estimating DNA damage induced by oxidative stress. Importantly, hepatic 8-OHdG accumulation was detected in patients with chronic hepatitis B[39,54]. Further, HBV replication causes oxidative stress in HepAD38 liver cells, with more than 3 fold increases in the GSSG/GSHtot ratio[37].

HuH-7 cells carrying the pre-S mutant (a truncated form of preS/S polypeptide) exhibited enhanced levels of ROS and oxidative DNA damage through endoplasmic reticulum (ER) stress pathways. Oxidative DNA damage has also been observed in livers of transgenic mice carrying the pre-S mutant[36]. HepG2-HBx cells and the livers of HBx mice also showed increased ROS levels (Figure 1), mtDNA deletion, and declines in the mitochondrial membrane potential compared to controls (data not shown). Through DNA chip analysis, several ROS-related molecules, such as members of the CYP450 families, were altered in HBx transgenic mice. The cytochrome p450s are a superfamily of hemeproteins that serve as terminal oxidases[55]. A major function of these p450s is to convert compounds into more polar metabolites[56]. Detoxification by cytochrome p450 can also produce ROS[57,58]. CYP2E1, a member of the p450 family that oxidizes ethanol, generates oxidative stress in the mitochondrial compartment of hepatocytes. This has been suggested to play a role in hepatotoxicity, as observed in ALD-related patients[59-61]. In a mouse model of nonalcoholic steatosis, CYP2E1 also plays key roles in ROS production and contributes to the pathogenesis of liver damage[62,63]. Thus, the involvement of mitochondria in the production of free radicals resulting from ethanol metabolism, and the fact that elevated free radical formation stimulates HBx activities, combined with the ability of mitochondria to oxidize ethanol may help to explain the apparent synergistic effects of chronic ethanol intake and HBx expression on the pathogenesis of CLD and HCC.

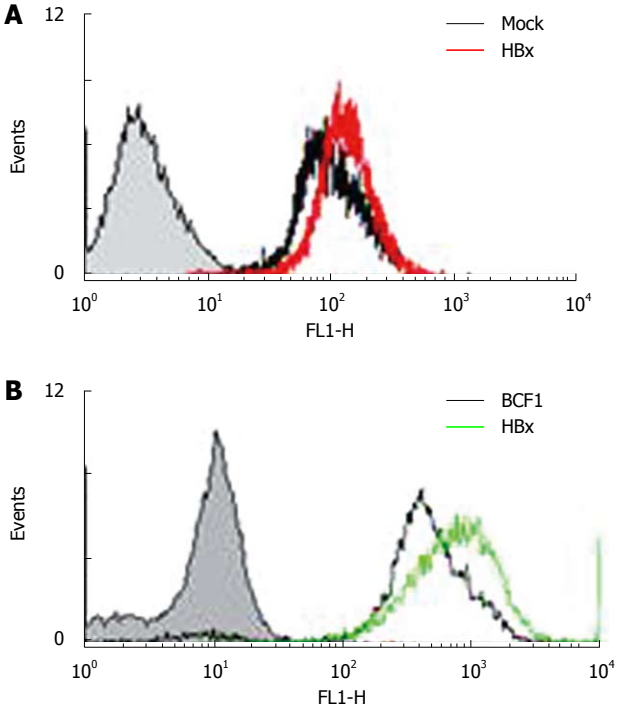

Figure 1 Increased reactive oxygen species in hepatitis B virus X protein transfected HepG2 stable cell line and hepatitis B virus X protein transgenic mouse hepatocytes. Reactive oxygen species (ROS) was detected by FACS caliber using dichlorofluorescein diacetate (DCFA-DA). A: HepG2 cell line stably transfected with hepatitis B virus X protein (HBx) showed a higher level of ROS compared to control cells; B: ROS production was checked after 4 wk of male HBx and control mouse hepatocyte growth. HBx mice hepatocytes generate more ROS than control mice.

LIVER PATHOGENESIS BY ALCOHOL-INDUCED OXIDATIVE STRESS

Chronic alcohol consumption has long been associated with progressive liver disease[64,65]. The liver is the major site of ethanol metabolism and thus sustains the most injury from chronic alcohol consumption. In alcohol-related liver disease, free radicals play a part in the pathogenesis of liver damage. Acute and chronic ethanol treatment increases ROS production, lowers cellular antioxidant levels, and enhances oxidative stress in many tissues, especially the liver[66,67]. It induces an accumulation of cysteine, a glutathione precursor/metabolite in the liver, probably due to gamma-glutamyltransferase induction[68]. Acetaldehyde produced by the oxidation of alcohol is able to inhibit the repair of alkylated nucleoproteins, to decrease the activity of several enzymes, and to damage mitochondria. Acetaldehyde also promotes cell death by depleting the concentration of reduced glutathione, by inducing lipid peroxidation, and by increasing the toxic effects of free radicals. Finally, acetaldehyde has been shown to directly stimulate proliferation of HSC and to increase collagen synthesis[69-71].

Chronic ethanol treatment has long been known to depress mitochondrial function[72-74]. The occurrence of DNA fragmentation in peripheral blood lymphocytes reflects a direct genotoxic effect of alcohol, HBV, and/or HCV, and suggests that the same genotoxic effect may operate in the liver and contribute to hepatocarcinogenesis[75].

Alcohol is also metabolized by mitochondrial CYP2E1. Ethanol exposure to VL-17A cells increased CYP2E1, decreased the activity of antigen-trimming enzymes

Table 1 Serum glutamate oxalate-transferase and glutamate-pyruvate-transferase values of wild and Hepatitis B virus X protein mice

Groups	Age (mo)	No. of animals	Treatment	Duration (wk)	GOT (U/L)	GPT (U/L)
HBx-tg	8	8	25% alcohol	12	193 ± 83.5	87.3 ± 35.5
	8	4	Normal water	12	60 ± 13.8	82 ± 19
C57BL/6J	8	8	25% alcohol	12	119 ± 31.9	61.7 ± 11.5
	8	9	Normal water	12	42 ± 11	68 ± 6

GOT: Glutamate oxalate-transferase; GPT: Glutamate-pyruvate-transferase; HBx: Hepatitis B virus X protein.

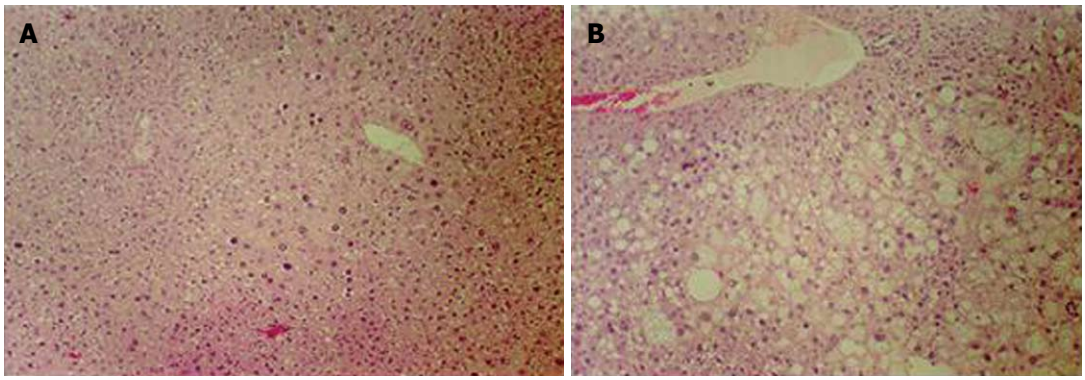

Figure 2 Chronic ethanol consumption caused liver damage in hepatitis B virus X protein transgenic mice. Ethanol fed hepatitis B virus X protein (HBx) tg mouse liver (B) showed severe liver damage, hepatocyte enlargement and fatty changes compared with water fed HBx (A). Original magnifications 100 ×.

like proteasome peptidase and leucine aminopeptidase (LAP). This defect may potentially result in decreased MHC class I -restricted antigen presentation on virally infected liver cells[68].

Alcohol-induced inflammatory and innate immune responses in Kupffer cells, due to elevated gut-derived plasma endotoxin levels, increase ROS-induced damage, and profibrogenic factors such as acetaldehyde or lipid peroxidation products, contribute to activation of HSCs[76]. Following a fibrogenic stimulus such as alcohol, HSCs transform into activated collagen-producing cells. There is much current interest in the likely synergistic interactions between hepatitis viruses and alcohol, especially with respect to generating oxidative stress.

Alcohol exacerbates pathological changes in HBx transgenic mice

C57BL/6J (control) and HBx transgenic mice 8 mo of age were fed with water or 25% ethanol liquid diets for 12 wk (Table 1). Glutamate oxalate-transferase (GOT) and glutamate-pyruvate-transferase (GPT) levels, both indicators of liver damage, were elevated in control and HBx ethanol-fed groups, but not in the water-fed groups. However, HBx mice showed higher levels of GPT (87.3 ± 35.5 U/L) and GOT (193 ± 83.5 U/L) than wildtype mice (GPT: 61.7 ± 11.5 U/L, GOT: 119 ± 31.9 U/L). This result indicated that HBx transgenic mice developed more severe liver damage from ethanol than control mice. This was confirmed by histological evaluation of the liver, which showed the development of more severe liver injury only in the HBx transgenic mice. Hyperplastic nodules, found in both the water- and ethanol-fed groups of HBx transgenic mice, were more frequent among the ethanol-treated group (Figure 2). Control mice fed ethanol showed mild steatosis (data not shown), but the alcohol-treated HBx transgenic liver had severe steatosis and hepatomegaly compared to the untreated controls (Figure 2). Thus, even moderate ethanol consumption promoted oxidative stress and liver injury in HBx transgenic mice, implying that compromised antioxidant defense promotes alcohol liver injury.

ANTIOXIDANT ENZYMES AND THE REDUCTION OF OXIDATIVE STRESS

Given that ROS production is a natural process, and that persistent, high levels of ROS could be damaging, the human body has developed antioxidant systems aimed at their neutralization. A variety of enzymatic and nonenzymatic mechanisms have evolved to protect cells against ROS. These include superoxide dismutase (SOD), which detoxifies the superoxide ion, catalase and the GSH peroxidase system, peroxiredoxins, which inactivate hydrogen peroxide (H_2O_2), and glutathione peroxidase, whose function is to detoxify cellular peroxides. Further, ceruloplasmin and ferritin help remove metals, such as iron, that promote oxidative reactions. There are also nonenzymatic, low-molecular-weight antioxidants, such as GSH, vitamin E, ascorbate (vitamin C), vitamin A, ubiquinone, uric acid, and bilirubin[77,78].

A CuZn-SOD is present in the cytosol and in the space between the inner and outer mitochondrial membranes, while a manganese-containing SOD is present in the mitochondrial matrix. Both of these enzymes are critical for prevention of ROS-induced toxicity[79].

Catalase is found primarily in peroxisomes; it catalyzes a reaction between two H_2O_2 molecules, resulting in the

formation of water and O_2. In addition, catalase can promote the interaction of H_2O_2 with hydrogen donors so that the H_2O_2 can be converted to one molecule of water, and the reduced donor becomes oxidized (peroxidatic activity of catalase).

The Prx family has the capacity to decompose H_2O_2 *in vivo* and *in vitro*. All Prx enzymes contain a conserved Cys residue that undergoes a cycle of peroxide-dependent oxidation and thiol-dependent reduction during catalysis. Mammalian cells express six isoforms of Prx (Prx I to VI), which are classified into three subgroups (2-Cys, atypical 2-Cys, and 1-Cys) based on the number and position of Cys residues that participate in catalysis. Prx I to Prx IV are members of the 2-Cys Prx subgroup. Prx I and Prx II exist in the cytosol. Prx III, which is synthesized with a mitochondrial targeting sequence, is imported into and matures within mitochondria. Prx IV is a secreted protein[80-83]. Prx V is expressed ubiquitously; it localizes to mitochondria and peroxisomes[84] and possesses antioxidant activity equivalent to that of catalase[85]. All peroxiredoxins have two cysteine residues, but Prx VI has only one at position 47. Prx VI is the only peroxiredoxin whose target is glutathione rather than thioredoxin. It is mostly cytosolic.

ANTIOXIDANT THERAPY FOR CHRONIC LIVER DISEASE

As discussed above, oxidative stress plays a central role in HBV- and alcohol-induced liver damage. There are several possible strategies for preventing this stress[34]. Among them is the addition of antioxidant agents to antiviral drugs for patients with chronic hepatitis B.

Curcuminoids

For example, curcuminoids, the main yellow pigments in Curcuma longa (turmeric), have been used widely and for a long time in the treatment of sprains and inflammation[86]. Curcumin is the main component of turmeric, and two minor components are also present as curcuminoids. Curcuminoids possess antioxidant activity[87]. They protect DNA against oxidative attack, thereby lowering the risk for mutations and other genetic damage[88,89]. They also activate detoxification enzymes such as glutathione S-transferase[90]. Curcumins can down-regulate NF-κB, a nuclear transcription factor and critical upstream regulator of genes that control acute and chronic inflammation cascades[91,92]. Curcumin exerts beneficial effects in animal models of liver injury and cirrhosis[93,94]. Curcumin prevents alcohol-induced liver disease in rats by blocking activation of NF-κB[95] and by induction of HO-1[96]. Curcumin inhibits the fibrogenic progression of murine steatohepatitis[97]. It inhibits extracellular matrix formation by enhancing HSC matrix metalloproteinase expression *via* $PPAR_\gamma$ and suppresses connective tissue growth factor expression[98]. CLL extract also represses HBV replication by enhancing the level of p53 protein[99].

Silymarin

Silymarin is a purified extract from milk thistle [*Silybum marianum* (L.) Gaertn], composed of a mixture of four isomeric flavonolignans: silibinin (its main, active component), isosilibinin, silydianin, and silychristin. This extract has been used as a remedy for almost 2000 years[100] and continues to be used as a medicine for many types of acute and chronic liver diseases. Silybin is an effective antioxidant, conserving GSH in liver cells while stabilizing the liver cell membranes against oxidative attack[100,101].

Inhibition of liver fibrogenesis in clinical trials, and promotion of liver regeneration[102,103] have been inconsistent with these treatments. In clinical trials among patients with viral hepatitis[104], alcoholic liver damage[105], and/or other liver diseases, silymarin and silybin lowered liver enzymes and (at times) improved antioxidant status, but did not consistently improve symptoms[104,105]. It is routinely used in the clinic as a hepatoprotectant. Silymarin exerts beneficial effects on the early stages of chronic liver disease, preventing and delaying the onset of HBV-related liver carcinogenesis[106-110].

Mechanistically, the anti-inflammatory and anticancer effects of silybin and the other flavonolignans are related to the potent inhibition of NF-κB. Silybin is a potent inhibitor of NF-κB activation, as induced by a variety of anti-inflammatory agents[111].

Green tea

Green tea, a product of the plant Camellia sinensis (family Theaceae), contains polyphenols, specifically catechins of the flavan-3-ol class and their gallate derivatives. They are potent antioxidant and anti-inflammatory agents[112]. The flavan-3-ol structure makes them efficient scavengers of superoxide, singlet oxygen, nitric oxide, and peroxynitrite[113]. They up-regulate antioxidant and other detoxifying enzymes and protect DNA from oxidative damage[114-116]. Like other flavonoids, the green tea catechins can down-regulate NF-κB and AP-1, both of which may promote chronic inflammation and carcinogenesis when abnormally activated[117].

When treated with natural green tea extract, cells supporting HBV replication had reduced virus gene expression and reduced cell growth[118].

Vitamins C and E

Vitamin C is essential to a healthy diet as well as a highly effective antioxidant. It is a substrate for ascorbate peroxidase. Vitamin E is a fat-soluble antioxidant that is the major antioxidant found in lipid-phase membranes. It blocks the production of ROS formed when fat undergoes oxidation[119]. Several studies have clearly shown that serum levels of vitamin E are significantly reduced in patients with alcoholic liver disease[120,121]. Vitamin E levels also negatively correlate with production of oxidative stress products and directly correlate with the extent of liver damage[122]. Therefore, maintenance of normal concentrations of vitamin E seems to be essential to prevent lipid peroxidation induced by alcohol consumption. Works from several laboratories have indicated that mitochondrial damage may present a common early event in cell injury[123]. Mitochondrial damage was prevented by vitamin E[124]. Vitamin E or C alone or in combination can facilitate scavenging free

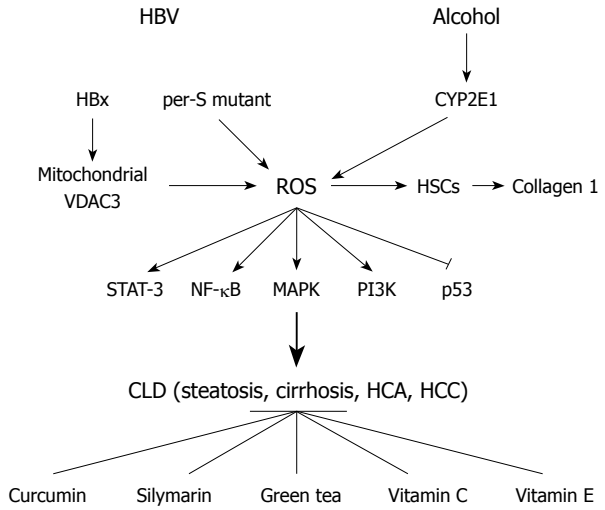

Figure 3 Summary of hepatitis B virus and alcohol induced reactive oxygen species effects on chronic liver disease and antioxidant's protective effects. HBV: Hepatitis B virus; HBx: Hepatitis B virus X protein; VDAC3: Voltage-dependent anion channel 3; ROS: Reactive oxygen species; HSCs: Hepatic stellate cells; STAT-3: Transducer and activator of transcription 3; NF-κB: Nuclear factor κB; MAPK: Mitogen-activated protein kinase; PI3K: Phosphatidylinositol 3-kinase; CLD: Chronic liver disease; HCA: Hepatocellular adenoma; HCC: Hepatocellular carcinoma.

radicals generated in liver tissue[125]. Pretreatment with vitamin C against imidacloprid-induced oxidative liver stress in mice is better than post-treatment administration[126]. Pretreatment with vitamin E reduced the degree of oxidative stress[90], although this vitamin produced only slight changes in hepatic injury[127]. In the mouse model, vitamin E supplementation restored alcohol-induced redox status, reduced apoptosis, and prevented oxidative stress[128]. In addition, vitamin E in doses of 600 mg daily was effective in suppressing HBV replication and normalizing ALT in a significant proportion of chronically infected patients with CLD[129]. In this context, it will be important to determine whether anti-oxidants reduce HBxAg expression and/or function in cultured cells, or promote the resolution of CLD in human carriers and/or among human carriers with CLD who are also chronic alcoholics. If so, then anti-oxidant treatments may reduce the risk for progressive CLD lesions ultimately resulting in HCC, and/or eliminate the synergy between HBV and chronic alcoholism in the pathogenesis of alcoholic liver disease.

CONCLUSION

In summary (Figure 3), HBV and alcohol-induced liver injury are multi-step processes involving several mechanisms. The ability of HBV and alcohol to induce oxidative stress and the role of ROS in HBV- or alcohol-triggered liver damage is an important area of research, particularly because that information could be of major therapeutic value in protecting the liver. As basic information continues to emerge regarding the role of oxidative stress in disease development and the mechanisms underlying ROS-related cellular toxicity, these findings will lead to more rational antioxidant therapeutic approaches.

Abstract

Hepatic ischemia and reperfusion (I/R) injury during liver surgery is still the main cause of postoperative liver failure and the subsequent rise of mortality in these patients. During the last few years, a multitude of underlying mechanisms have been extensively characterized and many different protective approaches have been evaluated under experimental conditions. Some of them have already found their way into small sized clinical trials. In this Topic Highlight series of articles, we present recent insights into promising protective concepts including the regulation and optimization of hepatic blood flow, molecular mechanisms of preconditioning and pharmacological approaches with the aim of limiting hepatic I/R injury. Leading international experts present the latest experimental evidence in their fields stressing clinically relevant ideas, which are now on the edge of entering clinical practice.

Key words: Heme oxygenase-1; Hepatectomy; Hepatic organ protection; Ischemia/reperfusion injury; Liver blood flow; Liver transplantation; Preconditioning

Schmidt R. Hepatic organ protection: From basic science to clinical practice. *World J Gastroenterol* 2010; 16(48): 6044-6045 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i48/6044.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i48.6044

The sequence of hepatic ischemia and reperfusion (I/R) is frequently associated with the destruction of liver cells thus contributing to postoperative liver failure and increased mortality. In liver transplantation, up to 30% of delayed graft function are caused by the consequences of hepatic I/R injury[1]. Intermittent clamping of hepatic blood inflow (e.g. Pringle's maneuver), an established technique to reduce blood loss during major liver resection, could have similar adverse effects by I/R mediated mechanisms. Furthermore, van der Bilt and colleagues demonstrated that I/R induced by vascular clamping is a strong stimulus that promotes the outgrowth of micrometastasis in the liver[2]. Therefore, the development of therapeutic concepts to prevent hepatic I/R injury has become the focus of intensive research efforts during the last few years. In this Topic Highlight series, we have put together a group of international experts providing an update on the latest achievements in their fields stressing clinically relevant ideas with the aim of protecting the liver against I/R injury. The maintenance of macro- and microvascular perfusion after hepatic ischemia plays a crucial role in the prevention of liver cell injury. In the first article of the present review series, Eipel *et al*[3] discuss recent insights into the regulation of hepatic blood flow and in particular the relevance of the "hepatic arterial buffer response", an important intrinsic mechanism of the hepatic artery to produce compensatory flow changes in response to changes in portal venous flow. The authors present detailed experimental and clinical information stressing the crucial importance of the hepatic arterial buffer response

as a regulatory mechanism to maintain adequate liver function and metabolic homeostasis. The second contribution focuses on preconditioning, an important phenomenon mediating cytoprotection in many different organs including the liver. Alchera *et al*[4] provide an interesting overview on the molecular mechanisms of liver preconditioning with special emphasis on the development of pharmacological approaches aimed at activating intrinsic protective systems in patients undergoing liver surgery. The next review concentrates on one of the most powerful inducible enzymes known today: heme oxygenase-1 (HO-1). HO-1 metabolizes heme into iron, carbon monoxide, and biliverdin, which is subsequently converted to bilirubin. Upregulation of HO-1 and administration of each of its reaction products has been shown to play a pivotal role in the maintenance of cellular function after sublethal stress in nearly all organ systems including the liver. However, the development of therapeutic strategies that utilize the protective effect of HO-1 induction is hampered by the fact that most pharmacological inducers of this enzyme perturb organ function by themselves and that gene therapy for upregulation of HO-1 has potential negative side effects, which currently preclude its clinical application under these conditions. Hence, most substances used for upregulation of HO-1 under experimental conditions are not available for use in patients because of their toxicity and undesirable or unknown side effects[5]. During the last years, a few non-toxic HO-1 inducing compounds have been identified in animal experiments including the β_1-agonist dobutamine, the phosphodiesterase-Ⅲ-inhibitor olprinone, and the volatile anesthetics isoflurane and sevoflurane. Isoflurane has been shown to profoundly protect the liver against I/R injury by upregulation of HO-1 gene expression under experimental conditions[6,7]. As a consequence, volatile anesthetics are currently being evaluated for their potential to induce HO-1 and protect the liver against I/R in humans. In the present series of reviews, Richards *et al*[8] summarize HO-1 mediated protective effects within the liver and point to its therapeutic potential in detail. The protective role of nitric oxide (NO) in the context of hepatic I/R injury is then nicely presented by Siriussawakul and coworkers in their contribution[9]. The authors discuss the influence of endogenous NO on hepatic I/R injury and the potential therapeutic role of inhaled NO, nitrite and other NO donors in ameliorating hepatic I/R injury. Next, Mathes systematically describes the current knowledge on the antioxidant and other protective actions of melatonin in the liver. Melatonin, the "hormone of darkness", has recently been shown to exert abundant hepatoprotective effects in a multitude of experimental studies. Mathes illustrates this topic in depth and highlights possible approaches for its beneficial use in patients[10]. Finally, Gurusamy *et al*[11] present the currently available clinical data concerning protective strategies in liver surgery and review the significance of these studies in an evidence-based approach.

The present Topic Highlight series "Hepatic organ protection: From basic science to clinical practice" is far from being a complete reference of all experimental evidence concerning liver protection. It presents fascinating clinically relevant experimental concepts aimed at the identification of surgical techniques and pharmacological compounds, which now have to be validated in large randomized clinical trials.

Abstract

The interest in the liver dates back to ancient times when it was considered to be the seat of life processes. The liver is indeed essential to life, not only due to its complex functions in biosynthesis, metabolism and clearance, but also its dramatic role as the blood volume reservoir. Among parenchymal organs, blood flow to the liver is unique due to the dual supply from the portal vein and the hepatic artery. Knowledge of the mutual communication of both the hepatic artery and the portal vein is essential to understand hepatic physiology and pathophysiology. To distinguish the individual importance of each of these inflows in normal and abnormal states is still a challenging task and the subject of ongoing research. A central mechanism that controls and allows constancy of hepatic blood flow is the hepatic arterial buffer response. The current paper reviews the relevance of this intimate hepatic blood flow regulatory system in health and disease. We exclusively focus on the endogenous interrelationship between the hepatic arterial and portal venous inflow circuits in liver resection and transplantation, as well as inflammatory and chronic liver diseases. We do not consider the hepatic microvascular anatomy, as this has been the subject of another recent review.

PHYSIOLOGY OF LIVER BLOOD FLOW AND HEPATIC MACROHEMODYNAMICS

Hepatic blood flow and hepatic pressures

The liver has the most complicated circulation of any organ. According to the anatomical peculiarity of the double afferent blood supply of the liver, 75%-80% of the blood entering the liver is partially deoxygenated venous blood supplied by the portal vein, which collects all the blood that leaves the spleen, stomach, small and large intestine, gallbladder and pancreas[1-3]. The hepatic artery accounts for the remaining 25% with well-oxygenated blood. Total hepatic blood flow ranges between 800 and 1200 mL/min, which is equivalent to approximately 100 mL/min per 100 g liver wet weight[4]. Although the liver mass constitutes only 2.5% of the total body weight, the liver receives nearly 25% of the cardiac output.

The valveless portal vein is a low pressure/low resistance circuit, while the hepatic artery supplies the liver with arterial blood in a high pressure/high resistance system[4]. The mean pressure in the hepatic artery is similar to that in the aorta, while portal vein pressure has been reported

to range between 6 and 10 mmHg in humans when determined by direct cannulation[5] or by splenic puncture[6]. Portal pressure depends primarily on the degree of constriction or dilatation of the mesenteric and splanchnic arterioles and on intrahepatic resistance. Both afferent systems merge at the sinusoidal bed, where the pressure is estimated to be slightly, namely, 2-4 mmHg above that in the smallest collecting veins or the inferior vena cava.

Hepatic blood volume

Although only limited data exist, it appears that hepatic blood volume ranges from 25 to 30 mL/100 g liver weight, and accounts for 10%-15% of the total blood volume[7]. Estimations of hepatic blood volume are highly variable, as indirect calculations of hepatic blood volume from red blood cell content of the liver and arterial hematocrit are inaccurate, and hepatic venous pressure largely influences hepatic blood volume[4]. Furthermore, rough estimation suggests that more than 40% of the hepatic blood is held in large capacitance vessels (portal vein, hepatic artery and hepatic veins), while the sinusoids accommodate up to 60% as small vessel content[4]. Of note is the high compliance of the hepatic vascular bed, calculated as the change in blood volume per unit change in venous pressure[8]. In cats, the hepatic blood volume increases in response to elevated venous pressure and is doubled when hepatic venous pressure is elevated to 9.4 mmHg[8]. Hepatic blood volume may expand considerably in cardiac failure and, in turn, serves as an important blood reservoir in case of bleeding episodes, and compensates up to 25% of the hemorrhage by immediate expulsion of blood from the capacitance vessels[9].

Hepatic oxygen consumption

As in any other artery of the body, oxygen saturation of the hepatic artery usually exceeds 95%. Oxygen saturation of portal blood during the fasting state ranges up to 85%, which is greater than that of other systemic veins; however, it substantially drops after food ingestion. It is generally accepted that 50% of the oxygen requirements of the liver are provided by portal venous blood and the other half derives from the hepatic artery[1]. If oxygen demand is increased, the liver simply extracts more oxygen from the blood in order to maintain oxygen uptake. In line with this, alterations of hepatic oxygen supply, attained by isovolemic hemodilution or stimulation of hepatic enzymes, lead to reduced oxygen content in the inflow and outflow vessels, but do not cause dilatation of the hepatic artery, which disproves the view that the hepatic artery might be regulated by the metabolic activity of the liver cell mass[10].

Hepatic blood flow control

Liver blood flow is controlled by mechanisms that are independent of extrinsic innervation or vasoactive agents that regulate (1) hepatic arterial inflow; (2) portal venous inflow; and (3) the interrelationship between hepatic arterial and portal venous inflow circuits. The relationship between arterial pressure and hepatic arterial blood flow has been analyzed in several species. However, there is disagreement as to whether the hepatic arterial vasculature exhibits autoregulation of blood flow. The term autoregulation is specifically used to describe the non-linearity of the arterial pressure-to-arterial flow relationship and comprises the tendency for local blood flow to remain constant in the face of pressure changes in the arteries that perfuse a given organ. Some studies have revealed evidence of pressure-dependent autoregulation of blood flow in the hepatic arterial bed[11-15]. In denervated dog liver preparations, Hanson and Johnson have shown that a step-wise reduction of hepatic artery pressure from 90 to 30 mmHg was accompanied by a substantial reduction in hepatic artery resistance[15]. Comparably, livers with intact peri-arterial nerve plexi showed a 60% decrease in arterial resistance upon a 63% pressure reduction[11]. Overall, however, the degree of autoregulation is considered small[11] and present in only about 60% of all preparations[15]. The fact that papaverine infusion can abolish hepatic artery dilatation indicates that the observed effects are primarily mediated by myogenic adaptation of the vasculature to changes in transmural pressure[11]. Besides that, a metabolic washout hypothesis is also tenable, where the hepatic artery washes out the endogenous adenosine, thereby completely accounting for autoregulation of the hepatic artery[16].

Less controversy exists concerning pressure-to-flow autoregulation of the portal venous vascular bed. Only a few studies have indicated autoregulation of portal venous blood flow[13], while the majority of studies have revealed a linear pressure-to-flow relationship with constant or increased portal venous resistance at low pressure gradients. In fact, there is even evidence for an opposite effect with (1) a partial passive collapse of the portal vascular bed taking place upon reduction of portal pressure; and (2) a reciprocal decrease in resistance upon a step-wise increase in portal venous pressure[15].

REGULATION OF LIVER BLOOD FLOW BY THE HEPATIC ARTERIAL BUFFER RESPONSE

Besides the intrinsic regulation of the hepatic artery by the classical arterial autoregulation, that is, the myogenic constrictive response of the hepatic artery if the arterial pressure rises, there is a second form of intrinsic regulation, termed the hepatic arterial buffer response (HABR). This unique mechanism represents the ability of the hepatic artery to produce compensatory flow changes in response to changes in portal venous flow. Although Burton-Opitz observed an increase in hepatic arterial blood flow upon reduced portal venous inflow in 1911[17], this intimate relationship between these two vascular systems was termed HABR for the first time in 1981 by Lautt[18]. If portal blood flow is reduced, the hepatic artery dilates, and the hepatic artery constricts, if portal flow is increased[19,20]. Using transit-time ultrasonic volume flowmetry, intraoperative

measurement of the hepatic artery and portal venous flows in anesthetized patients with carcinoma of the splanchnic area has revealed a sharp and significant increase in hepatic arterial flow of about 30% after temporary occlusion of the portal vein, while temporary occlusion of the hepatic artery did not have any significant effect on portal venous circulation[20]. The HABR seems to operate in each individual under physiological conditions regardless of age. In addition, by establishing a method for measuring fetal hepatic arterial blood velocity, it has been reported that HABR even operates prenatally[21].

The increase in hepatic arterial blood flow is capable of buffering 25%-60% of the decreased portal flow[22,23]. The physiological role of this response is to minimize the influence of portal venous flow changes on hepatic clearance and to maintain adequate oxygen supply to tissues[24]. The latter function, however, may be of minor importance, since the liver normally receives more oxygen than it requires, and it can extract more oxygen to compensate for reduced delivery[25]. Thus, metabolic activity of the hepatic parenchymal cells does not directly control the hepatic arterial flow[22,25]. Instead, hepatic arterial flow subserves the hepatic role as a regulator of blood levels of nutrients and hormones by maintaining blood flow and thereby hepatic clearance as steadily as possible[24,26]. Because the portal vein cannot control its blood flow, which is simply the sum of outflows of the extrahepatic splanchnic organs, there is no reciprocity of the HABR, that is, alterations of the hepatic arterial perfusion do not induce compensatory changes of the portal vascular flow[18,20] or resistance[27].

The current view is that the HABR can be accounted for by the adenosine washout hypothesis[23]. This hypothesis states that adenosine is released at a constant rate into fluid in the space of Mall that surrounds the hepatic resistance vessels and portal venules. The space of Mall is contained within a limiting plate that separates this space from other fluid compartments. The concentration of adenosine is regulated by washout into the portal vein and the hepatic artery. If portal blood flow is reduced, less adenosine is washed away from the space of Mall, and the elevation in adenosine levels leads to dilation of the hepatic artery with a subsequent increase in hepatic arterial flow[10].

There are several lines of evidence that adenosine mediates the HABR: (1) adenosine produces hepatic arterial dilation[23]; (2) portal venous application of adenosine exerts one-half to one-third the effect of the same dose infused directly into the hepatic artery, which indicates that portal blood has some access to the arterial resistance vessels[10]; (3) adenosine uptake antagonists potentiate the HABR[23]; and (4) pharmacological antagonists of adenosine produce competitive blockade of the buffer response[16,28-30]. However, it has been suggested that adenosine itself does not diffuse from the portal venous to hepatic arterial bed to elicit the arterial response[31,32]. Rather ATP is released from the portal venous vasculature as a response to hypoxia associated with portal flow reduction, and diffuses into the hepatic arterial vasculature. No difference in the degree of inhibition of HABR by an adenosine antagonist has been observed between intra-arterial and intraportal injection of ATP in a rabbit model. This suggests that only the adenosine produced from ATP catabolism in the hepatic arterial vasculature contributes to arterial dilation. The adenosine produced from ATP in the portal venous vasculature is taken up effectively by the endothelium and vascular smooth muscle cells as soon as it is formed, and it does not diffuse to the hepatic arterial vasculature[30]. Mathie and Alexander have pointed out that adenosine is unlikely to be the sole regulator of HABR[33]. Other vasoactive compounds, such as nitric oxide and carbon monoxide, may be potential candidates to affect hepatic arterial flow and contribute to the HABR. Nitric oxide participates in regulation of hepatic arterial blood flow with changes in portal venous blood flow *via* ATP-dependent stimulation of endothelial purinergic receptors in the hepatic artery, which results in vasodilation[30,34,35]. Although nitric oxide is an important regulator of hepatic arterial resistance[36], it does not mediate the HABR and it is not found to play any significant role in total hepatic capacitance regulation[37].

Although nitric oxide serves as a potent vasodilator in the hepatic arterial circulation and exerts only a minor vasodilatory effect in the portal venous vascular bed, carbon monoxide is reported to maintain portal venous vascular tone in a relaxed state and to exert no vasodilation in the hepatic artery[38]. Recently, a third gaseous mediator, H_2S, has been recognized as an important endogenous vasodilator and neuromodulator[39]. There is now major evidence that H_2S also contributes to the HABR and partly mediates the vasodilatory response of the hepatic artery. This conclusion is based on the fact that supplementation of H_2S increases hepatic arterial conductance and almost doubles the buffer capacity. In turn, inhibition of the H_2S function by application of a selective inhibitor of K_{ATP} channels, which mainly mediate the ability of H_2S to relax vascular smooth muscle cells, markedly decreases buffer capacity[40].

Next to vasoactive mediators, there is evidence that sensory innervation and sensory neuropeptides are, at least to some extent, involved in the HABR. Accordingly, sensory denervated rats[41] and pigs[42] have revealed a reduced HABR upon partial occlusion of the portal vein. Furthermore, pretreatment with antagonists of calcitonin gene-related peptide (CGRP) and neurokinin (NK)-1 receptors significantly reduce the hepatic arterial blood flow, which indicates that the observed vasodilation in the vascular bed of the hepatic artery is due to stimulation of CGRP and NK-1 receptors[41].

IMPLICATIONS OF THE HABR IN LIVER DISEASES

HABR in liver resection, transplantation and laparoscopic surgery

The ability of the liver to regenerate after major resection has been studied extensively, but the factors responsible

for regeneration are not fully understood[43]. Although a clear association between flow and regenerative response has been suggested, the exact role of hepatic blood flow in liver regeneration is still a matter of intense debate. The increased blood flow to liver mass ratio immediately after partial hepatectomy (pHx) and the resultant increased intrahepatic shear stress have been proposed to stimulate and regulate liver regeneration[44-47]. On the other hand, the failure of the liver to control directly the portal venous blood flow has the consequence of portal hyperperfusion of the reduced-size liver (Figure 1A and B), which has been shown to impair seriously postoperative recovery of patients who are undergoing living donor liver transplantation or extended pHx[48,49]. In humans, 60% pHx results in a doubling of the portal flow in the 40% of remnant liver tissue[50]. This extent of pHx is followed by a transient and minor degree of small-for-size syndrome that usually resolves spontaneously within a few days. In contrast, major liver resection (> 75%) is followed by a more pronounced and long lasting small-for-size syndrome with much higher morbidity and mortality[50].

With the increasing practice of living-donor liver transplantation and the enlargement of the resectable limit, the small-for-size syndrome has emerged as an important clinical problem[51]. Although the pathogenetic causes of the small-for-size syndrome are still debated, it is assumed that the syndrome is primarily linked to portal hyperperfusion with high intravascular shear stress[52-54]. As a consequence of portal venous hyperperfusion, however, HABR may lead to hepatic arterial hypoperfusion of reduced-size livers (Figure 1B). In line with this, Smyrniotis *et al*[55] have shown in a porcine study that portal flow to split grafts with a graft-to-recipient liver volume ratio of 2:3 and 1:3 showed an inverse relationship to graft size, for example, the smaller the graft, the higher portal blood flow. By contrast, arterial flow decreased proportionately to graft size. In addition, HABR, which is present in all split-liver transplanted pigs, has been found to be increase as the graft-to-recipient liver volume ratio decreases[55].

A comparable hemodynamic pattern of hepatic blood flow has been observed in living related liver transplantation, in which size disparity between graft and native liver is the rule and almost universal[56]. In patients with living right lobe living donor transplantation, the grafts are subjected to impressive, more than double, increases of portal blood flow (Figure 1A and B). In the absence of active regulation, arterial flow might be expected to double as well. On the contrary, striking decreases in arterial flow have been seen in right lobe grafts[57], which represent the HABR as a reflexive response to changes in portal blood flow, to maintain total blood flow within an acceptable physiological range[58]. Troisi *et al*[59] have reported mean recipient portal venous flow values in small liver grafts (graft-to-recipient body weight ratio < 0.8) at least three times higher than those recorded in donors. Simultaneously, hepatic artery flow is significantly reduced and results in a decreased contribution to the liver from 30% in donors to only 6% in the recipients. In a porcine small-for-size liver transplantation model, the portal-to-arterial flow ratio remains increased until 5 d after surgery, which is poorly tolerated by transplanted livers[60].

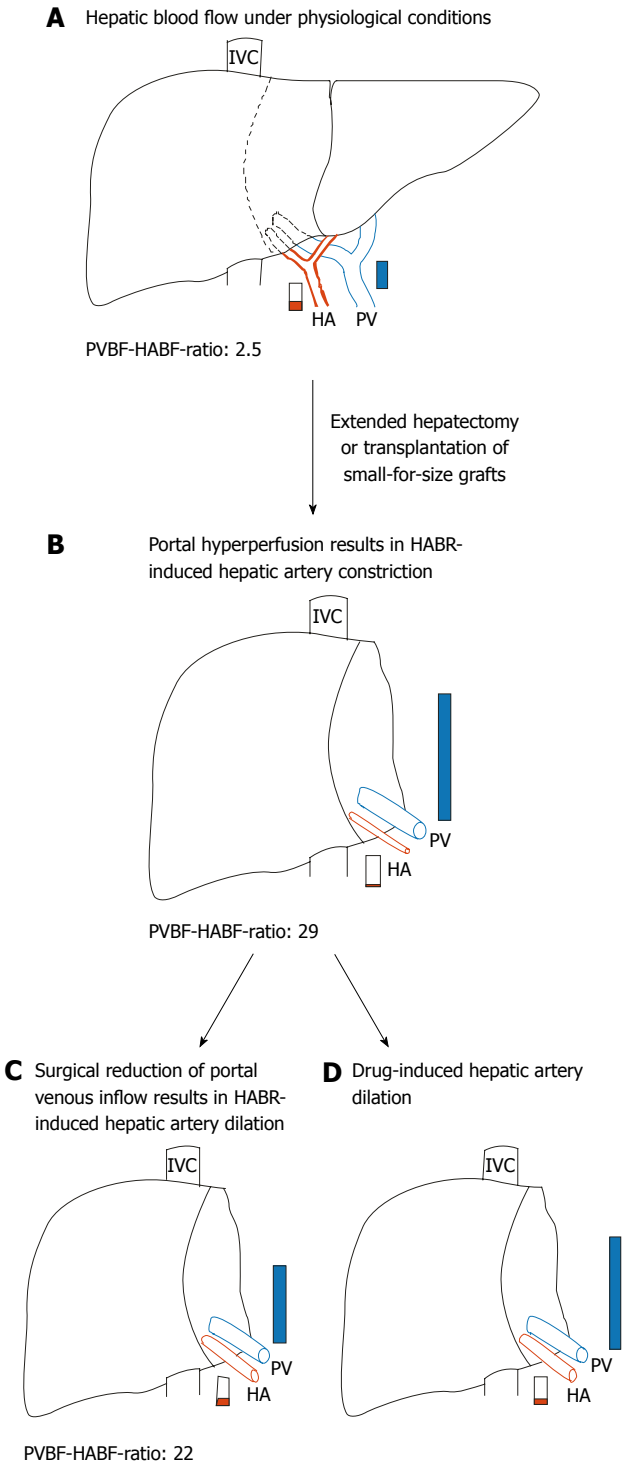

Figure 1 Hepatic hemodynamics in normal and reduced-size livers. A: Preoperative hepatic blood flow in a donor liver or before extended hepatectomy representing a normal portal vein blood flow-hepatic artery blood flow (PVBF/HABF) ratio of 2.5; B: As a consequence of portal hyperperfusion, hepatic arterial buffer response (HABR) leads to hepatic arterial hypoperfusion of reduced-size liver that is characterized by a dramatically increased PVBF/HABF ratio of 29; C: Surgical reduction of the portal venous inflow, for example, by splenectomy or hepatic artery ligation, leads to HABR-induced dilation of the hepatic artery and results in a reduced PVBF/HABF ratio of 22; D: Possible effects of pharmacological interventions to preserve hepatic artery supply. PVBF/HABF ratios are adopted from[59]. HA: Hepatic artery; IVC: Inferior vena cava; PV: Portal vein.

The HABR has been clearly demonstrated to be present also in patients after cadaveric liver transplantation[61]. Measurement of hepatic arterial and portal venous flow using ultrasound transit-time flow probes over the first 3 h after reperfusion has revealed a mean total liver blood flow of 2091 ± 932 mL/min, with a disproportionately high mean portal flow of 1808 ± 929 mL/min, which represents approximately 85% ± 10% of total liver blood flow. Correlation analysis has shown a positive correlation between cardiac output and portal venous flow, and a trend toward negative correlation between cardiac output and hepatic arterial flow[61]. In patients with a 50% reduced portal flow, Henderson and colleagues have reported a significant increase in hepatic artery flow, which indicates an intact HABR after cadaveric liver transplantation[61]. In line with this, Payen *et al*[62], by measuring hepatic arterial and portal venous blood flow during alternative clamping of both vessels every 12 h during 7 d in patients after orthotopic liver transplantation, have reported reciprocal increases of hepatic arterial flow only during selective clamping of the portal vein. By analysis of patients transplanted for liver cirrhosis, a high portal flow was present, together with an early increase of hepatic arterial resistance, which agrees with the HABR theory[63]. The presence of HABR in the transplanted liver is unequivocal[61,62,64], and because of liver denervation, it might be the only active mechanism that regulates liver arterial flow.

The consequences of inadequate hepatic arterial flow range from mild cholestasis to rapidly progressive graft failure[65,66]. In a porcine model of small-for-size syndrome, histological examinations of the grafts consistently confirm hepatic artery vasospasm and its consequences; namely, cholestasis, centrilobular necrosis and biliary ischemia[67]. In severe cases of small-for-size grafts, poor hepatic arterial flow and vasospasm lead to functional de-arterialization, ischemic cholangitis, and parenchymal infarcts[54,68]. Michalopoulos has concluded that the failure to regenerate is not different from the situation in which pHx is accompanied by ligation of the hepatic artery, which also results in failure to regenerate[68].

Prolonged CO_2 pneumoperitoneum in laparoscopic surgery reduces substantially the portal venous flow in humans, and the extent of the flow reduction is related to the level of intraperitoneal pressure[69,70]. HABR may serve for maintenance of total liver blood supply during laparoscopy-associated portal venous flow reduction. However, controversial data exist on the maintenance of HABR during high-pressure pneumoperitoneum. Yokoyama *et al*[71] have reported on activation of HABR in a rat model using fluorescent microspheres to measure splanchnic flow. Although portal venous flow decreased, the hepatic arterial flow was relatively preserved throughout all levels of intraperitoneal pressure studied. In contrast, Richter *et al*[72] have used ultrasonic flow probes in a rat model, and have shown reduced portal venous flow paralleled by a linear reduction of hepatic arterial flow during CO_2-pneumoperitoneum. HABR is also markedly impaired in cirrhotic rats undergoing CO_2 pneumoperitoneum[73]. Studies in large animals have revealed intact HABR with doubled hepatic arterial flow in neonatal lambs during abdominal distension[74], as well as loss of HABR with reduced hepatic arterial flow in pigs[75], or unchanged hepatic arterial flow in dogs upon CO_2 pneumoperitoneum[76]. In particular, head up body position leads to reduction in portal venous and arterial hepatic blood flow during elevated abdominal pressure[77]. Thus, head up position and intraperitoneal pressure elevation above 15 mmHg should be avoided during laparoscopic surgery to preserve hepatic blood flow[77,78].

HABR in inflammatory liver diseases

Owing to the scarcity of clinical studies on this subject, one must turn to experimental data, with reservations concerning their extrapolation to humans. In models of continuous intravenous infusion of *Escherichia coli* in rats, portal venous flow was reduced, and increased hepatic arterial flow resulted in unchanged total hepatic blood flow[79,80]. The increased hepatic arterial flow could be a result of an active HABR, although, in parallel, reports exist to demonstrate an increased hepatic artery flow without a reduction in portal venous flow during endotoxemia[81-83]. In a porcine model, it has been shown that endotoxin shock leads to time-dependent impairment of liver inflow beds, which results in increased portal venous back pressure and incremental resistance. The hepatic artery bed is dilated in the early phase of endotoxic shock but, over time, it is constricted[84]. There is ongoing discussion as to whether excessive production of nitric oxide is the cause of the endotoxin-induced alterations in hemodynamic homeostasis. While nitric oxide induces arterial hypotension and hepatic arterial vasodilation during endotoxic shock[85], ablation of the HABR has been shown to be independent of nitric oxide or an α-adrenergic-receptor agonist[84]. On the contrary, early administration of the nitric oxide donor sodium nitroprusside can reverse the negative effects on hepatic arterial flow induced by endotoxin[86,87]. Moreover, sodium nitroprusside partially reverses the detrimental effect of the nitric oxide synthase inhibitor L-NAME in experimental endotoxemia, which implies that the endotoxin-induced dysfunction of the HABR may be due to a selective inhibition of vascular endothelial function[87]. Furthermore, nitroprusside maintains mRNA levels of constitutive nitric oxide synthase in liver tissue that are decreased by endotoxin shock and tempers the burst in inducible nitric oxide synthase expression, thereby reestablishing the autoregulatory response of the hepatic artery following reduction of portal venous blood flow[86].

In turn, application of the vasopressin analog terlipressin during long-term hyperdynamic porcine endotoxemia significantly decreases portal venous flow, whereas hepatic arterial flow is markedly increased, which presumably reflects a restored HABR[88]. Furthermore, terlipressin attenuates the endotoxin-induced increase in exhaled nitric oxide[88], which points to the interaction between the vasopressin and the nitric oxide system in septic shock[89].

Almost no data exist on hepatic hemodynamics during conditions of acute or chronic viral hepatitis[90]. In addition, only a few studies have addressed hepatic hemodynamics under low-flow conditions, such as hemorrhagic shock. However, the data so far are consistent in that HABR is not abolished during sustained low abdominal blood flow[91-93]. In critically ill patients, mechanical ventilation has been found to decrease splanchnic perfusion. However, importantly, HABR is preserved and increased hepatic arterial blood flow compensates the decrease in portal blood flow under conditions of ventilation-associated positive end-expiratory pressure[94].

HABR in liver fibrosis and cirrhosis

The pathogenesis of liver fibrosis and cirrhosis is characterized by initial hepatocyte necrosis and inflammatory response, with subsequent activation of hepatic stellate cells and their transformation into myofibroblasts, which is responsible for excessive extracellular matrix synthesis and deposition. As a consequence, distinct alterations of the hepatic microvasculature, that is, rarefaction of sinusoids and structural changes of sinusoidal endothelia[95,96], result in deteriorated nutritive blood supply, increased total hepatic vascular resistance, and hence, portal hypertension and portosystemic collateralization[97]. Due to this increase in sinusoidal resistance, the capillarization of the hepatic microvasculature and the development of portocaval collaterals[98], portal venous blood flow progressively decreases in patients with cirrhosis[99,100]. An increase of hepatic arterial blood flow, that is, a decrease of hepatic arterial resistance, if it occurs, would indicate an activated HABR.

Studies in cirrhotic rats have underlined this hypothesis by demonstrating that, under baseline conditions, cirrhotic animals have higher hepatic arterial blood flow compared to controls[101]. Moreover, induction of HABR by a stepwise reduction of portal venous inflow causes a disproportionate increase in hepatic arterial flow in cirrhosis, which is further reflected by the significantly higher buffer capacity[101,102].

Although this concept has been well established, analyses in cirrhotic patients have produced conflicting results. Several studies have shown an increased hepatic arterial resistance in patients with cirrhosis. This is related to the degree of portal hypertension[103,104], portal resistance[104,105] and Child-Pugh score[104]. In contrast to these observations, a considerable body of evidence exists to indicate that, in cirrhosis, hepatic arterial vasodilatation occurs in response to reduced portal venous blood flow[106-109]. Accordingly, intraoperative measurements in patients with end-stage liver cirrhosis, who underwent living-donor liver transplantation, have revealed a continuously activated HABR under baseline conditions[109]. In these cirrhotic patients, the reduced portal venous blood flow is associated with an increased hepatic arterial blood flow (hepatic arterial to portal venous flow ratio = 0.88), which is in contrast to the relationship in healthy volunteers (hepatic arterial to portal venous flow ratio = 0.58)[109]. However, total clamping of the portal vein provokes a blunted response, as evaluated by the absolute and relative changes in hepatic arterial blood flow and by the buffer capacity[109]. In line with this, Iwao *et al*[110] have reported that the hepatic artery buffer index is significantly lower in cirrhotic than in control subjects. They have analyzed portal venous blood flow and hepatic artery pulsatility index as measures of hepatic artery resistance upon a 500-kcal mixed liquid meal consumption, which increases portal venous blood flow. They found an increase in hepatic artery resistance in all subjects, however, it was less pronounced in cirrhotic than control subjects[110,111]. Vice versa, the vasopressin-induced decrease of portal venous blood flow was met by a fall in hepatic arterial pulsatility index, which again was significantly lower in cirrhotic than control subjects[110]. In a large series of patients with advanced cirrhosis, who are undergoing transjugular intrahepatic portosystemic shunt (TIPS), Gülberg *et al*[108] have demonstrated that patients with hepatofugal blood flow show significantly lower resistance index before TIPS placement than patients with antegrade portal flow direction, and TIPS placement induces a significant decrease in the resistance index in patients with hepatopedal flow, but not in patients with hepatofugal flow. The fact that some degree of HABR is preserved even in patients with advanced cirrhosis and significant portal hypertension may further underline the biological need for this intrinsic mechanism. Although one might argue that the drop in resistance and thus increase in hepatic arterial flow may not fully compensate for the TIPS-induced reduction in portal blood flow, it has been shown that hepatic arterial vasodilatation provides substantial functional benefit in patients with cirrhosis, and that this effect does not depend directly on hepatic arterial microperfusion and is observed preferentially in patients with decompensated disease[107]. Thus, it is reasonable to state that the change in the ratio of portal venous to hepatic arterial blood flow in favor of the hepatic artery may sustain oxygen delivery and exert a protective effect on organ function and integrity. In line with this, portal vein occlusion does not cause deterioration in hepatic tissue pO_2 in the presence of HABR, although maximum buffer capacity of the hepatic artery was limited to 50%-60% in both cirrhosis and control animals, and total liver blood flow was found to be restored to only 71%-76% of baseline values[102].

MODIFICATIONS OF THE HABR

Surgical interventions for modification of the HABR

With the development of partial liver transplantation, either as living donation or as deceased donor split graft, much effort has been spent on improvement of surgical techniques. Full-right full-left splitting for two adult recipients is associated with risk of small-for-size syndrome, which manifests as a pattern of liver dysfunction associated with portal hypertension, diminished arterial flow,

delayed synthetic function, and prolonged cholestasis[112-115]. However, the present rates of splitting livers are too low in comparison with the calculated potential and it is to be expected that further improvement in the management of small-for-size grafts would bring splitting of the liver for two adult recipients within the reach of broad application[112]. Small-for-size syndrome is a clinical problem that is also observed after living donor liver transplantation and extended hepatectomy[52,116]. When the full portal vein flow has to transverse through a much reduced liver size, then the pressure building up in the portal vein effectively shuts down the flow through the hepatic arterioles and the liver becomes de-arterialized[68]. Arterial flow impairment appears as result of an active HABR, although in the past, reduced hepatic arterial flow has repeatedly been ascribed to the splenic artery steal syndrome[117-120]. This phenomenon describes the impaired hepatic artery flow by shifting of the main blood flow to the splenic or gastroduodenal artery in patients with hypersplenism. Quintini *et al*[121] have analyzed whole-organ liver recipients by Doppler ultrasonography, and have reported that hepatic artery vasoconstriction in response to portal hyperperfusion and exaggerated HABR produces a high resistive index with poor arterial perfusion. In all patients, splenic artery embolization reduces the resistance to distal hepatic artery flow by reducing flow in the splenic circulation and consequently in the portal vein. This has prompted the authors to revise the name of splenic artery steal syndrome to splenic artery syndrome, thereby underlining that the cause is portal hyperperfusion and not arterial siphon[121]. Most recently, a retrospective analysis of 650 orthotopic liver transplantations has revealed an incidence of 5.1% for splenic artery syndrome[122], which is well within the range of the estimated incidence of artery splenic syndrome of 3.1%-11.5% after orthotopic liver transplantation[117,118,123,124]. Prophylactic treatment with ligation of the splenic artery for all patients at risk for development of splenic artery syndrome is recommended and effectively prevents splenic artery syndrome[122]. In the case of postoperative diagnosis of splenic artery syndrome, coil embolization of the splenic artery can be recommended as the treatment of choice, with a low risk profile[122].

Clinical features of small-for-size syndrome are neither specific nor inevitable in low-weight livers, and many other factors than actual liver weight contribute to their occurrence. Among these, early elevation of portal venous pressure and persistent portal overperfusion most probably play a key role[48,49,125-128]. A reduction in the portal venous flow by means of splenic artery ligation, splenic artery embolization, or splenectomy has been shown to be efficient also in case of the small-for-size syndrome[48,59,127,129]. A case report by Lo *et al*[51] and prospective studies by Troisi *et al*[130] and Umeda *et al*[131] have shown that modulation of the recipient portal inflow by ligation or embolization of the splenic artery leads to an increase in recipient hepatic arterial inflow (Figure 1C), with improved liver function. The fact that splenic artery syndrome and small-for-size syndrome can be successfully

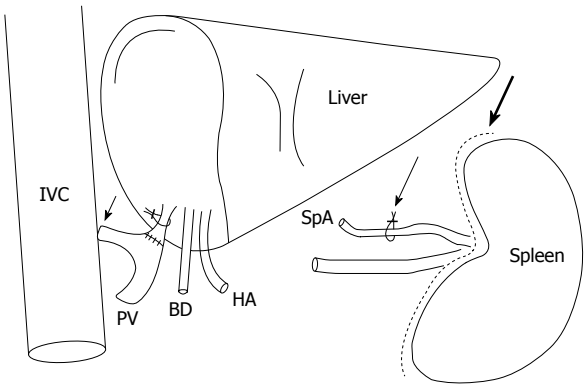

Figure 2 Surgical interventions for modulation of the hepatic inflow, showing the portocaval shunt (short arrow), ligation of the splenic artery (thin long arrow) and splenectomy (thick long arrow). BD: Bile duct; HA: Hepatic artery; IVC: Inferior vena cava; PV: Portal vein; SpA: Splenic artery.

treated by coil embolization of the splenic artery strongly underlines that both syndromes are pathophysiologically linked to the HABR. In line with this, detailed histopathological examination of sequential post-transplant biopsies and failed allografts with clinicopathological correlation has revealed that portal hyperperfusion, venous pathology, and the arterial buffer response make an important contribution to early and late clinical and histopathological manifestations of small-for-size syndrome[54]. In the most recent study of our group, we observed significantly increased survival of simultaneously splenectomized and hepatectomized rats compared to animals with 90% pHx alone[132]. It has been suggested that this effect is mainly caused by suppression of intrahepatic flow and less sinusoidal shear stress[49,55,133]. However, reduction of total hepatic inflow in simultaneously splenectomized and hepatectomized animals was marginal and not as pronounced as that required to improve survival by reduced shear stress. Instead, splenectomy before pHx caused a doubling of hepatic tissue pO_2 due to a HABR-induced rise of hepatic blood flow during extended pHx, which led to high tissue pO_2 values and reduced hypoxic stress. Supposedly, the increase of arterial inflow covers the oxygen demand and thereby improves organ regeneration and animal survival. Thus, improved arterial inflow rather than reduction of portal venous hyperperfusion is of great significance for the beneficial effect after inflow modulation in small-for-size livers[132].

Besides splenic artery ligation, established techniques such as portocaval or mesocaval shunts (Figure 2) may cause not only reduction of portal hyperperfusion, but also an increase of hepatic arterial inflow by reversion of the HABR (Figure 1C)[130,134-136].

In conclusion, the intraoperative measurement of both hepatic blood flows is important to predict the risk of small-for-size syndrome. The better ability to regulate finely the hepatic inflows would be useful in the treatment of liver dysfunction in settings of small-for-size transplantation, as well as extended hepatectomy, and necessitates further studies.

Pharmacological modifications of the HABR

The responsiveness of the hepatic artery to changes in portal flow is undoubtedly a desirable homeostatic mechanism under most circumstances, that is, the increase of hepatic arterial blood flow in case of reduced portal venous inflow. In contrast, the opposite situation, in which the dramatic excess of portal flow due to a smaller-than-average organ causes hepatic arterial constriction and hypoperfusion, might harm the liver (Figure 1A and B). Both extended hepatectomy and split-liver transplantation by fashioning two transplantable grafts from one liver result in small-for-size livers[50,116,137]. The regenerating liver requires an enormous amount of oxygen for its increased metabolic load and for DNA synthesis[138,139]. Suboptimal arterial inflow may be poorly tolerated in the reduced-size liver and increase the risk of organ dysfunction[60,68,138]. Possible pharmacological interventions could aim to enhance the hepatic arterial supply (Figure 1D). In line with this, in a porcine model of small-for-size syndrome, hepatic arterial infusion of adenosine significantly restored hepatic artery flow, reversed pathological changes in the graft, and finally improved survival[67]. In addition, an imbalance of vasorelaxing and vasoconstricting mediators is considered to be an important pathogenetic feature in reduced-size livers[140]. Maintenance of endothelin-1/nitric oxide balance by blocking endothelin A receptor reduces small-for-size injury by protecting the liver microcirculation and reducing hepatocellular damage[140]. Vice versa, substitution of nitric oxide has been shown to counteract the decline in hepatic arterial inflow in rats with 85% hepatectomy and cause a significantly greater increase in cell proliferation, with improvement of liver function[141].

Several programs in Japan have started clinical trials to reduce injury in small-for-size grafts by direct infusion of drugs such as prostaglandin E_1 and proteolytic enzyme inhibitors into the portal flow[126,142]. However, further experimental studies, including intraoperative measurement of both hepatic blood inflows, are warranted to clarify the precise strategies of pharmacological interventions and to select the appropriate drugs.

CONCLUSION

The crucial importance of the HABR as a regulatory mechanism to maintain adequate liver function and metabolic homeostasis has been recognized. Now, establishment of measures to modulate altered hemodynamics in small-for-size livers, as well as in cirrhotic and critically ill patients, warrants increased attention. Every effort for a timely diagnosis of altered or impaired HABR should be made in order to treat potential ensuing problems. Pharmacological and surgical interventions, which may be applied most easily, have to be proven in larger randomized clinical trials in order to improve the outcome of patients with liver disease with altered hepatic hemodynamics.

Abstract

Ischemia/reperfusion (I/R) injury still represents an important cause of morbidity following hepatic surgery and limits the use of marginal livers in hepatic transplantation. Transient blood flow interruption followed by reperfusion protects tissues against damage induced by subsequent I/R. This process known as ischemic preconditioning (IP) depends upon intrinsic cytoprotective systems whose activation can inhibit the progression of irreversible tissue damage. Compared to other organs, liver IP has additional features as it reduces inflammation and promotes hepatic regeneration. Our present understanding of the molecular mechanisms involved in liver IP is still largely incomplete. Experimental studies have shown that the protective effects of liver IP are triggered by the release of adenosine and nitric oxide and the subsequent activation of signal networks involving protein kinases such as phosphatidylinositol 3-kinase, protein kinase C δ/ε and p38 MAP kinase, and transcription factors such as signal transducer and activator of transcription 3, nuclear factor-κB and hypoxia-inducible factor 1. This article offers an overview of the molecular events underlying the preconditioning effects in the liver and points to the possibility of developing pharmacological approaches aimed at activating the intrinsic protective systems in patients undergoing liver surgery.

INTRODUCTION

The understanding of the proteomic features associated with cell response to stresses is one of the present-day challenges in medical science. This knowledge is increasingly necessary to identify new molecular targets for therapeutic interventions. A turning-point on this matter has been the discovery that tissues already possess a number of inducible systems able to make them more resistant to a wide array of injuries. One of these adaptive responses is represented by the capacity of a non-lethal ischemia to modulate cell functions by increasing resistance to subsequent lethal ischemia/reperfusion[1,2]. Since its first description in the myocardium[1], this phenomenon, termed "ischemic preconditioning" (IP), has been the subject of

rising interest in the scientific and medical communities. The effects of IP can be differentiated into early effects and late effects. The former, immediately follows the transient ischemia and involves the direct modulation of specific cell functions, while late effects are evident within 12-24 h from the transient ischemia and require the simultaneous activation of multiple stress-responsive genes associated with the synthesis of several proteins[2,3].

ISCHEMIA-REPERFUSION INJURY OF THE LIVER

Hepatic ischemia/reperfusion (I/R) injury occurs as a consequence of trauma and hemorrhagic shock as well as temporary clamping of the hepato-duodenal ligament during liver resection (Pringle manoeuvre).

I/R is the main factor responsible for primary graft non-function or malfunction following liver transplantation[3,4]. Even moderate reperfusion damage, which does not severely affect the graft, can impair long-term hepatic recovery and enhance patient susceptibility to infections and multiple organ failure[3,4]. The shortage of organs for liver transplantation, forces consideration of cadaveric and steatotic grafts (marginal grafts) which have a higher susceptibility to I/R injury[4]. Living donor liver transplantation (LDTL) is a promising alternative approach aimed at increasing the number of donor livers[5]. A major concern over the application of LDTL in adults is graft size disparity which is responsible for the appearance of the life threatening effects of the "small for size syndrome"[6]. "Small for size syndrome" can occur even when the critical mass for safe LDTL (40% of standard liver volume) is transplanted and this effect is related to the impaired regeneration of the reduced liver mass[7] induced by I/R[7,8].

LIVER ISCHEMIC PRECONDITIONING

Beside the heart, IP effects have been demonstrated in many other tissues[2,3]. Studies performed in rats and mice, showed that interruption of liver blood supply for 5-10 min followed by 10-15 min of reperfusion reduced hepatic injury during a subsequent extended period of ischemia followed by reperfusion[9-13]. These beneficial effects were particularly evident in fatty livers in which preconditioning almost halved transaminase release and histological evidence of necrosis[11]. The application of preconditioning protocols to rodent liver transplantations showed that IP applied before cold preservation, decreased transaminase release and sinusoidal endothelial cell killing in the graft, improving rat survival[12,13].

A further feature of hepatic IP was the capacity to promote hepatocyte regeneration. Hepatocyte proliferation in rats subjected to 70% hepatectomy is significantly reduced by 45 min of hepatic ischemia. Such an effect was entirely reverted by pre-exposure to IP[14]. Consistently, preconditioning procedures significantly enhanced liver regeneration in the experimental model of reduced-size rat liver transplantation[15,16].

MOLECULAR SIGNALS OF HEPATIC ISCHEMIC PRECONDITIONING

Despite a significant number of studies on liver preconditioning, knowledge on the mechanisms responsible for the induction of the "preconditioned" phenotype is still incomplete. Studies from our and other laboratories have indicated that the process of preconditioning implies the production of complex proteomic modifications within liver cells which are now beginning to be characterized.

Adenosine, adenosine triphosphate and nitric oxide as molecular inducers of hepatic preconditioning

"*In vivo*" and "*in vitro*" studies have clearly established that the onset of IP is triggered by the production of adenosine and by the subsequent stimulation of adenosine A2a receptor (A2aR)[9,17-21]. In particular, Peralta *et al*[9,17] showed that adenosine treatment reproduced the protective action of IP and that IP was reverted by adenosine deaminase and by the adenosine A2 receptor antagonist, 3,7-dimethyl-1-propargylxanthine. Pretreatment of rats with the adenosine A2 receptor agonist, CGS21680, but not with the adenosine A1 receptor agonist, *N*-phenylisopropyl adenosine, enhanced tolerance against IR damage[18]. By using primary rat hepatocytes preconditioned with 10 min of hypoxia plus 10 min of re-oxygenation, we confirmed that the extracellular release of adenosine induced hepatocyte protection by autocrine stimulation of the A2aR[20,21] (Figure 1). Indeed, studies in extra-hepatic and hepatic tissues have clearly shown that transient oxygen deprivation triggers the release of several metabolites including adenosine triphosphate (ATP)[2]. In the extracellular space, ATP is rapidly metabolized to adenosine *via* CD39 and CD73 ecto-nucleotidases[22,23] present on the extracellular portion of cell plasma membranes. In particular, ectoapyrase (CD39) converts ATP to adenosine monophosphate (AMP), while ecto-5'-nucleotidase (CD73) further degrades it to adenosine[24]. Thus, CD73 represents the major extracellular pathway for adenosine generation. Consistently targeted gene deletion or pharmacologic inhibition of CD73 was demonstrated to abolish hepatic protection by IP[19].

Recent observations from our group also suggested that ATP itself could act as an additional trigger of liver preconditioning. We observed that the release of ATP from hepatocytes enhanced their tolerance to hypoxia independently from the generation of adenosine[24] (Figure 1). Such an effect was mimicked by treatment with the non-hydrolyzable ATP analogue adenosine-5'-O-(3-thiotriphosphate) (ATPγS) and involved the stimulation of the P2Y2 purinergic receptor[25].

Further evidence indicated that during IP, hepatic endothelial cells responded to adenosine stimulation by generating nitric oxide (NO) which contributed to the modulation of hepatocyte tolerance to I/R[3,17,26-28]. Indeed, the administration of NO donors promoted tolerance to I/R in the absence of adenosine, while NO synthase inhibitors reverted IP[17,26]. Similarly, the treatment of primary

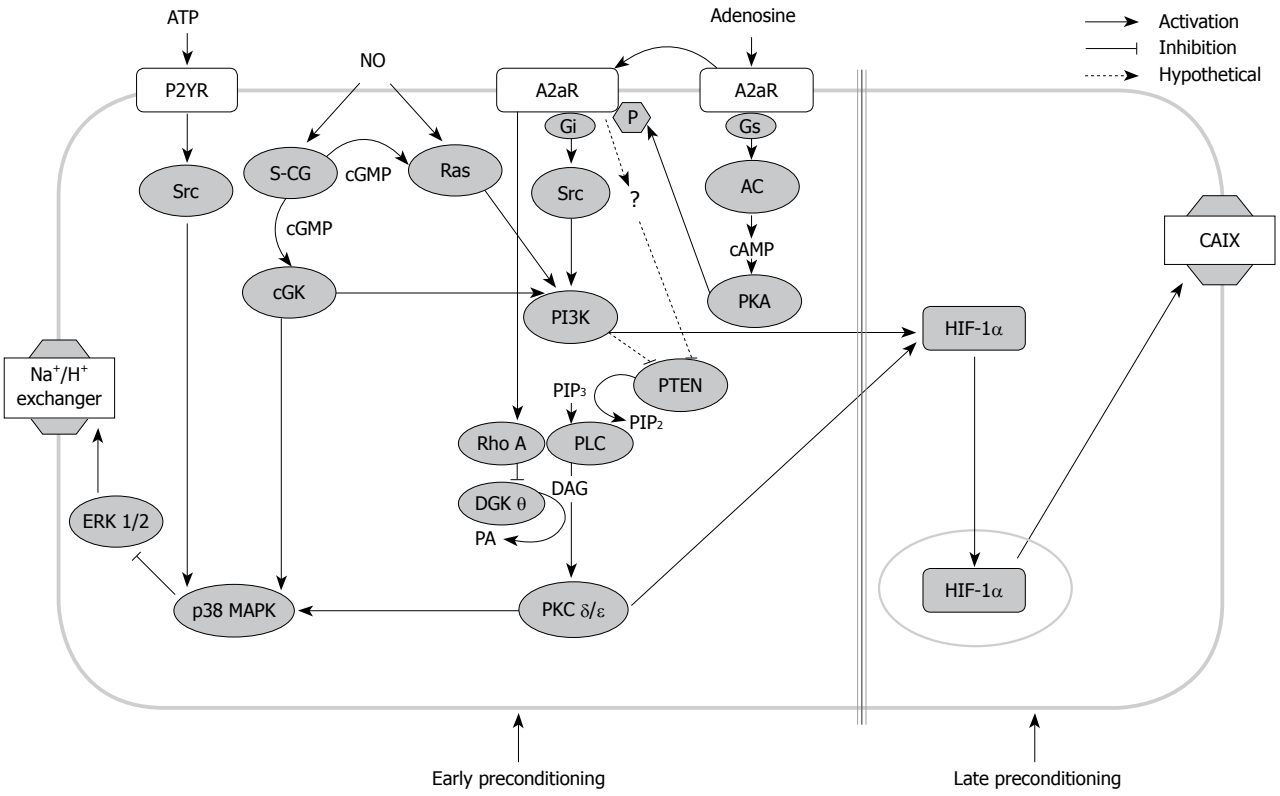

Figure 1 Signalling pathways involved in the development of ischemic preconditioning in rat hepatocytes. Adenosine triphosphate (ATP), adenosine and nitric oxide (NO) act as inductors of hepatocyte preconditioning by modulating a network of constitutive and newly synthesized signal mediators. Some of these mediators play a common central role in hepatocyte cytoprotection. p38 MAP kinase (p38 MAPK) is a mediator of the cytoprotective effects of all three preconditioning stimuli. Phosphatidylinositol 3-kinase (PI3K) mediates both adenosine and NO early resistance to hypoxia. PI3K together with protein kinase C (PKC) δ and ε, also induces hepatocyte late resistance to hypoxia contributing to the normoxic activation of hypoxia-inducible factor 1 (HIF-1). Diacylglycerol kinase theta (DGKθ) and the phosphatase tensin-homologues-deleted from chromosome 10 (PTEN) which metabolize diacyglycerol and phosphatidylinositol, respectively, are inhibited during preconditioning to sustain activation of the diacylglycerol (DAG)-dependent PKC δ and ε and the PI3K-dependent signals. See text and Refs[21,25,27,28,32,35,37,43]. P2YR: Purinergic P2Y receptors; A2aR: Adenosine 2A receptors; S-CG: Soluble guanylate cyclase; cGMP: Cyclic guanosine monophosphate; cGK: cGMP-dependent kinase; AC: Adenylate cyclase; cAMP: Cyclic adenosine monophosphate; PIP3: Phosphatidylinositol-3-phosphate; PKA: Protein kinase A; CAIX: Carbonic anhydrase IX; PLC: Phospholipase C; PA: Phosphatidic acid.

rat hepatocytes with the NO donor (Z)-1-{N-methyl-N-[6-(N-methyl-ammonio-hexyl) amino]} diazen-1-ium-1,2-diolate (NOC-9) reproduced hepatocyte resistance to hypoxic damage induced by IP, ATP or A2aR stimulation[27,28], suggesting that NO could act as an independent mediator of hepatic preconditioning[26].

Signalling pathways involved in adenosine and ATP-induced hepatoprotection

Using preconditioned rat hepatocytes, we observed that A2aR stimulation activated a cascade of intracellular signals involving Gi protein, phospholipase C (PLC), the novel isoforms of protein kinase C (PKC) δ and ε and p38 MAP kinase (p38 MAPK)[21] (Figure 1). The effective contribution of p38 MAPK in liver IP signalling was confirmed *in vivo* in mice where increased p38 MAPK phosphorylation was associated with tolerance against reperfusion injury[29]. Moreover, p38 MAPK inhibitors abolished resistance to I/R injury both "*in vitro*" and "*in vivo*"[21,30].

A2aRs are known to be typically coupled to Gs proteins that through adenylate-cyclase (A-C) stimulate protein kinase A (PKA)[31]. However, in an early study we excluded the involvement of PKA in mediating IP, as PKA pharmacological activation was devoid of protective action[21]. Subsequent research clarified this discrepancy, as we observed that A2aRs were actually coupled with Gs proteins and PKA[32]. PKA, however, by phosphorylating A2aR, shifted A2aR coupling from Gs proteins to Gi proteins and this led to the recruitment of the PLC-PKC pathway[32] (Figure 1). Interestingly, PKA phosphorylated A2aR only in the presence of its ligand (adenosine) and this explained why direct PKA activation in the absence of adenosine lacked protective activity[21,32] (Figure 1). The same research also highlighted the critical role of phosphatidylinositol-3-kinase (PI3K) in hepatic IP[32]. PI3Ks are a family of intracellular signal transducers that generate phosphatidylinositol (3,4,5)-triphosphate (PIP3), a second messenger that plays a central role in the regulation of cell proliferation, survival and metabolism[33]. In preconditioned hepatocytes, PI3K was activated upon A2aR engagement through Gi protein and Src kinase stimulation[32]. PI3K was shown to contribute to IP by promoting the activation of PLC and of PKC δ and ε (Figure 1)[32]. It is well known, however, that downstream of PI3K, protein kinase B (PKB/AKT) is a key modulator of a variety of pro-survival and pro-regenerative signals[33]. Thus, the PI3K-PKB/AKT pathway likely

represents an important pathway in the development of liver IP. Interestingly, PKB/AKT activation in connection with the development of tolerance to I/R was evident in rat hepatocytes and mouse livers[32,34] undergoing IP, as well as in preconditioned human liver grafts immediately after transplantation[35].

At present, the intracellular signals involved in ATP-dependent preconditioning are less well characterized. We reported that ATP-mediated activation of P2Y receptors was coupled with the phosphorylation of Src tyrosine kinase and of p38 MAP kinase that, in turn, inhibited the activation of ERK 1/2 consequent to hypoxic stress[25] (Figure 1).

Constitutive mediators of nitric oxide-induced cytoprotection

The signalling pathways responsible for the cytoprotective action of NO were investigated in rat hepatocytes treated with the NO donor, NOC-9, and then exposed to hypoxia. NOC-9-induced protection involved two parallel pathways. In one pathway, NO stimulated Ras GTPase, and in the other, NO directly activated the soluble guanylate cyclase (sGC) that by producing cyclic guanosine monophosphate (cGMP), stimulated the cGMP-dependent kinase (cGK) that also contributed to Ras GTPase activation[27,28]. Both the Ras and the cGK pathways then converged on the activation of PI3K, while only the sGC-cGK pathway was responsible for activating p38 MAPK (Figure 1)[27,28].

Negative regulators of liver preconditioning

It is increasingly clear that the development of hepatic IP requires the activation of a complex network of signals comprising cell-surface receptors, redox signals and a diverse array of protein kinases including PKCδ and PKCε. In preconditioned hepatocytes, the membrane recruitment and activation of PKCδ and PKCε was fully dependent on their direct interaction with diacylglycerol, generated by adenosine-induced activation of PLC-γ and diacylglycerol analogues which fully mimicked the activation of the signals that induce IP[3,21]. However, it is now clear that the accumulation of cellular diacylglycerol also depends on the rate of its metabolism to phosphatidic acid by diacylglycerol kinases (DGKs)[36]. In this regard, we recently observed that following IP or A2aR activation, the onset of hepatocyte tolerance to hypoxia was associated with a decrease in DGK activity[37]. Moreover, stimulation of A2aR specifically inhibited DGK isoform θ by activating RhoA-GTPase[37]. The pharmacological inhibition of DGKs has consistently led to a diacylglycerol-dependent activation of PKC δ/ε and of p38 MAPK. Moreover, both genetic and pharmacological inhibition of DGK θ induced cell tolerance to hypoxia[37]. Altogether these results unveiled a novel mechanism in the onset of hepatocyte preconditioning and demonstrated that the down-regulation of antagonist enzymes such as DGK was essential to obtain the diacylglycerol accumulation required to trigger PKC-mediated survival signals.

Similarly, preliminary data indicated that in parallel with the activation of PI3K, A2aR stimulation reduced the intracellular levels of the dual protein/lipid phosphatase tensin-homologues-deleted from chromosome 10 (PTEN) that inhibits PI3K-mediated signals by degrading phosphatidylinositol (3,4,5)-triphosphate[33]. We observed that PTEN inhibitors mimicked the induction of preconditioning (Cescon *et al*[35] unpublished results), while PKB/AKT activation and the clinical efficacy of IP in preconditioned human liver were fully explicated only in the presence of significant PTEN down-regulation.

Altogether these results demonstrated the importance of the down-modulation of key inhibitory enzymes for full activation of preconditioning responses. Moreover, these observations indicated the possible use of inhibitors of DGKs or PTEN as pharmacological inducers of hepatic preconditioning.

Nuclear transcription factors in liver preconditioning

As previously mentioned, the late effects of IP require the transcription of different stress-responsive genes and protein synthesis[2,3]. Growing evidence indicates that these responses are achieved by the coordinated activation of several transcription factors.

Nuclear factor-κB: Nuclear factor-κB (NF-κB) is typically devoted to the regulation of genes involved in inflammatory response and cell survival[38]. In experimental models of liver I/R, IP modifies NF-κB activity in different ways[29,39]. In one study, IP decreased NF-κB activity 1 h after reperfusion[39], and in another study, IP activated NF-κB during the ischemic period[29]. These contrasting results could be due to predominant NF-κB modulation in non-parenchymal *vs* parenchymal cells or to a differential regulation of NF-κB in the different phases of liver preconditioning. In addition, the NF-κB decrease during reperfusion was strictly related to a reduction in inflammatory cytokine expression[39], indicating a down-regulation of pro-inflammatory responses in Kupffer/sinusoidal endothelial cells. Conversely, NF-κB activation during ischemia was associated with the hepatoprotective action of IP[29], suggesting that, in hepatocytes, NF-κB-dependent genes contributed to survival responses.

Signal transducer and activator of transcription: The signal transducer and activator of transcription (STAT) transcription factors are a group of proteins implicated in the control of cell proliferation and survival processes[40]. IP induced the activation of the interleukin (IL)-6/STAT3 axis in liver and this pathway was involved in both cytoprotection and hepatic regeneration. On the one hand, as a result of hepatic preconditioning, NF-κB was shown to stimulate the expression of IL-6 and STAT3 that, in turn controlled cyclin beta1 synthesis and cell cycle progression[29]. On the other hand, studies with IL-6 null mice showed that the cytoprotective effects of IP against I/R injury depended on IL-6 signalling and were associated with hepatic STAT3 activation[41].

Hypoxia-inducible factor 1: Hypoxia-inducible factor 1

(HIF-1) is the main regulator of tissue adaptation to oxygen deprivation[42]. Active HIF-1 is a heterodimer consisting of an inducible HIF-1α subunit and a constitutively expressed HIF-1β subunit. HIF-1α is extremely labile in normoxia, as it is continuously degraded in proteasomes following hydroxylation, catalyzed by the oxygen-dependent HIF-prolyl-4-hydroxylase and arginyl-hydroxylase[42]. The lowering of intracellular oxygen prevents HIF-1α hydroxylation allowing its nuclear translocation and binding to hypoxic response elements of a number of genes regulating erythropoiesis, angiogenesis, glucose transport, glycolysis and cell survival[42]. Using preconditioned hepatocytes, we showed that HIF-1 activation was associated with the induction of a long lasting tolerance to hypoxic injury[43]. Furthermore, Amador and co-workers reported an increase in HIF-1α in concomitance with a lowering of hepatocyte apoptosis in human transplanted livers exposed to IP[44]. HIF-1 activation by IP was not due to the transient hypoxia occurring during the induction of preconditioning, but required A2aR activation[43]. This implicated an oxygen-independent mechanism in the regulation of HIF-1. Indeed, several reports demonstrated that a number of non-hypoxic stimuli (i.e. growth factors, cytokines, hormones and endotoxins) can activate HIF-1 in an oxygen-independent manner[45]. This process implies a PI3K- and PKC-dependent increase in the translation of HIF-1α mRNA, a process that shifts the synthesis/degradation balance towards HIF-1α accumulation[46]. We found that in hepatocytes, adenosine-dependent HIF-1 activation required the stimulation of both PI3K and PKC pathways[43]. This indicated that preconditioning stimuli, acting through the same survival pathways, could contextually lead to the early and late phase of response against cell injury.

Changes in the pattern of protein expression following liver preconditioning

Information concerning the genes modulated in response to liver IP is still limited. In accordance with the role of NO production as a trigger of IP, increased nitric oxide synthase expression was detected in preconditioned rat liver[47]. Microarray analysis of preconditioned human liver confirmed a significant increase in the amount of inducible nitric oxide synthase and also showed an increase in the anti-apoptotic protein, Bcl-2[48]. These analyses also showed that IL-1 receptor antagonist (IL-1Ra) was the most over-expressed gene in human preconditioned livers[48], in accordance with the anti-inflammatory effects of IP. Parallel studies investigating the gene expression pattern in preconditioned rat hepatocytes showed changes in 43 genes including those of the anti-inflammatory IL-10 and the antioxidant enzyme superoxide dismutase 2 (SOD2)[49]. In another study, a marked increase in SOD as well other endogenous antioxidants such as catalase (CAT) and glutathione peroxidase was also observed[50].

As previously mentioned, HIF-1 controls the expression of a variety of genes implicated in erythropoiesis, angiogenesis, glucose transport, glycolysis and cell survival[42]. In this context, we observed that the A2aR-dependent activation of HIF-1 in hepatocytes was associated with the expression of carbonic anhydrase IX (CAIX)[43], a transmembrane enzyme that by catalyzing bicarbonate production was implicated in preventing hepatocyte death (see later).

MOLECULAR MECHANISMS OF CELL RESISTANCE TO INJURY FOLLOWING HEPATIC PRECONDITIONING

The hepatoprotective effects of liver preconditioning impact on a number of different mechanisms. These include several processes acting against ischemia-induced damage as well as against reperfusion injury[2,3,50].

Protection against ischemic damage

A decrease in hepatic energy state is the main cause of liver cell injury during ischemia. Oxygen deprivation causes loss of mitochondrial potential, ATP depletion and intracellular acidification which are turning points in the onset of irreversible liver cell injury[3,50,51]. In early research, we found that activation of the Na^+/H^+ exchanger in response to cellular acidosis combined with the inhibition of Na^+ extrusion by the Na^+/K^+ ATPase, resulted in Na^+ accumulation within hepatocytes[52] (Figure 2). Na^+ overload was a critical step in hepatocyte damage during warm and cold hypoxia, as well as at the beginning of re-oxygenation, and its prevention markedly delayed the appearance of necrotic cell death[52-60]. Indeed, increased Na^+ caused an irreversible influx of Ca^{2+} by activating the Na^+/Ca^{2+} exchanger[56] and deranged cell volume regulatory mechanisms that ultimately led to osmotic hepatocyte lysis[53,58]. In rat hepatocytes, IP or treatment with A2aR agonists, ATP analogues or NO donors all protected against hypoxia-induced Na^+ overload and such protection was causally associated with increased cell survival[20,21,25,27,28,43]. Interestingly, the maintenance of Na^+ homeostasis was achieved both in the early phase of hepatocyte preconditioning[20,21,25,27,28], as well as in the late effects[43] (Figure 2). In the early phase of IP, inhibition of the Na^+/H^+ exchanger and activation of the vacuolar ATPase (V-ATPase) were mainly involved (Figure 2). Indeed, in hepatocytes treated with ATPγS, activation of the P2Y receptors/Src/p38MAPK axis inhibited ERK 1/2-mediated activation of the Na^+/H^+ exchanger responsible for Na^+ influx during hypoxia[25] (Figure 2). Adenosine- and NO-dependent maintenance of Na^+ homeostasis in preconditioned hepatocytes depended on p38 MAPK and PI3K signalling and involved the neutralization of intracellular pH achieved by the activation and translocation on plasma membrane of the V-ATPase (Figure 2). V-ATPase, acting as an alternative pH buffering system, extruded protons thus avoiding the activation of Na^+-dependent transporters[20,27,28]. The mechanism of Na^+ maintenance during the late phase of IP involved the HIF-1-mediated expression of CAIX in hepatocyte plasma membranes. The bicarbonate generated by CAIX was transferred to the cytosol through the Cl^-/HCO_3^- exchanger and neutralized intracellular pH avoiding Na^+ influx[42] (Figure 2). Beside these effects on

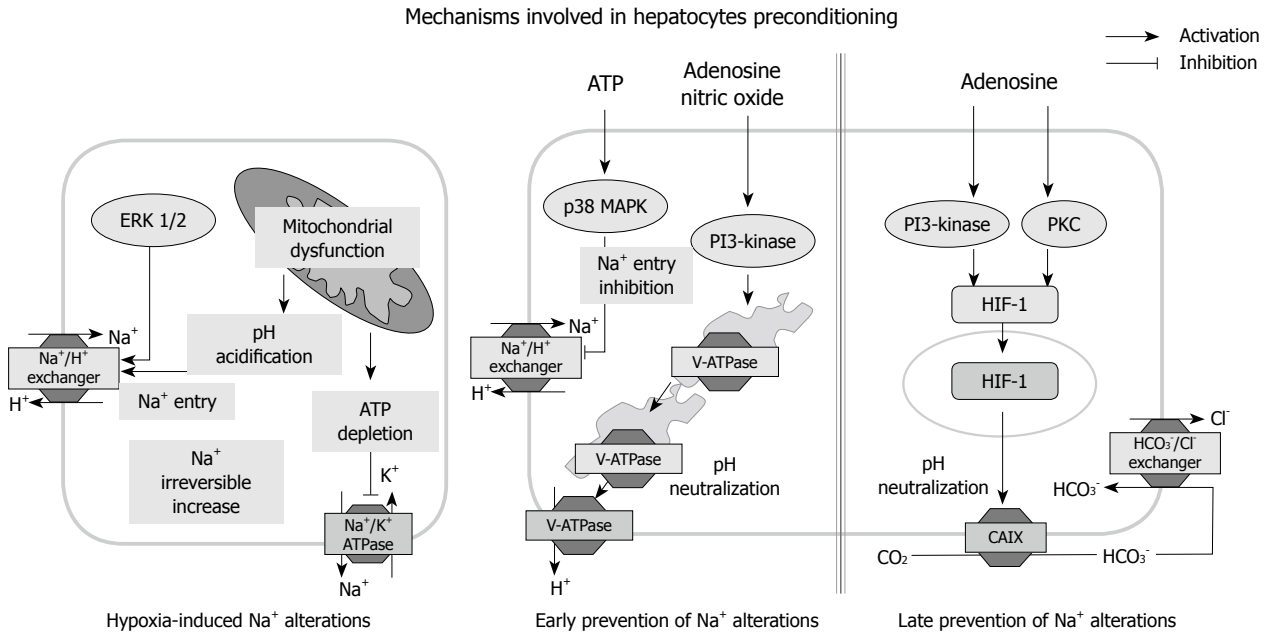

Figure 2 Na^+-dependent mechanisms involved in hepatocyte damage by hypoxia and their modulation by ischemic preconditioning. Hypoxia-induced adenosine triphosphate (ATP) depletion causes intracellular acidification, leading to inhibition of Na^+/K^+ ATPase and the activation of acid buffering systems (Na^+/H^+ exchanger). This leads to an increase in intracellular Na^+ that precipitates irreversible hepatocyte damage. ATP-dependent signalling through purinergic P2Y receptors prevents Na^+ accumulation by inhibiting the ERK 1/2-dependent activation of the Na^+/H^+ exchanger. Adenosine and nitric oxide (NO) activate the vacuolar proton ATPase that maintains intracellular pH avoiding activation of the Na^+/H^+ exchanger. Adenosine also induces the hypoxia-inducible factor 1 (HIF-1) target gene, carbonic anhydrase IX (CAIX), which converts CO_2 into bicarbonate, that once transported into the hepatocytes through the Cl^-/HCO_3^- exchanger, neutralizes the intracellular pH and prevents Na^+ accumulation. See text and Refs[20,21,25,27,28,43,52,53,58]. P38 MAPK: p38 MAP kinase; PI3-kinase: Phosphatidylinositol 3-kinase; PKC: Protein kinase C.

Na^+ homeostasis, during ischemia, IP also down-modulated hepatic energy metabolism by preserving the ATP and glycogen pools and limited lactate accumulation[61].

Protection against reperfusion damage

Mitochondria are a major target of the damaging effects of reperfusion[51]. Oxygen re-admission promotes free radical formation by uncoupled mitochondria with consequent mitochondrial oxidative damage and swelling[62]. IP protected mitochondria from oxidative reperfusion damage[63] and preserved mitochondrial redox-state[64], thus attenuating the impairment of ATP synthesis occurring at reperfusion. IP also improved hepatic intracellular oxygenation[65], preserved sinusoidal wall integrity and avoided liver microcirculatory failure induced by I/R[64]. Together these actions preserved aerobic ATP synthesis maintaining the hepatic energy status during re-oxygenation.

During reperfusion, preconditioned livers also showed a significant reduction in oxidative damage[66,67]. This effect could be ascribed to the increased content of antioxidant enzymes such as SOD, CAT and GSPx[49,50], as well as the reduced generation of reactive oxygen species by mitochondria and inflammatory cells. In the latter context, several studies have outlined the capacity of liver preconditioning to reduce inflammatory responses associated with reperfusion. IP decreased leukocyte adhesion to sinusoidal endothelial cells, lowering post-ischemic neutrophil infiltration[68,69]. IP also attenuated the production of pro-inflammatory cytokines/chemokines during reperfusion[10,68,69]. Finally, pharmacological stimulation of A2aR inhibited the activation of hepatic natural killer T lymphocytes, a process that was causally associated with the protective action of IP against hepatic reperfusion damage[70].

An important consequence of IP was the prevention of hepatocyte and sinusoidal endothelial cell apoptosis[3]. Such an effect can be ascribed to the amelioration of oxidative damage, to the reduced production of pro-apoptotic cytokines as well as to a direct interference with apoptotic mechanisms. Indeed, the increase in PKB/Akt observed in preconditioned hepatocytes[32] represents an important anti-apoptotic signal, since PKB/Akt blocks apoptosis by interfering with Bad, caspase-9 and cFLIP functions[71]. NF-κB might also be implicated in the regulation of hepatocyte response to pro-apoptotic stimuli and the increase in NF-κB nuclear binding observed as early as 30 min after liver IP[29] should be considered in this context. It cannot be excluded that NO-mediated signals might also contribute to the anti-apoptotic action of preconditioning by preventing loss of mitochondrial potential, cytochrome c release and caspase activation[72].

In conclusion, the combined effects of liver preconditioning on energy status, ion homeostasis, oxidative stress, pro-apoptotic responses and inflammation could explain the reduction in hepatocyte and sinusoidal endothelial cell death observed in preconditioned livers exposed to I/R[3,51].

Induction of hepatic regeneration

One of the key issues in the possible exploitation of preconditioning on LDTL is related to its effects on hepatocyte proliferation. The mechanisms involved in the pro-regenerative effects of liver preconditioning are beginning to be elucidated. Hepatocyte growth factor (HGF) and

transforming growth factor (TGF)-β are two cytokines that have opposite actions on liver regeneration, and promote and inhibit hepatocyte proliferation, respectively[73]. The capacity of IP to enhance liver regeneration after reduced-for-size transplantation was associated with increased HGF levels[15] and a lowering of TGF-β production[16]. These effects were causally related to a reduction in IL-1α and an increase in heat shock protein (HSP) 70 expression, respectively[15,16]. Furthermore, a recent study also associated the capacity of IP to attenuate injury in small-for-size liver grafts with the prevention of free radical production and mitochondrial dysfunction, through an increased expression of HSP90, a molecular chaperone that facilitates the mitochondrial import of Mn-SOD[74].

ISCHEMIC POST-CONDITIONING

The term ischemic post-conditioning refers to the capacity to prevent myocardial I/R injury by the application of brief cycles of ischemia during the reperfusion period after a sustained ischemic episode[75-77]. To date, the effects of post-conditioning in the liver have been reported in two studies. These studies showed that the application of brief ischemia in the early phase of reperfusion after rat liver transplantation, was associated with an amelioration of transaminase release and prevention of hepatocyte apoptosis[78-80]. These observations have new important clinical implications as these mechanisms may also act when hepatic damage has already started. In relation to the mechanisms involved in liver post-conditioning, preliminary results in our laboratory indicated that pharmacological post-conditioning with A2aR agonists induced PI3K activation and prevented post-ischemic damage in hepatocytes[81].

CLINICAL APPLICATIONS OF LIVER PRECONDITIONING

The clinical efficacy of hepatic preconditioning was clearly demonstrated in clinical trials performed in patients undergoing hemi-hepatectomy[4,82,83]. In these patients, IP obtained by 10 min of ischemia and 10 min of reperfusion before 30 min of inflow occlusion, significantly reduced transaminase release and ameliorated sinusoid endothelial cell apoptosis as compared to liver exposed to Pringle's manoeuvre only[82,83]. These effects were particularly evident in patients with mild or moderate steatosis, but were not observed in subjects older that 60 years[82]. Considering the possible impact that preconditioning may have in attenuating the effects of long-term graft exposure to cold and warm ischemia during liver transplantation procedures[2,4], the therapeutic use of IP in this setting should have important outcomes. The application of IP in human liver transplantation from deceased donors has, however, demonstrated conflicting results[44,84-88]. Indeed, some studies have shown the efficacy of IP in ameliorating transaminase release and in reducing primary graft malfunctions, whereas others have not observed significant differences[44,84-87]. In an attempt to gain some insight into the possible reasons for the failure of IP to protect liver grafts against reperfusion injury, we investigated the intracellular signals activated by IP in transplanted livers from heart-beating deceased donors. The data obtained indicated that IP stimulated PI3K-mediated signals in only half of the grafts and such variability correlated with the clinical effectiveness of IP. Our data also suggested that it was the failure of PTEN down-modulation that likely contributed to the lack of PI3K response to IP[35]. These observations indicated the necessity to explore alternative procedures to surgical IP to overcome the variability of human grafts in activating preconditioning responses. In this regard, the pharmacological induction of liver preconditioning likely represents a more reliable technique for stimulating the intrinsic systems of cytoprotection in humans.

PHARMACOLOGICAL INDUCTION OF HUMAN LIVER PRECONDITIONING

The clinical potential of pharmacological liver preconditioning is clearly suggested by animal studies, however, only two trials have so far addressed this aspect. In one study, Lang and co-workers reported that patients receiving volatile NO during orthotopic liver transplantation displayed an accelerated restoration of liver function as compared to the control group[89]. In the other report, Beck-Schimmer and co-workers showed that preconditioning with the halogenated anaesthetic, sevoflurane, in 64 patients undergoing liver surgery significantly ameliorated transaminase release and the incidence of severe post-operative complications[90]. These observations are consistent with increasing data regarding the efficacy of sevoflurane preconditioning in preventing myocardial ischemia/reperfusion injury[90]. Nonetheless, the availability of several liver specific NO donors and of a variety of effective adenosine A2A receptor agonists[91-93] offers the possibility of extending the number of studies aimed at directly evaluating new approaches to pharmacological liver preconditioning in humans.

CONCLUSION

In spite of a large number of studies on liver preconditioning, general knowledge on this phenomenon is far from complete. The available data give some insight into the signalling pathways responsible for both the early and late responses of IP, as well as some of the cellular modifications involved in the hepatoprotective effects of preconditioning. Additional extracellular inductors and constitutive or newly synthesized mediators are, however, likely to be involved. Little is known about the proteomic changes associated with inhibition of the inflammatory responses and the promotion of hepatic regeneration. Further research is thus needed to clarify these aspects. In particular, preclinical studies are necessary to identify a panel of the most suitable targets of liver preconditioning whose modulation by means of pharmacological or genetic therapies will allow effective activation of endogenous hepatoprotective systems in patients.

Abstract

Hepatic ischemia-reperfusion injury (IRI) limits access to transplantation. Heme oxygenase-1 (HO-1) is a powerful antioxidant enzyme which degrades free heme into biliverdin, free iron and carbon monoxide. HO-1 and its metabolites have the ability to modulate a wide variety of inflammatory disorders including hepatic IRI. Mechanisms of this protective effect include reduction of oxygen free radicals, alteration of macrophage and T cell phenotype. Further work is required to understand the physiological importance of the many actions of HO-1 identified experimentally, and to harness the protective effect of HO-1 for therapeutic potential.

Key words: Ischemia-reperfusion injury; Heme oxygenase; Transplantation; Ischemic pre-conditioning

THE CLINICAL IMPACT OF HEPATIC ISCHEMIA-REPERFUSION INJURY

The rate of liver failure is increasing in the UK population[1]. Liver transplantation is an effective treatment for patients with end-stage disease, giving an average of 17-22 years of additional life[2,3]. Access to liver transplantation is limited by donor availability; several innovations, including split liver, living donor transplantation, non-heart beating donation (NHBD) and the expansion of the donor criteria, have been attempted to tackle this disparity[4].

Ischemia-reperfusion injury (IRI) causes a spectrum of early organ dysfunction after transplantation; the most severe form, termed primary non-function, may result in patient death. "Marginal organs", including those from older donors, those affected by steatosis and those from donors with long pre-donation intensive care unit stay, may be judged to pose an excessive risk of IRI and be discarded, placing additional pressure on the already scarce donor resource[5].

Due to shifting patterns of organ donation, there is a tendency towards the increased use of marginal organs. Year on year, the mean donor age is increasing, in part due

to improvements in road safety and declining numbers of traumatic deaths. Furthermore, NHBD (also termed donation after cardiac death) is becoming an increasingly important component of the donor resource[6]. Compared with the "gold standard" of heart beating donation (HBD), NHBD is associated with a decreased quantity of donated organs (2.1 organs per donor compared with 3.4 organs per HBD). Albeit in small studies, NHBD liver transplantation is also associated with a higher risk of IRI leading to elevated incidence of primary non-function[7].

Our group has previously estimated that negating the effects of IRI in HBD would lead to a 6% increase in the donor supply through recruitment of these marginal organs back into the donor pool[4]. In the current climate of rapidly increasing NHBD and increasing donor age, the imperative to better understand and avert hepatic ischemia is becoming ever stronger.

DEFINITION OF IRI

Interruption of blood flow to any tissue results in inadequate tissue oxygenation and an increase in cellular anaerobic pathways: if adequate oxygenation is not restored then disruption of cellular functions and cell death results. On reperfusion, despite restoration of adequate cellular oxygenation, there is further damage caused both by direct cytotoxicity from oxygen free radicals (OFR)[8] and by a secondary immunological assault upon the injured organ involving components of both the innate and adaptive immune system[9]. The sequence of injuries resulting from interruption then reinstatement of blood flow is termed IRI.

HEME OXYGENASE-1

Heme oxygenase (HO) is a nicotinamide adenine dinucleotide phosphate (NADPH)-dependent microsomal enzyme, which catalyzes the breakdown of heme to biliverdin, iron and carbon monoxide (CO)[10] (Figure 1). Biliverdin is subsequently reduced to bilirubin by biliverdin reductase while free iron is sequestrated by ferritin. Of the three heme oxygenase isoforms (HO-1, HO-2 and HO-3), only HO-1 (also known as heat shock protein 32) is inducible[11]. HO-1 is a 32 kDa enzyme encoded by the *hmox1* gene. It has been found to be upregulated during states of oxidative and cellular stress and plays an important role in maintaining oxidative/antioxidant homeostasis[12].

Induction of HO-1 and its metabolites is protective in a large number of seemingly unrelated pathologies, including sepsis, malaria, endotoxic shock, IRI, organ transplant rejection, induction of tolerance, myocardial infarction, type 2 diabetes and obesity[13]. This spectrum of protection is attributed to multi-level mechanisms of cytoprotection and inflammatory modulation.

Polymorphism in the (GT)n microsatellite of the *HMOX1* promoter is thought to be responsible for the variations seen in the human response of HO-1 to stimuli[14]. This may account for the differences in the susceptibility of individuals to certain pathologies and in the apparent longevity associated with increased HO-1 expression[15,16].

HO-1 in hepatic IRI

In the context of IRI and transplantation, HO-1 induction or supplementation with its metabolites has been shown repeatedly to be protective in both the liver and other organs.

In early experiments, HO-1 was induced by heat shock in donor livers prior to 44 h of cold ischemia preceding liver isogeneic transplantation in rats, resulting in marked improvements in recipient survival[17]. HO-1 upregulation with adenoviral HO-1 or cobalt protoporphyrin (CoPP) resulted in improved portal venous flow on *ex-vivo* perfusion, while on transplantation into syngeneic hosts, recipient survival doubled, histological injury was ameliorated and influx of macrophages and T cells was reduced[18]; findings confirmed in similar experiments using transplantation[19,20] and hepatic warm ischemia models[21]. More recently, targeted deletion of *Bach-1*, which normally suppresses HO-1 transcription, led to HO-1 upregulation and protection from myocardial ischemia[22], although these experiments have yet to be repeated in models of hepatic ischemia.

In our own laboratory we have shown that HO-1 is upregulated in Kupffer cells during ischemic preconditioning (IPC)[23], and that targeted deletion of *hmox-1* resulted in aberrant Kupffer cell differentiation and susceptibility to ischemia-reperfusion insults[24]. Our work has suggested that Kupffer cells are a likely site of HO-1 action: recent work from Kupiec Weglinski's laboratory has demonstrated that adoptive transfer of HO-1 overexpressing bone marrow-derived macrophages was capable of protecting mice from hepatic ischemic insults[25]. Developing this theme, other experiments have shown HO-1 induction with CoPP to protect mice from hepatic ischemia arising from liver transplantation: Kupffer cells recovered from HO-1-induced animals produced less tumor necrosis factor α (TNFα) and interleukin (IL)-6 under stimulation in *ex vivo* culture[26].

HO-1 in hepatic IPC

IPC is a surgical maneuvre in which an organ is paradoxically protected by a brief period of controlled ischemia and reperfusion immediately prior to a longer index ischemic event, which by itself would normally lead to injury[27,28]. Several small randomized controlled trials have looked at the effectiveness of IPC in both liver transplantation and resection; subsequent Cochrane reviews conclude that further trials are still required to evaluate its role in hepatic and transplant surgery[29,30].

Kanoria *et al*[31] demonstrated in their rodent model that the application of a hindleg tourniquet (remote IPC) led to a protective phenotype from hepatic IRI. Ischemic post-conditioning has also been described, in which injury is abrogated by modified reperfusion. This emphasizes that tissue damage from ischemia-reperfusion continues following the end of the ischemic insult[32].

The mechanisms behind IPC are poorly understood. Numerous candidate molecules, including nitric oxide, adenosine, protein kinase C, tyrosine kinase and mitogen-activated-protein kinase, have been identified as potential mediators of protection[33]. Given that IPC can act re-

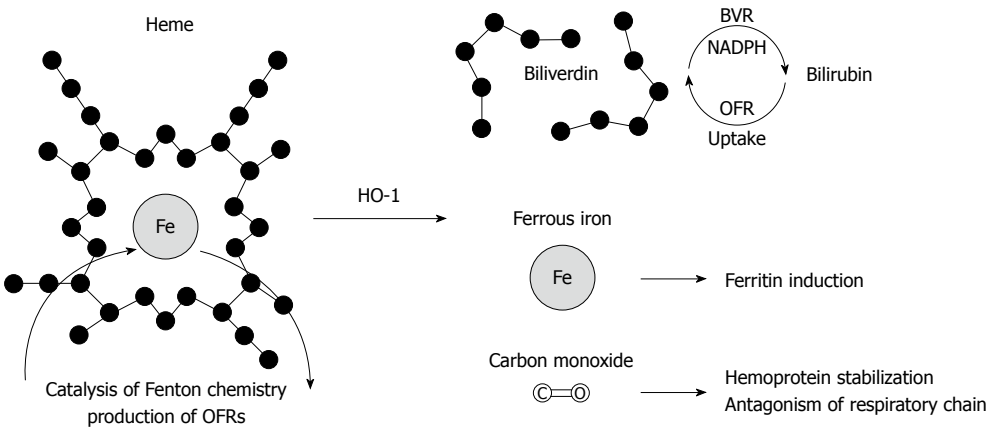

Figure 1 Putative mechanisms of heme oxygenase-1 antioxidant effect. HO-1: Heme oxygenase-1; BVR: Biliverdin; OFR: Oxygen free radicals; NADPH: Nicotinamide adenine dinucleotide phosphate.

motely, it may involve an immunomodulatory mechanism.

HO-1 is upregulated following IPC and may be responsible for the observed protection[23]. HO-1 is also upregulated in sites distant to the site of preconditioning. In a remote preconditioning model, renal ischemic insults led to cardiac HO-1 induction[34]. Likewise, HO-1 induction occurred in the liver following four 10 min episodes of femoral artery occlusion, and protection afforded by remote preconditioning was lost when HO-1 was inhibited with SnPP[35].

Given that HO-1 is upregulated in IPC and is known to be powerfully protective when upregulated, it is likely that HO-1 has a role in IPC together with other up- and downstream molecules.

Mechanisms of HO-1-mediated cytoprotection

As described above, it is now beyond doubt that HO-1 induction is protective in the context of hepatic ischemia and transplantation. HO-1's cytoprotective effects can be credited to a combination of removal of toxic metabolites (heme), and production of protective second messenger molecules in the forms of biliverdin (and subsequently bilirubin), CO, and free iron (which induces ferritin)[36]. HO-1 may also have other mechanisms of protection, independent of its enzyme activity[37].

Catabolysis of free heme

Heme consists of an iron atom contained within a porphyrin ring: heme moieties are usually contained within the "heme pockets" of hemoproteins. Although the most abundant hemoproteins are hemoglobin and myoglobin, heme moieties are contained within many other ubiquitous enzymes, for example iNOS and the mitochondrial electron transfer chain.

Under conditions of oxidative stress, hemoproteins may be oxidized, leading to the release of free heme which causes cellular injury by multiple mechanisms. Firstly, the central iron ion of the heme moiety catalyzes the production of free radicals by Fenton chemistry as follows: Step 1: $Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH\cdot + OH^-$; Step 2: $Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + OOH\cdot + H^+$.

Heme-dependent free radical generation can cause direct cytotoxicity, including damage to the cytoskeleton, lipid bilayer, intermediary metabolic enzymes and DNA[38,39], while circulating heme can cause LDL oxidation leading to endothelial cell toxicity[40]. Heme sensitizes cells to pro-death signals including TNFα and Fas, an effect abrogated by treatment with antioxidants, implying dependence upon free radical production[36].

HO-1 reduces free heme concentrations by two mechanisms. Firstly, catabolysis of heme into metabolites biliverdin, iron and CO directly removes free heme. Secondly, binding of CO to hemoglobin, forming carboxyhemoglobin, prevents its oxidation to methemoglobin and ensuing release of free heme moieties[36].

Some authors have argued strongly that neutralization of free heme during cellular injury can account for a large proportion of the protection offered by HO-1. In experimental malaria, it was found that C57/Bl6J mice had reduced HO-1 induction compared with BALB/c animals, and consequently had higher levels of circulating free heme and greater disease severity. Administering exogenous heme to BALB/c animals caused worsening of their disease severity whereas conversely, CO treatment of C57Bl6J mice was protective[41]. In the same model, HO-1 protected animals from hepatic failure induced by overwhelming circulating heme[42].

Hepatic HO-1 expression is focused in Kupffer cells. This cell type is highly adapted to detect hemolysis: the hemoglobin-haptoglobin complex receptor CD163 is able to induce HO-1 in an IL-10-dependent manner[43,44].

Production of biliverdin

Biliverdin is produced by catalysis of the heme porphyrin ring and is almost immediately converted by biliverdin reductase to unconjugated bilirubin. This, in turn, is glucuronidated to render it water soluble. Bilirubin is a powerful antioxidant believed to be responsible for much of the antioxidant activity of serum[45]. At micromolar concentrations it is capable of scavenging large volumes of reactive oxygen species (ROS), protecting cells from high concentrations of peroxide, with enhanced efficacy in

hypoxic conditions, making this effect particularly relevant in the context of ischemia[46]. Bilirubin's extraordinary antioxidant capacity may arise from an active cycle in which biliverdin reductase undertakes NADPH-dependent reduction of biliverdin to bilirubin: in turn bilirubin is oxidized by free radicals back to biliverdin, before enzymatic reduction back to bilirubin. Although controversial[47], this cycling mechanism has been proposed as a highly adapted mechanism through which cells and whole organisms maintain redox status[45].

Bilirubin's effects may extend beyond its antioxidant action. It has been identified as an endogenous ligand of the aryl hydrocarbon receptor (AHR), present on many immune cell populations[48]. In some experiments AHR ligands have suppressed T cell proliferation through expansion of T regulatory (Treg) cells[49], although expansion of either Treg or their polar opposite, Th17 cells, has been shown depending upon which experimental AHR ligand is used[50].

Patients with persistent hyperbilirubinemia (Gilbert's syndrome) have been observed to have significantly lower incidence of atherosclerotic disease in several studies, an effect attributed to enhanced antioxidant potential of serum[51]. The effect of chronic hyperbilirubinemia upon T cell phenotype is unclear, although immunosuppression has been reported in patients with cholestatic jaundice[52].

Work using *ex vivo* liver perfusion models in which explanted livers were stored for 16[53] or 24 h[54] at 4℃ in University of Wisconsin solution, prior to mechanical perfusion, found that addition of low concentrations of bilirubin to the graft perfusate mimicked the protective effect of heme oxygenase induction. Graft function was improved in terms of portal venous flow and bile production, and hepatocellular injury was ameliorated in terms of histological injury scoring and transaminase release. Biliverdin has also been shown to have an immunomodulatory effect. In an MHC-mismatched cardiac allograft model, twice or three times daily injections of biliverdin for 2 wk increased graft survival, and led to complete allograft tolerance in 50% of animals[55].

To test whether bilirubin was protective in the clinical setting, our group hypothesized that hyperbilirubinemia would protect transplant recipients from IRI, in which case there would be an inverse correlation between preoperative bilirubin and post-operative transaminase measurements. In a small retrospective study, no relationship was observed, although given the heterogeneity of the study population an effect could not be ruled out[56].

Production of Fe^{2+}

Paradoxically for an antioxidant enzyme, one of HO-1's reaction products, free iron, is a powerful oxidant. Free iron catalyzes the generation of OFR by Fenton chemistry in a manner comparable to free heme as described above. However, it is more effectively neutralized than when contained within a heme ring, being actively exported from the cell[57] and chelated by iron-binding proteins, including ferritin. Ferritin sequesters Fe^{2+} by oxidation and placement of iron ions within a "core" in which they are unable to catalyze Fenton reactions[58]. HO-1 induction leads to increased ferritin expression[59], through a mechanism dependent upon the production of free iron[60,61].

Since other HO-1 metabolites had been shown to be capable of substituting for HO-1 induction in protecting animals from IRI, Berberat *et al*[62] hypothesized that ferritin overexpression could also confer protection. Using an *ex vivo* perfusion model of hepatic IRI, this group identified that transfection with adenoviral heavy chain ferritin conferred protection in terms of bile flow, portal blood flow, histological injury scoring and transaminase release, and improved survival of syngeneic liver recipients.

Ferritin induction has been observed in retinal[63] and cardiac IPC[64] in a manner dependent upon an iron signal[65]: although there are no published studies of ferritin expression in hepatic preconditioning, it would be reasonable to hypothesize that similar results would be obtained.

Although ferritin is capable of protecting cells and organs from oxidative stress, it is worth noting that its induction is unlikely to be the only mechanism of cellular protection by HO-1. Sheftel *et al*[61] compared heme and sodium arsenite (a non-heme inducer of HO-1) *in vitro*, and found sodium arsenite to confer protection through HO-1 induction without parallel ferritin induction.

Production of CO

CO is best known for its toxicity, causing death at atmospheric concentrations of 500-1000 ppm, however, at lower doses CO has been shown to have important cytoprotective and immunomodulatory functions: it is released by HO-1 during the catabolysis of heme and can substitute for the protective effect of HO-1.

CO cannot have a specific receptor since it binds only to transition metals and is not thought to be capable of direct interaction with amino acids. Therefore, its pharmacology as a signaling molecule is necessarily novel, and subject to ongoing debate. An important hypothesis is that CO effects must be mediated by interactions with proteins which contain transition metal cores, for example in heme rings contained within a range of enzymes including soluble guanylate cyclase (sGC), cytochromes, hemoglobin, myoglobin and nitric oxide synthase[66]. It has been suggested that CO protects from oxidative stress by preventing hemoprotein oxidation and subsequent release of heme rings[36], diminishing production of free radicals and subsequent apoptosis[67]. Others have suggested that the protection may be mediated by antagonism of respiratory chain enzymes, reducing cellular oxygen requirements[66], by inducing vasodilatation *via* sGC[68] or by opening calcium-sensitive ion channels[69].

Using an *ex-vivo* liver perfusion model, Amersi *et al*[70] demonstrated enhanced portal blood flow and bile production, and amelioration of hepatic IRI, in terms of histological injury score and transaminase release when perfusate was supplemented with CO at 300 ppm. Blockade of heme oxygenase using zinc protoporphyrin (ZnPP) did not obliterate the protective effect, indicating that CO

was capable of substituting for HO-1 function. Inhibitor studies have demonstrated that the CO effect was independent of iNOS and cGMP but dependent upon p38 MAPK.

In a cardiac transplantation model, no hearts stored at 4℃ for 24 h prior to implantation into syngeneic recipients functioned after implantation, whereas 5 out of 6 grafts survived when HO-1 was induced with CoPP, an effect lost with HO-1 inhibition. Administration of 400 ppm CO to the heart donor during cold storage resulted in survival equivalent to that achieved with HO-1 induction[71]. In xenotransplant models, HO-1 inhibition with tin protoporphyrin (SnPP) caused rejection, whereas this effect was overcome by recipient CO inhalation[72].

Although the finding that CO can be protective at low doses is scientifically exciting, the potential therapeutic use of inhaled CO can be limited by practical difficulties, both in control of dosage, and spillage of the gas into the environment around the patient. For this reason, Motterlini has developed transition metal carbonyl "CO releasing compounds" (CORMs). Of these (CORM-A1, CORM-2, CORM-3), the most commonly used has been CORM-3 [tricarbonylchloro(glycinato)ruthenium(II)], which releases CO when dissolved in saline but not water[73]. To control for the presence of the ruthenium compound, a CO depleted substance (iCORM3) can be prepared by dissolving CORM-3 in PBS prior to the experiment.

Using a coronary occlusion model in which mice were subjected to 30 min of ischemia followed by 24 h of reperfusion, investigators administered CORM-3 during the first hour of reperfusion, which halved the area of myocardial infarct compared to iCORM control[74]. In a further study, the same group compared the effects of CORM-3 with a late-phase IPC protocol. Animals received either IPC or intravenous CORM-3 infusion lasting 60 min, with appropriate controls. Animals then underwent 30 min coronary ischemic insults 24 to 120 h later. The reperfusion phase lasted for 24 h post-operatively before animals were killed and hearts examined for infarct size. Both IPC and CORM-3 infusion resulted in cardioprotection at between 24 and 72 h compared with appropriate control groups[75].

In the context of transplantation, the potential for using CO to enhance graft function has been explored in various transplantation models. In the kidney, several studies have successfully protected grafts using storage media supplemented with CORM-3/CORM-A1[76] or CORM-2[77] for extended periods of cold ischemia prior to isogenic transplantation. In a vascular allograft model, donor HO-1 induction or CORM treatment reduced subsequent CD8 influx and intimal hyperplasia lasting until animals were sacrificed at 6 wk[78].

In the liver, CO persufflation of University of Wisconsin (UW) storage solution improved subsequent graft function[79], a result replicated using CORM-3 supplemented UW[80,81] after cold ischemic times of 48 h. Use of CO treatment in experimental liver transplant recipients has also been explored. Tomiyama *et al*[82] transplanted livers from wild-type donors into E-GFP transgenic rat recipients who received inhaled CO prior to and for the 24 h post transplantation. Grafts within CO-treated recipients were found to have reduced numbers of infiltrating CD45+ host leucocytes, while purified donor CD68+ Kupffer cells produced less IL-6 and TNFα: primary cultured *ex vivo* Kupffer cells from CO-treated animals secreted less IL-6 and TNFα in response to lipopolysaccharide (LPS) stimulus.

CO clearly has powerful antioxidant and anti-inflammatory effects in a variety of systems. For this reason, despite the difficulties presented by administering it in its inhaled form, phase 2 clinical trials are underway in renal transplantation (www.clinicaltrials.gov identifier NCT00531856), chronic obstructive pulmonary disease (NCT00094406) and post-operative intestinal ileus (NCT01050712). Further development of CORMs should make CO therapies more convenient, thereby widening their potential clinical applications: on the basis of the preclinical data presented above such applications would be expected to include hepatic IRI and transplantation.

Other mechanisms of HO-1-mediated cytoprotection

The bulk of data exploring mechanisms of HO-1-induced cytoprotection supports the concept that it is its antioxidant function which protects cells and animals from injury. Two separate pieces of data suggest that other mechanisms should be considered. Firstly, Ponka's laboratory have demonstrated that the amounts of intracellular heme available for degradation may be insufficient to account for HO-1's powerful antioxidant effects[61]. Secondly, Dennery's laboratory has shown HO-1 translocation to the nucleus after cellular hypoxia or heme treatment, suggesting a role in transcriptional regulation[37]. Developing this work, this group has published research using a reporter system with catabolically inactive HO-1 which suggests HO-1 may have a forward-acting positive effect upon its own transcription[83], although as yet there has been no work demonstrating a protective effect of catabolically inactive HO-1.

HO-1 AND IMMUNOMODULATION IN IRI

It is likely that HO-1 protects organs from IRI by modulation of both direct cellular injury and both the innate and adaptive immune systems[84]. Deficiency of HO-1 in both humans and mice is associated with a pro-inflammatory phenotype[85,86].

According to Matzinger's "Danger Model" of the initiation of immune responses to injured organs, injured parenchymal cells release "Danger-Associated Molecular Patterns" (DAMPs) which stimulate antigen presenting cell (APC) activation through pattern recognition receptors[87,88]. Activated APCs subsequently activate and recruit immune effector cells through the secretion of pro-inflammatory mediators (cytokines, chemokines and adhesion molecules) and antigen presentation[9], resulting in

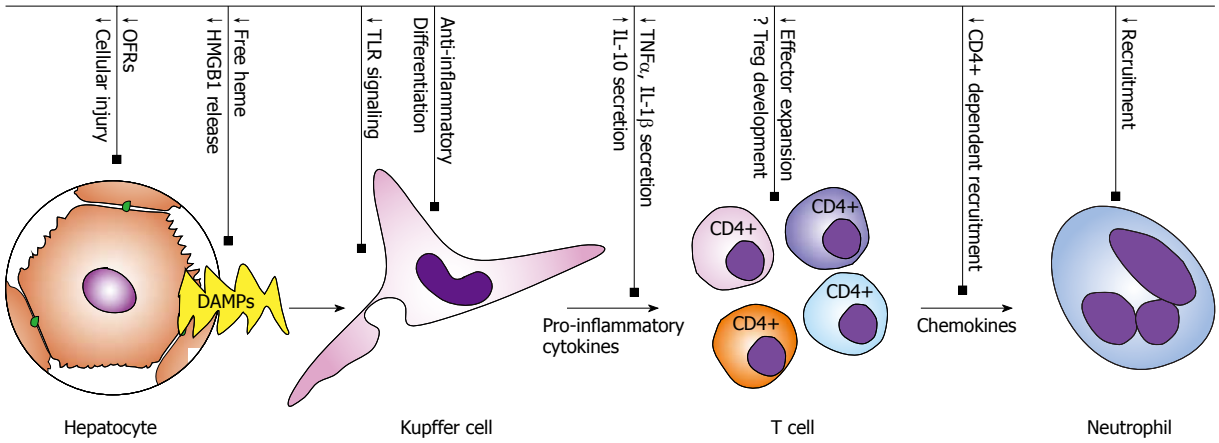

Figure 2 Heme oxygenase-1-mediated suppression of the inflammatory response in hepatic ischemia-reperfusion injury. HMGB1: High Mobility Group Box-1; TLR: Toll-like receptor; DAMPs: Danger-associated molecular patterns; TNFα: Tumor necrosis factor α; IL: Interleukin; OFR: Oxygen free radicals.

the activation and recruitment of T cells and neutrophils (Figure 2). This recruitment of leucocytes into the tissue is further facilitated by increased endothelial permeability and adhesion molecule expression resulting from endothelial activation.

Danger-associated molecular patterns

Hypoxic cellular injury can be regarded as the initiating event in a cascade of immunological activation. "Danger-Associated Molecular Patterns" or "alarmins" spilt by dying cells act on tissue resident immune populations *via* various molecular sensors including the toll-like receptor (TLR) family and purinergic receptors. A prototypic "alarmin", High Mobility Group Box-1 (HMGB1) is released passively from injured cells, a signal amplified by active secretion from surrounding viable immune and non-immune cells[89]. Several authors have published studies demonstrating that circulating HMGB1 levels rise after experimental hepatic ischemia and that anti-HMGB1 neutralizing antibodies are capable of lowering circulating TNFα and IL-6 levels, and ameliorating injury[90-92]. Human clinical studies have confirmed the synthesis of HMGB1 during early reperfusion after liver transplantation, an effect exaggerated in steatotic livers, and with levels correlating with injury severity as measured by peak ALT[93]. Recombinant HMGB1 has been found to worsen the severity of experimental hepatic ischemic injury, an effect neutralized by targeted deletion of its receptor TLR-4[92].

HO-1 is capable of modulating the HMGB1 alarmin system. In sepsis[94] and acute lung injury[95] models, macrophage LPS-mediated HMGB1 release was suppressed by HO-1 induction by CORMs resulting in improved survival. Oxidative stress can initiate macrophage HMGB1 synthesis which occurs in a dose response relationship with peroxide stress *in vitro*[96]. It is therefore unclear whether HO-1's modulation of HMGB1 secretion arises simply by reducing the extent of parenchymal cell injury or whether it is dependant upon another mechanism.

Free heme is another potential DAMP, being released from damaged cells and acting on TLRs[97]. Heme has also been shown to induce neutrophil chemotaxis using *in vitro* transmigration assays and after intraperitoneal injection *in vivo*[98]. By metabolising free heme, HO-1 induction would be expected to reduce this immune stimulus, further contributing to the possible mechanisms of protection from injury.

Intriguingly, HO-1 and CO also modulate TLR signaling upon which many DAMPs converge[99]. CO treatment of cultured RAW264.7 macrophages was found to reduce TLR4 signaling by reducing TLR4/Myd88 interactions and movement of TLR4 receptors to the cell surface[100].

It is likely that much of the immune modulation offered by HO-1 is owed to its antioxidant action which quietens the initial immune stimulus by reducing cellular injury and spillage of DAMPs.

Kupffer cells

Hepatic tissue resident macrophages (Kupffer cells) are the first immune cells to be activated by IRI, being acted upon by DAMPs released from surrounding parenchymal cells as well as being subject themselves to cellular hypoxia. Subsequently, they coordinate an appropriate influx of other immune cells by secretion of chemokines and cytokines. Kupffer cells have the ability to harm surrounding parenchymal cells by secretion of pro-inflammatory cytokines including TNFα, IL-6 and IL-1, which may be directly toxic[101]. On the other hand, Kupffer cells may protect the tissues by secretion of anti-inflammatory cytokines including IL-10. Furthermore, as the principle HO-1-expressing cells of the liver[24] they may secrete diffusible CO which may act in a paracrine manner upon surrounding cells to protect them from oxidative stress.

In our work, we have identified that HO-1 acts as a powerful switch on resting macrophage differentiation. We found HO-1-deficient Kupffer cells *in vivo* and bone marrow-derived monocytes (BMDMs) *in vitro* to differentiate down a Ly6c+ MARCO+ F4/80- pathway associated with macrophage inflammatory protein (MIP)-1 responsive pro-inflammatory monocytes[102]. HO-1 deficiency was associated with marked susceptibility to hepatic IRI measured in terms of ALT release and histological injury

score[24]. Parallel work elsewhere using an *in vitro* migration assay has demonstrated enhanced migration of *Hmox-1*$^{-/-}$ BMDMs towards MIP-1α[95]. In an experimental liver transplant model, inhaled CO conferred protection from injury and reduced secretion of pro-inflammatory cytokines from recovered CD68+ cells cultured *ex vivo*[82], reducing the subsequent influx of CD45+ leucocytes. *In vitro* and *in vivo,* low dose CO downregulates the production of macrophage pro-inflammatory cytokines [TNFα, IL1β and MIP-1β (CCL4)] and increases the expression of the anti-inflammatory cytokine IL10[103].

Data from injury models showing modulation of pro-inflammatory cytokine secretion by HO-1 induction is subject to the criticism that the changes observed are merely the downstream effects of parenchymal cellular protection, and suppression of DAMPs. However, data from our laboratory has shown HO-1 effects upon the resting state of macrophage differentiation implying that HO-1 may modulate immune responses themselves.

Adaptive immune system

There is growing evidence from a variety of animal IRI models (T cell-deficient nude rats, severe combined immunodeficiency mice, RAG 1$^{-/-}$ mice, CD4+/CD8+$^{-/-}$ mice and CD4+ depleted mice) that there is a significant decrease in biochemical and histopathological evidence of injury in the absence of T cells (reviewed by Linfert *et al*[9]). More specifically, Khandoga *et al*[104] demonstrated it was a CD4+ rather than CD8+ T cell-dependent phenomenon; depletion of CD4+ T cells leads to a significant reduction in the observed injury. This influx of CD4+ cells on reperfusion is rapid and may determine the mode of neutrophil activation and subsequently the extent of the observed tissue damage[105,106]. In a series of elegant adoptive transfer experiments with CD4+ cells in a renal model, Burne *et al*[107] found IRI to be an interferon-γ-dependent process; this may imply the importance of the T helper 1 lineage in the pathology of IRI.

HO-1 has a number of immunomodulatory effects on effector and Treg cells. HO-1 and CO appear to inhibit T cell proliferation and activation through the suppression of IL-2 secretion[108]. HO-1 induction has also been shown to induce the apoptosis of activated T helper cells through activation-induced cell death[109].

Treg cells suppress the activation of the immune system and inhibit the activation of autoreactive T cells[110]. In clinical studies, Treg/Th17 "imbalance" has been associated with acute coronary syndromes[111]. HO-1 is induced by FoxP3: inhibition of HO-1 function *in vivo* reduced the suppressive ability of naturally occurring Tregs[112]. Furthermore, studies from Fritz Bach's group have shown tolerogenesis to require HO-1[109]. Recently, however, these studies have been challenged by showing that *Hmox-1*$^{-/-}$ mice have normal numbers of Treg cells[113] and that HO-1 is not necessary or sufficient for T reg function[114]. These controversies may be resolved by work from the Agarwal group which showed that although *Hmox-1*$^{-/-}$ mice had normal (or elevated) numbers of circulating Treg cells, their suppressive function was dependant upon HO-1 expression by antigen-presenting cells[115].

In the context of hepatic ischemia, further work is needed firstly to establish which T cell populations are responsible for IRI and IPC, and secondly to resolve the controversy concerning the role of HO-1 in the expansion of different T cell subsets.

Neutrophils

Severe IRI is associated with significant influx of neutrophils[9]. Their recruitment from the vascular compartment into the liver is mediated by the expression of chemokines, cytokines and adhesion molecules[9]. Accumulation of activated neutrophils directly injures hepatocytes and the vascular epithelium through the release of proteases and the generation of ROS[116]. The initial recruitment of neutrophils appears to be a CD4+-dependent process[105]; continued neutrophil recruitment and activation may be dependent on the neutrophil production of IL-17A, which is important in a positive feedback mechanism[117]. As described above, heme is also capable of initiating neutrophil chemotaxis[98].

Although neutrophil influx is enhanced in *Hmox-1*$^{-/-}$ animals after ischemia-reperfusion insults[24], it is unclear whether this is due to a direct effect upon neutrophils or merely as a result of reduced stimulation due to upstream effects.

CONCLUSION

A wealth of data has now proven that HO-1, and its metabolites iron, bilirubin and CO, protect the liver from IRI. HO-1 appears to ameliorate ischemic injury through synergistic actions at many levels in the danger pathway. Powerful effects have been identified upon neutralization of OFR, and apparently at every step of the ensuing danger pathway. What remains is to understand the true physiological importance of each of these effects, and to attempt to separate apparent immunomodulation from suppression of upstream danger signals. Further understanding of the detailed pathophysiology of IRI and the mechanisms underlying IPC would also be invaluable in identifying the full range of potential therapeutic targets.

The protective effect of HO-1 upregulation in IRI was first discovered over a decade ago, and is proven beyond doubt in preclinical studies. Work to date has highlighted multiple potential therapeutic strategies ranging from CORM infusions to cell therapies with HO-1-transduced macrophages. In light of the severity of the many clinical problems caused by IRI including the liver donor shortage, there is now some urgency to translate this body of scientific knowledge into viable treatments which will benefit patients.

Abstract

Hepatic ischemia-reperfusion injury (IRI) occurs upon restoration of hepatic blood flow after a period of ischemia. Decreased endogenous nitric oxide (NO) production resulting in capillary luminal narrowing is central in the pathogenesis of IRI. Exogenous NO has emerged as a potential therapy for IRI based on its role in decreasing oxidative stress, cytokine release, leukocyte endothelial-adhesion and hepatic apoptosis. This review will highlight the influence of endogenous NO on hepatic IRI, role of inhaled NO in ameliorating IRI, modes of delivery, donor drugs and potential side effects of exogenous NO.

Key words: Nitric oxide; Liver; Ischemia-reperfusion injury; Drug delivery

INTRODUCTION

Ischemia-reperfusion injury (IRI) is a series of multifaceted cellular events that takes place on the resumption of oxygen delivery after a period of hypoxia. This injury could be severe enough to lead to a significant morbidity and mortality.

The liver may be involved in IRI in procedures that are associated with sequential vascular impediment and restoration of blood flow; for example hepatic resections and orthotopic liver transplantation. During these procedures, unclamping of the vascular inflow to the liver after a temporary period of cross clamping results in major hepatocellular damage.

Nitric oxide (NO) has various protective effects on cells during IRI. NO has been demonstrated to inhibit oxidative stress, cytokine release, leukocyte endothelial adhesion and apoptosis[1]. On a cellular-signaling level, NO effects are mediated *via* redox-sensitive sites, and include: inhibition of protein kinase C, activation of tyrosine kinase, inactivation of nuclear factor (NF)-κB and activation of G proteins[2]. Previous studies have demonstrated that a reduction of NO during hepatic IRI, generally *via* a reduction in endothelial nitric oxide synthase activity, leads to liver injury[3]. Inhaled NO or NO donor drugs are novel treatments that have been used clinically to attenuate liver IRI[4]. This review will discuss the pathophysiology of liver involvement during IRI, and the clinical use of nitric oxide in ameliorating the impact of liver IRI.

BRIEF REVIEW OF THE PATHOPHYSIOLOGY OF IRI

The complex mechanisms of IRI have been revealed by advanced molecular biology[5] (Figure 1). During the isch-

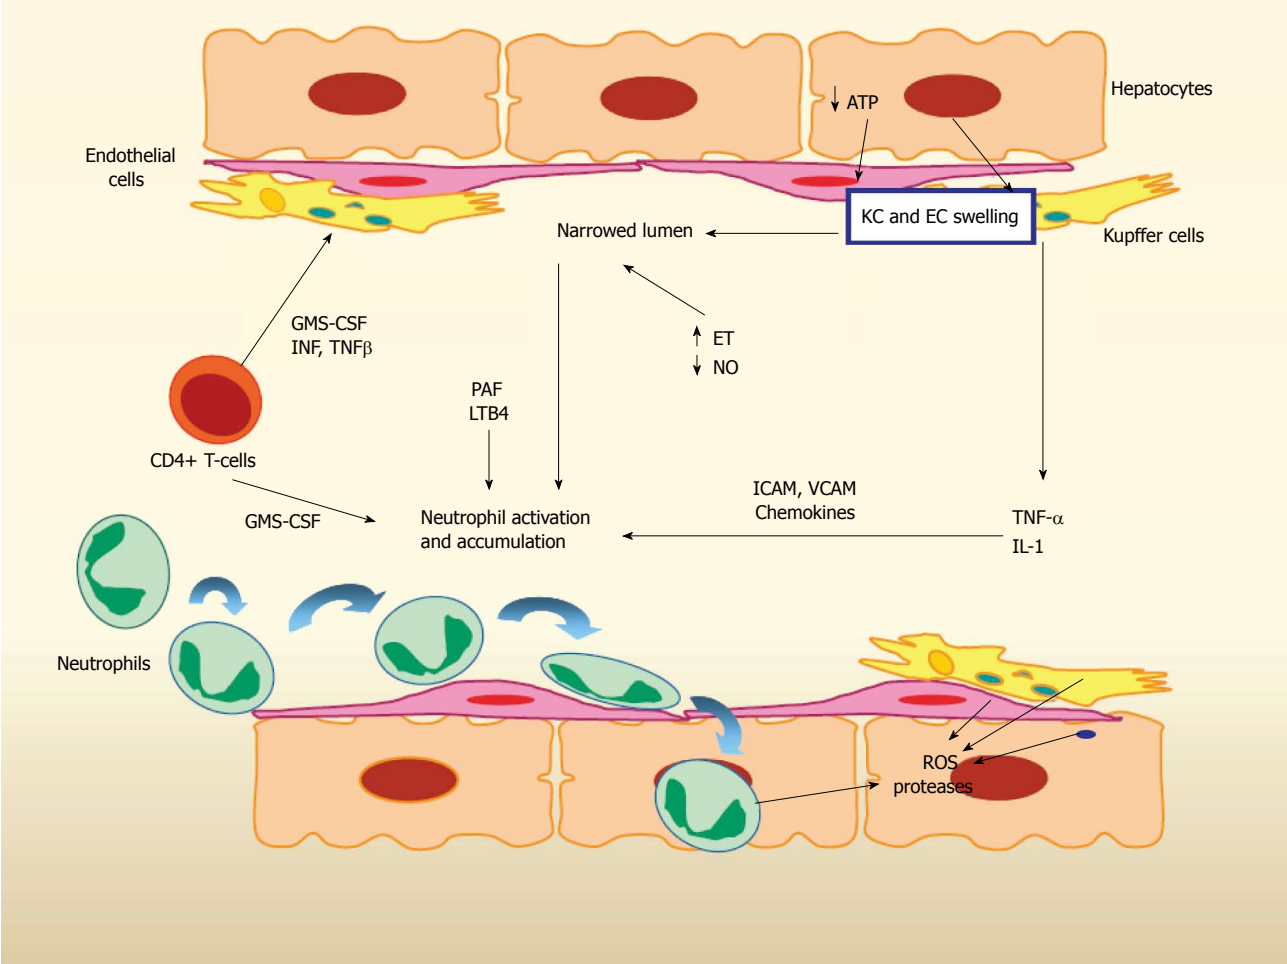

Figure 1 Multifaceted hepatic ischemia-reperfusion injury. Kupffer and endothelial cells produce cytokines and chemokines, recruiting neutrophils that further accentuate injury. EC: Endothelial cell; KC: Kupffer cell; ATP: Adenosine triphosphate; TNF: Tumor necrosis factor; IL: Interleukin; ICAM: Intercellular adhesion molecule; VCAM: Vascular adhesion molecule; PAF: Platelet activation factor; LTB4: Leukotriene B4; GMS-CSF: Granulocyte macrophage colony stimulating factor; INF: Interferon; ROS: Reactive oxygen species (Courtesy of Dr. Joan Rosello-Catafau, Barcelona, Spain).

emic phase, anaerobic metabolism ensues and produces an inadequate amount of high-energy phosphates which are fundamental to most cellular functions. Low levels of high-energy phosphates affect a myriad of cellular functions: homeostasis, signaling interactions, cellular proliferation and processing of the apoptotic death cycle. Adenosine triphosphate (ATP) depletion impairs sodium/potassium ATPase (Na^+/K^+-ATPase) function, resulting in an impairment of the efflux of sodium from the cell. Additionally, toxic metabolites, which are generated during ischemia, attract free water into ischemic cells and organelles leading to the formation of cellular edema[6]. If the ischemic insult lasts greater than 24 h, it is likely that ATP-synthase activity becomes irreversible after blood restoration, leading to cellular necrosis, apoptosis or neuroapoptosis[7]. Ischemia also causes an increased expression of adhesion molecules that leads to endothelial cell and neutrophil adhesion, resulting in vascular studding and occlusion[8]. Furthermore, disequilibrium between NO and endothelin (ET) induces vasoconstriction and subsequent microcirculatory failure even though blood circulation has been re-established[9]. Re-establishment of blood flow will serve to amplify inflammation with consequent injury that is highly variable but dependent on numerous variables including the extent of mediators produced (i.e. reactive oxygen species), the degree of endothelial and neutrophil adhesive responses and the degree of Kupffer cell activation.

PRINCIPAL PARTICIPANTS IN LIVER IRI

Sinusoidal endothelial cells

Injury to these cells is initiated during cold ischemia whereby Ca^{2+}-ATPase results in the accumulation of intracellular calcium[10]. Following this event, a series of actions occur making the endothelium more susceptible to platelet adhesion and reduced sinusoidal flow.

Kupffer cells

Kupffer cells are crucial in liver injury orchestration. Metabolic alterations of these cells occur during no-flow ischemia leading to the formation of reactive oxygen species during early reperfusion[11]. Additionally, at the onset of reperfusion, Kupffer cells undergo further activation by Toll-like receptor 4 signaling and/or by complement. Subsequently, Kupffer cells release pro-inflammatory cytokines such as TNF-α and interleukin-1 which them-

selves can perpetuate inflammatory injury by such means as leukocyte activation.

Hepatocytes

While major participants in the promotion of injury, during cold ischemia hepatocytes undergo intracellular bioenergetic perturbations that reduce ATP stores due to mitochondrial dysfunction and predispose these cells to injury during reperfusion[12].

Leukocytes and lymphocytes

As a result of IRI, cellular adhesion molecules (i.e. intercellular adhesion molecule-1 or ICAM-1, vascular adhesion molecule-1 or VCAM-1), selectins and integrins are activated and upregulated on the surface of endothelial cells, neutrophils and platelets. The activated neutrophils adhere to endothelial cells at the initial stages of reperfusion, and subsequently transmigrate across the endothelium where they continue to injury orchestration. The accumulation of activated neutrophils contributes to microcirculatory disturbances both locally and remotely. Activated neutrophils release reactive oxygen species, specifically superoxide radical (O_2^-•), proteases and various cytokines[13]. Monocytes and macrophages are also activated shortly following reperfusion[14]. Recent studies propose an important role for lymphocytes, especially $CD4^+$ T cells, in augmenting injury responses after IRI. However, lymphocytes may also play a protective role, but this is probably dependent on cell type and time course of injury[15].

Reactive oxygen species and reactive nitrogen species

During periods of ischemia, reactive oxygen species (ROS) and reactive nitrogen species (RNS) are generated which can promote intracellular damage. Due to electron transport chain alterations, mitochondrial dysfunction ensues leading to reductions in ATP production and with subsequent loss of inner membrane stability resulting in mitochondrial swelling and rupture. With the reintroduction of oxygen during reperfusion, ROS are produced due to reactions of oxygen introduced during reperfusion with xanthine oxidase. ROS serve to stimulate other cell lines including Kupffer cells to produce proinflammatory cytokines[16]. The major ROS are hydroxyl radical (OH•) and hydrogen peroxide (H_2O_2). Reactions of ROS such as O_2^-• with NO yield products such as peroxynitrite ($ONOO^-$), a RNS which can be an extremely aggressive oxidant.

Cytokines

Cytokines play a vital role in IRI, both by inducing and sustaining the inflammatory response, and by modulating IRI severity. Tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) are the two cytokines most commonly implicated in liver IRI. TNF-α is a pleiotropic cytokine generated by various different cell types in response to inflammatory and immunomodulatory stimuli. TNF-α modulates leukocyte chemotaxis and activation, and induces ROS production in Kupffer cells[17]. Additionally, IL-1 is known to promote production of ROS, induce TNF-α synthesis by Kupffer cells and induce neutrophil recruitment[18].

Complement

The complement system also contributes significantly to IRI and is composed of approximately 30 soluble and membrane-bound proteins. This system can be stimulated in three pathways: (1) the antibody-dependent classical pathway; (2) the alternative pathway; or (3) the mannose-binding lectin pathway[19]. Complement, when activated, acts as a membrane-attacking complex that stimulates the production of proinflammatory cytokines and chemotactic agents. Furthermore, it can regulate adaptive immunity[20].

THE INFLUENCE OF ENDOGENOUS NO ON LIVER IRI

Damage to the liver due to IRI is a culmination of inflammatory cross talk with the principal participants mentioned previously. IRI is the main cause of liver injury in response to vascular clamping during hepatic procedures such as hepatectomy and liver transplantation. This insult on the liver results in disturbances of the sinusoidal microcirculation and the generation of a variety of mediators such as ROS, cytokines, activation of chemokines and other cell signaling molecules previously mentioned.

Hepatic IRI can cause severe hepatocellular injury that contributes to morbidity and mortality after liver surgery. As briefly mentioned previously, reductions of NO during liver IRI occur and are associated with increased liver injury[3]. This is now appreciated to be due to decreases in NO steady state production resulting from low concentrations of endothelium-derived nitric oxide synthase (eNOS). This event coupled with NO inactivation due to reactions with abundant ROS, such as O_2^-•, results in reduced NO bioavailability. The consequences of this reduced bioavailability include, but are not exclusive to, increased oxidative stress, increased apoptosis, increased leukocyte adhesion, increased microcirculatory tone, and perturbed mitochondrial function. Interestingly, restoration of NO to more "physiologic" concentrations serves to diminish the liver ischemic injury *via* countering of the adverse actions mentioned previously. Studies have demonstrated findings that are consistent with the premise that eNOS is crucial for minimizing injury during liver IRI. For example, liver injury was demonstrated to be less in wild type mice compared to eNOS knockouts ($eNOS^{-/-}$)[21] (Figure 2), in addition to the findings that agents given to increase eNOS expression or donate NO afford greater liver IRI protection[22,23]. It is also well established that the NO concentrations during various inflammatory states are significantly increased by increasing expression of inducible nitric oxide synthase (iNOS). However, the influence of iNOS and its true contribution in conferring liver protection (or not) deserves additional studies. In a rat model of liver IRI, iNOS expression was significantly increased correlating with increases in iNOS RNA at 1 and 5 h[24]. This is consistent with other studies measuring iNOS expression in conditions of liver IR. In

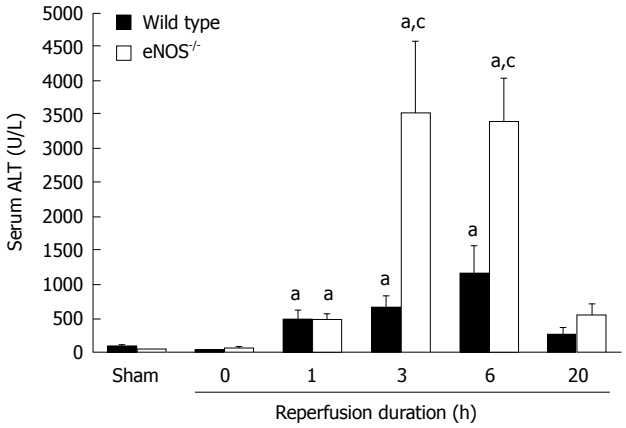

Figure 2 Increased liver injury as assessed by serum alanine aminotransferase in endothelium-derived nitric oxide synthase knockout mice compared with their wild type controls. $^{a}P < 0.05$ *vs* sham-operated controls. $^{c}P < 0.05$ *vs* time-matched wild type control. ALT: Alanine aminotransferase; eNOS: Endothelium-derived nitric oxide synthase (Courtesy of Dr. Ianes N. Hines, Chapel Hill, NC).

a porcine model of IRI, intraportal injection of the selective iNOS inhibitor, aminoguanidine, was demonstrated to decrease injury[25]. In an intriguing study, iNOS knockout mice (*iNOS*$^{-/-}$) exposed to warm liver IRI demonstrated a much greater magnitude of injury compared to wild type mice. Of notable interest was the finding that even though injury was greater in the iNOS knockout mice, little to no iNOS RNA was detectable in the wild type mice. It would appear that for now, the true influence of iNOS on liver injury during IR remains unclear.

A number of other endogenous NO-mediated mechanisms thought to confer protection have been published. For example, NO has been shown to inhibit caspase proteases *via S*-nitrosylation, thereby inhibiting apoptosis[26]. This appears to be somewhat concentration-dependent. Low physiological concentrations of NO may inhibit apoptosis. In contrast, higher concentrations may lead to the formation of toxic products such as $ONOO^{-}$ or other ROS which lead to cell necrosis and apoptosis[27]. Other published mechanisms of NO-mediated protection include inhibition of NF-κB[28], reversible inhibition of mitochondrial complex I, and decreased mitochondrial calcium accumulation[29]. As to be expected, controversy exists concerning "if" and "how" NO exerts cellular protection. For instance, in a study by Jaeschke *et al*[11], administration of a NO synthase inhibitor did not attenuate or accentuate liver injury during the initial reperfusion period. Inhibition of NO was observed not to influence neutrophil migration to the injured sites. While this contradicts a number of other studies, based on their findings, the authors concluded that NO availability was unlikely to be involved in the post-ischemic oxidant stress and reperfusion injury[30]. Nevertheless, the majority of published literature has demonstrated the beneficial effects of NO during liver IRI. These conflicting results might be explained by the fact that the mechanism of NO-mediated protection varies depending on cell type, quantities supplied, laboratory methods applied, timing and duration of NO exposure.

While iNOS was shown to be protective against hepatic IRI in some studies, it was shown to be deleterious in others. In a rat model of hepatic IRI, Takamatsu *et al*[31] observed increased hepatic expression of iNOS mRNA, ALT, and plasma iNOS at 3, 12, and 24 h after hepatic reperfusion. Concomitantly, there was evidence of histologic damage and nitrotyrosine formation in the liver sampled post-reperfusion. These changes were absent in the control group given the selective iNOS inhibitor, ONO-1714. The authors concluded that peroxynitrite may be involved in iNOS-mediated hepatic injury following IR[31].

In another model of hepatic IR in rats, Wang *et al*[32] observed an increase in iNOS protein and mRNA expression on the first day following hepatic reperfusion. Higher levels of iNOS correlated with evidence of increased hepatic injury in the form of elevated serum levels of ALT and AST. Administration of the non-selective nitric oxide synthase (NOS) inhibitor, L-NAME, significantly increased AST and ALT, while administration of the selective iNOS inhibitor, AE-ITU, significantly decreased AST and ALT levels, respectively[32]. The authors postulated that the deleterious effects of L-NAME were due to inhibition of eNOS, while the protective effects of AE-ITU were due to inhibition of injury-provoking iNOS. In a rat model of hepatic IR and small-for-size living-related liver transplantation, Jiang *et al*[33] observed increased iNOS mRNA and protein expression post-reperfusion from a warm ischemic insult with peak expression at 3 h post-reperfusion. This was accompanied by significant increases in concentrations of AST, ALT, malondialdehyde (MDA) and histologic evidence of damage compared to controls. The authors postulated that iNOS-induced hepatic damage was *via* significant production of ROS[33]. We summarize some key studies investigating endogenous NO and NOS in hepatic IRI in Table 1[3,21,25,31-37].

THE USE OF EXOGENOUS NO ADMINISTRATION IN ATTENUATING HEPATIC IRI

Inhaled nitric oxide

Inhaled NO was approved by the US Food and Drug Administration in December of 1999 for the treatment of persistent hypertension of the newborn. Over the last decade, the primary advantage of inhaled nitric oxide (iNO) was seen to be its ability to selectively decrease pulmonary vascular resistance with minimal effects on systemic blood pressure; however, there is currently much interest in exploring its other benefits, including its antioxidant properties and its cytoprotective abilities[4]. In many animal studies, iNO decreased infarct size and left ventricular dysfunction after IRI, increased coronary artery patency after thrombosis, increased blood flow in brain, kidney and peripheral vasculature, decreased leukocyte adhesion in bowel during ischemia-reperfusion, and decreased platelet aggregation[38]. Date *et al*[39] reported the use of iNO in 15 out of 32 patients who suffered from immediate severe allograft dysfunction, with iNO administered at 20 to 60 ppm. The mortality was significantly lower in the

Table 1 Effect of endogenous nitric oxide and nitric oxide synthase on liver ischemia-reperfusion injury

Species	Experimental methods	Ischemic time (min)	NO or NOS effects	Ref.
Pigs	Aminoguanidine, 5 min before ischemia	120	NO derived from iNOS, antioxidant	[25]
Dogs	FK 409, 30 min before ischemia and15 min before and 45 min after reperfusion	60	NO, improves hepatic microcirculation	[34]
Rats	L-arginine, 7 d before IRI	60	NO, antioxidant	[35]
Rats	L-NAME 60 min before ischemia	30	NO, antioxidant	[3]
Mouse	Gadolinium chloride 24 h before ischemia L-NAME methyl ester 15 min prior to ischemia	45	NO derived from eNOS, antioxidant, suppresses Kupffer cell function, regulated basal hepatic blood flow, but did not affect blood flow after reperfusion, attenuated neutrophils infiltration	[21]
Rats	L-arginine or Sodium nitroprusside or L-Name prior to ischemia	60	NO, improves peripheral liver blood flow after reperfusion, cytoprotective	[36]
Male rats	Arginine or L-NAME or 8-bromo guanosine 3′ 5′-cyclic monophosphate or rat atrial natriuretic peptide (ANP 1-28) 30 min before ischemia	45	NO, antioxidant, antiproinflammatory cytokines, improves microcirculation by the cGMP pathway, inhibits neutrophil infiltration and platelet aggregation	[37]
Male rats	IRI group: had partial clamping of portal vein and hepatic artery ONO-1714 group: as above plus ONO-1714 just prior to reperfusion and 6 h thereafter Control group: sham operation	90	iNOS expression peaked at 3 h and diminished at 24 h post reperfusion in IRI and ONO-1714 groups ONO-1714 significantly inhibited plasma nitrates at 24 h post reperfusion ONO-1714 significantly inhibited plasma ALT at 12 h post reperfusion, together with inhibiting histological damage and peroxynitrate expression in liver	[31]
Male rats	Microvessel clamping of portal vein and left hepatic artery L-NAME and AE-ITU given to each of 6 rats exposed to microvessel clamping (time unknown)	60	L-NAME worsened, elevated levels of ALT/AST in IRI groups AE-ITU mildly and significantly decreased levels of AST	[32]
Male rats	Portal vein, hepatic artery and bile ducts clamped by microvessel clamp followed by reperfusion	60	Significant elevation of AST/ALT, MDA/SOD in IRI and small-for-size liver transplantation groups	[33]

NO: Nitric oxide; NOS: Nitric oxide synthase; iNOS: Inducible nitric oxide synthase; eNOS: Endothelium-derived nitric oxide synthase; cGMP: Cyclic guanosine monophosphate; L-NAME: L-nitroarginine; ANP: Atrial natriuretic peptide; IRI: Ischemia-reperfusion injury; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; AE-ITU: Aminoethyl-isothiourea; MDA: Malondialdehyde; SOD: Superoxide dismutase.

iNO group (7% and 24%, respectively). The gross benefits reported were that iNO improved oxygenation, decreased pulmonary artery pressure, shortened the period of postoperative mechanical ventilation, and reduced airway complications and mortality[39]. Likewise, a recent retrospective study also presented a picture of improvement of overall respiratory functions. The authors encouraged the administration of iNO for the prevention and treatment of early graft failure in lung transplant recipients[40]. Varadarajan *et al*[41] were the first group to study the relationship between NO metabolism and IRI in human liver transplantation[41]. From their study, they concluded that reduced bioavailability of eNOS contributed to IRI one hour after portal reperfusion. On the other hand, iNOS did not contribute to early IRI after human liver transplantation. Clinical and mechanistic reports on therapeutic use of iNO demonstrated action well beyond vascular relaxation, subsequently inactivated by oxy- or deoxyhemoglobin in the red blood cells. iNO has various positive effects on extrapulmonary systems. However, how iNO mediates these extrapulmonary effects remains unclear. Evidence supporting stable forms of iNO is probably strongest for *S*-nitrosothiols (SNOs) and nitrite[38]. In a prospective, blinded, placebo-controlled study, 80 ppm of iNO was administered to patients undergoing orthotropic liver transplantation[42]. Many advantages were reported in the iNO group, including reduced platelet transfusion, an improvement in the rate at which liver function was restored post-transplantation, and a decrease in the length of hospital stay. Most interesting was the finding of an approximate 75% reduction of hepatocellular apoptosis in patients treated with iNO[42] (Figure 3). Possible biochemical intermediates of iNO include plasma and red blood cell nitrate, nitrite, SNOs, C- or N-nitrosamines and red blood cell ferrous nitrosylhemoglobin. In this study, a detailed analysis indicated that the most likely candidate transducer of iNO in liver IRI was nitrite.

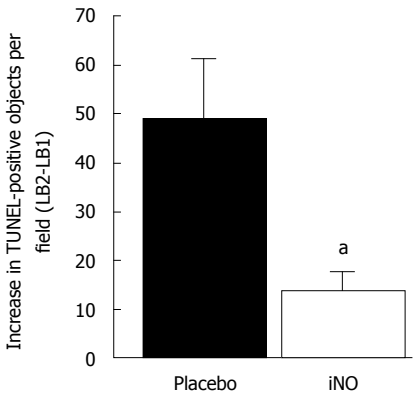

Figure 3 Decreased apoptosis indicated by TUNEL staining in patients treated with inducible nitric oxide compared to controls (Courtesy of John D. Lang, MD, Seattle, WA). $^{a}P < 0.05$. iNO: Inducible nitric oxide.

iNO delivery systems

An iNO delivery system should allow for constant and accurate measurements of NO and nitrogen dioxide (NO_2)

Table 2 Nitric oxide donors

Model	Drugs	Outcomes	Ref.
Canine liver IRI	FK-409	Promoted hepatic tissue blood flow, decreased serum endothelin-1, cytoprotection	[34]
Isolated hepatocytes	S-nitroso-N-acetylpenicillamine	Drug induced the expression of heat shock protein 70 mRNA and protein resulting in cytoprotection from TNFα	[2]
Murine liver IRI	Sodium nitroprusside	Promotes hepatic tissue blood flow after reperfusion-cytoprotection	[36]
Murine liver IRI	PEG-poly SNO-BSA, a sustained release of NO	Decreased neutrophil accumulation, prevented the excessive production of iNOS	[54]
Murine liver IRI	Macromolecule S-nitrosothiols	Prevented hepatocellular injury	[55]

concentration in inspired gas, as well as minimization of the contact time between oxygen and NO, in order to decrease the feasibility of producing high NO_2 concentrations. The measurement of iNO and NO_2 concentrations can be undertaken using chemiluminescence or electrochemical devices. There are some drawbacks of chemiluminescence devices such as cost, the need for a relatively high sample volume, noise and maintenance difficulties[43]. However, an electrochemical analyzer is relatively insensitive, and these measurements may be affected by pressure, humidity, temperature and the presence of other gases in the environment[44]. The delivery system should display the pressure of iNO in the cylinder and should have a backup power supply to avoid sudden discontinuation of iNO. Inhaled NO is usually supplied in nitrogen at various concentrations. The gas mixture concentration should be sampled downstream of the input port just proximal to the patient manifold. iNO also can be administered *via* nasal cannula, oxygen mask and oxygen hood[45]. Finally, the exhausted gas should be scavenged by passing it through carbon and filters, soda lime or activated charcoal[46].

POTENTIAL TOXICITIES DURING INHALATION

In the presence of high concentrations of O_2, NO oxidizes to nitrogen dioxide (NO_2). NO_2 reacts with the alveolar lining fluid to form nitric acid. NO dissolved in the alveolar lining fluid reacts with O_2^- yielding $OONO^-$, then decomposes into a hydroxyl anion[47]. Nitration of tyrosine residues of proteins is used as a marker of oxidative stress[48]. The rate at which NO is oxidized to NO_2 depends on the square of NO concentration and fractional concentration of oxygen to which it is exposed. The Occupational and Health Administration recommend 5 ppm exposure to NO per 8 h per 24-h-interval as the upper safe limit of human exposure[49]. In order to protect against NO_2 toxicity, iNO should be given with the least possible O_2 concentration. Inhaled NO and NO_2 concentrations should be monitored, exhaled gases should be scavenged, and a soda lime canister should be placed in the inspiratory limb of the breathing circuit.

Nitrite

The simple molecule nitrite had been thought to be just an index of NO production for decades[3]. Recently, a number of lines of evidence suggest that nitrite is a pro-mediator of NO homeostasis[50]. Administration of nitrite at near physiological concentrations (< 5 μg) leads to vasodilatation in animal and human studies[46]. Shiva *et al*[51] observed that nitrite was metabolized across the peripheral circulation. In addition, nitrite caused an increase in peripheral forearm blood flow when 80 ppm iNO was administered[51]. Under distinct conditions such as hypoxia and acidosis, nitrite can be reduced to NO by a number of deoxyhemeproteins (hemoglobin, myoglobin, neuroglobin and cytoglobin), enzymes (cytochrome P_{450} and xanthine oxidoreductase), and components of the mitochondrial electron transport chain[4]. Since nitrite can be converted back to NO during hypoxia, nitrite therefore is expected to be utilized during IRI. Furthermore, nitrite shows more potential benefits than NO in terms of safety and ease of administration. In other words, nitrite concentrations administered need only to be a small dose in order to increase plasma and tissue nitrite levels several folds. Routes of administration are oral, intravenous injection or infusion, intraperitoneal, *via* nebulizer or topical[52]. Nitrite has now been demonstrated to have cytoprotective effects in animal models of ischemia-reperfusion in organs. Duranski *et al*[52] evaluated the effects of nitrite therapy in *in vivo* murine models of hepatic and myocardial IRI, and showed that nitrite was associated with cytoprotective effects. In that setting, nitrite reduced cardiac infarct size by 67% and limited elevations of liver enzymes in a dose-dependent manner. These workers also demonstrated that nitrite was reduced to NO regardless of eNOS and heme oxygenase-1 enzyme activities[52]. The exact mechanisms as to how nitrite protects against this particular condition are being explored, but it appears that the benefit is mediated through the modulation of mitochondrial function by involving the posttranslational *S*-nitrosation of complex I to attenuate reperfusion oxygen radical generation and prevent cytochrome-C release[51].

NO donor drugs

Since nitric oxide is not considered to be an ideal gas for the treatment of IRI, NO donor drugs are now being explored as an alternative to the parent compound. Novel drugs have been developed and used for the delivery of NO in order to compensate for the very short half-

life of NO *in vivo*. However, there are only two types of NO donor drugs that are currently used clinically: organic nitrates and sodium nitroprusside. Organic nitrates are the most commonly used NO donor drug treatment for coronary artery disease and congestive heart failure because the drugs produce clear clinical responses through their vasodilatory effects. Preparations of drugs include slow release oral forms, ointments, transdermal patches, nebulizers and traditional intravenous forms. The main limitation of organic nitrates is the induction of drug tolerance with prolonged continuous use. NO release from nitroglycerin is likely *via* the enzyme, mitochondrial aldehyde dehydrogenase[53]. The mechanism of NO release from sodium nitroprusside, on the other hand, is more complex, as demonstrated by Yang *et al*[53] in a murine model of hepatic IRI. Sodium nitroprusside is thought to down-regulate the mRNA expression of several enzymes related to hepatic injury[54]. We summarize other novel NO donor drugs in Table 2[2,34,36,54,55].

CONCLUSION

Ischemia-reperfusion injury is a well-defined threat to the liver during periods of interruption and restoration of oxygen delivery, as occurs in certain procedures such as hepatic resections and orthotopic liver transplantations. Relative NO deficiency seems central in the pathogenesis of this injury. Replacing NO *per se* either by inhalation, nitrate anion or *via* donor drugs represents a novel means for ameliorating IRI. Further randomized controlled trials are needed to evaluate this therapy in patients undergoing operative procedures causing IRI.

Abstract

Melatonin, the hormone of darkness and messenger of the photoperiod, is also well known to exhibit strong direct and indirect antioxidant properties. Melatonin has previously been demonstrated to be a powerful organ protective substance in numerous models of injury; these beneficial effects have been attributed to the hormone's intense radical scavenging capacity. The present report reviews the hepatoprotective potential of the pineal hormone in various models of oxidative stress *in vivo*, and summarizes the extensive literature showing that melatonin may be a suitable experimental substance to reduce liver damage after sepsis, hemorrhagic shock, ischemia/reperfusion, and in numerous models of toxic liver injury. Melatonin's influence on hepatic antioxidant enzymes and other potentially relevant pathways, such as nitric oxide signaling, hepatic cytokine and heat shock protein expression, are evaluated. Based on recent literature demonstrating the functional relevance of melatonin receptor activation for hepatic organ protection, this article finally suggests that melatonin receptors could mediate the hepatoprotective actions of melatonin therapy.

INTRODUCTION

It has been suggested that the substance melatonin (5-methoxy-N-acetyltryptamine), discovered by Aaron Lerner in 1958, exists in almost every animal species, and possibly even in all plants[1,2]. Its physiological functions are said to be diverse; while melatonin may be involved in modifications of vasomotor tone[3,4] and thermoregulation[5], it is primarily known as the signal of darkness[6].

In vertebrates, melatonin is synthesized in the pineal gland and secreted during darkness as a hormonal message of the photoperiod[7]. The rhythm of melatonin synthesis is mainly driven by an oscillator which is situated in the hypothalamic suprachiasmatic nucleus (SCN)[8]. This oscillator is usually entrained to a 24-h rhythm by environmental lighting conditions, which are perceived in the retina by rods, cones and intrinsically photosensitive retinal ganglion cells[9].

Based on the photoperiodic information transduced from the retina *via* the SCN to the pineal gland, melatonin is secreted during darkness after *de-novo* synthesis from tryptophan[10]. This nocturnal melatonin signal is proportional to the length of the night, thus encoding not only

circadian, but also seasonal variations in the photoperiod[11]. In so-called photoperiodic animals, like the Siberian hamster, these seasonal variations in melatonin output may have a profound influence on the regulation of reproduction[12,13], prolactin secretion[14], as well as coat color[15]. The nocturnal secretion of melatonin is generally independent of an animal's active period: in both nocturnal and diurnal species, melatonin levels rise during darkness[6].

Melatonin synthesis is not exclusively located in the pineal gland, but has also been described in numerous peripheral organs, such as the retina[16], bone marrow[17], skin[18], Harderian gland[19], platelets[20], lymphocytes[21], testes[22], and in the gastrointestinal tract[23]. Data on messenger RNA expression of two key enzymes responsible for melatonin synthesis, arylalkyamine-N-acetyltransferase and hydoxyindole-O-methyltransferase, suggest that even more peripheral organs may be able to produce this hormone[24].

So far, the physiological significance of extrapineal sites of melatonin synthesis remains unclear. However, besides its relevance in the time-keeping system, melatonin has been demonstrated to be a powerful radical scavenger[25]; it is tempting to assume that extrapineal melatonin may serve as a tissue protective agent.

MELATONIN AS AN ANTIOXIDANT

Processes of acute inflammation, e.g. sepsis, hemorrhagic shock or ischemia/reperfusion, typically result in an imbalance of oxidative homeostasis with excess generation of reactive oxygen species (ROS) and a relative deficiency of endogenous antioxidants; this state is called oxidative stress. ROS include oxidants, such as peroxynitrite, and free radicals, such as hydroxyl radicals and superoxide; these substances are toxic and may induce lipid peroxidation (LPO), as well as protein, sugar and DNA degradation[26].

The powerful antioxidant capacity of melatonin is usually attributed to its potential to eliminate free radicals by the donation of electrons[27,28]. For example, melatonin may neutralize hydroxyl radicals by forming 3-hydroxymelatonin, which is excreted in the urine[29]. Furthermore, melatonin was demonstrated to interact with toxic reactants like peroxyl radicals[30], singlet oxygen species[31], and hydrogen peroxide[32]. Metabolites of melatonin, including the major hepatic metabolite 6-hydroxymelatonin, as well as N-acetyl-N-formyl-5-methoxykynuramine and N-acetyl-5-methoxykynuramine have been shown to detoxify radicals themselves[32-34]. This powerful pyramid scheme of radical scavenging has been named "the antioxidant cascade of melatonin"[1,34].

In addition to these direct interactions with ROS, melatonin may induce upregulation of the activity of antioxidants and antioxidant enzymes, such as superoxide dismutase (SOD), glutathione (GSH), glutathione peroxidase (GPx) and glutathione reductase (GSR), in the environment of oxidative stress[35,36]. In addition, the pineal hormone may induce downregulation of pro-oxidant enzymes like nitric oxide synthase (NOS)[37,38] and lipoxygenases[39], thus reducing the formation of nitric oxide (NO), superoxide anions, and subsequently peroxynitrite anions.

Both the direct detoxification of radicals, as well as the modification of pro- and antioxidative enzyme activities are thought to be relevant for the pineal hormone to act as a protective substance, for example when administered in models of oxidative stress. This valuable effect appears to be independent of the type of injury and the species investigated. Exogenous melatonin may exhibit beneficial actions in a myriad of models of organ damage; this is especially true for the liver.

HEPATOPROTECTION BY MELATONIN ADMINISTRATION

With respect to its hepatoprotective effects, countless publications have demonstrated that exogenous melatonin may be used successfully to treat a great variety of different pathophysiological conditions[40-146]: Table 1 gives an overview of the hepatoprotective effects of exogenous melatonin administration, without the pretension of being complete. Included in this summary are investigations mainly presenting a model of liver damage *in vivo*, evaluating parameters of hepatic integrity as a major endpoint, and the administration of melatonin as the primary therapeutic agent. Studies on chronic disease development, aging, investigations on nutritional or dietary changes, exercise-induced stress, remote organ injuries with the liver as a secondary target, as well as investigations on tumor development, cancer progression and liver metastases were excluded.

Based on this extraordinary pool of data, treatment with melatonin appears to be a versatile hepatoprotective strategy in models of experimental liver injury as demonstrated *in vivo* for rats, mice and chicks. There are remarkable variations concerning both the route of melatonin administration, as well as the dose given, the latter ranging a thousand-fold from 100 μg/kg[93,124] to 100 mg/kg[77] melatonin. Only limited data are available on dose-response relationships, and most studies did not include measurements of plasma melatonin levels. Furthermore, it should be mentioned that in some investigations, melatonin was given either as a single dose or repetitively - in some publications for weeks - as a pretreatment, before or while the damage was induced. Unfortunately, not all researchers used melatonin as a therapeutic substance following the infliction of damage, although this would be of high relevance for the evaluation of its clinical use.

Nevertheless, all these studies show similar or even identical results concerning the hepatoprotective effects of treatment with melatonin. Improvements are consistently demonstrated for - but not limited to - parameters of antioxidant enzymes, hepatocellular integrity, interleukin response, NO signaling, and survival.

Antioxidant effects

A strong antioxidant effect of melatonin seems evident as almost all investigators describe that in liver homogenates,

Table 1 Hepatoprotective effects of melatonin in different models of stress

Model	Induction/type	Melatonin treatment	Hepatoprotective effects of melatonin	Species	Ref.
Septic shock	CLP/LPS/LPS + BCG	0.25-60 mg/kg ip/iv/*po* 1-10 ×	hLPO↓, AST/ALT/GGT/ALP/BIL↓, hGSH/hGPx/hSOD/hCAT↑, hNEC↓, hPMN infiltration↓, hTNF-α/hIL-1/hNO↓, 72-h survival rate↑	Rats, mice	[40-49]

melatonin strongly attenuated hepatic LPO[40-49,53-99,102,103,106-114,116-123,125-146], usually measured by means of malondialdehyde quantification. Furthermore, melatonin appears to increase the activity and/or expression of hepatic antioxidant enzymes, such as GSH, GPx and SOD, after most types of injury[40-49,53-63,66-93,97-99,103,106-123,125-127,130-146]. Many in-

vestigators also report an increase in hepatic catalase after melatonin treatment[44,71,78,83-85,89,108,111,115,116,118,125,132,135,139].

Hepatocellular integrity

Administration of the pineal hormone appears to reduce the rise in serum enzyme levels of aspartate transaminase, alanine transaminase, lactate dehydrogenase, alkaline phosphatase, γ glutamyl transferase and bilirubin after almost all types of injury, indicating that the extent of cell damage was reduced[40-62,66-68,77,83-92,94-96,98-103,111-114,116-120,125-127,130-146]. This is supported by histopathology results when performed, showing that animals treated with melatonin typically presented with reduced hepatocellular necrosis or attenuated infiltration of polymorphonuclear granulocytes. Reduced hepatic levels of myeloperoxidase further indicate that neutrophil granulocyte infiltration was strongly reduced by the pineal hormone[41,55,67,108,109,111,134,143].

Interleukin response

With respect to interleukin signaling, melatonin was reported to suppress the formation of pro-inflammatory cytokines such as tumor necrosis factor α, interleukin (IL)-1, IL-1β, IL-6, as well as the cellular interleukin response protein, nuclear factor κ-light-chain-enhancer of activated B cells[42,43,53,62,88,99]. This was demonstrated in sepsis and after ischemia/reperfusion, as well as after carbon tetrachloride and dimethylnitrosamine toxicity. Thus, parts of the hepatoprotective actions of the pineal hormone could be based on its suppressive effects on the pro-inflammatory pathway of the immune response.

NO signaling

A large number of studies have investigated the relevance of the NO pathway in the protective effects of melatonin treatment[40,42,43,45,47,49,53,56,57,60,72,73,75,108,125,128,129,142,146]. Melatonin seems to reduce NO release in the vasculature and attenuate the expression of inducible NOS in the liver, as was demonstrated in models of sepsis, ischemia/reperfusion, cholestasis, ionizing radiation, and toxic liver injury with aflatoxins, carbon tetrachloride, methanol, and thioacetamide. As NO reacts with superoxide to form the potentially toxic oxidant peroxynitrite, the reduction in the expression of iNOS may well be another key element in the antioxidant potential of melatonin.

Survival

When investigated, the observed hepatoprotective effects of melatonin were associated with an improvement in survival rate or mean survival time, which was observed in models of sepsis, ischemia/reperfusion, acetaminophen and diquat toxicity, and malaria[41-43,49,53,60,68,101,146].

Taken together, the results from more than 100 experimental studies included here, show convincingly that various regimens of melatonin treatment may be used to reduce hepatic damage in acute liver injury *in vivo*[40-146]. However, this overview is likely to be incomplete: many other studies indicate similar results for chronic disease development and tumor therapy.

So far, only one investigation has been published regarding hepatoprotection by melatonin in humans: in a prospective study, increased survival, attenuated liver damage and reduced immunological activity after transcatheter arterial chemoembolization (TACE) and melatonin treatment were reported in patients with inoperable advanced hepatocellular carcinoma, compared with control patients who underwent TACE but were not given melatonin[147].

Limitations of melatonin

Despite the enormous amount of data supporting the idea of melatonin as a liver protective agent, it should be noted that there are reports which show no hepatoprotective effect of melatonin in a few models of stress. Daniels *et al*[148] were unable to demonstrate any benefit of melatonin administration with respect to carbon tetrachloride-induced liver injury *in vivo*, although ten other studies unanimously showed the value of such a treatment[83-92]. Furthermore, melatonin had no effect on 2-nitropropane-induced LPO in rat liver[149].

Equally interesting and disappointing, melatonin does not appear to be a protective agent with respect to hepatic ethanol toxicity. In a model of acute or chronic ethanol exposure, melatonin administration did not influence hepatic LPO, or GSH and GPx activities in rat[150]. El-Sokkary *et al*[151] demonstrated that administration of ethanol for 30 d did not increase hepatic LPO in the same species. Yet, a recent study showed that melatonin may reduce ethanol-induced liver injury in terms of reduced hepatocellular injury and inflammatory response in a rodent model[152]. As a consequence, further data are required to resolve the issue on whether melatonin may be helpful in reducing ethanol-associated liver damage.

Both positive and negative findings raise the question of how melatonin's intense hepatoprotective potential may be mediated. With respect to this matter, it has been suggested that the activation of membrane-bound melatonin receptors may be an important step in the induction of the antioxidant properties of the pineal hormone[35,36].

HEPATIC MELATONIN RECEPTORS

Melatonin receptors in mammals are classified as membrane-bound, high-affinity G-protein coupled receptors, officially named MT_1 and MT_2 (previous terminology: Mel_{1a} and Mel_{1b}, respectively)[153]. Both receptors are coupled to heterotrimeric G-proteins, and involve signaling through inhibition of cyclic adenosine-monophosphate (cAMP) formation, protein kinase A activity and phosphorylation of cAMP responsive element binding, as well as effects on adenyl cyclases, phospholipase A2 and C, and calcium and potassium channels[154-158]. A third receptor, named MT_3, was demonstrated to be equivalent to intracellular quinone-reductase-2[159]. Non-mammalian species express yet another receptor subtype named Mel_{1c}, which is the first type of melatonin receptor to be discovered[160].

In the liver, the presence of MT_1, MT_2 and MT_3 has been reported in various species[161-171]; Table 2 gives an

Table 2 Melatonin receptors in the liver of various species

Species	MT1	MT2	MT3/QR2	Technique	Ref.
Wistar rat	+	+	NT	RT-PCR	[161,162]
CH3/He mouse	+	+	NT	RT-PCR	[163]

+: Detected; -: Not detected; MT1: Melatonin receptor type 1; MT2: Melatonin receptor type 2; MT3/QR2: Melatonin receptor type 3/quinone reductase-2; NT: Not tested; RT-PCR: Reverse transcription-polymerase chain reaction.

overview on the current literature demonstrating hepatic melatonin receptor expression or specific iodine ligand binding. So far, there are no original research publications showing proof of hepatic MT_1 or MT_2 receptors in humans. Some evidence points to the possibility that melatonin receptor expression may exhibit circadian variations; this has also been demonstrated for hepatic MT_1 and MT_2[163,166-168].

The physiological significance of hepatic melatonin receptors is mostly unknown. Two studies indicated that hepatic melatonin receptors may be involved in regulating blood glucose[164,172]. Melatonin receptor double knock-out mice do exist, and they appear to have a generally unaltered phenotype. So far, there are no reports showing disadvantages regarding the lack of hepatic melatonin receptors under physiological conditions.

Unfortunately, there are currently no reliable antibodies available for MT_1 and MT_2 receptors[154]. Only a few publications have demonstrated data on the MT_1 or MT_2 protein[162,173]; the results are either non-specific or cannot easily be reproduced. Thus, additional techniques will be required to convincingly demonstrate melatonin receptor protein in the liver.

Nonetheless, our own laboratory was able to generate preliminary results concerning the immunohistochemical distribution of MT_1 in the liver[173]. It appeared that MT_1 was primarily localized in the pericentral area of liver lobules. Due to their metabolic state, pericentral fields of the liver are particularly sensitive to ischemic stress, compared to slightly better oxygenated periportal areas. Thus, this differential distribution of melatonin receptors could provide a way of focusing melatonin receptor-dependent liver protection to areas in need. It is tempting to speculate that this pattern of MT_1 expression might allow the preferential protection of centrolobular hepatocytes.

Further studies, using different techniques or improved antibodies, will be required to support this idea of differentially distributed hepatic melatonin receptors. Thus, the presence and distribution of both melatonin receptor protein subtypes in the liver remain to be determined.

RECEPTOR-MEDIATED ACTIONS OF MELATONIN IN THE LIVER

Only a few studies have analyzed the significance of melatonin receptors in the hepatoprotective effects of melatonin administration *in vivo*[50,51,174]. In a model of hemorrhage and resuscitation, the melatonin receptor antagonist luzindole was able to attenuate the protective effects of melatonin pretreatment and therapy with respect to liver function as measured by plasma disappearance rate of indocyanine green[50,51]. However, not all of the beneficial effects of melatonin were abolished. The use of this antagonist may not clarify all aspects of the effects of melatonin administration, as luzindole itself has been demonstrated to have a strong direct antioxidant potential[175], and to reduce LPO *in vitro*[176].

In the same model of hemorrhagic shock, therapy with the selective melatonin receptor agonist ramelteon improved liver function and hepatic perfusion in rats[174]; this melatonin receptor agonist does not possess any relevant radical scavenging properties[174]. These results point to the possibility that although beneficial, the radical scavenging capacity of melatonin may not be necessary for its protective actions.

This hypothesis is supported by the observation that in other organ systems, the protective potential of melatonin may also be antagonized by luzindole: this antagonist has been reported to abolish the protective capacity of melatonin after myocardial ischemia/reperfusion injury[177], after cyclosporine-A cardiotoxicity[178], in a model of neonatal brain injury[179], and with respect to stress-induced gastric lesions[180].

The following preliminary data from our own research laboratory may have even more impact: in a murine model of sepsis, we were able to demonstrate that the improvements in survival seen after melatonin therapy were not present in melatonin receptor double knock-out mice. This finding indicates once more that membrane-bound melatonin receptors may be responsible for the beneficial effects of melatonin administration.

As a consequence, if (1) no radical scavenging properties are necessary to provide organ protection *via* melatonin receptor activation[174]; (2) the melatonin receptor antagonist luzindole may abolish almost all protective effects of melatonin[177-180]; and (3) the absence of melatonin receptors impedes the protective action of melatonin administration, then it appears reasonable to conclude that melatonin receptors are necessary to mediate at least some of the beneficial effects of the pineal hormone in peripheral organs.

POTENTIAL INFLUENCE ON HEPATIC GENE EXPRESSION

The specific intracellular signal transduction cascade leading to hepatoprotective effects after melatonin receptor activation is presently unknown. However, a number of

hypotheses have been published, suggesting that cAMP responsive element- or estrogen responsive element-containing genes may be regulated by melatonin receptor activation[35,181]. Most certainly, melatonin has a profound influence on hepatocellular gene expression; this has been demonstrated in heat shock protein expression by various investigators[69,73,95]. Our research group was able to present preliminary data showing that melatonin influences different pathways of hepatocellular transcription, including modifications of a variety of heat shock proteins, as well as intense regulation of other membrane-bound receptors and signal transduction factors, in a rat model of hemorrhagic shock[182]. These findings allow the assumption that melatonin therapy may induce beneficial changes with respect to gene transcription in hepatocytes, in the environment of oxidative stress. However, it remains to be determined whether these modifications of hepatic gene expression are indeed mediated by melatonin receptor activation.

FROM BENCH TO BEDSIDE

While the current literature leaves little doubt that melatonin administration may induce hepatoprotective actions[40-146], many questions remain on how this effect may be transduced. The putative signaling cascade, leading from melatonin receptor activation to specific hepatoprotective gene expression profiles, remains to be determined. Based on the evidence available, it appears possible that melatonin receptors mediate the intense protective effects of the pineal hormone in the liver.

To bring this experimental knowledge into clinical use, a pilot study was initiated by Schemmer *et al*[183] in Germany to evaluate the use of melatonin in patients undergoing major liver resections. Should this investigation be successful, this would open the door for yet another important indication for the use of melatonin in human liver surgery: as an adjunct to reduce ischemia/reperfusion injury in liver transplantation. The research group of Freitas and Vairetti has already demonstrated in two studies that melatonin may reduce cold ischemic injury in rat liver[184,185], and suggested that the pineal hormone may be useful in the event of liver transplantation. This idea was supported by Casillas-Ramírez in a review on liver transplantation[186]. Thus, melatonin administration could be beneficial in patients not only to reduce damage to the transplant, but also to serve as a protective agent for the attenuation of reperfusion injury.

Future studies will demonstrate whether melatonin will meet our high expectations not only in the laboratory, but also for our patients. However, the currently available literature allows us to believe that melatonin will successfully continue its way from bench to bedside as a powerful hepatoprotective agent.

Abstract

During liver resection surgery for cancer or liver transplantation, the liver is subject to ischaemia (reduction in blood flow) followed by reperfusion (restoration of blood flow), which results in liver injury [ischemia-reperfusion (IR) or IR injury]. Modulation of IR injury can be achieved in various ways. These include hypothermia, ischaemic preconditioning (IPC) (brief cycles of ischaemia followed by reperfusion of the organ before the prolonged period of ischaemia i.e. a conditioning response), ischaemic postconditioning (conditioning after the prolonged period of ischaemia but before the reperfusion), pharmacological agents to decrease IR injury, genetic modulation of IR injury, and machine perfusion (pulsatile perfusion). Hypothermia decreases the metabolic functions and the oxygen consumption of organs. Static cold storage in University of Wisconsin solution reduces IR injury and has prolonged organ storage and improved the function of transplanted grafts. There is currently no evidence for any clinical advantage in the use of alternate solutions for static cold storage. Although experimental data from animal models suggest that IPC, ischaemic postconditioning, various pharmacological agents, gene therapy, and machine perfusion decrease IR injury, none of these interventions can be recommended in clinical practice. This is because of the lack of randomized controlled trials assessing the safety and efficacy of ischaemic postconditioning, gene therapy, and machine perfusion. Randomized controlled trials and systematic reviews of randomized controlled trials assessing the safety and efficacy of IPC and various pharmacological agents have demonstrated biochemical or histological improvements but this has not translated to clinical benefit. Further well designed randomized controlled trials are necessary to assess the various new protective strategies in liver resection.

Key words: Liver; Hepatectomy; Liver transplantation; Ischemia-reperfusion injury; Hypothermia; Ischaemic preconditioning

INTRODUCTION

Approximately 11 000 liver transplantations and an estimated 7000 to 10 000 liver resections are performed every year in US[1-3]. During liver resection and transplantation, the liver is subject to ischaemia (reduction in blood flow). A period of ischaemia is unavoidable in organ transplantation between the time the donor heart stops pumping blood through the circulation and the circulation to the organ is restored in the recipient. When the blood flow is restored (reperfusion), the liver is subjected to further injury. The damage caused by ischemia and then reperfusion in an organ is called ischemia-reperfusion injury (IR injury).

MECHANISM OF IR INJURY

The mechanisms involved in the production of the tissue damage by the IR injury are complex. Overviews of the mechanisms involved in liver IR injury have been described by various authors[4-6]. In simple terms, the sequence of ischaemia followed by reperfusion results in the activation of Kupffer cells (liver macrophages) and polymorphonucleocytes resulting in the production of reactive oxygen species (ROS), cytokines, and adhesion molecule activation leading to liver parenchymal damage.

PROTECTIVE STRATEGIES TO DECREASE LIVER IR INJURY

Modulation of IR injury can be achieved in various ways. These include hypothermia[7,8], ischaemic preconditioning (IPC)[9,10], ischaemic postconditioning[11], pharmacological agents to decrease IR injury[12,13], genetic modulation of IR injury[14], and machine perfusion[7,15]. Systematic reviews of well designed randomized controlled trials (with homogeneity) are currently considered the highest level of evidence to assess the effects of interventions[16]. A well designed randomized controlled trial is the next highest level of evidence[16]. The safety and effectiveness of the different interventions based on randomized controlled trials and systematic reviews of randomized controlled trials in humans is discussed under each of the methods.

Hypothermia

Hypothermia decreases the metabolic functions and the oxygen consumption of organs[17]. Although the organ can be preserved by warm perfusion, hypothermia has been used to decrease IR injury in the transplantation setting for several decades.

Invasive cooling of the donor liver: Ischaemic injury to the liver begins when the donor heart stops pumping blood through the circulation. During the liver retrieval operation, current standard practice involves perfusion of the liver through the aorta with or without perfusion through the portal vein using cold solution[18]. There are no randomized controlled trials comparing hypothermic with normothermic perfusion of the donor organ. Currently, there is evidence from one randomized controlled trial that the incidence of primary graft non-function decreases when double perfusion (aortic and portal vein perfusion) is used compared with single perfusion (aorta alone perfusion) in marginal donors (sub-optimal donors)[18]. In the optimal donor, there is currently no evidence of difference in clinical outcomes between single perfusion and double perfusion[18]. Apart from this comparison of the donor perfusion technique, there is currently no evidence for any difference in the graft or patient survival between the different solutions used for donor perfusion or different pressures used for perfusion[19-21].

Surface cooling of donor liver: There is currently no evidence that surface cooling of the donor liver in addition to invasive cooling by aortic and portal vein perfusion improves liver transplant outcomes.

Static cold storage and storage solutions: After removal of the liver from the cadaver, the liver is stored for a few hours till it can be transplanted to the recipient. This is the time required for the transport of the liver from the retrieval site to the transplant site. During this time, preservation injury occurs. This is because of lack of adequate oxygenation of the tissues. The current standard method for preservation is static cold storage. There have been no randomized controlled trials comparing static cold storage with other methods of organ preservation during transport of the liver. However, static cold storage remains the standard against which all other organ preservation methods can be compared. The introduction of University of Wisconsin (UW) solution in 1988[22] increased the capability of long distance procurement and sharing and decreased the costs associated with long distance procurement by decreasing the preservation injury[23,24]. Although the efficacy of UW solution compared with other solutions available at that time (Collin's solution) was not assessed by randomized controlled trial, the evidence for the benefits of UW solution over Collin's solution was so overwhelming[23,24] that a randomized controlled trial would have been considered unethical. To date, UW solution has remained the gold standard solution against which all other solutions are compared[25]. There is no evidence from randomized controlled trials that any of the other solutions such as Celsior solution or histidine-tryptophan-ketoglutarate solution result in a better graft or patient survival than UW solution[26-30].

Hypothermia in liver resections: While hypothermia has been used as the standard method of decreasing IR injury in liver transplantation, the role of hypothermia as a method of decreasing IR injury in liver resection surgery has not been established. The only randomized controlled trial assessing the impact of in-situ hypothermia in liver resections failed to demonstrate any major clinical benefits of in-situ hypothermia[8].

IPC

IPC is the mechanism by which brief periods of ischaemia followed by reperfusion of the organ results in the ability of the organ to withstand a subsequent prolonged period of ischaemia[31]. Overviews of the mechanisms of IPC have been provided by various authors[5,6,32,33]. Adenosine and nitric oxide play a pivotal role in the IPC response.

IPC can be achieved by a local preconditioning stimulus (direct IPC)[9,10] or by a remote stimulus (remote IPC)[6,34,35]. Remote IPC (RIPC) is the mechanism by which IPC of one vascular bed (area supplied by one artery) protects another vascular bed (area supplied by another artery) from IR injury[35]. The mechanisms involved in RIPC have been reviewed previously[6,34]. Currently, both neural and humoral pathways are believed to be involved in RIPC.

There is experimental evidence that direct IPC and RIPC protects against liver IR injury in the animal model[36-38]. In humans, a systematic review of randomized controlled trials showed that direct IPC decreases the enzyme markers of liver parenchymal injury after liver resections performed under vascular control (i.e. temporary occlusion of blood vessels supplying the liver)[9]. However, this did not translate into any clinical benefit[9]. One randomized controlled trial of remote IPC demonstrated a similar finding i.e. a decrease in the enzyme markers of liver parenchymal injury after liver resections without demonstrating any clinical benefit[39]. There is no evidence for benefit from direct IPC in liver transplantation based on a systematic review of randomized controlled trials[10]. Currently, there are no published randomized controlled trials of RIPC in liver transplantation. Thus, routine IPC (direct IPC or remote IPC) cannot be recommended in either liver resection or transplantation.

Ischaemic postconditioning

As opposed to IPC where the conditioning stimulus is applied prior to the prolonged period of ischaemia, ischaemic postconditioning (IPost) involves the application of the conditioning stimulus (brief intermittent cycles of IR) after the prolonged period of ischaemia but prior to permanent reperfusion i.e. ischaemia followed by conditioning stimulus followed by permanent restoration of blood flow[11]. Overviews of the mechanisms of ischaemic postconditioning have been reviewed previously[40,41]. As with IPC, adenosine and nitric oxide play a pivotal role in ischaemic postconditioning. As in the case of IPC, ischaemic post-conditioning can also be achieved by a local postconditioning stimulus (direct IPost)[11,42-44] or by a remote postconditioning stimulus (RIPost)[45].

In animal models, there is experimental evidence that IPost protects against liver IR injury[42-44]. There are currently no randomized controlled trials of ischaemic postconditioning (direct or remote) in either liver resection or liver transplantation. So, routine ischaemic postconditioning (direct IPost or RIPost) cannot be currently recommended in either liver resection or liver transplantation.

Pharmacologic interventions to decrease IR injury

Various pharmacologic interventions have been attempted with an intention of decreasing IR injury. Considering that ROS and inflammatory mediators play significant roles in IR injury[4-6], pharmacological interventions to neutralise or modulate the pathways using antioxidants and steroids are a subject of significant research[13].

There is experimental evidence that some pharmacological interventions[46,47] protect against liver IR injury in the animal model. In humans, a systematic review of randomized controlled trials assessing the role of pharmacologic interventions in decreasing IR injury after liver resections showed that some interventions such as methyl prednisolone decrease the enzyme markers of liver parenchymal injury after liver resections but without demonstrating evidence of clinical benefit[13]. The role of numerous pharmacological interventions in decreasing IR injury in liver transplantation has been investigated[48-77]. None of the interventions have shown any benefit in graft or patient survival.

Genetic modulation of IR injury

As the molecular mechanisms of IR injury are increasingly understood, more research is being performed on the genetic modulation of the pathways in IR injury both for better understanding of the mechanisms involved in IR injury and for potential therapeutic applications[78]. Experimental evidence to demonstrate the potential role of genetic modulation of liver IR injury exists[14]. There are no randomized clinical trials assessing the impact of genetic modulation of IR injury in liver resections or liver transplantation.

Machine perfusion

Machine perfusion involves pulsatile perfusion of the liver using a machine as opposed to static cold storage. This can be performed by perfusing the liver with a hypothermic perfusate[79] or with a normothermic perfusate[80]. There is experimental evidence in animal models that machine perfusion protects against liver IR injury[80,81]. The safety and efficacy of machine perfusion compared to static cold storage to decrease liver IR injury is yet to be assessed in humans by randomized controlled trials.

DIFFERENCES IN RESULTS BETWEEN ANIMAL MODELS AND HUMAN TRIALS

As discussed above, there are major differences in the results of the role of the different interventions in decreasing liver IR injury between animal models and clinical results. Some possible reasons for this include the lack of fidelity of the model used (i.e. how truly are the results transferable from the model to humans)[82], the use of unvalidated surrogate outcomes, and the use of inadequate sample size in human trials.

FUTURE TRIALS

Future trials of adequate sample size and low risk of bias (low risk of prejudice towards the treatment arm or the control arm)[83] should be performed to decrease the random errors (arriving at wrong conclusions because of pure chance, usually due to inadequate sample size) and systematic errors (arriving at wrong conclusions because of prejudice towards the treatment or the control arm). Measurement of meaningful differences in clinical outcomes requires a large trial. Development and validation of composite outcomes and surrogate outcomes will enable evaluation of the interventions using a smaller sample size.

CONCLUSION

Currently, the only intervention that has shown to be beneficial in the protection of the liver during liver transplantation is hypothermia. In liver resection surgery, there is currently no established intervention targeted at modulating

IR injury that provides any major clinical benefit. However, many new therapies and targets are being discovered. Well designed randomized controlled trials are necessary to assess the new protective strategies in liver resection and liver transplantation.

Abstract

AIM: To investigate the effect of the G-1666A polymorphism in the multidrug resistance related protein-1 (*MRP1*) on outcome of hepatocellular carcinoma (HCC).

METHODS: A cohort of 162 patients with surgically resected HCC who received no postsurgical treatment until relapse was studied. Genotyping was performed by polymerase chain reaction-restriction fragment length polymorphism analysis. Electrophoretic mobility shift assay (EMSA) was used to evaluate the influence of the G-1666A polymorphism on the binding affinity of the *MRP1* promoter with its putative transcription factors.

RESULTS: Kaplan-Meier analysis showed that patients with GG homologues had a reduced 4-year disease-free survival compared with those carrying at least one A allele (P = 0.011). Multivariate Cox regression analysis indicated that the -1666GG genotype represented an independent predictor of poorer disease-free survival [hazard ratio (HR) = 3.067, 95% confidence interval (CI): 1.587-5.952, P = 0.001], and this trend became worse in men (HR = 3.154, 95% CI: 1.604-6.201, P = 0.001). A similar association was also observed between 4-year overall survival and the polymorphism in men (HR = 3.342, 95% CI: 1.474-7.576, P = 0.004). Moreover, EMSA suggested that the G allele had a stronger binding affinity to nuclear proteins.

CONCLUSION: The *MRP1* -1666GG genotype predicted a worse outcome and was an independent predictor of poor survival in patients with HCC from Southeast China.

Key words: Multidrug resistance related protein-1; Single nucleotide polymorphism; Hepatocellular carcinoma; Prognosis

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide and the third leading cause of cancer death[1]. Optimal surgical resection is regarded as the best treatment for a curative outcome of HCC. However, long-term survival remains poor because of high rates of tumor recurrence or progression. Substantial effort has been made to identify prognostic factors

that can be used for improving therapeutic regimens and survival prediction. However, only a few factors, such as TNM stage or patient performance status, are consistent predictors, and their accuracy remains limited. Therefore, molecular markers that can accurately predict patient outcome are urgently needed.

The human multidrug resistance protein-1 (MRP1), also known as ABCC1, belongs to the ATP-binding cassette superfamily of cell-surface transport proteins. It participates in the transport of a wide variety of endogenously produced and exogenously administered molecules in an adenosine-triphosphate (ATP)-dependent manner[2,3]. Besides its well-known roles in drug resistance, MRP1 is proposed to contribute to the cellular antioxidative defense system by actively extruding glutathione (GSH)-conjugated xenobiotics and GSH-conjugated metabolites from cells[4]. Recent studies have also revealed that MRP1 is involved in inflammatory reactions, such as, dendritic cell differentiation and function[5]. MRP1 is expressed at moderate levels in most normal tissues, including lung, muscle, and kidney, but is barely detectable in normal liver[6-8]. However, in several liver diseases including HCC, its expression in the basolateral membrane is upregulated, which suggests a significant role for this transport protein during carcinogenesis[8,9].

Single nucleotide polymorphisms (SNPs) in the *MRP1* gene have been extensively studied in the past few years, and several genetic variants in the coding region have been shown to affect the function of MRP1[10-13]. For example, G2168A (Arg723Gln) can affect patients' sensitivity to chemotherapy in ovarian cancer[11]. G1299T (Arg433Ser) confers resistance to doxorubicin by reducing intracellular drug accumulation in HeLa cells that stably express mutant MRP1, whereas the G3173A (Arg1058Gln) variation increases the response to etoposide in HEK293 and CHO-K1 cells[12,13]. Recently, it has been observed that SNPs in the gene promoter can affect expression by disturbing the binding affinity of transcription factors, and are associated with disease prognosis[14]. However, whether SNPs in the *MRP1* promoter region have any clinical significance remains obscure. The expression level of *MRP1* is upregulated in HCC, therefore, we hypothesized that sequence variants in the promoter region potentially affect the expression of the *MRP1* gene and the prognosis of cancer, by modulating the efflux of toxins. To test this hypothesis, we investigated the potential of the *MRP1* G-1666A polymorphism (rs4148330) as a prognostic marker in a cohort of patients with HCC in Guangdong province of Southeast China.

MATERIALS AND METHODS

Study population

The study included 162 patients with HCC at the Cancer Center of Sun Yat-sen University (Guangzhou, China) from 2001 to 2005. All patients underwent hepatectomy as initial therapy, and did not receive chemotherapy or radiotherapy as follow-up treatment before recurrence. All samples were histologically confirmed. After surgical resection, the tissue samples were immediately frozen in liquid nitrogen and then stored at -80℃ until use.

Clinicopathological details and follow-up information were obtained from hospital records. The patients enrolled in the study were residents of Guangdong Province. Infection with hepatitis B virus (HBV) or hepatitis C virus (HCV) was diagnosed when HBV surface antigen or HCV antibody was detected by enzyme linked immunosorbent assay in the serum isolated from peripheral blood. The TNM criteria and the Edmondson and Steiner grading system were used to classify tumor stages and differentiation grades, respectively. Informed consent was obtained from each patient. This study was approved by the Clinical Research Ethics Committee of Sun Yat-sen University Cancer Center.

DNA isolation and genotyping

Total genomic DNA was isolated with a standard protocol that included proteinase digestion, phenol-chloroform extraction, and ethanol precipitation. Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis was used to detect the genotype. A 160-bp fragment that covered the G-1666A polymorphism was generated using sense primer 5'-GCAACAGCATAACTGGCATT-3' and reverse primer 5'-GAGACCTCCCCCCAATCA-3'. PCR was performed as follows: 20 ng genomic DNA was amplified in a 20-μL reaction mixture that contained 2 mmol/L $MgCl_2$, 0.4 mmol/L dNTPs, 0.2 μmol/L each primer, and 0.5 U *Taq* polymerase (Promega, Madison, WI, USA). After a total of 36 cycles of amplification at an annealing temperature of 58℃, 3 μL PCR products was then incubated overnight at 37℃ with 15 U *Hpa*Ⅱ (MBI Fermentas, Hanover, MD, USA). Digested products were analyzed by 2% agarose gel. PCR fragments that demonstrated altered electrophoretic patterns were purified and characterized by direct DNA sequencing. Results represent two independent experiments.

Cell lines and nuclear protein extraction

Liver cancer cell lines Huh7 and Hep3B were obtained from the American Type Culture Collection (Manassas, VA, USA) and grown in Dulbecco's Modified Eagle's Medium (Invitrogen, Carlsbad, CA, USA) supplemented with 10% fetal bovine serum in a humidified environment of 37℃ that contained 50 mL/L CO_2. Nuclear protein extracts from Hep3B and Huh7 cells were prepared according to the manufacturer's protocol (NucBuster Protein Extraction Kit; Novagen, Darmstadt, Germany).

Electrophoretic mobility shift assay

Electrophoretic mobility shift assay (EMSA) was performed with the Gel Shift Assay System (Promega), according to the manufacturer's instructions. The following oligonucleotides that corresponded to the promoter region of *MRP1* and covered the G-1666A polymorphism were synthesized (underline letters indicate polymorphism): -1666A allele, 5'-GGGGGACCCGGGCCAATAAAAAAATCA-3'; -1666G allele, 5'-GGGGGACCCAGGCCAATAAAAAAATCA-3'; nonspecific (scrambled) oligonucleotide, 5'-GAAGCGGTGACACGGAACATCACGAAA-3'. Oligonucleotides were annealed and end-labeled with [γ-^{32}P]-ATP. Five micrograms of Hep3B or

Huh7 nuclear extracts were added in each binding reaction. For the competition assay, a 10-, 50- or 100-fold molar excess of unlabeled oligonucleotide was added to the binding reaction mixture as a competitor. The products were separated on pre-electrophoresed 5% polyacrylamide gels at 4℃. The gels were then dried at 80℃ for 4 h and exposed to a Storage Phosphor Screen (Amersham Bioscience, Sunnyvale, CA, USA), which was subsequently read with a Typhoon Phosphor Imager (Amersham Bioscience). The putative transcription factors that recognized the sequences that overlapped the G-1666A site were predicted with Alibaba2.1 (http://www.gene-regulation.com/pub/programs/alibaba2/index.html) and the transcription element search software (TESS, http://www.cbil.upenn.edu/cgi-bin/tess/tess).

Statistical analysis

The χ^2 and Fisher's exact tests were used for the analysis of the relationship between the genotypes and clinicopathological characteristics. Disease-free survival (DFS) was calculated from the day of surgery to either relapse or death without relapse, and it was censored only for patients who were alive and recurrence-free at the last follow-up. Overall survival (OS) was measured from the date of hepatectomy to the time of death or the last follow-up. Survival curves were obtained by the Kaplan-Meier method, and the statistical significance of the differences in survival among subgroups was evaluated with the log-rank test. The Cox proportional hazards model was employed to assess the independent prognostic values of the polymorphisms. Statistical analyses were all performed with SPSS software package (version 13.0; SPSS, Inc., Chicago, IL, USA). All statistical tests were two-sided, and $P < 0.05$ was considered to be statistically significant.

RESULTS

Patient characteristics and genotype

Demographic and clinicopathological characteristics of the 162 patients with HCC are summarized in Table 1. The mean age at first diagnosis of HCC was 48 years. Consistent with our previous study[15], most patients showed excessive γ-glutamyl transpeptidase and α-fetoprotein, along with liver cirrhosis, and > 80% of the enrolled patients were infected with HBV (140/161, 87.0%), which implicated HBV infection as a leading cause of HCC in Southeast China. In contrast, only a small number of patients were infected with HCV.

Genotyping was performed by PCR-RFLP. A 160-bp *MRP1* promoter region that covered the G-1666A variant was digested with *Hpa*Ⅱ. After full digestion of the amplified PCR products, those from AA homozygotes still existed as a single 160-bp fragment, whereas those from the GG homozygotes had been divided into two fragments of 71 bp and 89 bp, respectively. The allele frequency of patients with HCC was 0.61 for *MRP1* -1666A and 0.39 for -1666G. However, no significant correlations were found between the nucleotide variants and clinical variables (data not shown).

Association analysis between the G-1666A polymorphism and survival

Growing evidence suggests that SNPs are closely related to the risk and outcome of cancer[14,16,17]. To investigate the impact of the G-1666A polymorphism on the prognosis of patients with HCC, we next analyzed the 4-year DFS and OS of patients with different genotypes. A significant correlation between the -1666 polymorphism and postoperative survival was found. The mean survival times of patients with the AA, AG and GG genotypes were 30.4 ± 18.2, 30.7 ± 17.4 and 24.8 ± 17.3 mo, respectively. The survival curves showed that the 4-year rate of DFS among patients who carried GG decreased significantly compared with those who carried the AA or AG allele (P = 0.031,

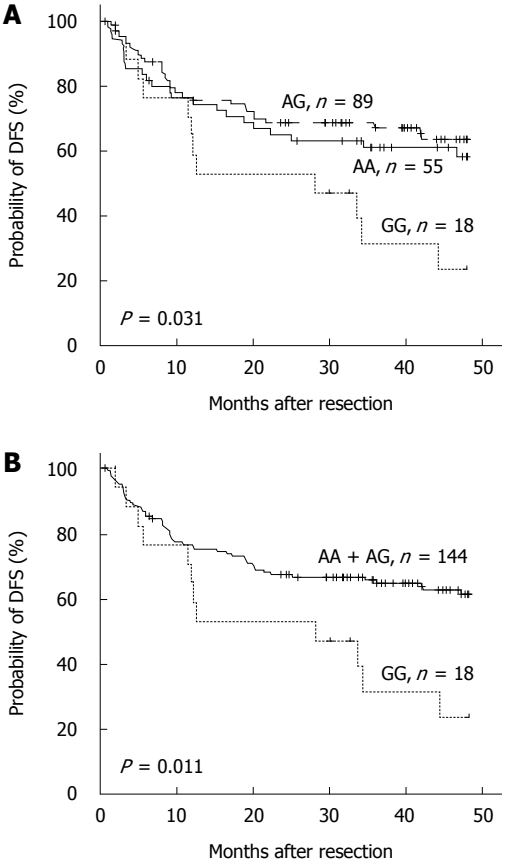

Figure 1 Kaplan-Meier disease-free survival curves for hepatocellular carcinoma patients who carried different *multidrug resistance related protein-1* -1666 genotypes. A: Comparison between three genotypes; B: GG genotype compared with the other two genotypes. Log-rank *P* values are indicated. Tick marks represent censored data. DFS: Disease-free survival.

Figure 1A). Moreover, if the patients with AA and AG genotypes were combined, the discrepancy became more obvious ($P = 0.011$, Figure 1B). Further analysis revealed a similar, albeit non-significant, trend between the -1666 polymorphism and 4-year OS (Table 2). Multivariate Cox proportional hazard analysis was then performed, and the variables that showed significance by univariate analysis were adopted as covariates (Table 2). The results revealed that the *MRP1* G-1666A polymorphism was an independent prognostic factor for 4-year DFS [hazard ratio (HR) = 3.067, 95% confidence interval (CI): 1.587-5.952, $P = 0.001$, Table 3].

One of the key features of HCC is the much higher incidence in men than in women[1]. In our study cohort, the male/female ratio was 9.8:1. Further stratification of the patients by sex revealed an even more pronounced association of the -1666GG genotype with poorer survival ($P < 0.05$, Figure 2). Multivariate analysis suggested that the -1666GG genotype was an especially powerful independent prognostic factor of 4-year DFS (HR = 3.154, 95% CI: 1.604-6.201, $P = 0.001$) and OS (HR = 3.342, 95% CI: 1.474-7.576, $P = 0.004$) in the men with HCC (Table 3).

Influence of the G-1666A polymorphism on the affinity of binding with nuclear proteins

G-1666A polymorphism on the binding affinity of the *MRP1* promoter with putative transcription factors. The radiolabeled -1666G probe showed strong DNA-protein binding ability in the presence of nuclear proteins extracted from the Hep3B cell line, whereas the -1666A probe barely showed any interaction (Figure 3A, lane 2 and lane 10, respectively). In order to assess the binding specificity and the differences in binding affinity between the G and A alleles, competition assays were performed with unlabeled -1666A and -1666G oligonucleotides. A 50-fold excess of unlabeled -1666A oligonucleotides only partially disrupted the binding of the radiolabeled -1666G probe with nuclear extracts (Figure 3A, lane 7 and Figure 3B, lane 6), whereas this amount of unlabeled -1666G oligonucleotides almost completely abolished the binding (Figure 3A and B, lane 4). In contrast, a non-specific competitor had no effect (Figure 3B, lane 8). Similar results were obtained when using the nuclear extracts from Huh7 cells (data not shown). These data suggested that the G-1666A polymorphism could affect the binding affinity of the *MRP1* promoter with transcription factors, and

[a]Hazard ratio (HR) and *P* values were calculated using multivariate Cox regression. $P < 0.05$ was considered to indicate statistical significance; [1]Multivariate analysis of disease-free survival (DFS) in all patients was adjusted for sex, γ-glutamyl transpeptidase (GGT), α-fetoprotein (AFP), tumor size, ascites, and TNM stage; in male patients, it was adjusted for GGT, tumor size, and TNM stage; [2]Multivariate analysis of OS in male patients was adjusted for GGT, tumor size, ascites, cirrhosis, and TNM stage. OS: Overall survival; CI: Confidence interval.

that the G allele had a stronger binding affinity than the A allele.

DISCUSSION

The multidrug resistance protein family transports a wide range of physiological substrates and diverse therapeutic agents. In the past decade, much effort has been focused on MRP1-mediated drug resistance[18,19]; and emerging evidence indicates that SNPs within the *MRP1* gene have prognostic value in predicting the response to chemotherapy in different cancers[11,20]. Notably, MRP1 takes part in the transport of aflatoxin B1, a well-know human liver carcinogen that can induce a characteristic mutation in *p53* at codon 249[21,22]; and previous studies have shown that *p53* mutations are significantly associated with a poor prognosis for patients with HCC[15,23]. In addition, MRP1 also plays important roles in cellular antioxidant defense and immune cell function[4,5]. These observations and the upregulated expression level of *MRP1* gene in several liver diseases, including HCC, suggest the possibility that this protein is involved in tumorigenesis and progression[8,9]. Our present study examined the role of the *MRP1* G-1666A polymorphism as a prognostic factor in patients with HCC who were treated only with curative surgery, and proved that the GG genotype was an independent predictor of poor survival, especially in men with HCC. Furthermore, specific binding of nuclear proteins to G allele was found, which suggested a difference in transcription activity between different genotypes.

In the present study, there were 147 men (90.7%) and 15 women with HCC (9.3%), with a male-to-female ratio

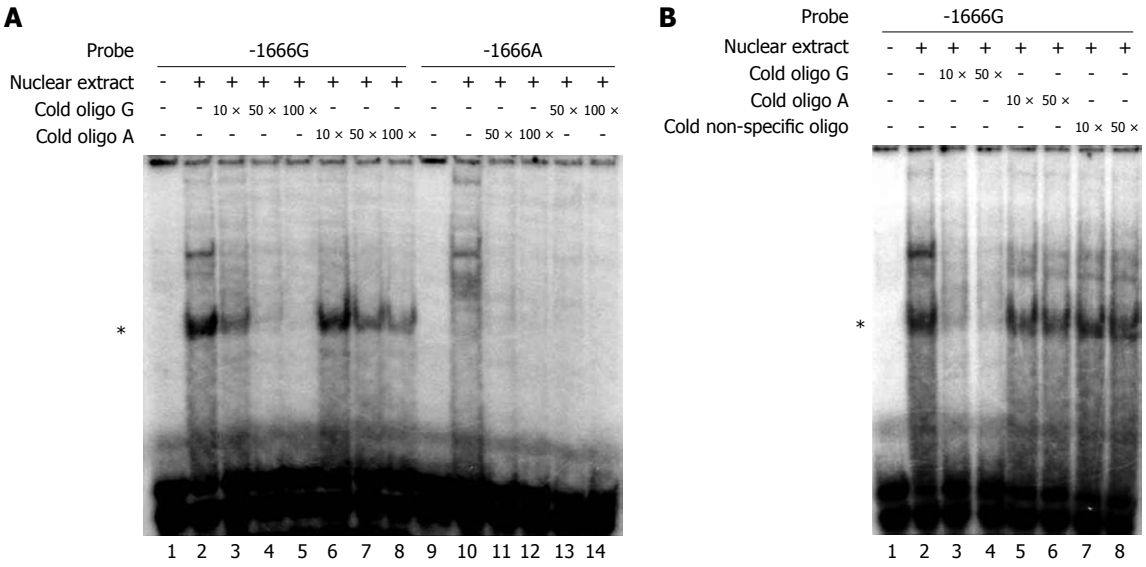

Figure 3 Electrophoretic mobility shift assay of the *multidrug resistance related protein-1* promoter region that contained the G-1666A site. A: Analysis was performed in the presence (+) or absence (-) of Hep3B nuclear extract. Each binding reaction contained γ-^{32}P-labeled -1666G (lanes 2-8) or -1666A (lanes 10-14) probes. A 10-, 50-, or 100-fold (as indicated) excess of unlabeled (cold) -1666A or G oligonucleotides (lanes 6-8, 11, and 12 or 3-5, 13, and 14) were included in the binding reactions as specific competitors. Labeled oligonucleotides incubated without the nuclear extracts were included as negative controls (lanes 1 and 9); B: In the present of Hep3B nuclear extract, 10- or 50-fold more excess of unlabeled -1666G oligonucleotides (lanes 3 and 4) or -1666A oligonucleotides (lanes 5 and 6) or non-specific oligonucleotides (lanes 7 and 8) were used as competitors. Lane 1 was the negative control. Lane 2 indicated the labeled -1666G oligonucleotides incubated with the nuclear extracts only. The asterisks indicated the DNA-protein complex.

of 9.8:1. We observed a remarkably significant association of the *MRP1* G-1666A polymorphism with 4-year OS in men with HCC, but not in the entire cohort. This phenomenon might result from the interaction between the polymorphism and sexual hormones during carcinogenesis, which has been demonstrated in the example of *MDM2* SNP309[24]. Therefore, the correlation between the *MRP1* G-1666A polymorphism and the survival of women with HCC requires further investigation to generate a definite conclusion.

SNPs in the promoter region of a gene can potentially alter the affinity of interactions between DNA and nuclear proteins and, in turn, affect the efficiency of transcription. We found that the G allele of the *MRP1* G-1666A polymorphism had a stronger binding affinity for nuclear proteins in hepatoma cells than the A allele had. This finding accords with our presumption that the G-1666A polymorphism might dominate the pumping ability of MRP1 by affecting the expression of the protein. Although a G-1666A polymorphism located 1.5 kb upstream of the core promoter of *MRP1*, and two major regulatory domains had already been found in tandem upstream of the core promoter[25], recent studies have revealed that distal regions (enhancer or suppressor) can influence gene transcription through physical association with the transcription start site[26]. Furthermore, allele G of the G-260C polymorphism could lead to lower activity of the *MRP1* promoter in cell lines, which suggests that nucleotide variants in the *MRP1* gene account, in part, for inter-individual variations and population differences in cellular efflux[27]. These data suggest that the G-1666A polymorphism functions as a distal element through the folding of the DNA strand.

The three transcription factors Sp1, NF-1 and CTF were predicted to bind to the promoter region, including the G-1666A site, by Alibaba2.1 software, but only the Sp1 consensus motif could partially disrupt the DNA-protein binding in a competition assay, whereas the other two did not show significant influence on the binding (data not shown). Sp1 antibody failed to reveal any super-shift band when added to the EMSA reaction complex (data not shown), which suggested that Sp1 binding to the cis-element, including the G-1666A site, required an interaction between Sp1 and other nuclear proteins. Future work will be required to identify such nuclear proteins.

In summary, our present study shows that the *MRP1* G-1666A polymorphism is an independent prognostic factor for patients with HCC, which implies a role for MRP1 in tumor progression. Clearly, much more work remains to be done to confirm our findings and overcome the limitations in our work before this SNP can be used as a marker for poor outcome in HCC.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide and the third leading cause of cancer death, and long-term survival remains poor because of high rates of tumor recurrence or progression. Therefore, markers that can be used for improving therapeutic regimens and survival prediction are urgently needed.

Research frontiers

The finding that human multidrug resistance protein-1 (MRP1) is expressed

in unusually large amounts in HCC suggests it has a role in the growth and progression of this cancer. Expression of MRP1 is affected by the genetic sequence in its promoter region, therefore, the authors of this study examined the potential of different sequences (polymorphisms) in the *MRP1* promoter to serve as indicators of prognosis and outcome in patients with HCC.

Innovations and breakthroughs

Recent studies have demonstrated that mutations within the *MRP1* gene have value in predicting the response to chemotherapy in different cancers, but the clinical significance of such mutations in the *MRP1* promoter for patients with HCC is unknown. This is believed to be the first study to identify a polymorphism in the promoter of *MRP1* that is an independent prognostic factor for 4-year overall survival in men with HCC. The correlation between the *MRP1* polymorphism and the survival of women with HCC requires further investigation. The authors also demonstrated that the polymorphism altered the affinity of nuclear proteins for the DNA in the HCC cells, which might explain the mechanism by which the expression of MRP1 was reducing.

Applications

The genetic sequence identified in this study can be used to test tissue samples from patients with HCC to help predict their outcome after therapy. This information can be used to guide treatment decisions and improve therapeutic regimens for individual patients.

Terminology

MRP1 is one of a family of proteins found on the surface of cells. These proteins transport a wide variety of substances and can contribute to resistance to chemotherapy by transporting anticancer drugs out of cancer cells. The promoter region of a gene is a sequence of nucleotides that regulates whether and how much of a protein is synthesized from that gene.

Peer review

This is a study of an important area of cancer genomics. The authors found that a single nucleotide polymorphism of *MRP1* promoter region is an independent prognostic factor for HCC patients. The study design was well-organized and they reached a conclusion by making full use of the data.

Abstract

AIM: To determine whether mitochondrial dysfunction resulting from high-fat diet is related to impairment of the phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt, also known as PKB) pathway.

METHODS: Rat models of nonalcoholic fatty liver were established by high-fat diet feeding. The expression of total and phosphorylated P13K and Akt proteins in hepatocytes was determined by Western blotting. Degree of fat accumulation in liver was measured by hepatic triglyceride. Mitochondrial number and size were determined using quantitative morphometric analysis under transmission electron microscope. The permeability of the outer mitochondrial membrane was assessed by determining the potential gradient across this membrane.

RESULTS: After Wistar rats were fed with high-fat diet for 16 wk, their hepatocytes displayed an accumulation of fat (103.1 ± 12.6 *vs* 421.5 ± 19.7, $P < 0.01$), deformed mitochondria (9.0% ± 4.3% *vs* 83.0% ± 10.9%, $P < 0.05$), and a reduction in the mitochondrial membrane potential (389.385% ± 18.612% *vs* 249.121% ± 13.526%, $P < 0.05$). In addition, the expression of the phosphorylated P13K and Akt proteins in hepatocytes was reduced, as was the expression of the anti-apoptotic protein Bcl-2, while expression of the pro-apoptotic protein caspase-3 was increased. When animals were treated with pharmacological inhibitors of P13K or Akt, instead of high-fat diet, a similar pattern of hepatocellular fat accumulation, mitochondrial impairment, and change in the levels of PI3K, Akt, Bcl-2 was observed.

CONCLUSION: High-fat diet appears to inhibit the PI3K/Akt signaling pathway, which may lead to hepatocellular injury through activation of the mitochondrial membrane pathway of apoptosis.

Impaired PI3K/Akt signal pathway and hepatocellular injury in high-fat fed rats. *World J Gastroenterol* 2010; 16(48): 6111-6118 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i48/6111.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i48.6111

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is caused by

triglyceride (TG) accumulation within the liver and can either be a benign self-limiting state or a condition associated with steatohepatitis (NASH), which may develop to fibrosis, cirrhosis and liver failure[1,2]. Triacylglycerol formation in the hepatocytes may also be cytotoxic to hepatocytes[3,4]. Multiple lines of evidence support the role of intrahepatic fat in causing hepatic insulin resistance. Hepatic insulin resistance is considered to be the fundamental mechanism in the prevalence and progression of the disease. It is also a critical component in the development of NAFLD, which is characterized by a marked reduction in the activity of the insulin signaling pathway[5].

In the presence of insulin, the insulin receptor normally phosphorylates insulin receptor substrate (IRS) proteins, which are linked to the activation of several signaling pathways, including the metabolic phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt, also known as PKB) pathway. Phosphatidylinositol 3-kinase (PI3K) and its downstream effector Akt regulate a diverse array of cellular events, including survival and apoptosis of a number of cell types[6].

Hepatocyte apoptosis is a key histologic feature of NAFLD, and correlates with progressive inflammation and fibrosis[7]. The molecular pathways leading to hepatocyte apoptosis are not fully defined; however, mitochondrial dysfunction is an important element in the pathogenesis of NAFLD[8]. Recent evidence showed that mitochondria participate in the regulation of both cell proliferation and death, including apoptosis[9], and are thus potential mediators of the PI3K/Akt signaling pathway. Although multiple lines of evidence have suggested a close linkage between insulin-induced signaling and mitochondrial functions[10], the potential relationship between the PI3K/Akt signaling pathway and the mitochondrial abnormalities that underlie NAFLD remain unclear.

The present study was undertaken to investigate the relationship between mitochondria impairment and the activity of the PI3K/Akt signaling pathway during the development of NAFLD.

MATERIALS AND METHODS

Animal groups and diet

Male Wistar rats, 12 wk old were obtained from Harbin Medical University.

Laboratories (stock No. 002207). All experiments and animal care complied with the guidelines for the humane treatment of animals set by the Association of Laboratory Animal Sciences and the Center for Laboratory Animal Sciences, Harbin Medical University. At 6 wk of age, the 60 mice were randomly divided into four groups: (1) Normal control (NC) group; (2) NC plus the PI3K inhibitor LY294002 (NC + LY, 15 μg/kg daily injected *via* the tail CA 440206, Calbiochem); (3) NC plus the AKT inhibitor 1-L-6-hydroxymethyl-chiro-inositol2-(R)-2-O-methyl-3-O-octadecylcarbonate (NC + AI, 20 μg/kg daily *via* tail injection CA124005, Calbiochem); and (4) High-fat diet (HFD). The normal control rats were fed a commercial rat diet (7%-10% fat, 68%-70% carbohydrates, 18%-20% protein, 1%-2% vitamins and minerals; 210 kcal/100 g per day) for 16 wk, while rats in the treatment group (HFD group) were fed a high-fat diet (40% fat, 38%-40% carbohydrates, 18%-20% protein, 1%-2% vitamins and minerals; 210 kcal/100 g per day) for the same period of time.

Calculation of metabolic index and resistance index

Blood samples from the retro-orbital sinus were collected before and after the treatment. Rats were fasted overnight before the collection of the blood samples. Plasma insulin was determined using ELISA. Insulin resistance was evaluated using a homeostasis model assessment of insulin resistance (HOMA). Serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyltransferase (GGT) levels were measured using spectrophotometric assay kits (Sigma-Aldrich, St. Louis, MO, USA) according to the manufacturer's instructions. Insulin resistance was assessed by computing insulin resistant index (HOMA-IR). The formula used was as follows: HOMA-IR = Insulin (μg/L) × glucose (mmol/L)/22.5.

Measurement of hepatic TG

The liver (100 mg wet tissue) was homogenized in an ice-cold 0.05% butylhydroxytoluene solution. After lipids were extracted from the liver according to the method of Folch *et al*[11], TG content in each sample was measured with a commercial assay kit (Wako Pure Chemical Industries, Osaka, Japan CA 290-63701).

Isolation of hepatocytes

Hepatocytes were isolated from the liver (20-25 mg) of each mouse by the collagenase perfusion method. Each liver was pre-perfused at 37℃ with buffer containing 100 mmol/L HEPES (pH 7.4), 143 mmol/L NaCl, and 7 mmol/L KCl, and then perfused with buffer containing 0.05% collagenase and 5 mmol/L $CaCl_2$. Following digestion, the liver was dispersed in the perfusion solution and incubated in the perfusion buffer at 37℃ for an additional 5 min. The dispersed cell suspension was then filtered through a nylon mesh and centrifuged at 100 × *g* for 3 min at 25℃. The resulting cell pellets were resuspended in the hepatocyte medium, and cell viability was then determined using a trypan-blue-exclusion test.

Measurement of mitochondrial membrane potential of hepatocytes

The integrity of the inner mitochondrial membrane was assessed by determining the potential gradient across this membrane. Rhodamine 123 (Rh123) powder was dissolved in methanol and stored at -20℃ as a 1 g/L solution, which was diluted to 5 mg/L with phosphate buffered solution (PBS) before each experiment. Hepatocytes (1×10^6) were washed three times with PBS that had been preheated to 4℃. They were then resuspended in 300 mL PBS, incubating with Rh123 (final concentration 2.5 mg/L) for 1 h at 37℃, and then filtered through a 200-mesh screen. Approximately 10000 cells were measured using a FACS Calibur flow cy-

tometer (BD Biosciences, San Diego, CA, USA) using Cell Quest software (a maximum absorbing wave length 590 nm, an excitation wave length 488 nm) (BD Biosciences). Rh123 and tetramethylrhodamineethylester (TMRE) were purchased from Invitrogen (Karlsruhe, Germany).

Electron microscopy

For transmission electron microscopy, small liver fragments were fixed in 4% glutaraldehyde and then processed using standard methods. Sections were viewed under microscope by a pathologist (Dr. Chang H, Department of Pathology, Harbin Medical University). Mitochondrial number and size were determined using quantitative morphometric analysis under transmission electron microscope (Model HB601UX, Vacuum Generators, Hastings, United Kingdom).

Western blotting

Ten μg protein was subjected to SDS-PAGE (10% acrylamide gel) and then transferred to a PVDF membrane for 2 h (120 V) using a Bio-Rad Mini Trans Blot electrophoretic transfer unit (Bio-Rad, Marnes-la-Coquette, France). The membranes were blocked for nonspecific binding with 5% nonfat dry milk and then probed with the specific primary antibodies (Abcam, CA ab74136, ab63566, ab79360, ab8805, 1:1000 dilution) at 4℃ overnight. After 3 washes with TBS-T, membranes were incubated with appropriate horseradish peroxidase-conjugated secondary antibodies (Santa Cruz, CA SC2030). Separated proteins were visualized by an ECL kit (GE Healthcare Life Sciences, CA RPN2135) and light emission was captured on X-ray film (GE Healthcare). Intensities of the respective bands were examined by densitometric analysis (Scion Image Analyst program).

Statistical analysis

Results were presented as mean ± SE and were analyzed using one-way analysis of variance followed by the Bonferroni multiple comparisons test. All tests were 2-sided, and $P < 0.05$ was considered to be statistically significant. All statistical analyses were performed using INSTAT version 3 (Graph Pad Software, San Diego, CA, USA).

RESULTS

Comparison of body and liver weight, biochemical parameters, insulin resistant index among four groups

Compared with normal control groups, the mean serum transaminase, hepatic TG content, body and liver weight, insulin resistant index were all increased in PI3K inhibitor, Akt inhibitor and high-fat groups ($P < 0.05$, Table 1). Hepatocytes could be damaged after PI3K/Akt pathway signal transduction was blocked, but blocked PI3K/Akt pathway signal transduction could lead to TG accumulation in liver to liver weight gain and insulin resistance.

Table 1 Weights of the liver and serum levels of biochemical parameters in high-fat fed rats

	NC	NC + LY	NC + AI	HFD
Tissue weight				
Liver (g)	1.55 ± 0.14	1.99 ± 0.32[a]	1.89 ± 0.43[a]	3.98 ± 0.64[a]
Serum				
TG (mg/dL)	183.8 ± 70.4	396.7 ± 72.3	376.7 ± 68.4	589 ± 98.4[b]
ALT (U/L)	34 ± 3.1	86 ± 5.58[a]	89 ± 5.2[a]	207 ± 35.5[b]

IRI (HOMA-IR)	1.06	4.03[a]	3.8[a]	6.6[b]
TG (mg/g)	103. 1 ± 12.6	324.6 ± 13.4	2336.8 ± 11.6	421.5 ± 19.7[b]

Rats were fed and subjected to each measurement. Data are presented as the mean ± SD. [a]$P < 0.05$, [b]$P < 0.01$ *vs* rats fed with normal diets. NC: Normal control; NC + LY: NC plus the PI3K blocker LY294002; NC + AI: NC plus the AKT blocker; HFD: High-fat diets for 16 wk ($n = 10^{-12}$); ALT: Alanine aminotransferase; AST: Aspartate aminotransferase. GGT: γ-glutamyltransferase; TG: Triglycerides; IRI (HOMA-IR): Insulin resistant index.

Expression of PI3K and Akt protein in hepatocytes in high-fat fed mice

To further investigate whether the PI3K/Akt pathway mediates injury of hepatocytes, we measured the protein expression levels of total and phosphorylated PI3K and Akt in the four groups. The protein expression levels of total PI3K and Akt showed no significant difference among the four groups (Figure 1). But compared with the normal control groups, the expression levels of pPI3K and pAkt markedly decreased in the high-fat group. Moreover, in PI3K inhibitor groups, neither pPI3K nor pAkt was expressed. In Akt inhibitor groups, pAkt showed no expression, and pPI3K had no significant difference compared with the normal control group (Figure 1). These results suggested that fat mass accumulation in the liver may lead to decreased expression of pPI3K and pAkt in fatty liver induced by high fat.

Fat accumulation in the liver and PI3K/Akt pathway

To investigate further whether the fat accumulation in the liver was involved in PI3K/Akt pathway, TG content in each sample was measured in the four groups. The results showed that TG content of liver was elevated in high-fat diet, PI3K and Akt inhibitor groups.

Ultrastructure of hepatocellular mitochondria and PI3K/Akt pathway

To determine whether the PI3K pathway has an anti-apoptotic effect in liver cells, we compared the mitochondrial morphology in the four groups (Figure 2A). Electron microscopy revealed that the hepatocytes of the control group rats were rich in mitochondria, the shape and size of mitochondria were normal and had few lipid droplets. In contrast, many mitochondria from rats in the high-fat group were enlarged and showed morphological changes, including a rarefied matrix and large lipid droplet. In the high-fat group, 83.0% ± 10.9% of mitochondria had abnormal morphology, compared to 9.0% ± 4.3% in the control group ($P < 0.05$) (Figure 2B). The changes

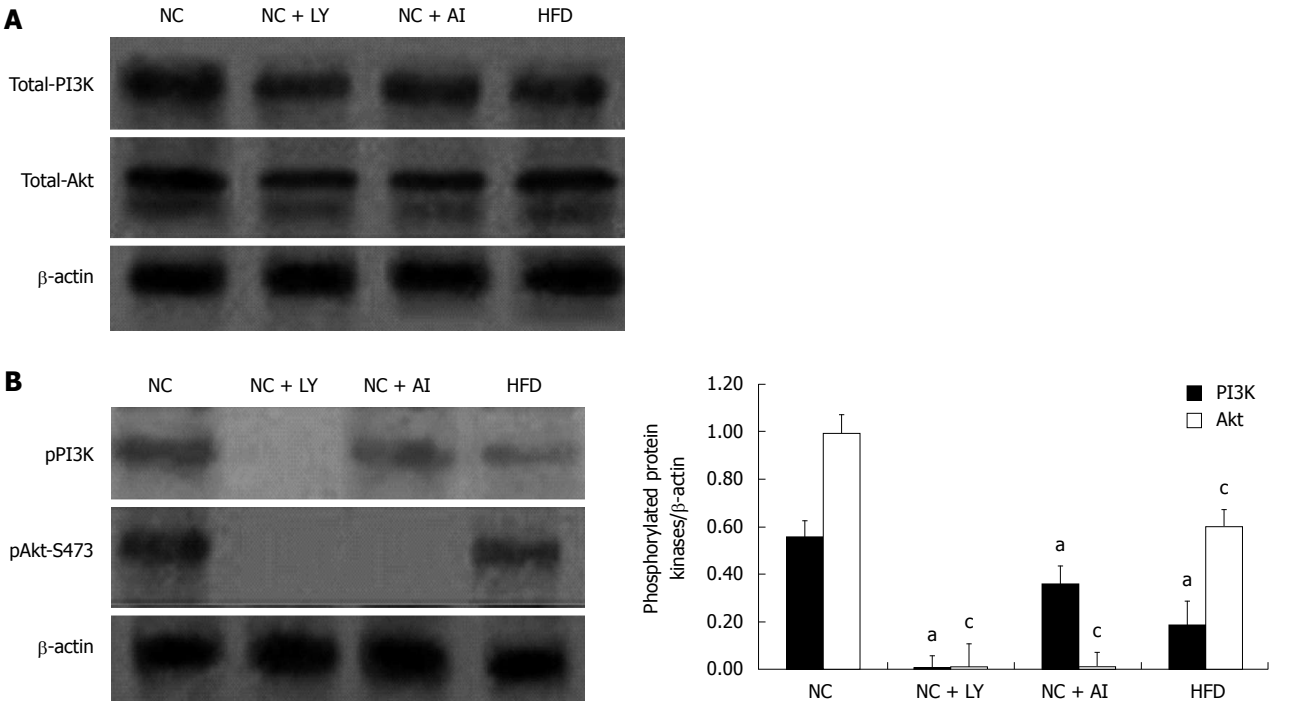

Figure 1 Western blotting analysis of phosphatidylinositol 3-kinase and protein kinase B in hepatocytes. A: Western blotting analysis of total phosphatidylinositol 3-kinase (PI3K) and protein kinase B (Akt). The protein expression levels of total PI3K and Akt showed no significant difference among the four groups; B: Western blotting analysis of phosphorylated PI3K and Akt. Left: In high-fat fed groups (HFD), the protein expression levels of both phosphorylated PI3K and Akt decreased compared with the normal control (NC) group. In PI3K blocker groups (NC + LY), pPI3K and pAkt showed no expression. In AKT blocker groups (NC + AI), pPI3K was normally expressed and pAkt showed no expression. Right: Band density values are compared with those of the β-actin loading control. $^{a,c}P < 0.05$ *vs* NC group.

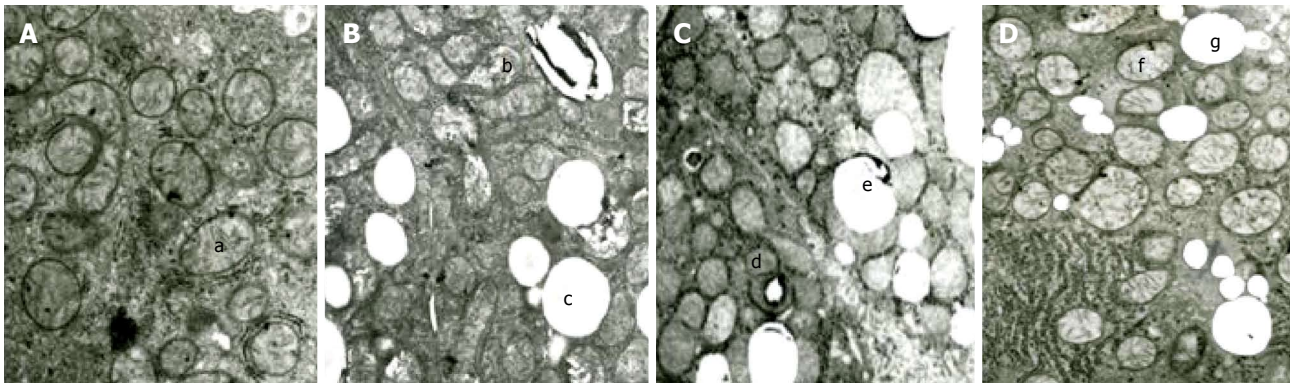

Figure 2 Ultrastructural changes in hepatocellular mitochondria. A: Mitochondria (a) in normal diet group; B: Enlarged mitochondria (b) and lipid droplet (c) in high-fat diet group; C and D: Animals treated with either phosphatidylinositol 3-kinase blocker (C) or protein kinase B blocker (D) showed similar changes in mitochondrial shape, size (d, f) and lipid droplet (e, g) to those of the high-fat group. Magnification × 18 000.

of mitochondria in the PI3K-inhibitor and Akt- inhibitor groups were similar to those of the high- fat group, although they differed significantly from the high-fat group in the PI3K and Akt inhibitor groups (Figure 2C and D). This indicated that PI3K/Akt pathway blocking could affect ultrastructural changes of hepatocellular mitochondria. The change was similar to that resulting from a high-fat diet.

Hepatocellular mitochondria function and PI3K/Akt pathway

To investigate whether PI3K/Akt signaling is associated with an increase in the permeability of the outer mitochondrial membrane, we measured the mean fluorescence intensity (MFI) of Rh123 on the mitochondrial membrane in animals of the four groups. The MFI was 249.121% ± 13.526% in the high-fat group, and 389.385% ± 18.612% in the control group, indicating that there was a significant decrease in the mitochondrial membrane potential in the high-fat group. The PI3K and Akt inhibitor groups showed similar decreases in the mitochondrial membrane potential (211.326% ± 12.114% and 214.326% ± 13.321%, respectively) compared with the control group (Figure 3). These results suggested that mitochondrial function was impaired to the same degree in the high-fat and both inhibitor groups, strongly sug-

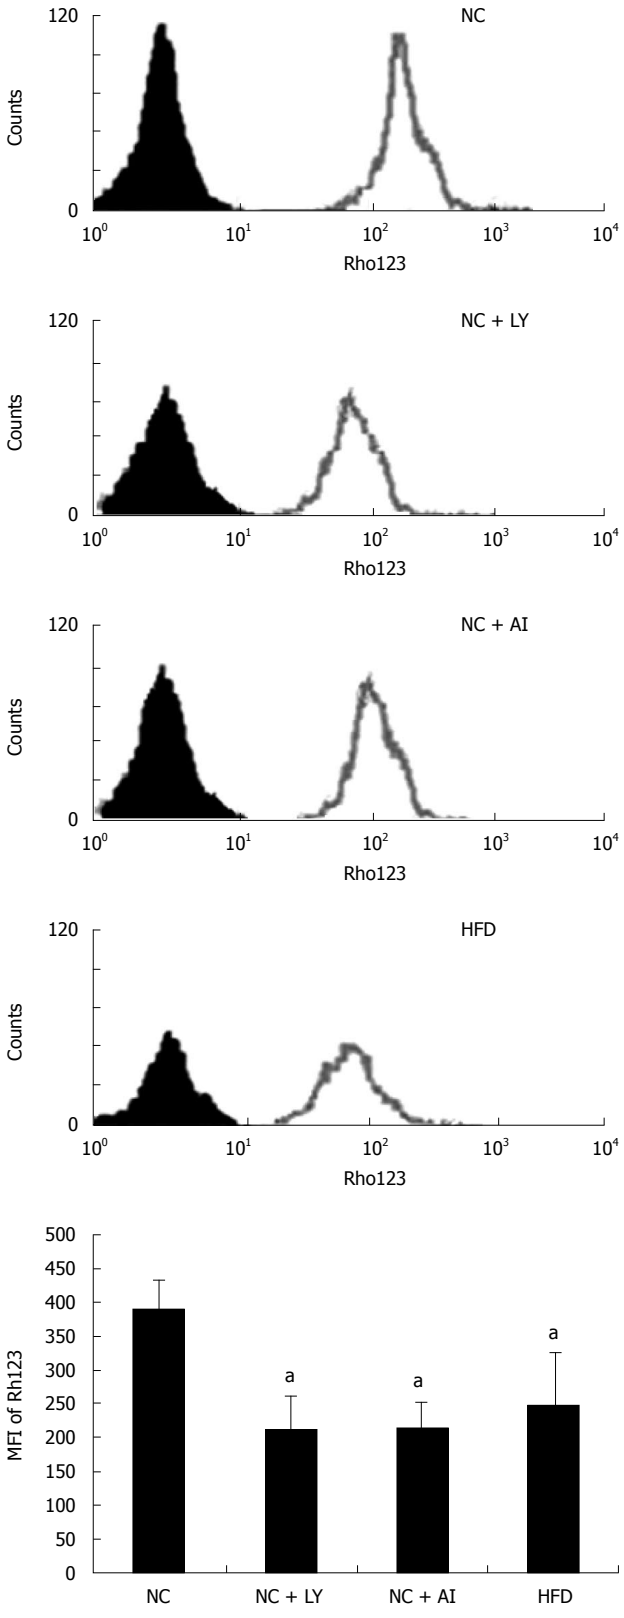

Figure 3 Changes in the membrane potential of hepatocyte mitochondria. Fluorescence intensity (MFI) of Rh123 was 389.385% ± 18.612% in the normal control (NC) group, but decreased to 268.326% ± 13.526% in the high-fat group (HFD); and in PI3K and Akt blocker groups, MFI had a very similar change (211.326% ± 12.114%, 214.326% ± 13.321%, respectively), indicating a decrease in the mitochondrial membrane potential (Dym) in high-fat, PI3K and Akt blocker groups. $^{a}P < 0.05$ *vs* NC group.

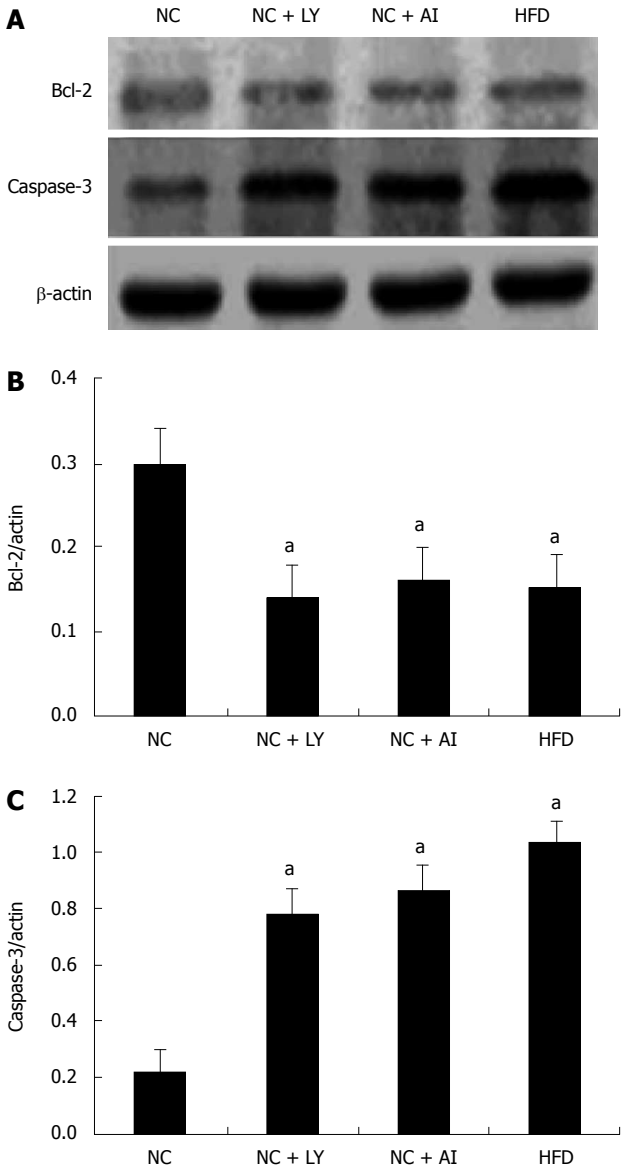

Figure 4 Western blotting analysis of caspase-3 and Bcl-2 in hepatocytes. A: Compared with control values [normal control (NC) group, lane 1], the expression levels of Bcl-2 protein decreased in the phosphatidylinositol 3-kinase (PI3K), protein kinase B (Akt)-blocker and high-fat groups (lanes 2-4). In contrast, caspase-3 expression was equally elevated in each of the three treatment groups compared with the control value; B, C: Band density values are compared with those of the β-actin loading control. $^{a}P < 0.05$ *vs* NC group.

gesting that the PI3K/Akt signal transduction pathway is associated with permeabilization of the outer mitochondrial membrane.

Apoptotic genes and PI3K/Akt pathway

One way in which changes in the PI3K/Akt signaling pathway might have induced mitochondrial apoptosis was through the effects of the apoptosis-related proteins Bcl-2 and caspase-3. To test this theory, we measured the expression level of these two proteins using Western blottings (Figure 4). We found that Bcl-2 expression showed a similar decrease in the high-fat, P13K-inhibitor, and

Akt-inhibitor groups (by 64%, 61% and 62%, respectively) compared to the control group, Conversely, the level of caspase-3 increased by a similar margin in the 3 experimental groups (42%, 31% and 29.5%, respectively) compared to the control group. This result demonstrated that there may be a link between the PI3K/Akt signaling pathway and the mitochondrial pathway of apoptosis in rats treated with high-fat, P13K inhibitor, or Akt inhibitor.

DISCUSSION

In this study, we attempted to investigate whether the PI3K/Akt pathway could mediate mitochondrial impairment during the development of NAFLD, and whether this might explain why hepatic insulin resistance is critical to the development of this disease. We found that hepatocytes of rats fed a high-fat diet accumulated fat and developed deformed mitochondria, a decreased mitochondrial membrane potential, and decreased expression of PI3K and Akt proteins. Unexpectedly, we found that blocking the PI3K/Akt pathway with either a PI3K or Akt inhibitor led to hepatocellular fat accumulation and mitochondrial impairment indistinguishable from that of high-fat fed rats. These findings suggest that signals transduced by the PI3K/Akt pathway are involved in the pathogenesis of NAFLD.

The phosphatidylinositol 3-kinase (PI3K)/Akt signaling cascade is an important component of insulin signaling in normal tissues, where it mediates glucose uptake and homeostasis, as well as being an important regulator of cell survival in numerous cell types[12]. In this study, we found that both the insulin resistance index (HOMA-IR) and serum levels of hepatocellular enzymes were significantly increased in response to a high-fat diet, suggesting that insulin resistance and hepatocyte damage may coexist in our high-fat experimental model.

Mitochondrial dysfunction is known to play a central role in the hepatocyte damage of NAFLD[13]. Although our current experiment confirmed that mitochondrial dysfunction is associated with progression of liver pathological changes, the mechanisms initiating mitochondrial dysfunction in this disease are unknown. Specifically, it is not clear whether mitochondrial damage and changes in insulin signal transduction are directly related to the pathophysiology of nonalcoholic fatty liver induced by high fat. A number of studies have indicated that insulin can stimulate mitochondrial biogenesis[14] and alter mitochondrial morphology in obese, insulin-resistant and type 2 diabetic individuals[15]. In the current study, we found that a high-fat diet led to an increase in the proportion of morphologically abnormal mitochondria as well as an increase in the insulin resistance index. Similarly, less marked results were seen with treatment of the P13K- or Akt inhibitors, suggesting that changes in the PI3K/Akt signal transduction pathway may mediate these changes in mitochondria morphology.

The transmembrane potential (Dym) of mitochondria is known to play a crucial role in their normal function[16]. We found that the mitochondrial transmembrane potential

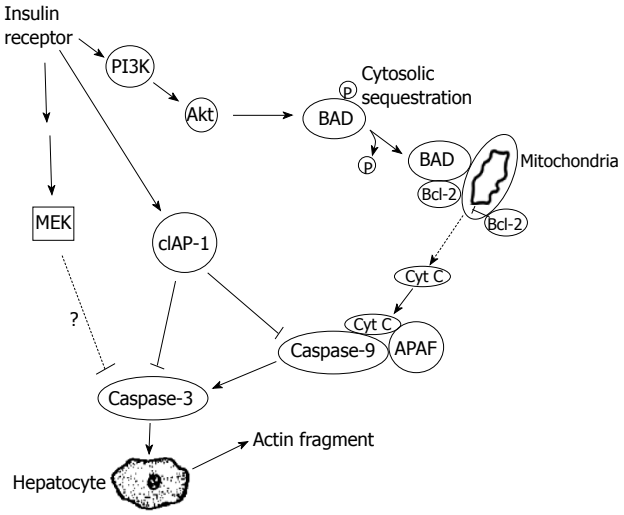

Figure 5 Simulation diagram of the relationship between insulin signaling pathway and hepatocyte apoptosis. PI3K: Phosphatidylinositol 3-kinase; Akt: Protein kinase B; BAD: Bcl2-associated agonist of cell death; MEK: Mitogen-activated protein kinase kinase; cIAP-1: Cell inhibitors of apoptosis protein-1; Cyt C: Cytochrome c; APAF: Apoptotic peptidase activating factor.

in the high-fat group, as well as those treated with either the PI3K- or AKT inhibitor, was significantly lower than control values, further implicating the P13K/Akt pathway in mitochondrial dysfunction.

Our results have confirmed some previous findings by Mehta *et al*[17], who reported that hepatic steatosis is frequently associated with obesity, type 2 diabetes, and hyperlipidemia, with insulin resistance being a key pathogenic factor in NAFLD and mitochondrial damage being characteristic of the disease. However, the current study is the first to implicate the PI3K/Akt signal transduction pathway in the morphological and functional changes in hepatocyte mitochondria, as well as insulin resistance induced by high fat.

Recent evidence suggests that hepatocellular injury in a number of liver diseases is accompanied by activation of the apoptotic pathways[18]. We found morphological (deformed mitochondria), and functional abnormalities (a reduction in the mitochondrial membrane potential) in hepatocyte mitochondria consistent with apoptosis in high-fat, PI3K and Akt inhibitor groups. We also examined the expression of two proteins in the Bcl-2 family of anti-apoptotic proteins. Proteins in this family are known to regulate apoptosis at peri-mitochondrial sites. The PI3K/Akt signaling pathway has been shown to have an anti-apoptotic effect by activating Bcl-2 to inhibit the apoptotic mediator caspase-3[19]. We found that, in rats fed a high-fat diet, expression of PI3K, phosphorylated Akt, and Bcl-2 decreased, but the expression of caspase-3 increased, suggesting a mechanism by which apoptosis may be triggered in NAFLD. To further support a role for the P13K pathway in mediating apoptosis in NAFLD, we found that the P13K- and Akt inhibitors led to a similar decrease in Bcl-2 expression and a significant increase in caspase-3 expression (Figure 5).

Apoptosis is a process of active cellular self-destruc-

tion that requires the expression of specific genes including those of the Bcl-2 gene family[20]. Of these, Bax, Bad and Bak promote cell death, whereas Bcl-2 and Bcl-xL inhibit apoptosis and promote cell survival[21]. The results of a recent study suggest that caspase-3 can cause permeabilization of cells, with the help of pro-apoptotic Bcl-2 proteins. Until recently, the prevailing view has been that caspase-3 activation represents the apex of the caspase cascade within the mitochondrial apoptotic pathway.

Some Bcl-2 family members located on the mitochondrial membrane have been shown to be able to alter the permeability of the mitochondrial membrane and trigger the activation of caspases[22]. Programmed cell death might thus be activated *via* a membrane bound pathway, in which the signal is initiated at the mitochondrion[23]. Pro-apoptotic compounds are normally sequestered in the intermembrane space[24]. When the permeability of the outer mitochondrial membrane increases, these proteins are released into the cytosol, forming the apoptosome and subsequently activating caspase-3[25]. The results of the current study indicate that not only high fat, but also blockage of the PI3K/Akt pathway signal, lead to an increase in the permeability of the hepatic mitochondrial membrane, implicating this pathway in the apoptotic mechanisms triggered by a high-fat diet. All these results lead us to propose a disease model in which the PI3K/Akt signal transduction pathway induces apoptosis *via* a Bcl-2/caspase-3 mitochondrial-dependent pathway, in which phosphorylation of Bad results in targeting of Bcl-xL to the mitochondrial membrane, where Bcl-2 interacts with and inactivates anti-apoptotic Bcl-2 proteins, thereby inducing apoptosis[26].

In conclusion, the present study suggests that fat accumulation in the liver may impair PI3K/Akt pathway signal transduction and thereby activate the mitochondrial membrane pathway of apoptosis, leading to hepatocyte damage.

COMMENTS

Background

Nonalcoholic fatty liver disease (NAFLD) is caused by triglyceride (TG) accumulation within the liver, which may progress to fibrosis, cirrhosis and liver failure. Mitochondrial dysfunction which caused hepatocyte apoptosis is an important element in the pathogenesis of NAFLD. Hepatic insulin resistance is also a critical component in the development of NAFLD, which is characterized by a marked reduction in the activity of the insulin signaling pathway, including the phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt, also known as PKB) pathway. But the potential relationship between the PI3K/Akt signaling pathway and the mitochondrial abnormalities that underlie NAFLD remain unclear.

Research frontiers

Recent reports have highlighted the insulin-induced signaling pathways in various cells. In the presence of insulin, the insulin receptor normally phosphorylates insulin receptor substrate (IRS) proteins, which are linked to the activation of several signaling pathways, including the PI3K/Akt pathway. PI3K and its downstream effector Akt regulate a diverse array of cellular events, including survival and apoptosis of a number of cell types. The mitochondrial impairment during the development of NAFLD is also an area of intense research. Mitochondrial dysfunction is an important element in the pathogenesis of NAFLD, mainly hepatocyte apoptosis. Recent evidence showed that mitochondria participates in the regulation of both cell proliferation and death, including apoptosis, and are thus potential mediators of the PI3K/Akt signaling pathway.

Innovations and breakthroughs

This is the first study to report the relationship between mitochondria impairment and the activity of the PI3K/Akt signaling pathway during the development of NAFLD, which suggests that fat accumulation in the liver may impair PI3K/Akt pathway signal transduction and thereby activate the mitochondrial membrane pathway of apoptosis, leading to hepatocyte damage.

Applications

The results of this study indicated that the PI3K/Akt pathway may mediate mitochondrial impairment during the development of NAFLD, and this might explain why hepatic insulin resistance is critical to the development of this disease.

Terminology

Insulin signaling pathways, including the metabolic PI3K/Akt pathway. PI3K and its downstream effector Akt regulate a diverse array of cellular events, including survival and apoptosis of a number of cell types. Mitochondrial impairment, an important element in the pathogenesis of NAFLD. Mitochondria participates in the regulation of both cell proliferation and death, including apoptosis, and are thus potential mediators of the PI3K/Akt signaling pathway.

Peer review

This is a well written paper with well thought out, well-controlled data. The paper evaluates the effect of a high-fat diet and correlates it with similar findings seen with blocking the P13K or Akt inhibitors, and thereby implicated this pathway as the mechanism for high-fat diet hepatic injury.

Abstract

AIM: To assess the prevalence of nonalcoholic fatty liver disease (NAFLD) in patients with idiopathic venous thromboembolism (VTE).

METHODS: In a case-control study, after excluding subjects with well-consolidated risk factors for VTE, idiopathic VTE was documented in 138 consecutive patients who were referred to our department. Two hundred and seventy-six healthy sex/age/body-mass-index-matched subjects, without any clinical/instrumental evidence of VTE, served as controls. All underwent a clinical/laboratory/ultrasound assessment for the presence of metabolic syndrome and NAFLD.

RESULTS: NAFLD was detected in 112/138 cases (81%) and in 84/276 controls (30%) [risk ratio: 2.7, 95% confidence interval (CI): 2.2-3.2, $P < 0.0001$]. Metabolic syndrome and smoking habit were more prevalent in patients with idiopathic VTE. The high prevalence of NAFLD in VTE was also confirmed after adjustment for inherited thrombophilia. NAFLD was clearly predicted by VTE (odds ratio: 1.8, 95% CI: 1.2-2.7, $P < 0.0001$).

CONCLUSION: NAFLD was independently associated with idiopathic VTE.

Key words: Thromboembolism; Metabolic syndrome; Nonalcoholic fatty liver disease

INTRODUCTION

Venous thromboembolism (VTE) has an annual incidence of 1-2 events/1000 people in the general population, and is considered to be an emerging health problem[1,2]. Arterial and venous thromboses have been historically considered as distinct entities due to thrombus composition and different response to antiplatelet or anticoagulant drugs[3]. Metabolic syndrome (MS), which affects > 20% of the whole population[4,5], increases cardiovascular risk[6] by a blood hypercoagulability-related mechanism. This phenomenon is the result of abnormally high plasma levels of plasminogen activator inhibitor-1 (PAI-1), fibrinogen and factors Ⅶ, Ⅷ and von Willebrand, as well intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1[7-12]. Indeed, antiphospholipid syndrome and hyperhomocysteinemia predispose to venous and

cardiovascular events[13-15]. Ageno *et al*[16] have reported an association between idiopathic VTE and MS, which has been confirmed by Ay *et al*[17]. Arterial hypertension is a cardiovascular risk factor for VTE[18,19]. In addition, type 2 diabetes is associated with several coagulation and fibrinolysis alterations that lead to a procoagulant, thrombogenic predisposition, and is likely to have a significant impact on VTE occurrence[20]. Abdominal obesity is currently accepted as an independent risk factor for VTE[21].

Nonalcoholic fatty liver disease (NAFLD) has been strictly associated with MS[22]. Insulin resistance is reckoned to be the major mechanism. NAFLD refers to a wide spectrum of liver damage, which ranges from simple steatosis to nonalcoholic steatohepatitis, advanced fibrosis and cirrhosis.

In a series of patients with idiopathic VTE, we tried to assess the prevalence of NAFLD, further expression of MS, comparing the data with those achieved in control subjects.

MATERIALS AND METHODS

Inclusion criteria

One hundred and thirty-eight patients with recent (< 6 mo) objective diagnosis of idiopathic VTE were enrolled in the study. One hundred and twenty patients had deep vein thrombosis (DVT), of which, 21 were associated with superficial vein thrombosis, nine were suffering from isolated pulmonary embolism (PE), and 16 with PE plus DVT. DVT was confirmed by Doppler ultrasonography (DUS). PE was documented by computed tomography.

VTE was defined as idiopathic in the absence of pregnancy or puerperium, known active malignancies, recent (< 3 mo) surgery or trauma, fracture, immobilization, lack of prophylaxis, acute medical disease, use of oral contraceptives, long-distance travel, a history of VTE or repeated birth loss. In contrast, when at least one of the previous risk factors was present, VTE was defined as secondary and the patients were excluded from the study.

As many as 276 healthy sex/age/body mass index (BMI)-matched subjects served as controls. In all of them, exclusion of DVT was based on clinical examination, use of D-dimer testing, and clinical pretest probability and, in some uncertain cases, by two DUS examinations within 1 wk of each other.

Exclusion criteria

Cases and controls who presented with unstable medical conditions were excluded. Other exclusion criteria were a history of infectious chronic diseases including hepatitis B and C, autoimmune and storage diseases, drug-induced hepatic steatosis, and prior use of medication known to affect inflammation, glucose metabolism or blood lipids. Alcohol abuse was ruled out, according to the DSM-IV diagnostic criteria, by means of screening tests such as MAST (Michigan Alcohol Screening Test) and CAGE (Cut down, Annoyed, Guilty, and Eye opener), as well as random tests for blood alcohol concentration and the use of a surrogate marker, e.g. mean corpuscular volume. Patients on antihypertensive therapy maintained a balanced medical regimen throughout the study.

Clinical, laboratory and imaging data

Sex, age, BMI, waist circumference, history of symptomatic atherosclerosis (i.e. ischemic stroke, transient ischemic attack, acute myocardial infarction, angina, intermittent claudication), arterial hypertension or use of antihypertensive drugs, diabetes mellitus or use of antidiabetic drugs, hyperlipidemia or use of statins or clofibrate, smoking habit (daily consumption of $\geqslant$ 1 cigarette), current use of heparin, oral anticoagulant or antiplatelet drugs were recorded. Subsequently, all patients underwent liver ultrasound (US), measurement of blood pressure, fasting glucose, transaminases and γ-glutamyl transferase activity, high-density lipoprotein (HDL) cholesterol and triglyceride levels. MS was diagnosed by the presence of at least three criteria (National Cholesterol Education Adult Treatment Panel Ⅲ) on the basis of abdominal obesity (waist circumference > 102 cm for men and > 88 cm for women), triglycerides $\geqslant$ 150 mg/dL, HDL-cholesterol < 40 mg/dL for men and < 50 mg/dL for women, blood pressure $\geqslant$ 130 mmHg and/or $\geqslant$ 85 mmHg, and fasting glucose $\geqslant$ 100 mg/dL. Obesity was recognized as a BMI $\geqslant$ 30.

The classification of "bright liver" or hepatic steatosis grade was based on the following scale of hyperechogenity at US: 0 = absent, 1 = light, 2 = moderate, 3 = severe, pointing out the difference between the densities of the liver and the right kidney[23]. Diagnostic criteria for DVT were observation of an intraluminal venous thrombus, loss of compressibility, and lack of flow at DUS.

Statistical analysis

We observed how many times the event of interest, i.e. NAFLD occurred in the experimental group or cases (VTE) and in controls. Statistical confidence was increased by taking two controls per case. The RR and 95% CI was the ratio of the proportions of cases with a positive outcome in the two groups. Patients' clinical characteristics were compared using Student's *t* test (continuous variables) and the χ^2 test (dichotomous variables). A logistic regression (stepwise model) was adopted, in which NAFLD was the dependent variable and sex, anthropometric parameters (BMI, waist circumference), metabolic features (serum HDL-cholesterol, triglycerides and glucose), systolic blood pressure, diastolic blood pressure, smoking habit and finally VTE were employed as independent variables. MS as entity was not considered in prediction, to avoid multicollinearity. The same tool (enter method) was carried out to predict VTE presence the by US grade of steatosis. Statistical analysis was performed with MedCalc® 11.2.

RESULTS

The mean age in the cases and controls was 41.8 ± 13.0 and 43.4 ± 15.7 years, and the mean BMI in the two groups was 30.4 ± 4.1 and 29.6 ± 3.9 (P = 0.79 and P

Table 1 Prevalence of clinical and laboratory findings and smoking in the whole population

	Cases (138) yes/not	Controls (276) yes/not	RR (95% CI)	*P*
Smoking habit	81/57	108/168	1.5 (1.2-1.8)	0.000
Fasting glucose ⩾ 110 mg/dL	84/54	110/166	1.5 (1.25-1.9)	0.000
Abdominal obesity	98/40	107/169	1.8 (1.5-2.2)	< 0.0001
Hypertriglyceridemia	72/66	131/145	1.1 (0.8-1.3)	0.35
Low HDL-cholesterolemia	91/47	146/130	1.2 (1.1-1.5)	0.008
Hypertension	94/44	111/165	1.7 (1.4-2.0)	< 0.0001

RR: Risk ratio; CI: Confidence interval; HDL: High-density lipoprotein.

= 0.81, respectively). Sex distribution between the two groups did not show significant differences (χ^2, $P = 0.95$).

Among the 138 VTE patients, 112 (81%) had concomitant NAFLD, whereas 84 out of 276 (30%) controls suffered from NAFLD (RR = 2.7, 95% CI: 2.2-3.2, $P < 0.0001$). The RRs of smoking habit and single components of MS are shown in Table 1.

Factor V G1691A and/or prothrombin G20210A polymorphisms (major determinants) were not detected in 80 out of 138 cases (58%) and in 188 out of 276 controls (68.1%). A higher prevalence of NAFLD in patients with VTE but without inherited thrombophilia versus controls was also confirmed on the basis of this further selection; 62 patients in cases and 61 in controls (RR = 2.4, 95% CI: 1.9-3, $P < 0.0001$). When predicting NAFLD, VTE played an important role, which confirmed the aforementioned findings, but also smoking habit and some MS components gave a good prediction (Table 2). In contrast, age, BMI and sex did not enter the model, because their significance was > 0.1. The presence of VTE was well predicted by grade of steatosis, as revealed by US (OR = 1.9, 95% CI: 1.05-3.8, $P < 0.0001$).

DISCUSSION

Our main finding was a significantly higher prevalence of NAFLD in idiopathic VTE patients than in controls, which was confirmed after adjusting for inherited thrombophilia. Although these results were partially expected, they were highlighted for the first time in the present study. What is more, this report extends previous data[16] on MS. In a recent report[24], rather than considering "all-or-nothing" definitions for MS, the additive effect of having more than one of the MS features has been considered. This is a controversial point. However, what if physicians use an indirect parameter of MS presence, e.g. NAFLD? The present study supports a significant correlation between every single component of MS and VTE, even though the strictest association was demonstrated between NAFLD, a further expression of MS as a whole[22], and VTE, which by-passes the restrictive criteria of MS.

These data lend credence to the possibility that VTE is an early clinical event in a generalized vascular disease

Table 2 Prediction of nonalcoholic fatty liver disease

that involves venous and arterial circulation. Our results support the need for further studies to evaluate the risk of subsequent cardiovascular events in VTE patients without MS, but with NAFLD.

In trying to establish the complex interaction between VTE and NAFLD, we stress that they share common mechanisms. First of all, we should pinpoint the role of PAI-1. In fact, abdominal fat, liver steatosis and serum triglycerides levels have been shown to be significant and independent determinants of PAI-1 plasma level in an unselected sample of male adults upon adjustment for age and therapy[25]. Additionally, the pro-angiogenic factor, vascular endothelial growth factor, which is generally thought to be the main factor that determines VTE in patients with cancer[26], plays a key role in NAFLD[27]. Recent evidence has substantiated that NAFLD is associated with elevated circulating levels of ICAM-1, which throws further light on inflammation-related liver damage[28]. Another intriguing link is represented by smoking, which is a plain risk factor for the development of VTE. Indeed, this relationship could be justified by the presence of NAFLD. In fact, Yuan *et al*[29] have provided novel evidence to demonstrate that tobacco smoke exposure can accelerate the development of experimental NAFLD.

The limitations of the present study are as follows. Our control group comprised individuals who were referred for signs or symptoms initially suggestive of VTE, and it may not adequately represent a general healthy population. However, the prevalence of MS in our control group was comparable to that reported in the general Italian population[5], which suggests that, with a differently selected control group, our findings could have been comparable to those reported in the previous study. Although patients with cancer were excluded from our study, some VTE patients might have had occult cancer at the time of investigation. The impact of occult cancer on the components of MS is unknown; however, its impact on the results of our analysis was likely to have been low. With regard to the definition of idiopathic VTE, we have defined it as VTE that occurs in patients without the most common known risk factors. Based on our definition, other risk factors might have been missed, but this is unlikely to have significantly influenced our results. Another potential point of criticism relates to the size of the study, which was not very large.

In conclusion, an eventual association between VTE and NAFLD should be always pursued.

COMMENTS

Background

Venous thromboembolism (VTE) with an annual incidence of 1-2 events/1000 people in the general population is considered to be an emerging health problem.

Research frontiers

Metabolic syndrome affects > 20% of the whole population, and increases the cardiovascular risk by a blood hypercoagulability-related mechanism.

Innovations and breakthroughs

This is believed to be the first evidence to show a strict link between idiopathic VTE and nonalcoholic fatty liver disease (NAFLD). Smoking could increase the risk of VTE by worsening NAFLD.

Applications

Patients suffering from MS should be warned against their increased risk of VTE.

Peer review

In this paper, research on the prevalence of NAFLD in idiopathic VTE is presented, which is an interesting topic.

Abstract

AIM: To explore the prevalence of local and genetic thrombophilic disorders as risk factors for portal vein thrombosis (PVT) in our series, the largest ever published in pediatric literature.

METHODS: We conducted a case-control study enrolling 31 children with PVT and 26 age-matched controls. All were screened for thrombophilia, including genetic disorders, protein C, protein S and homocysteine deficiencies. All coagulation parameters were studied at least 3 mo after the diagnosis of portal vein obstruction.

RESULTS: In our study we showed that most pediatric patients with PVT have local prothrombotic risk factors, which are probably the most important factors leading to PVT. However, there is a clear association between the presence of prothrombotic disorders and PVT, suggesting that these increase the risk of thrombosis in patients with local factors such as perinatal umbilical vein catheterization or sepsis.

CONCLUSION: Patients with PVT should be screened for inherited prothrombotic disorders regardless of a history of an obvious local risk factor.

INTRODUCTION

Portal vein thrombosis (PVT) is a common cause of portal hypertension. To date, the pathogenesis of PVT in children still remains unexplained, yet it is the major cause of portal hypertension in children and adolescents.

Variceal bleeding due to PVT is a recognized cause of upper gastrointestinal bleeding in children in developing countries[1,2]. Hereditary thrombophilias that are known to predispose to venous thrombosis and PVT include certain mutations of the prothrombin (*PTHR*), factor V Leiden (*FVL*) or methylenetetrahydrofolate reductase (*MTHFR*) genes or deficiency of one of the natural anticoagulant proteins C and S[3-6].

Some neonatal events such as abdominal surgery, sepsis or umbilical vein catheterization (UVC) are typically identified in patients with PVT[7], with an incidence of thrombosis complicating UVC reported in the literature as high as 44%[8-10]. Moreover, other factors, such as dehydration, also have been suggested to play a part in PVT development[11].

Finally, despite all efforts, the cause of the blocked portal vein remains obscure in 50% to 90% of children[12]. Unlike in adults, studies of thrombophilic disorders in children are scant, and to date only a few studies have evaluated the prevalence of hereditary thrombophilic disorders in children and adolescents with PVT[1,2,13,14].

The aim of our study was to explore the prevalence of local and genetic thrombophilic disorders as risk factors in PVT in our series, the larger ever published.

MATERIALS AND METHODS

A 2-year prospective case-control study (December 2006 to December 2008) was carried out at Bambino Gesù Children's Hospital in Rome, Italy. The study was conducted according to the principles of the Declaration of Helsinki, informed consent was obtained, and the authors' institutional review board approved the study.

We enrolled two groups of subjects for the study. Group 1 included 31 (20 male) Caucasian patients with PVT; mean age, 7 yr 8 mo (range: 11 mo - 18 yr 2 mo). Group 2 comprised 26 children (15 male) free of liver disease and thrombotic events, age matched with group 1, who were inpatient in our hospital during the study. Upper endoscopy was performed in all patients of Group 1 and showed signs of portal hypertension but not always the presence of varices.

PVT was diagnosed by Doppler ultrasound scan or angiography [14 patients underwent both these procedures and we found a very high concordance (98%)]; both procedures were performed by the same radiologist. Normal liver function tests or no other sign of liver disease was an inclusion criteria, as well as the absence of histological abnormalities on liver biopsy examination when performed.

All patients were screened for thrombophilia including genetic disorders (*MTHFR C677T, FVL, PTHR G20210A*) protein C (PC), protein S (PS) and homocysteine. All coagulation parameters were studied at least 3 mo after the diagnosis of portal vein obstruction to avoid falsely low levels related to active thrombosis. Abnormal values of coagulation factors might be observed in patients with PVT due to impaired liver synthesis. Due to the lack of standards to define PC or PS deficiency in this setting, we used a ratio of these levels to prothrombin rate lower than 0.7 as a working definition for these deficits. This definition should exclude those patients with low PC and PS levels related to impaired liver synthesis, which would also affect prothrombin rate.

None of the patients were on anticoagulant or antiplatelet therapy at the time of the study. Detailed history was obtained with special emphasis on history of umbilical catheterization (50%), umbilical sepsis (6%), admission to neonatal intensive care unit (72%), severe gastroenteritis and dehydration (6%), history of thromboembolism in the patients and their family members (3%), and history of parental consanguinity (1%).

Genetic and specific analysis

Genomic DNA was isolated from white blood cells by standard procedures. A 222 bp fragment of the Factor V gene, a 165 bp fragment of the Factor Ⅱ gene and a fragment of the MTHFR gene are amplified from human genomic DNA using specific primers and the amplicon is detected by fluorescence using a specific pair of probes consisting of two different oligonucleotides that hybridize to an internal sequence of the amplified fragment during the annealing phase of a PCR cycle. The same specific probes are also used to determine the genotype by performing a melting curve analysis.

PC and PS activity was measured by coagulometric assay. PC activity was measured using a specific activator extracted from southern copperhead snake venom (*Agkistrodon c. contortrix;* STA protein C, Roche). PS activity was determined based on the principle of activated factor V inhibition (STA protein S, Roche). Protein activity was expressed as a percentage of a reference plasma pool.

Statistical analysis

Continuous variables were compared with unpaired *t*-test. Categorical variables were compared with the Fisher exact test. The association between the presence of an abnormality and PVT was assessed with odds ratios and their 95% confidence intervals (CI). All analyses were performed with SPSS version 15 (Chicago, IL, USA).

RESULTS

The characteristics of the patients and controls are summarized in Table 1. In patients, the first manifestation of portal vein thrombosis occurred at a mean age of 4 year 9 mo (range: 6 mo to 16 year 2 mo). This was upper gastrointestinal (GI) bleeding in 87% of patients followed by splenomegaly in 13%. Eighty-one percent of the patients had varices at presentation, while 74% had splenomegaly. Sixty-eight percent of the patients had a history of a local prothrombotic factor (neonatal sepsis or umbilical vein catheterization). Only 1 patient with a local prothrombotic factor was present in the controls.

Congenital thrombophilic disorders

FVL mutation was found in 2 (7%) patients and heterozygous *G20210A* mutation was found in 3 (10%), while

Table 1 Characteristics of the patients (mean ± SD)

	Controls	Patients
Age	6 yr 9 mo	7 yr 8 mo
Sex	15 males	20 males
INR (%)	1.05 ± 0.09	1.35 ± 0.21
ALT (UI/L)	31.15 ± 13.83	25.45 ± 14.71
AST (UI/L)	37.23 ± 11.86	31.42 ± 11.90
GGT (UI/L)	16.46 ± 16.89	17.68 ± 18.40
Albumin (g/dL)	4.16 ± 0.48	3.88 ± 0.37
Bil/tot (mg/dL)	0.78 ± 0.13	0.81 ± 0.27
Bil/dir (mg/dL)	0.12 ± 0.11	0.18 ± 0.14
ALP (UI/L)	404.09 ± 154.90	515.97 ± 180.44

INR: International normalized ratio; ALT: Aspartate aminotransferase; AST: Alanine aminotransferase; GGT: γ-glutamyl transpeptidase; Bil/tot: Bilirubin/total; Bil/dir: Bilirubin/direct; ALP: Alkaline phosphatase.

homozygosity for these two mutations was not found in any patient. No control patient had mutations in these two genes.

MTHFR-C667T mutation was found in 16 (68%) patients, and 4 (13%) were homozygous for this mutation. The corresponding figures in the control group were 6 (23%) and 0 patients, respectively (Table 2). Therefore, the odds ratio for having at least an allele with the *MTHFR-C677T* polymorphism in patients with portal vein thrombosis was 7.00 (95% CI: 2.15-22.85), suggesting that this polymorphism could increase the risk of PVT. However, intriguingly enough, levels of homocysteine in controls were similar to that found in cases ($P = 0.28$), and all subjects had normal values.

Coagulation inhibitor protein deficiency

Four patients presented PC levels compatible with prot C deficiency and 4 had PS levels compatible with prot S deficiency. We also investigated their parents to show any prot C alteration. Moreover, none of the controls had prot C deficiency while one had values consistent with prot S deficiency.

The overall frequency of inherited thrombophilic abnormalities (excluding mutations in *MTHFR*) in cases was 32% (8 patients had only one factor, one patient had two factors and one patient had three factors). This prevalence was significantly lower in controls (1/26, 4%) (Table 3). Thus, the OR of having any inherited prothrombotic disorder (excluding *MTHFR* polymorphism) in patients with portal vein thrombosis as compared to controls was 11.91 (95% CI: 1.41-100.77).

Eight patients (26%) had neither a thrombophilic nor a local factor (idiopathic portal vein thrombosis). This figure is in keeping with previously published series of adult portal vein thrombosis. Thirteen patients (42%) had only local factors, eight (26%) had both local and thrombophilic factors and only 2 patients (6%) had isolated inherited thrombophilic factors with no history of a local factor.

There were no associations between the presence of an inherited prothombotic disorder and the manner of initial presentation of PVT (splenomegaly or GI bleeding). However, patients with inherited thrombophilic factors were less likely to have varices at the time of presentation (6 out of 10 patients) as compared with patients without (19 out of 21; $P = 0.045$).

No recurrent thrombotic events were recorded in a 24 mo long follow-up, both in patients with and without prothrombotic disorders.

Table 2 Distribution of type and prevalence of mutations in study subjects *n* (%)

Type of mutations	Prevalence of mutations		
	Control (26)	Case (31)	Total (57)
Normal	20 (76.9)	10 (32.3)	30 (52.6)
Abnormal *MTHFRC677T*			
Heterozygous	6 (23.1)	17 (54.8)	23 (40.4)
Homozygous	0 (0)	4 (12.9)	4 (7.0)

$P = 0.001$. *MTHFR*: Methylenetetrahydrofolate reductase.

No	25 (96.2)	21 (67.7)	46 (80.7)
Yes	1 (3.8)	10 (32.3)	11 (19.3)
Total	26 (100)	31 (100)	57 (100)

$P = 0.008$ (Fisher's exact test).

DISCUSSION

In this study we show that most patients with pediatric portal vein thrombosis have a history of a local prothrombotic factor, such as sepsis or umbilical vein catheterization, a figure much higher than that reported for adult portal vein thrombosis (around 30%)[15]. Therefore, and distinctly from adult PVT, local factors seem clearly to be the major players implicated in the development of PVT in children. However, a major finding of this study is that inherited disorders of coagulation are also frequently found in these patients (38%, as compared with 4% in controls), though most times in association with a local factor. This suggests, on one hand, that inherited thrombophilic disorders might facilitate the development of PVT thrombosis after a "local" event. On the other hand, since the presence of a thrombophilic disorder might have an impact on the management and follow-up of these patients, our data support the notion that children with PVT should be thoroughly investigated for the presence of a thrombophilic factor, even if an obvious history of a local factor is present.

The most frequent thrombophilic disorder was a deficit in naturally occurring anticoagulants (proteins C or S). It is possible, however, that the prevalence of coagulation inhibitor protein deficiency might be overestimated, since these factors might decrease due to altered liver synthesis and decreased hepatic blood flow secondary to the thrombosis, as already suggested in literature[6,16]. Notably, some

studies have already shown a rise in the concentration of coagulation inhibitor proteins after a surgical correction directly bypassing the venous obstruction[17,18], confirming this hypothesis. However, even with our restrictive working definition of prot C and S deficit (less than 0.7 × prothrombin rate), we have found a high prevalence of these disorders, suggesting that their role is more relevant in pediatric than in adult PVT. Larger numbers with detailed family history (difficult to recruit in this setting) would be required to gain further insight into this finding.

In our population the *MTHFR-C677T* polymorphism was much more frequent in patients than in controls, suggesting that it behaves as a risk factor for PVT. However, in our cohort no difference in the levels of homocysteine between controls and patients was found. Thus, this polymorphism is not always associated with high plasma levels of homocysteine[19,20], even in patients with documented thrombotic events and no other risk factor for thrombophilia. This raises the question of whether the *MTHFR* gene polymorphism, without hyperhomocysteinemia, may itself contribute to thrombophilia. On the other hand, intermittent hyperhomocysteinemia may occur, which is not easily detectable even if clinically significant. In addition, the interpretation of homocysteine levels in these patients is problematic. Dietary imbalances, such as an inadequate intake of folate and vitamin B12 which are needed to break down excess homocysteine or methionine overabundance from dietary protein, may play a critical role in homocysteine metabolism[21,22].

Although the association between the *MTHFR* mutation and thrombosis has not yet been fully clarified[6,23,24], anticoagulation may be indicated in patients with *MTHFR* mutation (either homozygous or heterozygous, with or without hyperhomocysteinemia)[25] with previous thrombotic events and other thrombotic risk factors (pregnancy, oral contraceptives, surgery, sepsis and immobilization). Therefore, our data suggest that the presence of *MTHFR* mutations should be investigated in all pediatric patients with PVT. In addition, if hyperhomocysteinemia is present, therapy with folic acid and B6 and B12 vitamins should be instituted.

Another finding of this study was the lower prevalence of GI varices in patients with prothrombotic disorders. This might be an association by chance, or could reflect that those patients with a thrombophilic factor were more likely to be diagnosed in a phase of "recent thrombosis", when varices still have not developed. At any rate, no differences were observed in the clinical evolution of PVT between patients with genetic anomaly and those without.

In summary, most pediatric patients with PVT have local prothrombotic factors, which are probably the most important factors leading to PVT (Table 4). However, there is a clear association between the presence of prothrombotic disorders and PVT, suggesting that these increase the risk of thrombosis in patients with local factors such as perinatal UVC or sepsis. Patients with PVT should be screened for inherited prothrombotic disorders regardless of a history of an obvious local risk factor. Future trials should evaluate the role of prophylactic low molecular weight heparins in children requiring UVC, especially in those with a family history of thrombotic events or other thrombotic risk factors.

COMMENTS

Background

Portal vein thrombosis (PVT) is a common cause of portal hypertension. To date, the pathogenesis of PVT in children still remains unexplained despite the fact that it is the major cause of portal hypertension in children and adolescents. Unlike in adults, studies of thrombophilic disorders in children are scant, and to date only a few studies have evaluated the prevalence of hereditary thrombophilic disorders in children and adolescents with PVT.

Research frontiers

To date, many pediatric patients with PVT have local prothrombotic factors, which are probably the most important factors leading to PVT. However, there is a clear association between the presence of prothrombotic disorders and PVT, suggesting that these increase the risk of thrombosis in patients with local factors such as perinatal umbilical vein catheterization (UVC) or sepsis. Patients with PVT should be screened for inherited prothrombotic disorders regardless of a history of an obvious local risk factor. Future studies should evaluate the role of prophylactic low molecular weight heparins in children requiring UVC.

Innovations and breakthroughs

This series is the larger ever published so far. In this study the authors show that most patients with pediatric PVT have a history of a local prothrombotic factor, a figure much higher than that reported for adult portal vein thrombosis (around 30%). The authors suggest extending the thrombophilic screening of three different genetic mutations to better analyze this population.

Applications

Patients with PVT should be screened for inherited prothrombotic disorders regardless of a history of an obvious local risk factor.

Peer review

This is a well written and important contribution to the pediatric literature. The paper describes the wider case series of patients with these conditions and few published series are present at the moment, the data could be of interest for the readers.

Abstract

AIM: To study tissue factor (TF) in acute pancreatitis and evaluate the role of TF as a predictive marker of severity.

METHODS: Forty-nine consecutive patients admitted to Lund University Hospital, fulfilling the criteria of predicted severe acute pancreatitis (AP), were recruited prospectively between 2002 and 2004. Blood samples for TF analyses were drawn at inclusion in the study and 12 h, 1 d and 3 d later.

RESULTS: Twenty-seven patients developed mild AP, and 22 patients severe AP. At inclusion in the study, the groups were comparable with respect to gender, aetiology, Acute Physiology and Chronic Health Evaluation Ⅱ score, and duration of pain. At inclusion in the study and at 12 h, TF was higher in the severe AP group (P = 0.035 and P = 0.049, respectively). After 1 and 3 d, no differences in TF levels were noted. Interleukin (IL)-6 was significantly higher in the severe AP group at all of the studied time points. C-reactive protein (CRP) was significantly higher in the AP group at 1 and 3 d. In receiver operating characteristic-curves, the area under the curve (AUC) for TF was 0.679 (P = 0.035) at inclusion in the study, and a cut off level for TF of 40 pg/mL showed a sensitivity of 71% and a specificity of 67%, whereas corresponding AUC for IL-6 was 0.775, P = 0.001, and for CRP was 0.653. IL-6 showed better AUC-values than TF at all time points studied.

CONCLUSION: TF-levels are raised early in severe AP. TF as an early predictive marker of severe AP is superior to CRP, but inferior to IL-6.

INTRODUCTION

Severe acute pancreatitis (AP) is one example of critical illness where both the inflammatory system and the coagulation system are to be considered as ticking bombs, where the most extreme scenarios result in multiple organ dysfunction and disseminated intravascular coagulation. Microcirculatory disturbances with micro vascular thromboses appear to play an important role both in the inflamed pancreas itself and in remote organ failure[1,2]. Clinical evidence is still sparse[3-5], but several experimental studies have suggested an important role of the coagulation system in the pathophysiology of AP[6-8]. One key to the cross-talk

between inflammation and coagulation are proteases, with enzymatic capacity to activate both inflammation and coagulation. Coagulation factors, such as factor Ⅶ (FⅦ) and tissue factor (TF), as well as thrombin, can bind to protease activated receptors (PARs) on various cells and elicit intracellular signalling, resulting in modulation of inflammatory response[9]. The PAR family has at least four members (PAR 1-4) where TF-FⅦ has been shown to be able to act through PAR-2, while TF-FⅦ-FX also activates PAR-1. PAR-2 is the only PAR not activated by thrombin[10].

Tissue factor is a trans-membrane glycoprotein, initiating the most important pathway of coagulation[11,12]. Tissue factor is expressed in the vascular adventitia, but may also be expressed in micro-particles which can be shed from leukocytes, endothelial cells, vascular smooth muscle cells and platelets[13]. In the normal setting TF is not in contact with circulating blood. When vessels are injured or when TF-expressing cells are stimulated by circulating pro-inflammatory cytokines or lipopolysaccharide (LPS), TF is exposed to the bloodstream. TF then binds and activates factor Ⅶ. Factor Ⅶ is a vitamin K-dependent trypsin-like serine protease, produced in the liver. It circulates in an inactive form, and requires the action of its allosteric regulator, TF, to convert it to the active enzyme (FⅦa). The TF-factor Ⅶ complex initiates coagulation by activating FX, eventually resulting in conversion of pro-thrombin to thrombin. Thrombin cleaves fibrinogen, resulting in abundant fibrin production and the formation of a clot. The activity of TF is counterbalanced by circulating tissue factor pathway inhibitor (TFPI). In addition to its well-established role in coagulation, TF, and to a lesser extent FⅦ, have also been associated with various other physiological processes of gene transcription, apoptosis and cytoskeleton reformation, such as in inflammation, sepsis, metastasis, angiogenesis and atherosclerosis, where the TF-FⅦa complex acts as a signalling receptor[14-17]. The role of TF/FⅦa signalling in inflammatory conditions is confirmed by TF/FⅦa regulated expression of the pro-inflammatory cytokine interleukin (IL)-8 in keratinocytes[18], and a role in the regulation of both IL-6 and IL-8 expression in monocytes/macrophages[19]. Confirming the effect of FⅦa on expression of interleukins, recombinant FⅦa administered to healthy humans caused a three- to four-fold increase in plasma levels of IL-6 and IL-8[20]. A role of TF/FⅦa signalling in the regulation of inflammatory genes has been demonstrated in LPS-stimulated macrophages, where TF-FⅦa signalling activated genes coding for tumor necrosis factor-α, IL-6, and IL-8[21].

Recent clinical studies have suggested a potential role of coagulation variables, such as TF, TFPI and D-dimer, in predicting risk of developing organ failure and severe AP[22-24]. However, the evidence supporting their use as predictors of severity of AP is still weak, compared to C-reactive protein (CRP) and IL-6, which to date are the most well-documented laboratory parameters to predict severe AP[25-28].

The present study aimed to investigate plasma levels of TF in the initial phase of predicted severe AP, and to assess the ability of this biochemical marker to predict severe AP.

MATERIALS AND METHODS

Consecutive patients admitted to Lund University Hospital with the clinical diagnosis of acute pancreatitis, were recruited prospectively between June 2002 and December 2004. Inclusion and exclusion criteria are listed in Table 1.

Written informed consent was obtained and the study was approved by the local research ethics committee. This study was part of a prospective single-centre study on early enteral nutrition *vs* total parenteral nutrition in AP, where parts of the data on IL-6 and CRP have been published[29]. Venous blood was taken for measurement of plasma levels of TF, FⅦ, fibrinogen, IL-6 and CRP. Not all markers were measured at all time points in the study. TF and IL-6 were measured at inclusion, after 12 h, and after 1 and 3 d. CRP was measured at inclusion, and after 1 and 3 d. Fibrinogen and FⅦ were only measured at inclusion in the study.

Descriptive data were recorded including age, gender, aetiology, time from onset of pain to inclusion in the study, Acute Physiology and Chronic Health Evaluation (APACHE) Ⅱ score on day 1 and 3, organ failure, and mortality. The severity of pancreatitis was assessed according to the Atlanta classification[30].

Blood samples and assays

Peripheral blood samples were taken from each patient on study inclusion, at 12 h, and after 1 and 3 d. Admission plasma levels of FⅦ were analysed, and to detect the prevalence of fibrinolysis and fibrinogen consumption at admission, plasma fibrinogen was analysed. Fibrinogen is an acute phase protein, affected by pathologic proteolysis such as in disseminated intravascular coagulation, where low levels of fibrinogen are to be expected. TF, IL-6 and CRP were analysed at repeated time points during three days after inclusion in the study.

Tissue factor and fibrinogen were collected using citrate tubes, and ethylenediaminetetraacetic acid tubes were used for IL-6 and CRP. All samples were centrifuged at 2200 *g* for 10 min (3200 r/min, rotor diameter 19.1 cm). The plasma was decanted and stored at -70℃ until further analysis.

TF and FⅦ were assessed by enzyme-linked immunosorbent assay (ELISA)-kits according to the manufacturer's instructions (Assaypro St. Charles, MO, USA). The TF-ELISA recognizes TF-apo, TF and TF-Ⅶ complexes. The FⅦ-ELISA detects free FⅦ and FⅦa, as well as complexes with TF, TF/factor Ⅶ and TF/FⅦa.

Fibrinogen was analysed by Sysmex CA-7000 (Sysmex Corporation, Kobe, Japan) according to the operator's manual. The procedure involves mixing citrate plasma with buffer. After incubation, coagulation was initiated by adding an excess of thrombin. The time between addition of thrombin and coagulation was registered photo-optically and is inversely proportional to the concentration of fibrinogen.

IL-6 was measured by an ELISA-kit according to the manufacturer's instructions (Quantikine, R6D systems Europe, Abingdon, UK). CRP was measured by Cobas

Table 1 Inclusion and exclusion criteria

Inclusion criteria	Exclusion criteria
> 18 yr	Acute pancreatitis due to surgery
Abdominal pain	Trauma
Amylase > 3 times upper normal limit	Cancer
Onset of abdominal pain within 48 h	Inflammatory bowel disease
APACHE Ⅱ score > 8 and/or	Stoma
CRP > 150 and/or	Short bowel
Peripancreatic fluid collection on CT	Chronic pancreatitis

APACHE: Acute Physiology and Chronic Health Evaluation; CRP: C-reactive protein; CT: Computed tomography.

6000 (Roche Corporation, Basel, Switzerland) according to the operator's manual. The complex binding between CRP and CRP monoclonal antibodies attached to latex particles was registered as an increase in absorbance, measured photo-optically, and the increase in absorbance was related to the concentration of CRP.

Statistical methods

Data are presented as median and interquartile range, when applicable. Outliers are not shown in the box-plots, but are included in all calculations. Comparisons between groups were performed with the χ^2 test for binary data or Fisher's exact test for small samples. Continuous variables were compared with the Mann-Whitney *U*-test. To evaluate TF as a predictor of severe AP, receiver operating characteristics (ROC) curves were plotted and positive likelihood ratios (PLR) and negative likelihood ratios (NLR) were calculated to detect optimal cut-off levels. As a comparison, figures calculated from levels of CRP and IL-6 were used, as they are known to be good predictors of severity, IL-6 already at admission[27] while CRP peaks about 48 h later.

In a ROC curve, the true positive rate (sensitivity) is plotted in function of the false positive rate (100 - specificity) for different cut-off points. Each point on the ROC plot represents a sensitivity/specificity pair corresponding to a particular decision threshold. A test with perfect discrimination (no overlap in the two distributions) has a ROC plot that passes through the upper left corner (100% sensitivity, 100% specificity). The closer the ROC plot is to the upper left corner, and the greater the area under the curve, the higher the overall accuracy of the test is[31]. The Likelihood Ratio (LR) is the likelihood that a given test result would be expected in a patient with the target disorder, compared to the likelihood that the same result would be expected in a patient without the target disorder.

Statistical analyses were performed with SPSS version PASW Statistics 18 (SPSS Inc, Chicago, IL, USA).

RESULTS

Patient characteristics

According to the Atlanta classification, 22 patients (45%) fulfilled the criteria of severe AP, and 27 patients (55%) were classified as having mild AP. One patient in the severe AP group died, rendering an overall mortality rate of 2.0%. At inclusion in the study, the groups with mild and severe pancreatitis were comparable with respect to gender, aetiology, APACHE Ⅱ score, and duration of pain prior to inclusion. Age was lower in the severe AP group, compared to the mild AP group. Patient characteristics and laboratory variables at time of inclusion are presented in Table 2.

Table 2 Patient characteristics and laboratory variables at time of inclusion

	MAP (n = 27)	SAP (n = 22)	P
Age (yr)[1]	76 (63-85)	63 (56-77)	0.042
Sex (M:F)	14:13	10:12	0.664
APACHE Ⅱ[1]	9 (8-11)	9 (7-13)	0.860
Aetiology			
Biliary	15	16	0.248
Alcohol	4	3	1.000
ERCP	3	1	0.617
Unknown	5	2	0.436
Duration of pain (h)[1]	34 (21-43)	25 (22-29)	0.160
Amylase[1]	8.2 (2.7-13.7)	9.8 (4.3-15.3)	0.690
IL-6 (pg/mL)[1]	100 (55-210)	275 (158-315)	0.001
CRP (mg/mL)[1]	106 (69-167)	173 (104-209)	0.071
Tissue factor (pg/mL)[1]	35 (23-50)	49 (36-101)	0.035
Fibrinogen (g/L)[1]	4.8 (4.4-6.2)	4.0 (3.8-7.2)	0.047
FⅦ (ng/mL)[1]	155 (46-294)	136 (88-296)	0.608

[1]Values are expressed as median and inter-quartile range. MAP: Mild acute pancreatitis; SAP: Severe acute pancreatitis; APACHE: Acute Physiology and Chronic Health Evaluation; ERCP: Endoscopic retrograde cholangiopancreatography; IL-6: Interleukin-6; CRP: C-reactive protein; FⅦ: Factor Ⅶ.

Markers

Because some blood samples were not taken properly, there are different numbers of patients at the different time points. At inclusion in the study, TF was higher in the severe AP group, whereas fibrinogen was lower in the severe AP group compared to the group with mild AP [Figure 1, tissue factor (pg/mL)].

There was no difference in FⅦ-levels between the groups (P = 0.608). A large variation in inter-individual levels of FⅦ was noted [Figure 2, scattergram of FⅦ plasma levels at admission (ng/mL)]. IL-6 was higher in the severe AP group (P = 0.001), and CRP showed a tendency towards higher levels in the severe AP group (P = 0.071) at time of inclusion in the study (Table 2).

When looking at changes over time, TF was slightly higher in the severe AP group at 12 h (P = 0.049). After 1 and 3 d no differences in TF levels were noted between the mild and the severe AP group [Figure 1, tissue factor (pg/mL)].

IL-6 peaked at 12 h and was significantly higher in the severe AP group at all of the studied time points (at inclusion P = 0.001, 12 h P < 0.001, 1 d P < 0.001 and 3 d P = 0.000, respectively). CRP peaked at day 3, and was significantly higher in the AP group at 1 and 3 d (P = 0.001 and P < 0.001, respectively).

Prediction of severity

To evaluate the utility of TF as an early predictor of se-

Table 3 Area under the curve-values, possible cut-off levels, sensitivity, specificity, positive and negative likelihood ratio for tissue factor

Time point[1]	AUC	*P*	Cut-off TF (pg/mL)	Sensitivity	Specificity	PLR	NLR
0	0.679	0.035	32	86	48	1.65	0.30
			40	71	67	2.14	0.43
			46	62	74	2.39	0.51
0.5	0.681	0.049	33	90	43	1.57	0.26
			41	78	56	1.79	0.39
			47	72	70	2.37	0.40
1	0.652	0.078					
3	0.621	0.151					

[1]Time points: 0 = inclusion in study, 0.5 = 12 h, 1 = 24 h, 3 = 3 d. AUC: Area under the curve; TF: Tissue factor; PLR: Positive likelihood ratios; NLR: Negative likelihood ratios.

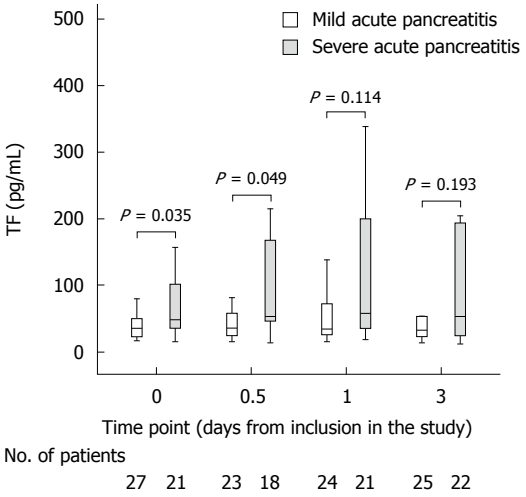

Figure 1 Tissue factor. Time points: 0 = inclusion in study, 0.5 = 12 h, 1 = 24 h, 3 = 3 d. TF: Tissue factor.

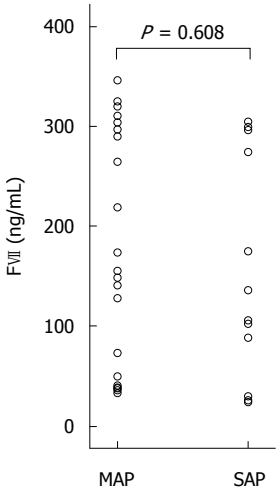

Figure 2 Scattergram of factor Ⅶ plasma levels at inclusion (ng/mL). FⅦ: Factor Ⅶ; MAP: Mild acute pancreatitis; SAP: Severe acute pancreatitis.

vere AP, ROC-curves were plotted for the time of inclusion (Figure 3A, ROC curves of TF, IL-6 and CRP at time of inclusion in the study), and for 12 h (Figure 3B, ROC curve of TF and IL-6 at 12 h after inclusion in the study), 1 d (results not shown) and 3 d after inclusion in the study (Figure 3C, ROC curves of TF, CRP and IL-6 at 3 d after inclusion). As a comparison, ROC-curves were plotted for CRP and IL-6. Area under the curve (AUC) values at the different time points were studied. Based on these results, possible cut-off levels for TF are suggested at inclusion and after 12 h, based on sensitivity, specificity, PLR and NLR. Table 3 shows AUC-values, P-values, possible cut-off levels, sensitivity, specificity, PLR and NLR for TF (pg/mL).

DISCUSSION

Several previous studies on coagulation factors in AP have been published. In a study on 36 patients with AP, elevated levels of TF were detected at admission. In that study only 5 patients were classified as having moderate AP, while 31 had severe AP according to the Japanese Severity Score[22]. A correlation between higher levels of TF and development of organ failure was demonstrated, but in contrast to the results from the present study no correlation with overall severity was detected. In the present study, TF was higher in severe AP compared to mild AP at inclusion in the study, i.e. close to admission, and after 12 h.

The levels of fibrinogen in both mild and severe AP were in the higher span or above the reference for normal human plasma levels, consistent with fibrinogen being an acute phase protein. A slightly lower level of fibrinogen was noted in the group with severe AP at inclusion in the study. The results are, however, hard to interpret as fibrinogen is an acute phase protein and the level of fibrinogen in the severe AP group was just above normal level. It should be stressed that the result for fibrinogen was of weak significance, and further studies of other parameters of fibrinolysis, such as D-dimer and fibrin degradation products should be conducted in order to tell whether early fibrinolysis is the explanation for the lower levels of fibrinogen in the severe AP group.

In a study on 91 patients with AP, D-dimer, prothrombin time and fibrinogen were different when comparing patients developing organ failure and patients not developing organ failure, both at admission and 24 h later. D-dimer was the best predictive marker of organ failure (sensitivity 90%, specificity 89%)[23]. In a study on 139 patients with AP, the levels of antithrombin Ⅲ (AT-Ⅲ),

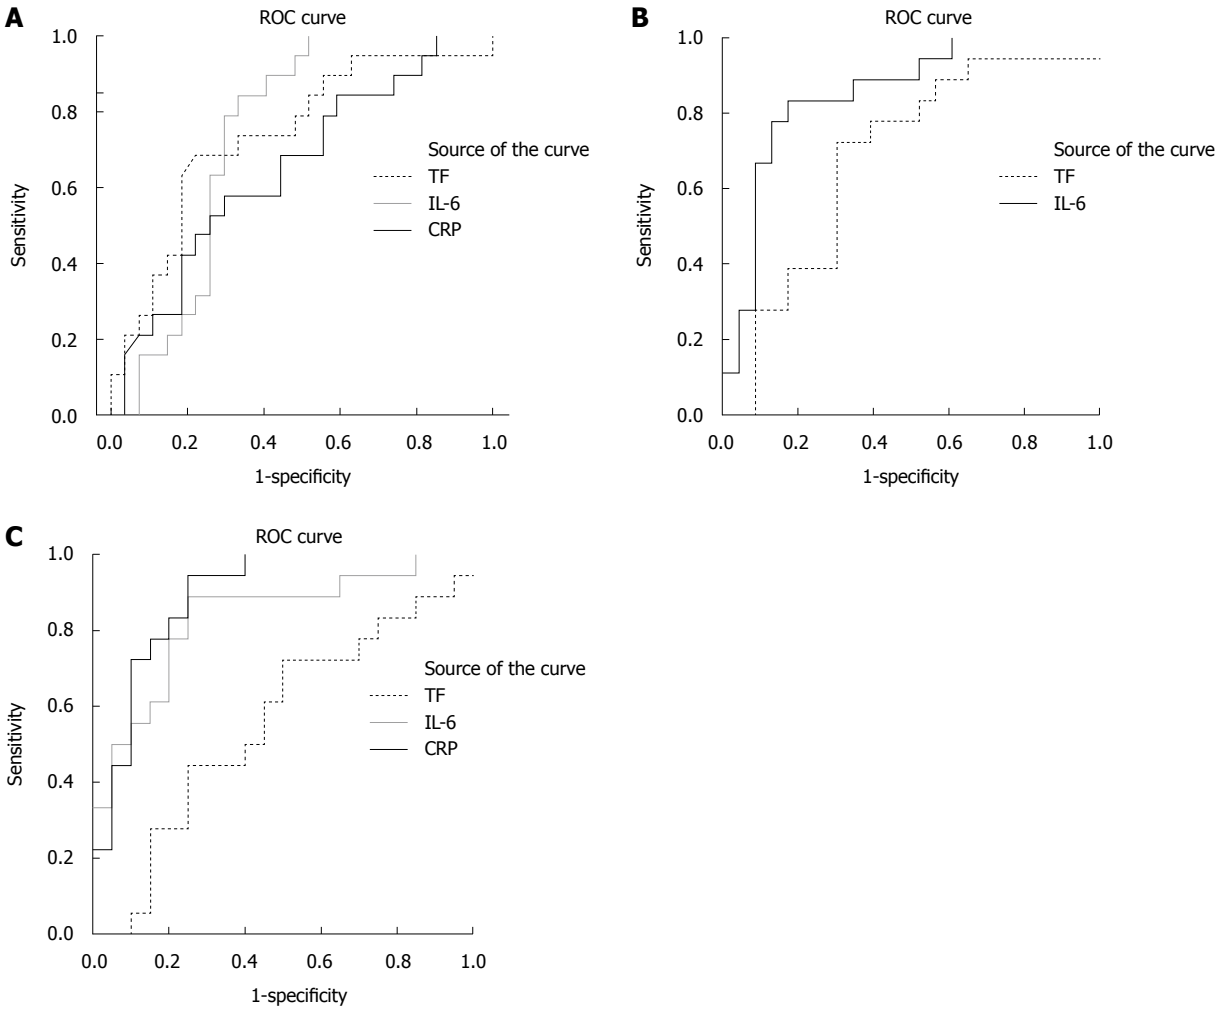

Figure 3 Receiver operating characteristic curves. A: Receiver operating characteristic (ROC) curves of tissue factor (TF), interleukin-6 (IL-6) and C-reactive protein (CRP) at time of inclusion in the study; B: ROC curves of TF and IL-6 at 12 h after inclusion in the study; C: ROC curves of TF, IL-6 and CRP at 3 d after inclusion.

fibrin/fibrinogen degradation products, platelet count, D-dimer, and antithrombin-AT-Ⅲ complex at admission were associated with severity and prognosis of AP. AT-Ⅲ, fibrin/fibrinogen degradation products, platelet count, D-dimer, and thrombin-AT-Ⅲ complex at admission showed better area under the ROC curve values compared to CRP. AT-Ⅲ was the best predictor of fatal outcome (sensitivity 81%, specificity 86%)[32].

In experimental studies, deficiency of FⅦ has been shown to reduce inflammation[33,34] and high levels of FⅦ have been suggested to be associated with ischemic heart disease and inflammation[35,36]. In the present study, concentrations of FⅦ did not differ between the mild AP group and the severe AP group, and hence levels of FⅦ do not seem to be affected in the early course of the disease. The large variation in levels of FⅦ is consistent with reported findings on a strong contribution of the FⅦ genotype to levels of FⅦ. Different FⅦ genotypes can result in up to several-fold differences in mean FⅦ levels[37].

Early recognition of patients at risk of developing severe AP with multiple organ failure and high risk of mortality remains a challenge, despite the use of multifactor scoring systems such as APACHE-Ⅱ and Ranson's score[38]. Obesity, age, alcohol consumption and use of tobacco are known to predispose to a severe disease course[39,40]. The most widely used laboratory parameter to predict severity of AP and development of complications is CRP. A meta-analysis on the ability of IL-6 to predict severe AP concludes that these cytokines perform at an acceptable level in predicting severe AP[26]. The pooled IL-6 sensitivities ranged between 81.0% and 83.6% and specificities between 75.6% and 85.3% with PLRs of 3.43, 4.90 and 4.40 for days 1, 2 and 3, respectively. The IL-6 AUCs were 0.75, 0.88 and 0.85 for days 1, 2 and 3, which are in accordance with the AUCs for IL-6 in the present study.

Data concerning the role of coagulation variables as predictors of severe AP are scarce. In a study of 44 patients with AP, TFPI measured at admission was shown to be related to severity[24]. Among the three variables in the present study, fibrinogen, FⅦ and TF, TF was significantly raised at admission, when comparing the severe and the mild AP group. With this result in mind, TF was explored as a marker of severity at four different time points, by area under ROC-curves. At admission and after 12 h, the AUC for TF was 0.68, and when evaluating different cut-off points the best PLR was 2.4, with a sensitivity of 62%

and a specificity of 72%, which implies a quite low impact on the likelihood of severe disease, much less impact than IL-6 at corresponding time points.

We conclude that levels of TF, but not FVII, are higher in "true severe" AP than in those patients with predicted severe AP who turn out to develop mild AP. Our results stress the need of more reliable predictors of severity, as only 45% of the patients in our study with predicted severe disease actually developed severe AP. The value of TF as a predictive marker of severe AP early in the course of the disease is not as good as IL-6, but superior to CRP. The results do not indicate a role for TF as a valuable predictive marker of severity on its own. The higher levels of TF in the early course of severe AP suggest, however, a potential role of TF in the development of severe disease, and may reflect a window for therapeutic inhibition of TF in AP.

COMMENTS

Background

Acute pancreatitis affects about 20-40/100 000 inhabitants each year. One fifth of these patients will develop a severe form of AP with multiple organ failure and a high risk of death. There is no reliable marker to early predict which patients will develop the severe form. In severe disease, such as AP, a close interplay between coagulation and inflammation is known to exist, and take part in the development of the disease. In this paper, tissue factor, which is a key player in the crosstalk between inflammation and coagulation, is measured in the plasma of patients with predicted severe pancreatitis.

Research frontiers

Data concerning the role of coagulation variables as predictors of severe acute pancreatitis (AP) are still sparse. The results from one study on patients with AP, showed that levels of tissue factor (TF) were related to the development of pancreatic necrosis in alcoholic severe AP, but no association with overall severity was demonstrated (Sawa *et al* 2006). In another study of AP, the coagulation parameters D-dimer, pro-thrombin time and fibrinogen were different in the group of AP patients developing organ failure compared to the patients who did not develop organ failure, both at admission and 24 h later. D-dimer was the best predictive marker of organ failure (Radenkovic *et al* 2009). In yet another study on AP, the levels of the coagulation parameters antithrombin Ⅲ (AT-Ⅲ), fibrin/fibrinogen degradation products, platelet count, D-dimer, and thrombin-AT-Ⅲ complex at admission were associated with severity and prognosis of AP. AT-Ⅲ was the best predictor of fatal outcome (Maeda *et al* 2006).

Innovations and breakthroughs

The authors show that levels of TF measured early in the course of the disease are higher in patients who develop severe AP. These results are consistent with the possible role of coagulation variables in the development of AP.

Applications

The role of TF as an early predictor of severe AP is inferior to interleukin-6, which has been shown to be of value in various previous studies, however, TF is superior to the most frequently used laboratory parameter, C-reactive protein. The results indicate a role for TF in the development of severe AP, and the effect of tissue factor pathway-inhibitors in AP should be studied.

Terminology

Acute pancreatitis is an acute inflammation of the pancreatic gland, most often elicited by alcohol ingestion or gall stone disease. Tissue factor is located in the membrane of various cells surrounding the blood vessels throughout the body, and is exposed to circulating blood when vessels are ruptured or may be expressed by white blood cells or cells on the inside of blood vessels in inflammatory conditions, such as acute pancreatitis. When tissue factor binds to factor Ⅶ, circulating in the blood, the coagulation cascade is initiated, but tissue factor - factor Ⅶ may also modulate the inflammatory response.

Peer review

This clinically relevant study of the predictors of pancreatitis severity looks fine.

Abstract

AIM: To determine the effect of free serotonin concentrations in plasma on development of esophageal and gastric fundal varices.

METHODS: This prospective study included 33 patients with liver cirrhosis and 24 healthy controls. Ultrasonography and measurement of serotonin concentration in plasma were carried out in both groups of subjects. The upper fiber panendoscopy was performed only in patients with liver cirrhosis.

RESULTS: The mean plasma free serotonin levels were much higher in liver cirrhosis patients than in healthy controls (219.0 ± 24.2 nmol/L *vs* 65.4 ± 18.7 nmol/L, $P < 0.0001$). There was no significant correlation between serotonin concentration in plasma and the size of the esophageal varices according to Spearman coefficient of correlation ($r_s = -0.217$, $P > 0.05$). However, the correlation of plasma serotonin concentration and gastric fundal varices was highly significant ($r_s = -0.601$, $P < 0.01$).

CONCLUSION: Free serotonin is significant in pathogenesis of portal hypertension especially in development of fundal varices, indicating the clinical value of serotonergic receptor blockers in these patients.

Key words: Serotonin; Portal hypertension; Esophageal varices; Fundal varices; Platelets

Role of serotonin in development of esophageal and gastric fundal varices. *World J Gastroenterol* 2010; 16(48): 6135-6138 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i48/6135.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i48.6135

INTRODUCTION

Portal hypertension has been increasingly regarded as a multi-organ disease with complex blood flow changes in the systemic and splanchnic vascular network.

The hepatic stellate cell (HSC) has a significant position in the sinusoid for regulation of portal flow. During liver damage, HSCs are "activated" which leads to HSC transformation into myofibroblast-like cells with a resulting increased collagen production[1,2]. Several mitogens are included in the triggering of HSC proliferation: platelet-derived growth factor (PDGF), insulin-like growth factor 1 and connective-tissue growth factor. During activation,

HSCs acquire the ability to express PDGF receptors on the cell membrane surface[3]. The HSC membrane contains numerous receptors whose expression is increased with the extent of liver damage, to which different vasoconstrictors are bound: catecholamines, endothelin, angiotensin I and Ⅱ, leukotrienes and serotonin [5-hydroxytriptamin (5-HT)][4,5].

Serotonin, at the level of hepatic sinusoids, causes endothelial fenestrae contractions of liver sinusoids through 5-HT_1 receptors mediated by a Ca^{2+}-dependent process. Due to different proinflammatory mediators releasing from the damaged liver, it comes to platelet adherence to sinusoidal endothelium, translocation into Disse's space and serotonin release. Thereafter, serotonin binds to receptors (5-HT_{2A}, 5-HT_{1B}, 5-HT_{1F} and 5-HT_7) which are expressed on HSC and hepatocytes, which additionally interferes with HSC proliferation[6,7].

The aim of our study was to determine to what extent a free serotonin concentration in plasma has an effect on development of esophageal and gastric fundal varices.

MATERIALS AND METHODS

The study included 33 patients with liver cirrhosis who were examined and treated at the Clinic of Gastroenterology, Clinical Center of Serbia, and 24 healthy subjects who made up the control group. The study was prospective and conducted during the period 2008-2009.

Ultrasonography was carried out by Toshiba Core Vision, with 3.5 MHz duplex Doppler convex tube in a standard procedure. Ultrasonography examined the liver size, echo structure of the hepatic parenchyma and possible focal changes with a view to rule out the patients with primary and secondary liver tumors from the study. To determine the spleen size, standard parameters were used, according to which in physiological conditions the spleen diameter measured in the X intercostal space exceeded no more than 12.0 cm and anteroposterior diameter was not over 5.0 cm.

The upper endoscopy was performed by endo-video system Olympus GIF-Q 165. To measure the esophageal varices size, Paquet's classification was used: I degree-lesser snake-like mucosal protrusions, Ⅱ degree-varices were predominating up to a half of the esophageal lumen radius, Ⅲ degree-varices were in contact at some points, and Ⅳ degree-heralds of the imminent rupture (cherry red spots)[8]. Endoscopic examination showed portal hypertensive gastropathy (snake skin mucosa) and varices of the gastric fundus.

Platelet poor plasma (PPP) was obtained from the venous blood which was collected in 3 mL original Vacutainer "BD" tubes, with 75 g/L K_3EDTA 0.072 mL. Blood samples were taken between 8 and 9 a.m. Platelet rich plasma (PRP) was obtained by low speed centrifugation (200 *g*, 10 min) on "Heraeus Digifuga GL". Exactly 1 mL of PRP was centrifuged at 1000 *g*, 10 min. The obtained PPP was separated and stored at -20℃ for no longer than 20 d[9].

The number of PPP serotonin samples was estimated in one series. One hundred μL plasma samples were spiked with 10 μL of original N-methyl serotonin solution (Recipe, Munchen), which was an internal standard. After that, PPP samples were deproteinized with 100 μL original deproteinating reagent (Recipe, München), and centrifuged at 10 000 *g*[10]. The obtained 20 μL supernatants were analyzed on reverse phase HPLC column (Recipe, München), with original mobile phase for serotonin (Recipe, München). Original "Recipe" external standard solution was used for calibration. The HPLC system consisted of "Bio-Rad AS 100" HRLC automatic sampling system with "Rheodine 7125 valve", "Bio-Rad 1350" HPLC pump and "Bio-Rad 1640" electrochemical detection. Chromatographic data were calculated using the "Chrome Line V 4.20" HPLC software. Amperometric detection was done at 0.6 V. The duration of chromatographic separation was 10 min.

Statistical analysis was performed using the Statistical Package for Social Sciences (SPSS®, version 17.0). Basic descriptive statistics included means, standard deviations, ranges and percentages. Differences between groups were compared with parametric *t*-test because data had a Gaussian distribution. Correlation analysis was processed *via* the Spearman method. Values at the $P \leqslant 0.05$ level were considered statistically significant.

RESULTS

The study included 11 (33.3%) female and 22 (66.7%) male patients, mean age of 52.32 (SD ± 11.55) years. The most common cause of liver cirrhosis was alcohol-in 15 (45.4%) cases. The incidence of posthepatitic cirrhosis was lower; HCV-8 (24.2%), HBV-5 (15.1%), while autoimmune diseases were quite rare-in 5 (15.1%) patients.

Splenomegaly was detected in 28 (84.8%) patients with liver cirrhosis. An average longitudinal splenic diameter was 17.5 ± 3.57 cm, and transversal diameter was 6.8 ± 1.77 cm, which was significantly different in relation to the controls, in whom an average longitudinal diameter was 10.21 ± 1.65 cm and transversal diameter was 3.03 ± 0.87 cm (*t*-test, $P < 0.05$).

There was a highly significant difference between the platelet count in the studied groups of patients ($t = -9.779$, $P < 0.01$).

The mean plasma free serotonin level was much higher in liver cirrhosis patients than in healthy controls (219.0 ± 24.2 nmol/L *vs* 65.4 ± 18.7 nmol/L; *t*-test, $P < 0.0001$).

There was no significant correlation between serotonin concentration in plasma and the platelet count according to Spearman coefficient of correlation ($r_s = 0.158$, $P > 0.05$).

Esophageal varices were not detected in 5 (15.1%) patients, grade Ⅰ-Ⅱ varices were detected in 9 (27.2%), grade Ⅱ-Ⅲ in 15 (45.4%) and the remaining 4 patients (12.1%) were grade Ⅳ. Gastric fundal varices were found in 7 (21.2%) patients, out of whom 2 had Ⅰ-Ⅱ, 4 had grade Ⅱ-Ⅲ esophageal varices, and one patient had Ⅳ degree varices.

Spearman's rank correlation verified a statistically significant correlation between the platelet count and varices size ($r_s = -0.479$, $P < 0.05$).

Spearman's rank correlation verified no significant difference between the serotonin concentration in plasma in relation to the size of esophageal varices (r_s = -0.217, P > 0.05). However, the mean plasma free serotonin level was higher in patients with esophageal varices than in patients without varices (t = -2.301, P < 0.05). Furthermore, the correlation of plasma serotonin concentration and fundal varices was highly significant (r_s = -0.601, P < 0.01). Also, we proved that the mean plasma free serotonin level was much higher in patients who had esophageal and gastric fundal varices than in patients who had only esophageal varices (t = -5.862, P < 0.01).

DISCUSSION

Different factors may affect the concentrations of circulating serotonin in liver cirrhosis, such as: impaired serotonin catabolism due to higher activity of the monoamino oxidases; impaired metabolism of tryptophane as a serotonin precursor; platelet sequestration in the spleen and/or platelet activation[11]. In addition, 5-HT as well as other vasoactive substances synthesized in the gastrointestinal tract *via* porto-systemic collaterals bypass the liver and directly enter the systemic circulation[12].

In the study of Beaudry *et al*[13], in 1994, the whole-blood serotonin levels were significantly lower in 30 patients with cirrhosis than in the age-matched controls, and no correlation was found between these levels and the severity of cirrhosis. However, in the same study the unconjugated plasma serotonin levels, an indication of the active form of serotonin, were significantly higher in patents with cirrhosis than in the controls.

In our previous study, free or unconjugated serotonin levels were investigated. The levels of free serotonin were higher in patients with liver cirrhosis than in healthy subjects[14].

In the study of Vorobioff *et al*[15], in 1989, it was confirmed that the application of ketanserin and ritanserin (serotonergic receptor inhibitors) caused the lowering of portal hypertension in patients with liver cirrhosis. The authors reported that the spleen congestion in liver cirrhosis brought about the platelet breakdown. Free serotonin, released in the sinusoidal spaces of the spleen, induced by S-2 receptor produced an intense vasoconstricting response in portal circulation which led to maintenance and elevation of the portal pressure. Moreover, it was documented that the reaction of the isolated mesenteric vein in rats with portal hypertension to 5-HT was hypersensitive, which was additional evidence of the role of this substance in pathogenesis of portal hypertension.

In our study, the correlation of unconjugated serotonin concentration (active form of serotonin) in plasma and varices of the gastric fundus was highly significant while the plasma unconjugated serotonin concentration did not correlate with the size of the esophageal varices. Moreover, mean longitudinal and transversal diameters of the spleen in patients was significantly higher as compared to controls.

The spleen has a crucial role in pathogenesis and maintenance of portal hypertension[16,17]. In portal hypertension, the anatomic changes of the spleen (pulp hyperplasia, congestion and fibrosis) and specific vascularization affect the hemodynamics of the splenic circulation[18].

Our finding may be accounted for different porto-systemic collateral pathways in esophageal and fundal varices as well as valuable flow changes in the left part of the portal venous system. Perisic *et al*[19] reported, in 2005, that the splenic vein flow in patients with liver cirrhosis was slower in comparison with healthy controls. In addition, in healthy controls, the splenic vein flow was significantly slower than in the portal vein. However, in patients with liver cirrhosis splenic vein flow was significantly faster than in the portal vein, probably because of the splenic venous congestion and compensatory hemodynamic mechanisms of the spleen.

Gastric varices are drained through the short gastric veins into the splenic vein. Serotonin released by platelet sequestration in the enlarged spleen reaches the lienal vein where the blood flow is faster than in the portal vein, and directly, *via* short gastric veins, it enters the fundal gastric veins, leading to vasoconstriction.

Our conclusion is that free serotonin is significant in pathogenesis of portal hypertension especially in development of gastric fundal varices which may have clinical value in use of serotonin receptor blockers in these patients.

COMMENTS

Background

In acute and chronic hepatic insufficiency, the serotonin system changes lead to development of hepatic encephalopathy, portal hypertension and hyperdynamic circulation. Portal hypertension has been increasingly regarded as a multi-organ disease with complex blood flow changes in systemic and splanchnic vascular network. The hepatic stellate cell (HSC) has a significant position in sinusoid for regulation of portal flow and during liver damage serotonin binds to receptors [5-hydroxytriptamin (5-HT)$_{2A}$, 5-HT$_{1B}$, 5-HT$_{1F}$ and 5-HT$_7$] which are expressed on HSC and hepatocytes, which additionally interferes with HSC proliferation.

Research frontiers

Free serotonin, released in the sinusoidal spaces of the spleen, induced by S-2 receptor, produces an intense vasoconstricting response in the portal circulation, which leads to maintenance and elevation of portal pressure. The highlight of our study was to determine to what extent a free serotonin concentration in plasma has an effect on development of esophageal and gastric fundal varices.

Innovations and breakthroughs

In the study of Vorobioff *et al*, in 1989, it was confirmed that the application of ketanserin and ritanserin (serotonergic receptor inhibitors) caused the lowering of portal hypertension in patients with liver cirrhosis. Moreover, it was documented that the reaction of the isolated mesenteric vein in rats with portal hypertension to 5-HT was hypersensitive, which was additional evidence of the role of this substance in pathogenesis of portal hypertension. In this study, the correlation of unconjugated serotonin concentration (active form of serotonin) in plasma and varices of the gastric fundus was highly significant while the plasma unconjugated serotonin concentration did not correlate with the size of the esophageal varices. The authors' finding may be accounted for by different porto-systemic collateral pathways in the esophageal and fundal varices as well as valuable flow changes in the left part of the portal venous system.

Applications

The conclusion is that free serotonin is significant in pathogenesis of portal hypertension especially in development of gastric fundal varices. This may have clinical value in use of serotonin receptor blockers in these patients.

Terminology

Portal hypertension: Portal hypertension (> 10 mmHg) most commonly results from increased resistance to portal blood flow. Cirrhosis is the most common

cause of portal hypertension. One of the major clinical manifestations of portal hypertension includes life-threatening hemorrhage from gastrointestinal varices. Serotonin: Serotonin is a vasoactive substance, synthesized by the intestinal enterochromaffin cells, which is actively incorporated into platelets and stored in platelet dense-storage granules.

Peer review

The manuscript reports that free serotonin is significant in pathogenesis of portal hypertension especially in development of gastric fundal varices which may have clinical value in use of serotonin receptor blockers in these patients.

Abstract

AIM: To investigate the value of duplex Doppler ultrasonography (US) in the assessment of the hemodynamics of the portal and hepatic veins in a cohort of children with chronic liver disease (CLD) and to detect any relationship between the US changes, etiology and severity (or stage) of CLD.

METHODS: We prospectively enrolled 25 children with biopsy-proven CLD. Thirteen had cirrhosis (aged 8.9 ± 2.0 years) and 12 had chronic hepatitis (aged 9.3 ± 2.3 years). Gray scale and color-coded duplex Doppler US were performed for all, as well as 30 healthy age and sex-matched controls. Findings were correlated with clinical, laboratory and histopathological characteristics.

RESULTS: Prominent caudate lobe was detected in 100% of cirrhotics, but none of the chronic hepatitis or controls. Thickened lesser omentum and loss of the triphasic waveform of the hepatic vein were present in 69.2% and 53.8% of cirrhotics *vs* 33.3% and 8.3% of chronic hepatitis respectively. Portal vein flow velocity was significantly lower ($P < 0.0001$) and the congestion index was significantly higher ($P < 0.005$) in both patient groups compared to controls. Child-Pugh's staging showed a positive correlation with both abnormal hepatic vein waveform and direction of portal blood flow; and a negative correlation with both hepatic and portal vein flow velocities. No correlation with the etiology of CLD could be detected.

CONCLUSION: Duplex Doppler added to grayscale US can detect significant morphologic and portal hemodynamic changes that correlate with the severity (stage) of CLD, but not with etiology.

Key words: Chronic hepatitis; Chronic liver disease; Cirrhosis; Doppler; Grayscale; Pediatrics; Ultrasound

INTRODUCTION

The search for a non-invasive biochemical or imaging marker for the severity (stage) and/or etiology of chronic liver disease (CLD) in adults, as well as children, is in extremely active nowadays. Real time ultrasonography (US) has become an integral part of the non-invasive evaluation of the liver in many clinical settings in adults. Color-coded duplex Doppler information regarding the presence or absence of flow and the direction and velocity of that flow can be obtained non-invasively, rapidly and relatively inexpensively[1]. In spite of being evaluated since 1983[2]; the accuracy, sensitivity and specificity of duplex Doppler imaging as a non-invasive diagnostic and prognostic modality for liver cirrhosis, and its correlation to the histopathologic findings as well as the degree of functional impairment of the liver, remains controversial and is still debated by many investigators[3]. Adding duplex Doppler evaluation in numerous studies has clarified the role of this modality in the evaluation of various CLD in adults and children, including liver cirrhosis[4-7]; portal hypertension[8-12]; presence or absence of esophageal varices[13], noninvasive diagnosis of the degree of hepatic fibrosis[14,15], assessment of the portal venous blood flow in cystic fibrosis[16], perioperative monitoring in orthotropic liver transplantation (LTx)[17], prediction of the severity of veno-occlusive disease and assessing its prognosis[18], assessment of the functional hepatic flow and total hepatic flow[19] and investigating the effect of fatty infiltration of the liver on the Doppler waveform pattern in the hepatic veins of obese children[3,20]. Other studies evaluated Doppler US measurement of the blood flow in the hepatic artery, hepatic veins and portal vein as a noninvasive indicator of disease severity in children who had undergone Kasai portoenterostomy for extrahepatic biliary atresia[21] and those who had CLD of unknown etiology[22]. However in the setting of LTx, serial intra- and post-operative Doppler US has largely been accepted as a useful technique for making an early diagnosis of abnormal hemodynamics of the graft circulation. Furthermore, intraoperative Doppler US is used to assess the reconstructed vessels objectively in order to reduce the incidence of vascular complications following LTx[6] and it is gradually replacing the more invasive angiographic techniques[23].

The aim of this study was to investigate the value of abdominal color-coded duplex Doppler US when added to the conventional grayscale scanning in the non-invasive assessment of the splanchnic morphology, as well as hemodynamics of the portal and hepatic veins in a cohort of Egyptian children suffering from CLD. We aimed also to detect any relationship between the US changes, etiology and severity (or stage) of the CLD.

MATERIALS AND METHODS

Materials and methods

We prospectively enrolled 25 children with CLD from the Pediatric Hepatology Unit at Cairo University Children Hospital, Cairo, Egypt. Thirteen patients (group 1) were diagnosed with established cirrhosis (7 girls and 6 boys) with a mean age of 8.9 ± 2.0 years, and 12 (group 2) were diagnosed with chronic hepatitis without cirrhosis (6 girls and 6 boys) with a mean age of 9.3 ± 2.3 years. Thirty healthy child relatives of the patients (13 girls and 17 boys) with a mean age of 8.1 ± 2.2 years were included as a control group. All patients were subjected to: (1) Careful interrogation and thorough physical examination for signs of CLD (jaundice, palmar erythema, bleeding diathesis, hand tremors, hepatomegaly, splenomegaly, ascites and edema); (2) biochemical tests of liver functions; (3) serological markers of viral and autoimmune hepatitis; (4) testing for inborn errors of metabolism when indicated; and (5) percutaneous liver biopsy using the Menghini aspiration technique for histopathological diagnosis, grading and staging of the CLD.

Patients, as well as controls, underwent conventional grayscale US using Toshiba® Sonolayer 2000 apparatus (Toshiba Corporation, Tokyo, Japan) equipped with 3.5 and 5 MHz convex linear transducers. Examination included liver size and echo pattern, portal vein diameter, splenic size and echo pattern, thickness of the lesser omentum in comparison to the aorta as well as detection of ascites. Both patients and controls also underwent color-coded duplex Doppler examination using Toshiba® Sonolayer SSH-60A apparatus (Toshiba Corporation, Tokyo, Japan) with a low frequency (3.5 MHz) transducer, in order to optimize the return of Doppler signals from deeper-lying tissues.

After being fasted overnight for a minimum of 8 h, all children were examined in the supine position. A low pulse repetition frequency was used initially, with manual adjustment when aliasing occurred. Approach for the vein of interest was selected to keep the beam vessel (angle 0) always less than 60°. Doppler recording of the hepatic veins was initially examined using a transverse sub-xiphoid approach, with the probe slightly cephalad. The right intercostal approach was used to obtain a longitudinal view of the middle hepatic vein. Every child was asked to stop breathing for a few seconds, in deep inspiration, during examination to avoid motion artifacts. Measurements were obtained from the hepatic veins at least 2 cm from the confluence with the inferior vena cava, to reduce the possible influence of the changes of flow pattern in the inferior vena cava on hepatic veins hemodynamics. We classified the hepatic vein Doppler waveforms according to Gorka *et al*[24] into: normal triphasic, abnormal biphasic or monophasic, and those with loss of the reverse-flow. Mean flow velocity of the middle hepatic vein was also measured in cm/s in all patients and controls.

The portal vein was examined from an anterior abdominal subcostal and/or right intercostal approach and scanned longitudinally throughout its entire length. Measurements were obtained in the middle segment between the splenoportal junction and the intrahepatic bifurcation (1-2 cm before the bifurcation). It was examined at a standard point for the diameter, patency, presence or absence

Table 1 Patients demographic and clinical data *n* (%)

Diagnosis	Group 1 (cirrhosis)	Group 2 (chronic hepatitis)
Symptoms		
Hematemesis	2 (15.4)	3 (25)
Jaundice	4 (38.5)	3 (25)
Dark urine	5 (38.5)	4 (33.3)
Abdominal distension	8 (61.7)	8 (66.7)
General physical signs		
Pallor	5 (38.5)	3 (25)
Jaundice	5 (38.5)	4 (33.3)
Lower limb edema	6 (46.2)	4 (33.3)
Abdominal signs		
Hepatomegaly	7 (53.8)	9 (75)
Splenomegaly	10 (76.9)	4 (33.3)
Ascites	5 (38.5)	3 (25)

of intraluminal echogenic material, direction of flow within the vein and blood flow velocity in cm/s.

The congestion index (CI) is determined by duplex Doppler US. It is the ratio between the cross-sectional area of the portal vein in cm^2 and the blood flow velocity in that vein in cm/s, and calculated using the following formula: CI = cross sectional area/blood flow velocity[25,26].

The cross sectional area was calculated using the following formula: Cross sectional area = $\pi \times (d^2/4)$; d = diameter of portal vein in cm; and $\pi = 3.14$[27].

Statistical analysis

All data were statistically analyzed using independent samples test, χ^2 test, post-Hock test and Armitage[28]. Probability (*P* value) was considered significant if $P < 0.05$.

RESULTS

Group 1 included 13 children with established cirrhosis (5 of metabolic etiology and 8 viral hepatitis C or B) and group 2 included 12 with chronic hepatitis and no cirrhosis (5 viral hepatitis C or B and 7 autoimmune). Table 1 shows the demographic and clinical data of the 2 groups. Biochemical tests of liver function showed no significant difference between either group (similar letters meant no significant difference, while dissimilar letters meant a significant difference, the *P* value is significant).

A prominent caudate lobe (as an important US sign) was found in 100% of patients with cirrhosis and none of patients with chronic hepatitis or controls. Thickened lesser omentum (i.e. lesser omentum: aortic diameter ratio > 1:1.7 in children[29]) was present in 69.21% of cirrhotic patients in comparison to 33.3% of patients with chronic hepatitis. Loss of the normal triphasic oscillation of the hepatic vein waveform was detected in 53.8% of group 1 in comparison to 8.3% of group 2 and none of the controls. Abnormal direction of portal blood flow was detected in 46.2% of group 1 and 25% of group 2, and none of the controls (Figures 1 and 2).

Hepatic vein flow velocity showed non-significant negative correlation with liver size (r = -0.125) and weak

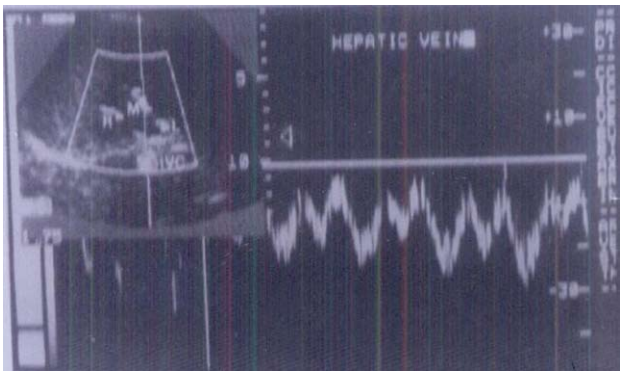

Figure 1 Triphasic waveform pattern of normal hepatic vein.

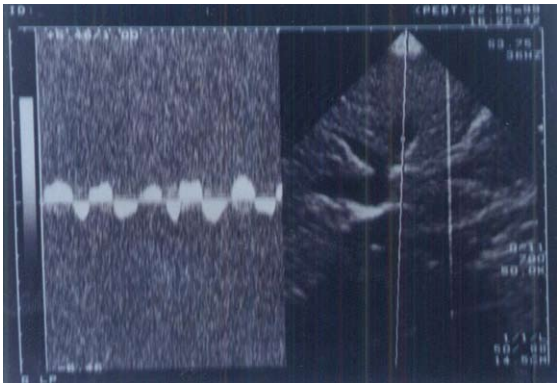

Figure 2 Abnormal waveform pattern of hepatic veins in a cirrhotic liver.

but significant correlation with both splenic size (r = -0.374) and portal vein diameter (r = -0.304) (Table 2).

Portal vein flow velocity had weak significant negative correlation with liver size (r = -0.431) and powerful significant negative correlation with both splenic size (r = -0.699) and portal vein diameter (r = -0.743, Figure 3).

CI had a weak significant negative correlation with liver size (r = -0.431) and powerful significant negative correlation with both splenic size (r = -0.699) and portal vein diameter (r = -0.743).

According to Child-Pugh's[30] classification, 4 (31%) of our cirrhotic patients were Class A; 4 (31%) Class B and 5 (38%) Class C. Those classes showed a powerful significant positive correlation with both abnormal hepatic waveform and abnormal direction of portal blood flow. Also there was a powerful significant negative correlation with both hepatic vein and portal vein flow velocity (r = -0.785 and -0.688, respectively, Figure 4) and weak significant positive correlation with CI (r = -0.595).

Analysis of the US findings according to the etiological categories (metabolic, viral or autoimmune CLD) did not reveal any significant correlations.

DISCUSSION

In the present study we tried to correlate the splanchnic morphological and hemodynamic parameters of the portal and hepatic veins with the severity of hepatic affection, as

Table 2 Grayscale and Doppler ultrasonography measurements in the studied groups (mean ± SD)

	Controls	Group 1	Group 2	*P* value
Liver size in cm	8.55 ± 0.69	10.19 ± 2.33[b]	12.2 ± 2.02[b,d]	< 0.01
Splenic size in cm	8.43 ± 0.92	11.82 ± 1.30[b]	10.10 ± 1.50[b,d]	< 0.01
Portal vein diameter (cm)	0.61 ± 0.13	1.16 ± 0.23[b]	0.95 ± 0.22[b,d]	< 0.01
Hepatic vein flow velocity (cm/s)	23.1 ± 2.09	21.84 ± 1.90	22.41 ± 2.02	> 0.05
Portal vein flow velocity (cm/s)	31.1 ± 3.92	21.23 ± 3.30[b]	22.22 ± 1.23[b]	< 0.01
Congestion index	4.61 ± 5.75[d]	9.50 ± 1.60	4.97 ± 1.14[d]	< 0.01

[b]$P < 0.01$ *vs* controls; [d]$P < 0.01$ *vs* group 1.

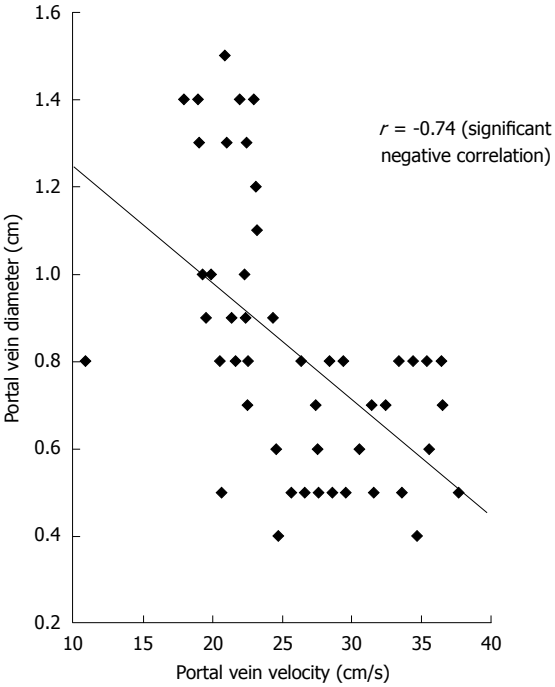

Figure 3 Correlation between portal vein flow velocity and portal vein diameter.

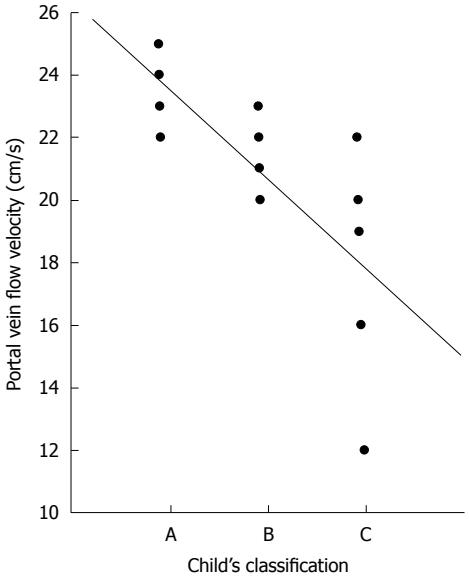

Figure 4 Correlation between Child-Pugh's classification and portal vein velocity.

evaluated by liver histopathology and Child-Pugh's classification of cirrhosis[30]. Prominent caudate lobe was a constant finding in all our patients with cirrhosis and not found in chronic hepatitis. The prominence of the caudate lobe in cirrhosis results from marked hyperplasic changes in the regenerative nodules with no cellular or structural atypia. The density of the regenerative hepatocytes becomes much higher, the quantity of bound water larger and free water smaller, increasing the US signals reflected. The reason why only the caudate lobe shows such huge hyperplasia in cirrhosis remains unclear[31].

Thickened lesser omentum (i.e. lesser omentum: aortic diameter more than 1:1.7[29]) is highly-suggestive of portal hypertension and the presence of esophageal varices in children, and allows the detection of portal hypertension earlier than detection of collaterals by Doppler and even earlier than clinical signs[32]. In our study there was a significant increase of lesser omentum thickness in cirrhotic patients than chronic hepatitis.

Koda *et al*[8], in 1996 described the decrease in portal vein flow velocity with the progress of chronic hepatitis as a sensitive indicator and a useful test with close correlation with the histological degree of liver fibrosis. Schneider *et al*[33], combined portal vein velocity with hepatic artery pulsatility index as a reliable, non-invasive evaluation of patients with liver cirrhosis. On the other hand Dinç *et al*[34], reported that portal vein flow velocity and portal vein flow volume alone are not useful parameters for discriminating cirrhotic patients from healthy subjects. In our study we did not measure the hepatic artery pulsatility index; however values of portal vein flow velocity were significantly lower in patients compared to controls and significantly lower in the group with liver cirrhosis than the chronic hepatitis. A significant correlation was also detected between both splenic size and Child-Pugh's class and the portal flow velocity; the lower the velocity, the larger the splenic size and the worse the Child-Pugh's class. Therefore in children with cirrhosis, portal flow velocity might be correlated with the severity of portal hypertension and the severity of liver parenchymal dysfunction as worsening Child-Pugh's class was associated with lower portal vein flow velocity conforming to reports in adults[35].

In the present study CI was significantly higher in the group with liver cirrhosis than both the chronic hepatitis group and the controls. CI showed no significant differ-

ence between chronic hepatitis group and controls. CI showed a positive correlation with Child-Pugh's class of cirrhotics. CI was reported to be a significant parameter in the evaluation of the risk of bleeding varices and prognosis of patients with liver cirrhosis, while in chronic hepatitis patients it was found to be similar to healthy controls and was not related to the grade of hepatic inflammation[36].

Loss of the normal triphasic oscillation of the hepatic vein waveform was detected in 53.8% of our cirrhotics, in comparison to 8.3% of chronic hepatitis and none of the controls. Bolondi *et al*[37], Ohta *et al*[38] and Arda *et al*[39], reported the loss of triphasic oscillation even in early-stage chronic parenchymal liver disease (Child-Pugh's class A).

In conclusion, grayscale and color-coded duplex Doppler US are very valuable, non-invasive diagnostic modalities in children with CLD. They could detect splanchnic morphological and portal hemodynamic changes that could be correlated to the degree of liver parenchymal affection but not to the etiology of the CLD. Therefore we recommend their wider application in the assessment of children with CLD.

COMMENTS

Background

The search for a non-invasive biochemical or imaging marker for the severity (stage) and/or etiology of chronic liver disease (CLD) in adults as well as children is in extremely active nowadays. Real time ultrasonography (US) has become an integral part of the non-invasive evaluation of the liver in many clinical settings in adults. Color-coded duplex Doppler information regarding the presence or absence of flow and the direction and velocity of that flow can be obtained non-invasively, rapidly and relatively inexpensively.

Research frontiers

The aim of the research is to investigate the value of duplex Doppler US in the assessment of the hemodynamics of the portal and hepatic veins in a cohort of children with CLD, and to detect any relationship between the US changes and etiology and severity (or stage) of CLD.

Innovations and breakthroughs

In the present study, the authors tried to correlate the splanchnic morphological and hemodynamic parameters of the portal and hepatic veins with the severity of hepatic affliction. In this study, the authors found that the values of portal vein flow velocity were significantly lower in patients compared to controls and significantly lower in the group with liver cirrhosis than the chronic hepatitis group. A significant correlation was also detected between both splenic size and Child-Pugh's class and the portal flow velocity; the lower the velocity, the larger the splenic size and the worse the Child-Pugh's class. Therefore in children with cirrhosis, portal flow velocity might be correlated with the severity of portal hypertension and the severity of liver parenchymal dysfunction.

Applications

In conclusion, grayscale and color-coded duplex Doppler US are very valuable, non-invasive diagnostic modalities in children with CLD. They could detect splanchnic morphological and portal hemodynamic changes that could be correlated to the degree of liver parenchymal affection but not to the etiology of the CLD. Therefore the authors recommend their wider application in the assessment of children with CLD.

Peer review

This article well documented that the grayscale and color-coded duplex Doppler US are very valuable for non-invasive diagnostic modalities in children with CLD, and this will interest the readers.

Abstract

AIM: To investigate the effect of pegylated interferon (IFN) α-2b on specific CD8+ T lymphocytes in patients with chronic hepatitis B (CHB).

METHODS: Twenty-one patients with CHB were treated with pegylated IFN α-2b. Periphery blood mononuclear cells were isolated from fresh heparinized blood by Ficoll-Hypaque density gradient centrifugation (density: 1.077 g/L, Pharmingen) at weeks 0, 4, 8, 12, and 24, respectively. Frequency of circulating hepatitis B virus (HBV) epitope-specific CD8 T cells was detected by flow cytometry. Cytokines were detected by cytometric bead assay.

RESULTS: The frequency of circulating HBV core or env-specific CD8 T cells was higher ($P < 0.05$), the number of HBV core specific CD8 T cells was greater at week 24 ($P < 0.05$), the level of Th1-type cytokines [interleukin (IL)-12, tumor necrosis factor-α, and IFN-γ] was higher, while that of Th2-type cytokines (IL-4, IL-6, and IL-10) was lower in responders than in non-responders ($P < 0.05$) after pegylated IFN α-2b treatment. The IL-6 level was correlated with HBV DNA ($r = 0.597$, $P = 0.04$), while the inducible protein-10 (IP-10) level was correlated with serum alanine aminotransferase (ALT) ($r = 0.545$, $P = 0.005$). The IP-10 level at week 8 after pegylated IFN α-2b treatment could predict the normalization of ALT in CHB patients (positive predict value = 56%, negative predict value = 92%).

CONCLUSION: Pegylated IFN α-2b can enhance the immune response of CHB patients by increasing the frequency of HBV specific CD8+ T cells and regulating the Th1/Th2 cytokines.

Key words: Chronic hepatitis B; Pegylated interferon α-2b therapy; Immune response; Cytokine

Pegylated interferon α-2b up-regulates specific CD8+ T cells in patients with chronic hepatitis B. *World J Gastroenterol* 2010; 16(48): 6145-6150 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i48/6145.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i48.6145

INTRODUCTION

More than two billion people have been infected with hepatitis B virus (HBV) and chronic HBV infection affects about 400 million people worldwide[1,2]. Chronic hepatitis B (CHB) is a chronic inflammatory liver disease,

which can progress to end-stage liver diseases, such as cirrhosis and hepatocellular carcinoma.

Adaptive immunity plays a central role in the pathogenesis of chronic HBV infection, and it is crucial to understanding the behavior of T cell response for the design of effective strategies for the control of HBV infection[3-5]. Different studies in chronic and early acute phases of HBV infection suggested that the functional impairment of HBV-specific cell-mediated immune response plays an important role in HBV persistence[6-14]. Moreover, recent studies showed that both positive and negative signals regulate the antigen-specific T cell function and are important for the better outcome of patients with HBV infections[15-17].

Pegylated interferon (IFN) α-2b can modulate and reduce antiviral function of CHB patients by enhancing their immune responses. However, the exact effect of pegylated IFN α-2b on the immune responses of patients with HBV infections remains unclear. The present study was designed to investigate the effect of pegylated IFN α-2b on HBV specific CD8+ T cells and secretion of cytokines in CHB patients.

MATERIALS AND METHODS

Patients and study design

Twenty-one consecutive CHB patients (17 males and 4 females) at the age of 20-39 years (mean 25 years), admitted to our hospital from January 2008 to May 2009 were included in this study. Diagnosis of HBV infection was established as previously described[18]. Clinical data and characteristics of the patients are summarized in Table 1. The patients were treated with pegylated IFN α-2b (PegIntron from Schering-Plough), at the dose of 0.5-1 μg/kg of body weight, once a week for 24 wk. Clinical and laboratory data about the patients were detected before treatment, or at weeks 4, 8, 12, and 24 after treatment. Patients co-infected with HBV and HCV or with detectable antibodies against hepatitis delta virus or against human immunodeficiency virus were excluded, as were those with other causes of liver disease, including alcohol abuse. No patient had decompensated liver disease (evidence or history of ascites, variceal bleeding, hepatic encephalopathy or jaundice).

Isolation of peripheral blood monouclear cells

Peripheral blood monouclear cells (PBMC) were isolated from fresh heparinized blood by Ficoll-Hypaque density gradient centrifugation (density: 1.077 g/L, Pharmingen). Blood was two-fold diluted with RPMI 1640 medium containing 300 μg/mL L-glutamin, 100 U/mL penicillin, 100 μg/mL streptomycin and 10% fetal calf serum, then added into the isovolumic Ficoll, centrifuged for 400 × *g* at 21℃ for 35 min. The cells were washed twice with phosphate buffered saline (PBS).

Human leukocyte antigen-A2 typing

One hundred microliters of fresh heparinized blood (100) was incubated with human leukocyte antigen-A2 primary antibody for 30 min. Erythrocytes were lysed with an erythrocyte lysate at 37℃, washed with PBS, and then incubated with secondary antibody, washed again and analyzed on Becton Dickinson FACS (Becton Dickinson, USA).

Analysis of HBV epitope-specific CD8+ T cells

Frequency of HBV epitope-specific CD8 T cells was detected by flow cytometry after incubated with HBV core18-27 tetramers (ProImmune, Oxford, UK) and HBV env 335-343 pentamers (ProImmune, Oxford, UK). Freshly isolated PBMC were incubated with PE-labeled tetramer or pentamer in PBS (10% FCS) for 15 min at 37℃, washed once with PBS (1% FCS) and then incubated on ice for 30 min with FITC-anti-CD8 (ProImmune, Oxford, UK), washed twice with PBS, adjusted to 1×10^6 cells/vial, and fixed in 2% paraformaldehyde for analysis. About 1×10^6 PBMC were harvested and analyzed within the CD8 gate on Becton Dickinson FACS using the CELLQuest™ software.

Secretion of cytokines

Serum levels of interleukin (IL)-2, IL-4, IL-5, IL-6, IL-10, IL-12, IFN-γ and inducible protein-10 (IP-10) in CHB patients were measured by cytometric bead assay (BD, USA) according to its manufacturer's instructions.

Serological assessment

Fasting serum levels of liver enzymes [alanine aminotransferase (ALT), aspartate aminotransferase] were measured with a Hitachi-7180 automatic biochemistry analyzer (Hitachi Inc., Japan) following the standard laboratory methods. HBV DNA was detected by real time polymerase chain reaction (Amplicor, Roche).

Statistical analysis

All data were analyzed using SPSS version 13.0 (SPSS Inc., Chicago, IL, USA). Descriptive baseline data were expressed as mean ± SD for continuous variables. Differences between groups were assessed using Kruskal-Wallis H for continuous variables. Spearman *P* test was performed for correlation analysis. The accuracy of serum factors for predicting virologic response was assessed using the receiver operating characteristic curve. $P < 0.05$ was considered statistically significant.

RESULTS

Frequency of circulating HBV epitope-specific CD8 T cells in CHB patients after pegylated IFN α-2b treatment

Circulating HBV epitope-specific CD8 T cells were detected 13 out of the 21 CHB patients (Table 1). The frequency of HBV core 18-27 tetramers+/CD8+ T cells at week 0 was 0.013 ± 0.002, which increased to 0.026 ± 0.015, 0.029 ± 0.019, 0.036 ± 0.025, and 0.045 ± 0.027, respectively, at weeks 4, 8, 12, and 24 after IFN α-2b treatment (Figure 1), with a significant difference between weeks 8 and 0, and between weeks 24 and 0 ($P < 0.05$). The frequency of HBV env 335-343 pentamers+/CD8+ T cells began to increase at week 8 with a significant difference between weeks 24 and 0 ($P < 0.05$). No significant difference was observed in frequency of HBV core and HBV env specific CD8 T cells.

Table 1 Clinical characteristics of chronic hepatitis B patients included in this study

Patient	Age (yr)/sex	HBV DNA (IU/L)	ALT (U/L)	Total bilirubin (mg/dL)	Albumin (g/dL)	Platelets ($\times 10^9$/L)	HBeAg	HBeAb	HBsAg	HBsAb	Genetype

HBV: Hepatitis B virus; ALT: Alanine aminotransferase; HBeAg: Hepatitis B e antigen; HBeAb: Hepatitis B e antibody; HBsAg: Hepatitis B surface antigen; HBsAb: Hepatitis B surface antibody.

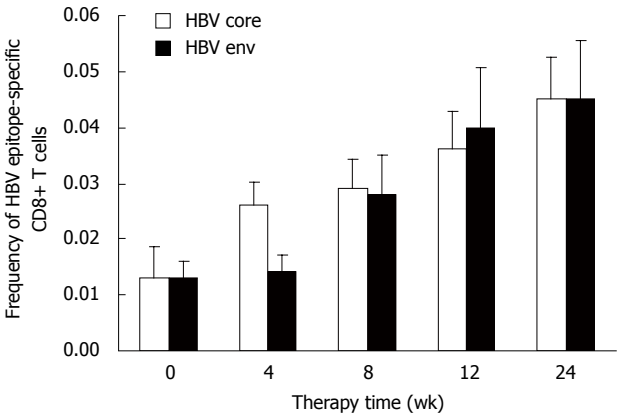

Figure 1 Frequency of hepatitis B virus epitope tetramer+/CD8+ T cell after pegylated interferon α-2b treatment. The frequency of hepatitis B virus (HBV) specific CD8+ T cells was increased connectively at weeks 4, 8, 12 and 24 after pegylated interferon α-2b treatment with no difference in frequency of HBV core specific CD8+ T cells and HBV env specific T cells.

To further analyze the effect of pegylated IFN α-2b on HBV-specific CD8 T cells, 13 patients were divided into responders (n = 7) and non-responders (n = 6). Responders were defined as their ALT returned to its normal level and their HBV DNA was decreased to over 2log, and/or their serum HBeAg was conversed. The frequency of HBV core18-27 tetramers+/CD8+ T cells was 0.014 ± 0.011, 0.029 ± 0.022, 0.029 ± 0.021, 0.067 ± 0.029, and 0.05 ± 0.025, respectively, in responders at weeks 0, 4, 8, 12 and 24 after treatment, which was higher than that in non-responders (0.012 ± 0.007, 0.018 ± 0.009, 0.028 ± 0.019, 0.025 ± 0.021 and 0.030 ± 0.01, respectively). No significant difference was found in frequency of HBV core specific CD8 T cells between responders and non-responders at baseline, even at weeks 4, 8, and 12 after treatment (Figure 2), with a significant difference observed at week 24 ($P < 0.05$, Figure 3). The frequency of HBV env specific CD8 T cells was higher in responders than in non-responders ($P < 0.05$, Figure 2).

Secretion of cytokines after pegylated IFN treatment and its correlation with virologic responses

The serum levels of IL-2, IL-4, IL-6, IL-10, tumor necrosis factor (TNF)-α, IFN-γ, IL-12, and IP-10 were measured at baseline, during the treatment and follow-up. The serum IL-2 level was very low in CHB patients, which was almost undetectable. The levels of Th1-type cytokines including IL-12, TNF-α and IFN-γ were increased while those of Th2-type cytokines including IL-4, IL-6 and IL-10 were decreased at week 48 after treatment (Figure 4). The baseline IP-10 level was increased from week 4 and decreased from week 48 after treatment.

The baseline IL-6 level was correlated with HBV DNA in responders (r = 0.597, P <0.05) but not with HBV DNA in non-responders. IL-10 was correlated with IL-6 (r = 0.762, P = 0.002), and IL-12 was correlated IFN-γ (r = 0.485, P = 0.026).

The IP-10 level was closely correlated with the serum ALT level not only in responders but also in non-responders (r = 0.545, P = 0.005, Figure 5), indicating that IP-10 level fluctuates with serum ALT level. The baseline IP-10 level was lower in patients with their ALT < 40 U/L than in those with their ALT > 40 U/L.

Predictability of IP-10

To determine whether IP-10 can predict the normalization of ALT (< 40 U/L) after peg-IFN α-2b treatment, receiver operating characteristic curve was plotted for IP-10. The

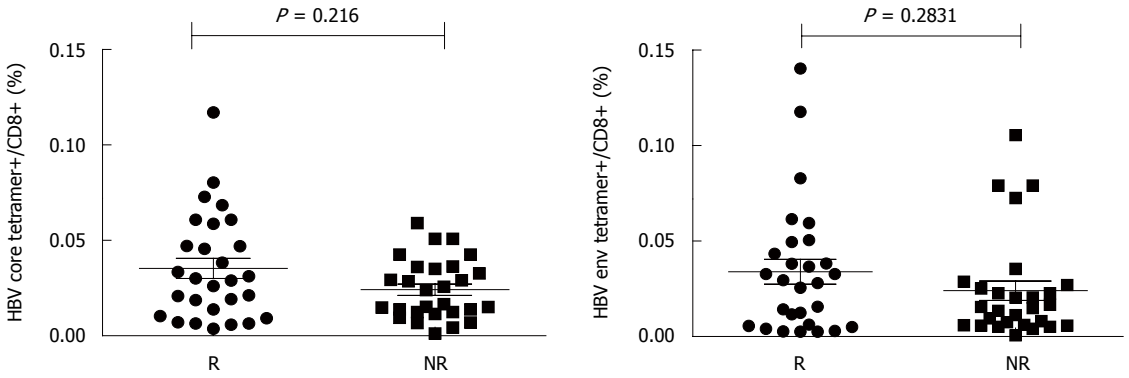

Figure 2 No correlation between increased hepatitis B virus epitope-specific CD8+ T cells and treatment outcome. The frequency of hepatitis B virus (HBV) core or env epitope-specific CD8+ T cells was higher in non-responders (NR) than in responders (R).

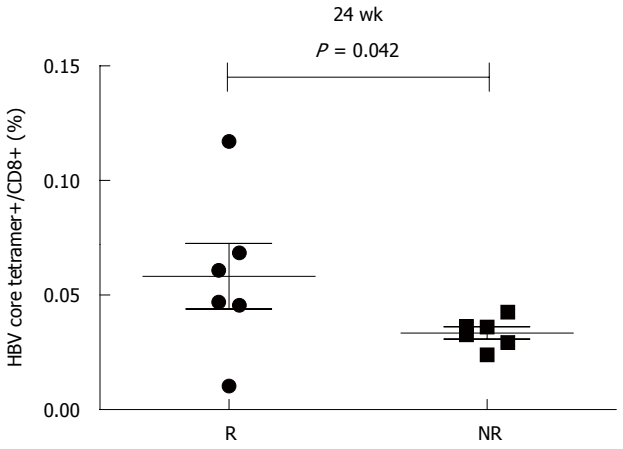

Figure 3 Correlation between increased hepatitis B virus specific T cells and treatment response 24 wk after therapy. The frequency of hepatitis B virus (HBV) core epitope-specific CD8+ T cells at week 24 was higher in responders (R) than in non-responders (NR).

IP-10 level at week 8 after treatment was predictable. The area under the curve was 0.741 ($P = 0.065$). A cutoff value of 437.78 was chosen. Correspondingly, the positive and negative predictive value was 56% and 92%, respectively (Table 2).

DISCUSSION

HBV has a high propensity to persist and several strategies have been developed for control of its evading from T cell responses, including the direct inhibitory effect of viral proteins on T cell responses and the emergence of escape mutations[19-21]. Moreover, HBV infection is more common in immune deficient individuals, such as infants, patients with cancer and those treated with steroid hormone, thereby can interfere with viral clearance by the innate immune system[22,23]. Inefficient innate responses and rapid spread of HBV may in turn delay and impair adaptive responses because of inefficient promotion of T cell priming by innate immunity and through T cell exhaustion induced by a rapidly increased viral load. However, the actual impact of exhaustion by persistent exposure to high antigen concentrations on virus persistence has only been partially defined.

Furthermore, two kinds of drugs (nucleoside analogs and IFN) are usually used in antiviral treatment of CHB

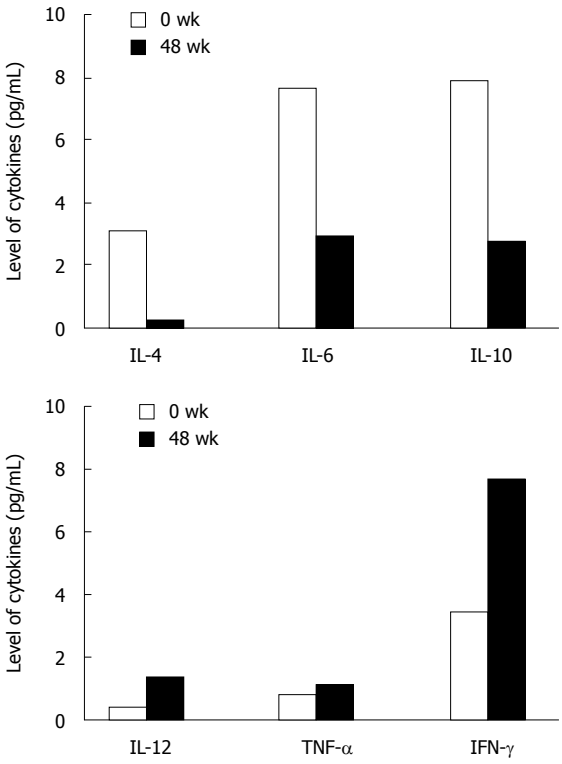

Figure 4 Level of cytokines after treatment. The levels of Th1-type cytokines [interleukin (IL)-12, tumor necrosis factor (TNF)-α and interferon (IFN)-γ] were higher, while the levels of Th2-type cytokines (IL-4, IL-6 and IL-10) were lower at week 48 after treatment.

patients. IFN is involved in numerous immune interactions during viral infection, as an inducer, regulator, and effector of both innate and adaptive antiviral systems. IFN-α and beta are produced rapidly due to viral factors, such as envelope glycoprotein, CpG DNA or dsRNA, and interact with cellular pattern-recognition receptors, such as mannose receptors, toll-like receptors, and cytosolic receptors[24]. In addition, IFN modulates both innate and adaptive immunity, ultimately resulting in an enhanced antiviral effector function.

In the present study, the frequency of HBV epitope-specific CD8+ T cells in peripheral blood was persistently increased at weeks 4, 8, 12 and 24 after peg-IFN α-2a treatment, while the number of HBV epitope-specific CD8 T cells in HBV core 18-27 tetramers and HBV env 335-343

Table 2 Predictive value of serum inducible protein-10 levels 8 wk after treatment

IP-10 (pg/mL)	ALT < 40 U/L	ALT ≥ 40 U/L	Predictive value
< 437.78	5	4	PPV = 56%
≥ 437.78	1	11	NPV = 92%

IP-10: Inducible protein-10; ALT: Alanine aminotransferase; PPV: Positive predict value; NPV: Negative predict value.

pentamers was greater in responders than in non-responders after pegylated IFN α-2b treatment, suggesting that the therapeutic effect of pegylated IFN α-2b on HBV infection may be attributed to the elevated HBV-specific CD8 T cells, and that the immune response mediated by HBV-specific cells plays an important role in control of HBV. However, the frequency of HBV core 18-27 tetramers+/CD8+ T cells was higher than that of HBV env 335-343 pentamers+/CD8+ T cells after pegylated IFN treatment, suggesting that the HBV core epitope plays a more critical role in induction of a stronger immune response to HBV infection than to HBV env epitope. Pegylated IFN α-2b could enhance specific immune response of CHB patients. Further study should be performed with a large sample size.

Cytokines play an important role in immune modulation. Clearance of HBV infection is mediated by a strong polyclonal cellular response of both CTL and Th1 cells. Chronic HBV infection is caused mainly by an increased response of Th2 cells and impaired production of type 1 cytokines. IL-10, a Th2-type cytokine secreted by T-cells, activated B cells and monocytes, is a powerful inhibitor of Th1 activation and suppresses cell-mediated immunity in mice and humans[25,26]. Of the detected cytokines, Th2-type cytokines such as IL-4, IL-6 and IL-10, were altered conspicuously. After treatment, the level of Th2-type cytokines (IL-4 and IL-10) was down-regulated, thus confirming the immune recover potential of pegylated IFN α-2b, the level of IL-12 which can promote the differentiation of Th1-type cytokines was low, and the production of Th1-type cytokines was increased, indicating that the immune function of pegylated IFN α-2b can be achieved by regulating the balance of Th1/Th2 cytokines.

IL-6 is a multifunctional cytokine with both differentiation and growth-promoting effects for a variety of target cells. IL-6 is generally considered an important cytokine in the network of cytokines that regulate immune reactions and acute phase responses[27]. It was reported that IL-6 is correlated with liver fibrosis/cirrhosis[28] and is a cell attachment site for HBV[29]. In the present study, the IL-6 level was correlated with HBV DNA plasma only in responders.

IP-10, a chemotactic CXC chemokine of 77 aa in its mature form[30,31], can be produced by a variety of cells, including hepatocytes[32,33]. The correlation between IP-10 levels and necroinflammatory activity, as well as the high and low IP-10 levels before and after pegylated IFN α-2b treatment, may imply that IP-10 plays a role in the natural pathogenesis of HBV-induced liver damage[34]. It was reported that the baseline IP-10 level can predictive the response of CHB patients to HCV treatment, and is correlated with liver inflammation and fibrosis[35,36]. In this study, the baseline IP-10 level in CHB patients could predict the normalization of ALT after pegylated IFN α-2b treatment.

In conclusion, given the importance of protective T cell responses in control of HBV, the correlation between immunomodulatory molecules and pegylated IFN α-2b treatment in restoration of the immune responses of antiviral T cells are highly desirable. Pegylated IFN α-2b therapy can enhance the immune response of CHB patients by influencing the production of cytokines. IP-10 can potentially predict the normalization of ALT, which is correlated with liver damage. Further study is needed with a large sample size.

COMMENTS

Background

More than two billion people have been infected with hepatitis B virus (HBV) and chronic HBV infection affects about 400 million people worldwide. Two kinds of drugs [nucleoside analogs and interferon (IFN)] are mainly used in treatment of chronic hepatitis B (CHB) patients. IFN is involved in numerous immune interactions as an inducer, regulator, and effector in treatment of viral infections. Cytokines play an important role in immune modulation. Clearance of HBV infection is mediated by a strong polyclonal cellular response of both CTL and Th1 cells. Chronic HBV infection is caused mainly by an increased response of Th2 cells and impaired production of type 1 cytokines. Inducible protein 10 (IP-10) is a chemotactic CXC chemokine of 77 aa in its mature form.

Research frontiers

IFN-α and β are produced rapidly due to viral factors, such as envelope glycoproteins, CpG DNA or dsRNA, and interact with cellular pattern-recognition receptors, such as mannose receptors, toll-like receptors, and cytosolic receptors. IP-10 can be produced by a variety of cells, including hepatocytes. The results of this study show that the baseline IP-10 level can predict the response of patients with HBV infection to its treatment with pegylated IFN α-2b.

Innovations and breakthroughs

The present study demonstrated the correlation between pegylated IFN α-2b treatment and HBV-specific T lymphocytes. In addition, the effect of pegylated IFN α-2b on HBV infection could be achieved by balancing the production of Th1/Th2 cytokines and IP-10 could predict the outcome of patients with HBV infection after pegylated IFN α-2b treatment.

Applications

In this study, pegylated IFN α-2b could up-regulate HBV epitope specific CD8+ T cells. The specific cellular immune response could control HBV. IP-10 serum

level could predict the outcome of patients with HBV infection after pegylated IFN α-2b treatment, thus providing a new index for the treatment of HBV infection. Pegylated IFN α-2b may be used as a novel strategy for the treatment of HBV infection by regulating the cytokines.

Terminology

Human leukocyte antigen (HLA) typing is a method to define the HLA+ and HLA+ blood for studied subjects. Flow cytometry is used to define the HBV epitope specific CD8+ T lymphocytes. Cytometric bead assay is a new technique for detecting serum concentration of cytokines.

Peer review

This is a very interesting study, showing that pegylated IFN α-2b therapy can increase the frequency of specific CD8+ T lymphocytes in CHB patients. This may contribute to the better control of HBV replication and to the recovery of CHB patients, thus having a promise for therapeutic interventions. The experiments support the claim of the authors.

Abstract

AIM: To investigate the endoscopy and histology of short-segment Barrett's esophagus (SSBE) and cardia intestinal metaplasia (CIM), and their correlation with *Helicobacter pylori* (*H. pylori*) gastritis and gastroesophageal reflux disease (GERD).

METHODS: Biopsy specimens were taken from 32 SSBE patients and 41 CIM patients with normal appearance of the esophagogastric junction. Eight biopsy specimens from the lower esophagus, cardia, and gastric antrum were stained with hematoxylin/eosin, Alcian blue/periodic acid-Schiff, Alcian blue/high iron diamine and Gimenez dye. Results were graded independently by one pathologist.

RESULTS: The SSBE patients were younger than the CIM patients ($P < 0.01$). The incidence of dysplasia and incomplete intestinal metaplasia subtype was higher in SSBE patients than in CIM patients ($P < 0.01$). *H. pylori* infection was correlated with antral intestinal metaplasia ($P < 0.05$), but not with reflux symptomatic, endoscopic, or histological markers of GERD in CIM patients. SSBE was correlated with reflux symptomatic and endoscopic esophagitis ($P < 0.01$), but not with *H. pylori* infection and antral intestinal metaplasia.

CONCLUSION: Dysplasia risk is significantly greater in SSBE patients than in CIM patients. CIM is a manifestation of *H. pylori*-associated and multifocal atrophic gastritis, whereas SSBE may result from GERD.

INTRODUCTION

The incidence of adenocarcinoma in esophagus and gastroesophageal junction (GEJ) has increased in recent years in North America, Europe, Japan and China[1-3]. Barrett's esophagus (BE) is thought to be a premalignant condition of esophageal adenocarcinoma, accounting for most cases of adenocarcinoma of the GEJ. The reported prevalence of Barrett's-associated adenocarcinoma varies widely, with an average of 10%[4-7]. A meta-analysis[8] of 4120 patients

in China reported that BE is found in 2.44% of patients undergoing endoscopy for various symptoms of upper gastrointestinal tract diseases.

It was reported that the frequency of short-segment Barrett's esophagus (SSBE), < 3 cm in length, is increased and implicated as a risk factor for adenocarcinoma of the cardia[9-11]. Endoscopic diagnosis of this entity is difficult and always requires histological demonstration of specialized columnar epithelium (SCE). Since most endoscopists do not perform biopsies unless the columnar epithelium is seen to extend from the proximity to the GEJ. Short segments are frequently unrecognized. Spechler *et al*[12] have recently described the presence of intestinal metaplasia in certain normal-appearing GEJ. The relation of this condition to SSBE has not yet been investigated.

In this study, SSBE and cardia intestinal metaplasia (CIM) were compared and their correlation with *Helicobacter pylori* (*H. pylori*) gastritis and gastroesophageal reflux disease (GERD) was studied, which may contribute to the clinical diagnosis, treatment, prevention, and susceptibility forecast of BE.

MATERIALS AND METHODS

Patients

Tissue specimens used in this study were provided by The Sixth Hospital of Shanghai Jiaotong University, with the approval of the hospital and patients. Endoscopy was performed in a standardized manner by experienced endoscopists. Appearance of the squamocolumnar junction was carefully studied in a prograde view after insufflation of air and retroversion in the stomach. Thirty-two consecutive patients with endoscopically apparent SSBE (< 3 cm in length) included in the study (group A) were selected from The Outpatient Clinic of our hospital over a two-year period. Two endoscopic features of the squamocolumnar transition were considered indicative of SSBE: a straight and regular Z line (< 3 cm) displaced upwards in relation to the GEJ (circumferential type), and an irregular Z line with eccentric tongues of red mucosa extending above the GEJ (digital type). The severity of SSBE was measured according to the Prague C&M classification[13]. The specimens were stained with Alcian blue (pH 2.5).

Group B was consisted of 41 adult ambulatory consecutive patients who underwent upper endoscopy in our endoscopy unit and were considered by the endoscopist to have a normal-appearing GEJ. Patients with a history of cancer or prior gastric/esophageal surgery were excluded, as were those who were unable to give their informed consent, or who had any contraindication to endoscopic biopsies. CIM was defined based on the presence of barrel-shaped goblet cells in normal-appearing GEJ.

All patients included in this study were questioned about symptoms of GERD (heartburn, regurgitation, and odynophagia). Endoscopic signs of esophagitis were recorded and graded according to the Los Angeles classification[14].

Endoscopy and biopsy protocol

Biopsy specimens were taken from 32 patients with SSBE and 41 CIM patients with normal-appearing GEJ. Eight biopsy specimens, taken from the lower esophagus, cardia, and gastric antrum, were stained with hematoxylin/eosin, Alcian blue/periodic acid-Schiff (AB/PAS, pH 2.5), AB/high iron diamine (AB/HID) and Gimenez dye. Results were graded independently by one pathologist.

Table 1 Incidence of dysplasia in short-segment Barrett's esophagus and cardia intestinal metaplasia patients

Patients	*n*	Dysplasia	%
CIM	41	1	2.4
SSBE	32	4	12.5[b]

[b]$P < 0.01$ *vs* cardia intestinal metaplasia (CIM). Biopsy specimens taken from 41 CIM patients and 32 short-segment Barrett's esophagus (SSBE) patients were stained with hematoxylin and eosin. The incidence of dysplasia was calculated. The incidence of dysplasia was significantly higher in SSBE patients than in CIM patients (12.5% *vs* 2.4%, $P < 0.01$).

Histology

Formalin-fixed, paraffin-embedded biopsy samples were stained with hematoxylin/eosin. PAS/AB (pH 2.5) was used to show the presence of acid mucins. BE was diagnosed based on the presence of SCE, which was defined by the unequivocal demonstration of intestinal-type goblet cells.

Statistical analysis

Statistical analysis was performed using the χ^2 test.

RESULTS

Incidence of dysplasia in SSBE and CIM patients

The SSBE patients were younger than the CIM patients ($P < 0.01$). The incidence of dysplasia was higher in SSBE patients than in CIM patients ($P < 0.01$) (Table 1).

Incidence of incomplete intestinal metaplasia in SSBE and CIM patients

The incidence of incomplete intestinal metaplasia (IM) was significantly different between the two types of epithelium ($P < 0.01$ *vs* CIM) (Table 2).

Prevalence of GERD in SSBE and CIM patients

The prevalence of GERD symptoms was higher in SSBE patients than in CIM patients ($P < 0.01$), as was endoscopic and histological evidence of esophagitis (Table 3).

Correlation between H. pylori and antral IM in SSBE and CIM patients

The correlation between *H. pylori* infection and antral IM in SSBE and CIM patients is shown in Table 4.

DISCUSSION

Over the past two decades, the incidence of adenocarcinoma of the esophagus and gastric cardia has increased rapidly. BE is recognized as a precancerous lesion of esophageal adenocarcinoma in most cases of adenocarcinoma

Table 2 Incidence of incomplete intestinal metaplasia in short-segment Barrett's esophagus and cardia intestinal metaplasia patients

Patients	*n*	Incomplete IM	Complete IM	%
CIM	41	8	33	19.5
SSBE	32	21	11	65.6[b]
Total	73	29	44	39.7

[b]$P < 0.01$ *vs* cardia intestinal metaplasia (CIM). Eight biopsy specimens taken from the lower esophagus and cardia were stained with hematoxylin/eosin, Alcian blue/periodic acid-Schiff (pH 2.5), AB/high iron diamine or Gimenez dyes. The prevalence of incomplete intestinal metaplasia (IM) was significantly higher in short-segment Barrett's esophagus (SSBE) patients than in CIM patients (65.6% *vs* 19.5%, $P < 0.01$).

Table 3 Incidence of reflux symptomatic, endoscopic, or histological markers of gastroesophageal reflux disease in short-segment Barrett's esophagus and cardia intestinal metaplasia patients *n* (%)

Patients	*n*	Reflux symptoms	Endoscopic esophagitis	Histological features of reflux esophagitis
CIM	41	12 (29.3)	5 (12.2)	12 (29.3)
SSBE	32	26 (81.2)[b]	30 (93.8)[b]	31 (96.9)[b]

[b]$P < 0.01$ *vs* cardia intestinal metaplasia (CIM). All patients were questioned about symptoms of gastroesophageal reflux disease (GERD). Endoscopic signs of esophagitis were recorded and graded. All biopsy specimens were stained with hematoxylin and eosin. Alcian blue/periodic acid-Schiff (pH 2.5) was used to show the presence of acid mucins. The incidence of reflux symptomatic, endoscopic, or histological markers of GERD was higher in short-segment Barrett's esophagus (SSBE) patients than in CIM patients ($P < 0.01$).

Table 4 Relation between *Helicobacter pylori* infection and antral intestinal metaplasia in short-segment Barrett's esophagus and cardia intestinal metaplasia patients *n* (%)

Patients	*n*	Cardia *H. pylori* infection	Antral IM	Antral *H. pylori* infection
CIM	41	18 (43.9)	21 (51.2)	20 (48.8)
SSBE	32	5 (15.6)[a]	4 (12.5)[b]	7 (21.9)[a]

[a]$P < 0.05$, [b]$P < 0.01$ *vs* cardia intestinal metaplasia (CIM). Eight biopsy specimens taken from the lower esophagus, cardia, and gastric antrum were stained with Alcian blue/periodic acid-Schiff (pH 2.5) and Gimenez dyes, respectively. The incidence of *Helicobacter pylori* (*H. pylori*) infection and antral intestinal metaplasia (IM) was lower in short-segment Barrett's esophagus (SSBE) patients than in CIM patients ([a]$P < 0.05$, [b]$P < 0.01$).

of the GEJ. Progression from metaplasia to dysplasia and adenocarcinoma is well documented[7]. Traditionally, BE is arbitrarily defined as a circumferential segment of columnar-lined epithelium (2 or 3 cm in length) in the lower esophagus. However, this macroscopic definition has been recently questioned, because it excludes shorter segments and "tongues of columnar-lined epithelium", which are frequently found in the distal esophagus, and endoscopic measurements can be imprecise. It has therefore been proposed that the diagnosis of BE should be reserved for patients with IM detected in biopsy specimens from the distal esophagus[15,16]. Recently, the presence of CIM in certain normal-appearing GEJ has been described[17-19]. Detection of IM in the distal esophagus as well as within the gastric cardia has been reported with an increasing frequency[15,16]. It was reported that the prevalence of BE and CIM is 2%-12% and 5%-23%, respectively, in patients undergoing routine upper gastrointestinal endoscopy[20,21]. Detection of IM in BE patients potentially commits the patients to regular surveillance endoscopy with biopsy. The incidence of adenocarcinoma in patients with BE is estimated to be 30-50 times greater than that in general populations, and is on the increase[6,7]. However, the exact incidence of cancer in patients with BE is unknown, and the role of CIM as a premalignant lesion is still unclear. The relation of this condition to BE has not yet been investigated. Whether CIM and IM originating from the esophageal mucosa have a common pathogenesis and identically associated risk factors remains unknown.

In the present study, the dysplasia risk was significantly higher in SSBE patients than in CIM patients (12.5% *vs* 2.4%). Sharma *et al*[15] also compared the incidence of dysplasia in 177 SSBE patients and 76 CIM patients. As in our study, the risk of dysplasia differed significantly between the two groups. Dysplasia was detected in 11.3% (20/177) of SSBE patients and in 1.3% (1/76) of CIM patients, indicating that dysplasia is two potentially different clinical processes. Future studies should separate SSBE from CIM to improve our understanding of the pathophysiology and malignant potential of each entity.

Although a few authors reported that the areas adjacent to CIM show normal foveolar epithelium, whereas those adjacent to BE contain pre-goblet cells that can be positively stained with Alcian blue[15,16]. Since these characteristics cannot be found in all biopsy specimens, it is not reliable to distinguish SSBE from CIM histologically. HID/AB staining has also been used to distinguish SSBE from CIM[17-19]. It was reported that IM at the GEJ (or ultra-short-segment BE) is more frequently found to express sulfomucins, which is defined as type Ⅲ IM and involves the surface glandular epithelium[11,17]. Liu *et al*[10] also found that the area covered by incomplete IM is significantly greater and the level of sulfomucins is obviously higher in the esophagus than in the stomach. In our study, the prevalence of type Ⅲ IM was significantly higher in SSBE patients than in CIM patients (65.6% *vs* 19.5%, $P < 0.01$). HID/AB staining can be used to distinguish SSBE from CIM initially, based on the different expressions of neutral mucins, sialomucins, and sulfomucins.

The incidence of reflux symptomatic, endoscopic, or histological markers of GERD was higher while that of *H. pylori* infection and antral IM was lower in SSBE patients than in CIM patients ($P < 0.05$). Since CIM is a manifestation of *H. pylori*-associated and multifocal atrophic gastritis, and SSBE can result from GERD, it is necessary to explore new and efficacious diagnostic methods to distinguish BE from CIM.

cDNA microarray methods have been used in the study of gene expression, DNA sequencing, novel genes and mutations, DNA polymorphism, drug screening, diagnosis of disease, and gene mapping, since they were reported by Schena *et al*[22] in 1995. We have previously

performed an analysis of three 4096 chips to investigate the difference in gene expression profiles between BE and CIM epithelium[23]. A total of 141 genes were screened that exhibited a differential expression in the three chips. A comparison between the two gene profiles showed that the gene expression patterns were different in BE and CIM epithelium, illustrating that detection of differences in gene expression between BE and CIM with gene chips is a new method for the diagnosis, treatment and prevention of BE. Future studies should separate SSBE from CIM to improve our understanding of the pathophysiology and malignant potential of such diseases.

COMMENTS

Background

The incidence of adenocarcinoma in the esophagus and gastroesophageal junction (GEJ) has increased in recent years. Barrett's esophagus (BE) is thought to be a premalignant condition. Recently, the presence of cardia intestinal metaplasia (CIM) in certain normal-appearing GEJ has been described. The relation between CIM and BE has not yet been investigated.

Research frontiers

Short-segment Barrett's esophagus (SSBE), < 3 cm in length, has been reported as a risk factor for adenocarcinoma of the cardia. Whether CIM and IM originating from the esophageal mucosa have a common pathogenesis still remains unknown. In this study, the authors demonstrated that CIM was a manifestation of *Helicobacter pylori* (*H. pylori*)-associated and multifocal atrophic gastritis, whereas SSBE could result from gastroesophageal reflux disease (GERD).

Applications

This study describing the he different characteristics of SSBE and CIM may contribute to the clinical diagnosis, treatment, prevention, and susceptibility forecast of BE.

Terminology

BE is thought to be a premalignant condition of esophageal adenocarcinoma, accounting for most cases of adenocarcinoma of the GEJ. BE is defined as IM detected in biopsy specimens from the distal esophagus. The extent of the Barrett segment is measured according to the Prague C&M classification.

Peer review

The authors examined the different characteristics of SSBE and CIM and revealed that CIM was a manifestation of *H. pylori*-associated and multifocal atrophic gastritis, whereas SSBE could result from GERD. The results are interesting and may contribute to the clinical diagnosis, treatment, prevention, and susceptibility forecast of BE.

Abstract

AIM: To analyze the correlation between cytokine-induced killer (CIK) cells adoptive immunotherapy and cancer-related death in gastric cancer patients.

METHODS: One hundred and fifty-six gastric cancer patients after operation at the Third Affiliated Hospital of Soochow University were enrolled in this study. Their clinical data including demographic characteristics, operation time, tumor size, pathological type and staging, tumor metastasis, outcome of chemotherapy or CIK cells adoptive immunotherapy, survival time or time of death were collected with a standard structured questionnaire. Kaplan-Meier method was used to estimate the median survival time, and the 2- and 5- year survival rates. Hazard risk (HR) and 95% confidence interval (95% CI) of CIK cells adoptive immunotherapy for gastric cancer were calculated using the two-stage time-dependent covariates Cox model.

RESULTS: The survival time of gastric cancer patients was longer after CIK cells adoptive immunotherapy than after chemotherapy (χ^2 = 10.907, P = 0.001). The median survival time of gastric cancer patients was also longer after CIK cells adoptive immunotherapy than after chemotherapy (49 mo *vs* 27 mo, P < 0.05). The 2- and 5-year survival rates of gastric cancer patients were significantly higher after CIK cells adoptive immunotherapy than after chemotherapy (73.5% *vs* 52.6%, 40.4% *vs* 23.9%, P < 0.05). A significant difference was observed in the survival curve for patients who received CIK cells adoptive immunotherapy (0, 1-10, 11-25, and over 25 frequencies) (χ^2 = 14.534, P = 0.002). The frequencies of CIK cells adoptive immunotherapy were significantly related with the decreasing risk of death in gastric cancer patients after adjustment for sex and age of the patients, tumor stage and relapse (HR = 0.54, 95% CI: 0.36-0.80) when the first stage Cox model was used to define the subjects who remained alive beyond 36 mo as survivors. However, no correlation was observed between the frequencies of death in CIK cells adoptive immunotherapy and the risk of gastric cancer patients (HR = 1.09, 95% CI: 0.63-0.89) when the second stage Cox model was used to define the subjects who survived for more than 36 mo as survivors.

CONCLUSION: The survival time of the gastric cancer

patients treated with chemotherapy combined with CIK cells adoptive immunotherapy is significantly longer than that of the patients treated with chemotherapy alone and increasing the frequency of CIK cells adoptive immunotherapy seems to benefit patients more.

Increasing the frequency of CIK cells adoptive immunotherapy may decrease risk of death in gastric cancer patients. *World J Gastroenterol* 2010; 16(48): 6155-6162 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i48/6155.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i48.6155

INTRODUCTION

Gastric cancer is one of the most common causes of cancer-related death in China[1]. Its incidence in Jiangsu Province of China is particularly high, and its mortality rate is much higher than the national average[2]. The early clinical detection rate of gastric cancer is less than 15%, and about 85% cases of gastric cancer are at the advanced stage when their gastric cancer is diagnosed[3]. Surgery is the standard treatment procedure for localized and resectable gastric cancer[4]. However, surgery alone does not improve the 5-year survival rate of local advanced gastric cancer patients[3]. Although standardized surgical resection and adjuvant therapeutic modalities are available for gastric cancer, the survival rate of advanced gastric cancer patients remains very low after operation[5]. About 60% of gastric cancer patients usually experience local recurrence and metastasis to other organs[6]. It has been demonstrated that local recurrence and distant metastasis constitute a major problem in the failure of cancer therapies[7]. Therefore, considerable efforts are needed to improve the current therapeutic modalities and to explore new therapies. In recent years, immune therapy has become the fourth important treatment modality for malignant tumors following surgery, radiotherapy and chemotherapy[8-10].

A number of adoptive immunotherapy with killer cells have been reported, including lymphokine-activated killer cells[11], tumor infiltrating lymphocytes[12], or anti-CD3 monoclonal antibody-induced killer cells[13]. However, their therapeutic efficacy is limited due to their low anti-tumor activities[14]. At present, cytokine-induced killer (CIK) cells are a new type of anti-tumor effector cells, which can proliferate rapidly *in vitro*, with a stronger anti-tumor activity and a broader target tumor spectrum than the reported anti-tumor effector cells[10,15]. Moreover, CIK cells can regulate and enhance immune function[16]. Studies have reported the level of tumor markers, change in cellular immune functions, exploration of molecule targets and a short-term efficacy in gastric cancer patients after chemotherapy plus CIK cells immunotherapy despite some side effects[17-19]. However, the relation between the frequencies of CIK cells immunotherapy and its clinical efficacy has not been examined. In the present study, data obtained from 156 gastric cancer patients in fitting multivariate Cox model showed that more frequencies of CIK cells immunotherapy could improve the survival rate of gastric cancer patients.

MATERIALS AND METHODS

Patients

One hundred and fifty-six primary gastric cancer patients after operation at the Third Affiliated Hospital of Soochow University (Jiangsu Province, China) were enrolled in this study. Those who did not meet the inclusion criteria, or had other tumors were excluded.

A standard questionnaire was designed to collect the data from the patients, including demographic characteristics, operation time, tumor size and location, pathological type and staging, tumor metastasis, outcome of chemotherapy or CIK cells immunotherapy. Meanwhile, time of relapse and death of the patients was recorded. Patients received 6 cycles of chemotherapy before CIK cells immunotherapy. Some patients underwent CIK cells immunotherapy due to cancer recurrence during chemotherapy. Recurrence of gastric cancer was defined when local, peritoneal or distant metastasis was detected at any site during chemotherapy[20]. The study was conducted according to the principles of the Declaration of Helsinki. All patients gave their informed consent prior to inclusion in the study. The study was approved by the Ethics Committee of the Third Affiliated Hospital of Soochow University.

Eighty-one patients (62 males, 19 females) at the age of 59.9 ± 10.5 years with a median age of 60.5 years who underwent chemotherapy alone served as chemotherapy group (group Ⅰ), and those (60 males at the age of 62.4 ± 10.8 years with a median age 60.5 years, 15 females at the age of 51.0 ± 10.7 years with a median age of 50 years) who received chemotherapy plus CIK cells immunotherapy served as treatment group (group Ⅱ) (Table 1).

Preparation of CIK cells and treatment

Peripheral blood mononuclear cells (PBMC) were collected with a COBE spectra blood cell separator (Gambro BCT, Inc., Lakewood, USA). Viability of PBMC was assessed by trypan blue exclusion. PBMC (2.0×10^6/mL) were plated onto 6-well dishes (Nunc, Denmark) and cultured with medium I containing RPMI 1640 in the presence of 1.0×10^6 U/L human interferon-γ (IFN-γ, Shanghai Fosun Pharma Co., China), 5.0×10^5 U/L recombinant human interleukin-2 (IL-2, Shangdong Quangang Pharmaceutical Co., China), 10% inactivated human serum, 25 mmol/L HEPES, 2 mmol/L L-glutamine, 100 U/mL penicillin and 100 μg/mL streptomycin. The cells were incubated in a humidified atmosphere containing 5% CO_2 at 37℃. Monoclonal antibody (MAb) against CD3

(100 μg/L, Antibody Diagnostic Inc., USA) and IL-1α (1.0 × 10^5 U/L, Promega) were added after 24 h culture. Supernatant was aspirated and the cells were cultured in Medium Ⅱ in the absence of INF-γ after another 48 h culture. The cells were transferred to Kolle flasks (Nunc, Denmark) and cultured in the same medium after 1 wk. The medium was changed every 3 d. The cytotoxic activity was assayed as previously described[17,21]. Patients in group Ⅰ were treated with oxaliplatin (120 mg/m^2 D1, 5-Fu 400 mg/m^2 CIV 24 h D1-5, CF 200 mg/m^2 D1-5) as previously described[22] with the doses adjusted according to the toxicity. Patients in group Ⅱ received CIK cells immunotherapy as previously described[17] after 6 cycles of chemotherapy, with 1.0 × 10^9 CIK cells transfused into the patients within 1 h.

Statistical analysis

All data were loaded into the Epidata3.0 database with double-check, and analyzed with the SAS software package (version 9.13; SAS Institute, Cary, NC, USA). The data were expressed as mean ± SD. χ^2-test or cmh2 χ^2-test was used to compare the difference in balance between the concerned clinical indexes and to find the confounding factors between the two groups. Survival data were analyzed using Kaplan-Meier method and log-rank test to estimate the median survival time, 2- and 5-year survival rates, and to determine if the survival curves for the two groups were different.

When the frequency of CIK cells immunotherapy and the survival time were introduced into the Cox model, the interaction item was significantly associated with the death of gastric cancer patients (wald-χ^2 = 4.946, P = 0.0261). A two-stage time-dependent Cox model was established to precisely estimate the hazard risk (HR) and 95% confidence interval (95% CI) of the association between the frequency of CIK cells immunotherapy and the death of gastric cancer patients. Because the median survival time of gastric cancer patients was about 36 mo, 36 mo was used as the optimum cutoff point.

The first stage Cox model involved 154 patients with a survival time of over 36 mo who were defined as survivors. Otherwise, the survival status was the same as the original definition.

The second stage Cox model only involved 56 patients with a survival time longer than 36 mo, and their survival status was defined as the original definition.

Pearson correlation test was performed between Schoenfeld residual of the frequencies of CIK cells immunotherapy and the survival time of gastric cancer patients to determine whether the frequency of CIK cells immunotherapy is a time-dependent variable in the two Cox models[23].

RESULTS

Distribution of demographic and clinical characteristics in two groups

No statistical difference was found in sex and age of the patients, tumor site, histological type, invasion depth, lymph node metastasis, pathological grade, tumor size and stage between the two groups. However, the number of patients was significantly greater in group Ⅱ with recurrent disease than in group Ⅰ (46.7% *vs* 28.4%, χ^2 = 5.566, P = 0.018) (Table 1), suggesting that more patients with relapse should receive CIK cells immunotherapy.

Demographic and clinical characteristics of patients after CIK cells immunotherapy

No statistical difference was observed in sex and age of the patients, tumor site, histological type, invasion depth, lymph node metastasis, pathological grade or tumor size after CIK cells immunotherapy (0, 1-10, 11-25, and over 25 frequencies). However, a significant difference was found in cancer recurrence and stage after CIK cells immunotherapy (Table 2).

[a]Tumor sites in some cases were repeated; [b]Because the theoretical value is less than 1, χ^2 was performed for patients who received cytokine-induced killer (CIK) cells immunotherapy at the frequencies of 11-25 and > 25, and for those who underwent CIK cells immunotherapy at the frequencies of 1-10, 11-25 and > 25; [c]Missed cases.

Survival time of patients in two groups

The survival time of gastric cancer patients in group Ⅱ was much longer than that of those in group Ⅰ (χ^2 = 10.907, P = 0.001, Figure 1). The median survival time of patients in group Ⅱ was also longer than that of those in group Ⅰ (49 mo *vs* 27 mo).

Two- and 5-year survival rates of patients in two groups

The 2- and 5-year survival rates of patients in group Ⅱ were significantly higher than those of patients in group Ⅰ (73.5% *vs* 52.6%, 40.4% *vs* 23.9%, P <0.05) (Table 3).

Survival time of patients after CIK cells immunotherapy

Because the CIK cells immunotherapy seemed effective against gastric cancer, whether the frequency of CIK cells immunotherapy affects its efficacy was determined. The survival curve was obviously higher for the patients after CIK cells immunotherapy plus chemotherapy than after chemotherapy alone. The survival time of gastric cancer patients was significantly longer after CIK cells immunotherapy than after chemotherapy (χ^2 = 14.534, P = 0.002, Figure 1).

Time-dependent Cox model analysis of CIK cells immunotherapy and prognosis of patients

The frequency of CIK cells immunotherapy was a strong time-dependent variable. A significant difference was observed in the survival time and the frequency of CIK cells immunotherapy between the two models (χ^2 = 27.990, P

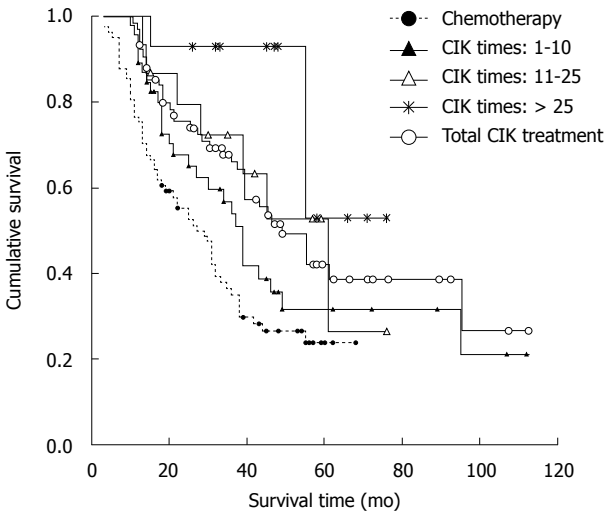

Figure 1 Survival rates of patients after cytokine-induced killer cells immunotherapy plus chemotherapy and chemotherapy alone. CIK: Cytokine-induced killer.

< 0.0001). However, it could not stratify the theoretical hypothesis of proportional hazard model. Hence, we tried to improve the analyzing results of the Cox model by dividing the patients into two stages with a relatively short survival time. Because of the relatively short interval time, the frequency of CIK cells immunotherapy may be a time-independent variable and can satisfy the assumption of proportional hazard model. The median survival time (36 mo) of the patients was used as the optimum cut-point.

In the first stage Cox model, the frequency of CIK cells immunotherapy was not a time-dependent variable, thus refusing the hypothesis of non proportional hazard model by Pearson correlation test between Schoenfeld residual of CIK cells immunotherapy frequency and survival time ($r = 0.04$, $F = 0.10$, $P = 0.751$). After the patients who remained alive beyond 36 mo after treatment were defined as survivors, the frequency of CIK cells immunotherapy was significantly associated with the decreasing risk of death in gastric cancer patients after adjustment for sex and age of the patients, tumor stage and relapse (HR = 0.54, 95% CI: 0.36-0.80) (Table 4).

In the second stage Cox model, the frequency of CIK cells immunotherapy was not a time-dependent variable ($r = 0.307$, $F = 1.98$, $P = 0.176$).When the second stage Cox model involving only 56 patients with a survival time of over 36 mo was fitted, no association was observed between the frequency of CIK cells immunotherapy and the survival time of gastric cancer patients (HR = 1.09, 95% CI: 0.63-0.89) (Table 5).

DISCUSSION

In China, gastric cancer patients are usually diagnosed at a relatively advanced stage with metastasis to other organs[24]. A number of treatment modalities are available for gastric cancer, such as surgical resection combined with chemotherapy[25,26], radiotherapy[27,28], thermotherapy[29,30] and/or traditional Chinese medicine[31,32]. However,

Table 3 Two- and five-year survival rates of gastric cancer patients in two groups

Groups	Survival rate (%)	95% CI	u-value	*P*
2-yr				
Chemotherapy	52.6	41.7-63.6	2.721	0.007
CIK treatment	73.5	63.3-83.7		
5-yr				
Chemotherapy	23.9	13.5-34.3	1.913	0.0526
CIK treatment	40.4	27.1-53.7		

CIK: Cytokine-induced killer; 95% CI: 95% confidence interval.

the 5-year survival rate of advanced gastric cancer patients is still very poor[33]. It has been shown that cellular immunotherapy can promote host anti-cancer immunity, thus prolonging the survival time of gastric cancer patients[34]. Treatment of gastric cancer with autologous CIK cells is one of the promising cellular immunotherapies[35].

The results of the present study demonstrate that CIK cells immunotherapy plus chemotherapy for gastric cancer has more potential benefits than chemotherapy alone. Therefore, the effect of adjuvant cellular therapies for gastric cancer has drawn more attention of oncologists. It has been shown that adjuvant radiotherapy and chemotherapy for gastric cancer after curative resection can improve the disease-free and overall survival time of gastric cancer patients[25,36]. Residual tumor cells after chemotherapy can be removed by the host immune system[37]. However, several cycles of chemotherapy can decrease the immune functions of gastric cancer patients[38], and have been suspected to be one of the reasons for the high relapse rate of gastric cancer after postoperative systemic chemotherapy. Immunotherapy can directly kill cancer cells and boost the immune responses against the tumor[39]. Therefore, immunotherapy should be beneficial for gastric cancer patients, and not conducive to the growth of tumor cells.

In the present study, CIK cells were obtained upon culturing PBMC in the presence of IFN-γ, IL-2, anti-CD3MAb, and IL-1α[13]. This method allows us to generate a large number of CIK cells. In addition, the anti-tumor cell activity of CIK cells is stronger than that of anti-tumor effector cells[16]. The effector cells in our culture are believed to be $CD3^+CD56^+$. CIK cells have a higher survival rate, proliferation capacity, and killing activity than their target cells[40,41], and can secrete a variety of cytokines, which further enhance the cytotoxicity of immune effector cells[42] and change the tumor microenvironment to favor cancer eradication. In addition, CIK cells can kill both autologous and allogeneic tumor cells[43,44], as well as multi-drug resistance cells and FasL-positive cells[45,46]. Accordingly, CIK cells immunotherapy combined with chemotherapy may have a synergistic effect.

Several studies[17,47-49] showed that CIK cells immunotherapy can significantly improve the immune functions of cancer patients, such as an increase in $CD3^+CD56^+$ level. However, the clinical data are not enough to demonstrate the effectiveness of CIK cells immunotherapy. The results of this retrospective study, based on the follow-up

[1]This model only involving the patients with a survival time longer than 36 mo. The survival rate of each patient was similar; [2]Pearson correlation test between Schoenfeld residual of cytokine-induced killer (CIK) cells immunotherapy frequency and survival time (r = 0.307, F = 1.98, P = 0.176); [3]Variable value definition in the Cox model (frequency of CIK cells immunotherapy: 0 = 0 time, 1 = 1-10 times, 2 = 11-25 times, 3 = more than 25 times; Sex: 1 = man, 2 = woman), age (0 = ≤ 45 yr, 1 = about 60 yr, 2 = over 60 yr), tumor stage (0 = stage Ⅰ, 1 = stage Ⅱ, 2 = stage Ⅲ, 3 = stage Ⅳ), relapse (1 = yes, 0 = no). HR: Hazard risk; 95% CI: 95% confidence interval.

of 156 gastric cancer patients, show that the frequency of CIK cells immunotherapy can significantly prolong the survival time of gastric cancer patients.

However, the frequency of CIK cells immunotherapy may significantly decrease the risk of cancer-related death in gastric cancer patients. The common Cox model was not preferred in our analysis because the balance test showed that tumor relapse and stage were different in patients of the two groups. There are two reasons that support our conclusion. First, except for tumor relapse and stage, the balance test showed the following factors, including age and sex of the patients, tumor size, site and invasiveness, lymph node metastasis and pathological grade did not affect us to assign the gastric cancer patients into groups Ⅰ and Ⅱ. Second, due to the fact that the frequency of CIK cells immunotherapy was a time-dependent variable in the Cox model, a two-stage time-dependent Cox model adjustment was made for some confounding factors (tumor relapse and stage), thus the false results were avoided when the common Cox model was used to make our analysis more reliable.

After the postoperative adjuvant chemotherapy, most residual tumor cells sensitive to chemotherapy were removed. Chemotherapy may suppress the immune function and therefore immunotherapy is necessary for boosting immunity. It was reported that the number of $CD3^+$ cells and the $CD4^+/CD8^+$ ratio are significantly lower in most gastric cancer patients than in healthy controls after chemotherapy[17]. In the present study, the number of $CD3^+$ and $CD4^+$ cells was significantly increased, while the number of $CD8^+$ cells was declined and the $CD4^+/CD8^+$ ratio was increased after CIK cells immunotherapy, suggesting that CIK cells also have an immune modulating function in addition to their anti-tumor function[50]. Single CIK cells immunotherapy has an *in vivo* effect against gastric cancer for about one month[51]. In contrast, the number of $CD3^+$ cells and the $CD4^+/CD8^+$ ratio maintain at a high level after three cycles of CIK cells immunotherapy[17].

Our study has a few limitations. First, it was a retrospective cohort/observational study rather than a strictly-designed randomized trial. Since the patients were not assigned into CIK cells immunotherapy group and chemotherapy group, imbalance of certain clinical factors between the two groups could not be avoided. Second, there were some unknown potential reasons for choice of treatment regimens, which might affect our conclusion, despite the fact that the balance test was performed and some confounding factors were adjusted in the Cox model. Therefore, a randomized clinical trial is necessary to justify the benefit of CIK cells immunotherapy for gastric cancer. The benefit of radiochemotherapy and S1 chemotherapy for gastric cancers, established in a recent clinical trial[52], is important to determine whether CIK cells immunotherapy provides additional benefit when it is used in combination with radiotherapy and chemotherapy.

In conclusion, more frequencies of CIK cells are necessary for gastric cancer. The survival time of gastric cancer patients is significantly longer after chemotherapy plus CIK cells immunotherapy than after chemotherapy alone.

COMMENTS

Background

Gastric cancer is one of the most common causes of cancer-related death in China. Although standardized surgical resection and numerous adjuvant therapeutic modalities are available for gastric cancer, the postoperative survival rate of advanced stage cancer patients remains very low. In recent years, immune therapy for malignant tumors has become the fourth important tumor treatment modality following surgery, radiotherapy and chemotherapy. Cellular immunotherapy can promote host anti-cancer immunity, thus prolonging the survival time of gastric cancer patients. Treatment with autologous cytokine-induced killer (CIK) cells is one of the promising cellular immunotherapies.

Research frontiers

A number of adoptive cells immunotherapy have been reported, including using lymphokine activated killer cells, tumor infiltrating lymphocytes, and anti-CD3 monoclonal antibody-induced killer cells. However, their therapeutic efficacy is limited due to their low anti-tumor activities. CIK cells, a new type of anti-tumor effector cells, can proliferate rapidly *in vitro*, with a stronger anti-tumor activity and a broader spectrum of tumor targets than the reported anti-tumor effector cells. Moreover, CIK cells can regulate and enhance immune function.

Innovations and breakthroughs

CIK cells immunotherapy can decrease levels of tumor markers, change immune functions, and achieve a short-term efficacy against gastric cancer. However, the relation between the frequency of CIK cells immunotherapy and its clinical efficacy has not been examined. In the present study, data obtained from 156 gastric cancer patients were used in fitting multivariate Cox model, showing that more frequencies of CIK cells immunotherapy improve the survival rate of gastric cancer patients.

Applications

The survival time of gastric cancer patients was significantly longer after chemotherapy plus CIK cells immunotherapy than after chemotherapy alone, and more frequencies of CIK cells immunotherapy benefited gastric cancer patients more. This strategy can be applied in treatment of gastric cancer.

Terminology

CIK cells are cytokine-induced killer cells and a new type of anti-tumor effector cells, which can proliferate rapidly *in vitro* with a stronger anti-tumor activity and a broader spectrum of tumor targets than the reported anti-tumor effector cells. Moreover, CIK cells can regulate and enhance immune function.

Peer review

This study showed beneficial effect of CIK cells immunotherapy on gastric cancer, thus improving the 2- and 5-year survival rates of gastric cancer patients. The study is well designed and the data are believable.

Acknowledgments to reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

January 25-26
Tamilnadu, India
International Conference on Medical Negligence and Litigation in Medical Practice

January 25-29
Waikoloa, HI, United States
Selected Topics in Internal Medicine

January 26-27
Dubai, United Arab Emirates
2nd Middle East Gastroenterology Conference

January 28-30
Hong Kong, China
The 1st International Congress on Abdominal Obesity

February 11-13
Fort Lauderdale, FL, United States
21th Annual International Colorectal Disease Symposium

February 26-28
Carolina, United States
First Symposium of GI Oncology at The Caribbean

March 04-06
Bethesda, MD, United States
8th International Symposium on Targeted Anticancer Therapies

March 05-07
Peshawar, Pakistan
26th Pakistan Society of Gastroenterology & Endoscopy Meeting

March 09-12
Brussels, Belgium
30th International Symposium on Intensive Care and Emergency Medicine

March 12-14
Bhubaneswar, India
18th Annual Meeting of Indian National Association for Study of the Liver

March 23-26
Cairo, Egypt
14th Pan Arab Conference on Diabetes PACD14

March 25-28
Beijing, China
The 20th Conference of the Asian Pacific Association for the Study of the Liver

March 27-28
San Diego, California, United States
25th Annual New Treatments in Chronic Liver Disease

April 07-09
Dubai, United Arab Emirates
The 6th Emirates Gastroenterology and Hepatology Conference, EGHC 2010

April 14-17
Landover, Maryland, United States
12th World Congress of Endoscopic Surgery

April 14-18
Vienna, Austria
The International Liver Congress™ 2010

April 28-May 01
Dubrovnik, Croatia
3rd Central European Congress of surgery and the 5th Croatian Congress of Surgery

May 01-05
New Orleans, LA, United States
Digestive Disease Week Annual Meeting

May 06-08
Munich, Germany
The Power of Programming: International Conference on Developmental Origins of Health and Disease

May 15-19
Minneapolis, MN, United States
American Society of Colon and Rectal Surgeons Annual Meeting

June 04-06
Chicago, IL, United States
American Society of Clinical Oncologists Annual Meeting

June 09-12
Singapore, Singapore
13th International Conference on Emergency Medicine

June 14
Kosice, Slovakia
Gastro-intestinal Models in the Research of Probiotics and Prebiotics-Scientific Symposium

June 16-19
Hong Kong, China
ILTS: International Liver Transplantation Society ILTS Annual International Congress

June 20-23
Mannheim, Germany
16th World Congress for Bronchoesophagology-WCBE

June 25-29
Orlando, FL, United States
70th ADA Diabetes Scientific Sessions

August 28-31
Boston, Massachusetts, United States
10th OESO World Congress on Diseases of the Oesophagus 2010

September 10-12
Montreal, Canada
International Liver Association's Fourth Annual Conference

September 11-12

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.
