Abstract

AIM: To investigate the relation between gastric cancer and microsatellite instability (MSI), loss of heterozygosity (LOH) and promoter region methylation.

METHODS: Fifty primary gastric carcinoma specimens were collected from patients with no family history of cancer. In addition, normal tissues were also collected from patients as controls. DNA was extracted by polymerase chain reaction for single-strand conformation polymorphism, bisulfite DNA sequencing, and methylation-specific band analysis.

RESULTS: The positive rate for MSI and LOH in gastric carcinoma was 16% and 20%, respectively. According to the tumor, node and metastasis staging

system, the LOH frequency was higher in gastric carcinoma at stages III and IV than in gastric carcinoma at stages I and II ($P = 0.01$), which was also significantly correlated with lymph node metastasis and clinicopathological characteristics of gastric carcinoma. Methylation of bone morphogenetic protein 3 (*BMP3*) gene promoter was detected in 64.44% of gastric carcinoma tissue samples. However, no statistical significance was observed between promoter region methylation and carcinoma differentiation. Interestingly, the *BMP3* gene methylation rate was 71.05% and 28.58%, respectively, in MSI positive and negative cases ($P = 0.031$), suggesting that *BMP3* genetic instability and promoter methylation are initiated during gastric carcinogenesis. LOH was detected mostly in the late stages of gastric carcinoma, indicating that gastric carcinoma at late stages has a higher infiltration and a poorer prognosis.

CONCLUSION: Promotor region methylation of the *BMP3* gene may cause gastric carcinoma in Chinese people.

INTRODUCTION

Gastric carcinoma is one of the leading causes of cancer-related death in China. Its incidence and mortality are increasing in Chinese people. Research has been focused on the development of cancer and its progression, by studying epigenetics and tumor suppressor genes. It was reported that microsatellite instability (MSI) and loss of heterozygosity (LOH) are associated with gastric cancer^[1-5]. In addition, gene promoter region hypermethylation can activate certain tumor suppressor genes. Most of the MSI and LOH studies have been focused on *p53*^[6], *p16* and fragile histidine triade genes^[7] with less efforts made on the role of bone morphogenetic protein (BMP) 3 epigenetics in tumor suppressor genes.

BMP3, belonging to the transforming growth factor β superfamily proteins, plays an important role in embryonic development by inducing and patterning early skeletal formation. It has been recently reported that *BMP3* is associated with tumor development and progression^[8]. However, no report is available on the role of *BMP3* in gastric carcinoma development. The present study was to investigate the D4S2922 and D4S2964 loci in 4q21 region of the *BMP3* gene by examining their MSI, LOH as well as the promoter region methylation and to reveal the relation between *BMP3* gene and gastric carcinogenesis.

MATERIALS AND METHODS

Gastric carcinoma specimens

Fifty gastric carcinoma samples were obtained from patients with no family history of cancer and normal tissue samples were also collected from patients as controls. The study was approved by the Ethics Committee and patient families before chemotherapy and radiotherapy.

DNA extraction and polymerase chain reaction (PCR)

DNA was extracted from gastric carcinoma and normal tissue samples using a QIAGEN kit according to its manufacturer's instructions. PCR for D4S2922 was performed using the primers (sense: 5'-TGCTTATGCAAGAG-GTTGTTTC-3' and antisense: 5'-AAAGGGCAGT-TAGGGATGCT-3') and for D4S2964 using the primers of (sense: 5'-CTTCCTTCCCAACTCACACA-3' and antisense: 5'-GGTCATTCATGCAATCCACA-3'). Thirty-five PCR amplification cycles were performed at 94°C for 1 min (denaturation), at 59°C for 1 min (annealing), and at 72°C for 1 min (extension) in a 25 μ L reaction buffer containing 1.0 mmol/L MgCl₂ and PCR buffer (QIAGEN PCR kit). The PCR products were resolved in 2% agarose gels. The fragment size of D4S2922 and D4S2964 was 230 bp and 164 bp, respectively.

Single-strand conformation polymorphism (SSCP) analysis

For SSCP analysis, 3 μ L of each amplification product was added to 3 μ L denaturing buffer containing 98% formamide and 0.09% bromophenol blue. The samples

were heat-denatured at 98°C for 10 min and then placed on ice for 10 min. The denatured DNA was electrophoresed on 8% non-denaturing polyacrylamide gels (140 V for 2 h, 4°C). SSCP patterns on the gels were visualized with silver staining.

Bisulfite DNA sequencing analysis

Using a CpGenome™ fast DNA modification kit (Chemicon International, Inc.), genomic DNA (1 μ g) in a volume of 100 μ L was denatured with 7 μ L of 3 mol/L NaOH freshly prepared at 37°C for 10 min, 550 μ L of freshly prepared DNA modification reagent was then added and the reaction was continued at 55°C for 16-20 h. The modified DNA was cooled on ice for 5 min before 750 μ L binding buffer was added. After centrifugation, the products were washed with 750 μ L 1 \times washing buffer and denatured with 50 μ L 20 mmol/L NaOH/90% EtOH for 10 min, followed by an additional 750 μ L 1 \times washing buffer. The eluted products were stored at -20°C for use.

Methylation-specific PCR analysis

Primers (sense: 5'-GGAGTTTAATTTTGGTTTT-GTTGTT-3' and antisense: 5'-ATCAACTCCCAACATCACTACA-3') were used for the nonmethylated specific *BMP3* gene, yielding a PCR product of 73 bp. Primers (sense: 5'-GTTTAATTTTCGGTTTCGTCGTCGT-3' and antisense: 5'-GTCGACTCCCGACGTCG TACG-3') were used for the methylated specific *BMP3* gene, yielding a PCR product of 70 bp. After an initial preheating step at 94°C for 10 min, 40 cycles of PCR were performed at 94°C for 30 s, at 64°C for 45 s, at 72°C for 75 s, and a final extension at 72°C for 10 min. The amplified PCR products were examined on 8% agarose gels.

Band analysis

PCR-SSCP showed one main band of the D17S396 locus in normal lymph node genomic DNA. The presence of two main bands indicated that a sample could be further evaluated in LOH analysis. LOH was considered when less than 50% bands or a lower band density was found in tumor tissue samples than in normal tissue samples, while MSI was considered when more than 50% bands or a band migration was observed in tumor tissue samples.

Statistical analysis

All data were analyzed with SPSS version 16.0 by one-way ANOVA and *t*-test. *P* < 0.05 was considered statistically significant.

RESULTS

Correlation between *BMP3* genetic instability and clinicopathological features of gastric carcinoma

Both D4S2922 and D4S2964 from tumor and normal tissue samples were successfully amplified and the bands on gel images were heterozygous for the allele. Com-

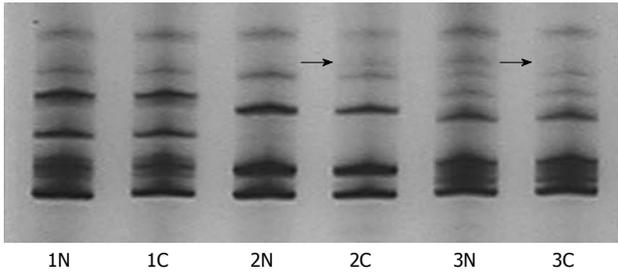

Figure 1 Polyacrylamide gel electrophoresis (PAGE) of bone morphogenetic protein 3 (*BMP3*) gene. No difference was found between tumor tissue (1C) and normal tissue (1N). Compared with normal tissue (2N), positive MSI was represented as an added allele band (arrow) in tumor tissue (2C). Compared with normal tissue (3N), positive LOH was represented as lacking an allele band (arrow) in tumor tissue (3C).

Table 1 Relation of genetic instability and methylation of *BMP3* gene with clinicopathological features of gastric cancer

Clinicopathological features	MSI		LOH	
	%	(+ / n)	%	(+ / n)
Differentiation degree	16.00	(8/50)	20.00	(10/50)

Negative	23.53	(4/17)	0.00 ^b	(0/17)
TNM stage				
I + II	15.16	(5/33)	6.06	(2/33)
III + IV	17.65	(3/17)	47.05 ^c	(8/17)

^b*P* < 0.001 *vs* positive lymph node metastasis; ^c*P* = 0.01 *vs* TNM stages I + II. MSI: Microsatellite instability; LOH: Loss of heterozygosity; *BMP3*: Bone morphogenetic protein 3; TNM: Tumor, node and metastasis.

pared with the normal tissue samples, MSI was considered when more bands were found in gastric carcinoma tissue samples and LOH was considered when less bands were observed in gastric carcinoma tissue samples (Figure 1). A *BMP3* was considered positive when the two loci showed at least one MSI or one LOH.

In the present study, 16.00% of the gastric carcinoma tissue samples were positive for MSI of the *BMP3* gene (Table 1). However, MSI was not correlated with tumor differentiation, infiltration, lymphatic metastasis and tumor, node and metastasis (TNM) staging. The frequency of LOH was 20.00% (Table 1). Interestingly, LOH was significantly related with lymphatic metastasis and TNM staging of gastric carcinoma. The frequency of LOH was not correlated with differentiation and infiltration of gastric carcinoma and much higher in gastric carcinoma with lymph node metastasis than in gastric carcinoma without lymph node metastasis (30.30% *vs* 0.00%, *P* < 0.05). The LOH detection rate was higher in tumors at stages III and IV than in tumors at stages I and II (47.05% *vs* 6.06%, *P* < 0.01).

Relation between *BMP3* gene promoter region methylation and clinicopathological features of gastric carcinoma

The methylation status in promoter region of *BMP3* gene was analyzed by methylation-specific PCR (Table 1). Positively methylated *BMP3* promoter region was found in 45 of the 50 gastric carcinoma tissue samples, with a methylation rate of 64.44%. The frequency of methylation in normal tissue was 53.49% (43/50) with no statistical difference between gastric carcinoma and normal tissue samples (*P* > 0.05). In addition, *BMP3* gene promoter region methylation was not correlated with tumor differentiation, infiltration, lymphatic metastasis and clinical TNM staging.

Correlation between gastric carcinoma gene *BMP3* instability and its promoter region methylation

The frequency of *BMP3* gene promoter region methylation was much lower in MSI negative than in MSI positive cases (28.58% *vs* 71.05%, *P* < 0.05, Table 2). However, the frequency of *BMP3* gene promoter region methylation was 68.75% and 50.00%, respectively, in LOH negative and positive cases with no statistical difference.

DISCUSSION

Microsatellites are the short sequences of DNA, usually 2-6 base pairs in a row along a DNA molecule. MSI is mutations in genes, whereby repair of damaged DNA causes microsatellite-associated regions to become longer or shorter. LOH in a cell represents the loss of normal function in one allele of a gene in which the other alleles have been inactivated. MSI and LOH play an

important role in tumor development and progression. LOH occurs when the remaining functional allele in a somatic cell of the offspring becomes inactivated due to mutation. No normal tumor suppressor is produced, thus resulting in tumorigenesis^[9].

Microsatellites were first reported in 1981 by Miesfeld *et al*^[10] and further elucidated in 1993 by Aaltonen *et al*^[11] who revealed a higher MSI frequency in hereditary non-polyposis colorectal cancer cells. MSI has been reported in colon, gastric, cervical, breast, prostate and pancreatic carcinomas^[12-17].

Alexander *et al*^[18] investigated the sporadic colon carcinoma cases and found that MSI occurs in early stages with a better prognosis, suggesting that MSI can serve as an early diagnostic index for gastric and colon carcinomas. Our previous report also demonstrated that the frequency of MSI is higher in D17S396 loci of the *nm23H1* gene in gastric and colon carcinomas at stages I and II with a better prognosis than in those at stages III and IV with a worse prognosis, suggesting that MSI can serve as an early diagnostic index for gastric and colon carcinomas^[19]. In this study, however, no statistical significance was found between MSI of *BMP3* gene and tumor differentiation, infiltration, lymphatic metastasis and tumor TNM staging.

Berney *et al*^[20] showed that the LOH frequency of *nm23H1* gene is significantly correlated with tumor infiltration and metastasis. Candusso *et al*^[21] reported that LOH is more frequently found in late stage tumors, often with lymphatic metastasis. In our study, the LOH frequency of *BMP3* gene was much higher in gastric carcinomas at stages III and IV with lymphatic metastasis than in those at stages I and II without lymphatic metastasis, suggesting that LOH occurs more often in late tumor stages with lymphatic metastasis and can thus serve as an index for the evaluation of malignancy, metastasis and prognosis of gastric carcinomas.

DNA methylation is believed to be closely associated with tumor development and progression. Reduced methylation and hypermethylation in gene promoter regions can inactivate tumor suppressor genes, leading to tumor development. In the present study, the methylation level in promoter region of *BMP3* gene in gastric carcinomas was high, leading to the occurrence of gastric carcinoma. Loh *et al*^[8] reported that *BMP3* gene methylation is associated with MSI in colon cancer, indicating that the higher the methylation is, the higher the MSI frequency is. In this study, the level of methylation was higher in MSI negative than in MSI positive gastric carcinoma cases, which is not consistent with the findings of Loh *et al*^[8]. Further study is needed to verify the differences.

In conclusion, genetic instability of the *BMP3* gene and promoter region methylation occur in gastric carcinomas, thus affecting tumor characteristics through different pathways. LOH is observed more frequently in late stage tumors with infiltration. Hypermethylation in promoter region of *BMP3* gene may result in gastric carcinoma in Chinese people.

COMMENTS

Background

Gastric carcinoma is one of the leading causes of cancer-related death in China. Its incidence and mortality are increasing in Chinese people. Microsatellite instability (MSI) and loss of heterozygosity (LOH) are known to be associated with gastric cancer. Moreover, gene promoter region hypermethylation can inactivate certain tumor suppressor genes.

Research frontiers

Genetic instability and gene promoter region methylation play an important role in gene mutation, gene inactivation, and carcinogenesis. However, the role and mechanism of bone morphogenetic protein 3 (*BMP3*) in cancer development are poorly characterized. The relation between the development of gastric cancer and the number of altered microsatellite loci (D4S2922 and D4S2964), LOH, and promoter region methylation was elucidated in the present study.

Innovations and breakthroughs

In the present study, the methylation levels in promoter region of *BMP3* gene in gastric carcinoma was high, which may lead to gastric carcinoma and is not consistent with the reported findings. The methylation level was higher in MSI negative than in MSI positive gastric carcinoma.

Applications

MSI and LOH of the *BMP3* gene can serve as an index for the evaluation of malignancy, metastasis and prognosis of gastric carcinoma.

Terminology

MSI is a condition manifested as damaged DNA due to defects in normal DNA repair process. LOH in a cell represents the loss of normal function in one allele of a gene in which the other allele has been inactivated.

Peer review

The paper is well-written and interesting. *BMP3* gene, MIS, LOH and promoter region methylation were evaluated in patients with gastric adenocarcinoma, thus making an additional contribution to studies on the role of MIS and LOH in carcinogenesis.

Abstract

We report a case of severe thrombocytopenia following pegylated interferon- α 2a (Peg-IFN- α 2a) treatment of hepatitis C virus infection and summarize the clinical characteristics of 16 cases of IFN- α induced severe thrombocytopenia and its immune-mediated mechanism. Discontinuation of IFN- α and early administration of immunosuppressants are the effective therapy for IFN- α induced severe thrombocytopenia.

INTRODUCTION

Interferon- α (IFN- α) and pegylated IFN- α 2a (Peg-IFN- α 2a) are the effective antiviral drugs for chronic liver diseases. However, IFN- α is associated with a number of side effects, including mild thrombocytopenia, a common adverse effect largely ascribed to bone marrow suppression. IFN- α treatment-associated severe thrombocytopenia, like immune thrombocytopenia or thrombotic thrombocytopenic purpura, has rarely been reported in the literature. Here, we report a patient who developed immune thrombocytopenia 3 mo following Peg-IFN- α 2a (Pegsys, Roch) treatment and report the clinical features of severe thrombocytopenia.

CASE REPORT

A 54-year-old female was diagnosed as chronic hepatitis C virus (HCV) infection in 1998. Laboratory test showed that her serum anti-HCV and HCV RNA were positive, viral genotype was 1b, and serum alanine aminotransferase (ALT) level was 60-100 U/L. The patient was treated with standard recombinant IFN- α 2a (Roch, 3 MU), 3 times per week, at a clinic in 2003. Hepatic cirrhosis was excluded before treatment. Her auto-antibodies including antinuclear antibody (ANA), anti-smooth muscle antibody (ASMA) and anti-thyroid antibody were negative. HCV RNA turned negative 1 mo after treatment with IFN- α 2a. Three months later, IFN- α 2a was discontinued due to adverse effects, including poor appetite, fatigue, nausea and mild gingival bleeding. Her platelet (PLT) count was slightly decreased to $80 \times 10^9/L$. Six months later, her HCV RNA was positive again and she administered no antiviral drugs.

In May 2008, the patient felt mild fatigue. Laboratory test showed that the levels of HCV RNA, ALT, and AST were 1.5×10^5 copies/L, 67 U/L (normal < 40 U/L), and 42 U/L (normal < 40 U/L), respectively, while her PLT count was $110 \times 10^9/L$ and the aforementioned auto-antibodies were negative. One month after treatment with

Peg-IFN- α 2a (180 μ g, *sc*, once a week), her HCV RNA turned negative with normal ALT and peripheral blood cell count. After discharged from hospital, she continued to administer the same dose of Peg-IFN- α 2a and was followed up. Three months later, the patient was admitted to our hospital again due to severe gingival bleeding, fatigue, poor appetite, and nausea. Laboratory test on admission showed that her haematocrit was 29.2%, leucocyte count was 3.23×10^9 /L (including 76.5% of polymorphonuclear cells, 15.2% of lymphocytes, and 6.8% of monocytes), PLT count was 2×10^9 /L, ALT was 53.6 U/L, AST was 44.9 U/L, total bilirubin was 5.2 μ mol/L, prothrombin time was 10.5 s, activated partial thromboplastin time (APTT) was 30.9 s, fibrinogen was 2.82 g/L and HCV RNA was negative. Bone marrow aspirate showed a large number of megakaryocytes in her hypercellular marrow with few granules, scanty cytoplasm and no PLT around. Indirect immunofluorescence showed a high anti-platelet IgG titer (1:1280, normal < 1:80) and negative ANA and ASMA. Complements C₃ and C₄ were 0.79 g/L (range: 0.88-2.01 g/L) and 0.13 g/L (range: 0.16-0.47 g/L), respectively. B-mode gray scale ultrasonography showed no splenomegaly.

She was diagnosed as immune-mediated thrombocytopenia with Peg-IFN- α 2a highly suspected as its cause. Peg-IFN- α 2a was discontinued and two units of PLT was transfused on the day at admission. The PLT count was then increased to 27×10^9 /L, but decreased to 1×10^9 /L on the second day with a mild fever caused by rapid destruction of PLT. Immunoglobulin (400 mg/kg) and intravenous methylprednisolone (1 mg/kg per day) were administered during the following 5 d. On day 7, PLT count was increased to 33×10^9 /L, and methylprednisolone was replaced with prednisone (30 mg/d). Two weeks later, her PLT count was increased to 107×10^9 /L, and prednisone was withdrawn 1 mo later. Her PLT count remained normal during the follow-up, but her HCV RNA turned positive 3 mo after discharge. She has not received any other antiviral therapy since then.

DISCUSSION

In this case, Peg-IFN- α 2a was considered the cause of autoimmune thrombocytopenia due to the following reasons^[1]. First, thrombocytopenia presented following Peg-IFN- α 2a treatment and recovered after the drug was discontinued. Second, Peg-IFN- α 2a was the only candidate drug used before the onset of thrombocytopenia. Third, etiologies unrelated with drugs, such as splenomegaly, viral infection, acute hepatitis, and aplastic anemia, were excluded. Fourth, re-exposure to Peg IFN- α 2a resulted in recurrence of thrombocytopenia. Fifth, anti-PLT antibody was positive and bone marrow aspirate showed signs of megakaryocytic hyperplasia. All these factors suggest that immune-mediated mechanism is involved in thrombocytopenia.

IFN- α is one of the drugs inducing thrombocytopenia. Based on its pathogenesis, drug-induced throm-

bocytopenia is usually due to bone marrow suppression, immune-mediated destruction, and PLT aggregation^[2]. Acute thrombocytopenia can often present as immune-mediated thrombocytopenia or PLT aggregation thrombocytopenia, whereas a slow decline of PLT often indicates a thrombocytopenia due to marrow suppression. In this case, the number of thrombocytes was rapidly decreased to 1×10^9 /L after PLT transfusion due to acute damage of PLTs. Elevated level of anti-PLT antibody and decreased level of complements C₃ and C₄ support that immune-mediated mechanism is involved in the pathogenesis of thrombocytopenia.

Only few reports are available on IFN- α -induced severe thrombocytopenia (Table 1). A PubMed search with the key words 'interferon α ' and 'thrombocytopenia' yielded 16 reports. Common IFN- α (9 cases) and Peg-IFN- α 2a (8 cases) were found to be associated with IFN- α -induced immune-mediated thrombocytopenia.

The mean age of the patients was 44.06 ± 14.27 years (range: 20-73 years). No significant difference was observed in gender. All the patients were infected with HCV. Serotype or genotype was examined in 7 cases. Of them, 4 had serotype 1b, 2 had genotype 3 and 1 had genotype 4. Since only a small number of cases were examined, whether the serotype 1b is more susceptible to immune-mediated thrombocytopenia than other types of thrombocytopenia needs to be further studied.

The median time from administration of IFN- α to the onset of thrombocytopenia was 3.6 mo (range, 1-36 mo). Fifteen out of 17 (83%) cases had epistaxis, gingival bleeding, oral mucosa bleeding, petechia, skin ecchymosis of trunk or lower extremities but no severe internal organ bleeding. The average PLT count was $(4.8 \pm 3.1) \times 10^9$ /L. The anti-platelet antibody or platelet-associated IgG was positive in 12 and negative in 3 of the 17 (67%) cases, respectively, but not detected in 2 cases. Bone marrow aspirates showed signs of megakaryocytic hyperplasia with decreased platelet count in 16 patients. Besides the discontinuation of IFN- α /Peg-IFN- α 2a and administration of immunosuppressants (Table 1), two cases received platelet transfusion and ten cases received immunoglobulin simultaneously. The PLT count of all patients was gradually increased within 2 wk and recovered finally with no severe bleeding or death occurred, indicating that IFN- α induced severe thrombocytopenia can be reversed by discontinuing IFN- α /Peg-IFN- α 2a and giving immunosuppressant in time.

Interestingly, all the 17 cases had hepatitis C virus (HCV) infection rather than hepatitis B or other virus infections. Extrahepatic manifestations including thrombocytopenia were more frequently observed in HCV infection rather than in other virus infection^[3]. HCV-related immune thrombocytopenia has been reported by Nakajima *et al*^[4]. It was also reported that IFN- α can exacerbate thrombocytopenia by triggering the production of auto-antibodies in patients with HCV infection^[5]. However, no patient with thrombocytopenia or positive anti-platelet antibodies has been reported in the literature

before interferon treatment, indicating that interferon may increase the incidence of ITP in HCV-infected patients.

IFN- α has been widely used not only in treatment of viral infections but also in treatment of malignancies, skin diseases, and myeloproliferative disorders. IFN- α induced thrombocytopenia also occurs not only during antiviral treatment but also during treatment of other malignant diseases such as chronic myeloid leukemia^[6], and renal cell carcinoma^[7]. It is, therefore, essential for clinicians to recognize the disorder early and give patients appropriate treatment for a favorable prognosis.

In conclusion, severe immune-mediated thrombocytopenia may occur during IFN- α /Peg-IFN- α 2a treatment, especially in chronic HCV-infected patients. Discontinuation of IFN- α and administration of immunosuppressant is the key to the avoidance of severe bleeding or death due to thrombocytopenia.

Abstract

Insulinomas are the most common category of pancreatic endocrine tumors, with an annual incidence of 1-4 cases per million people. Most are intrapancreatic, benign and solitary. Therefore, they have an excellent prognosis after surgical resection. However, the localization diagnosis of insulinomas still poses a challenge to surgeons and radiologists. In this case, the tumor was occult and could not be found by either abdominal enhanced spiral computed tomography (CT) or ultrasonography. Therefore, we tried a new method of CT scanning and localized the tumor.

INTRODUCTION

Insulinomas are the most common category of pancreatic endocrine tumors, with an annual incidence of 1-4 cases per million people. Most are intrapancreatic, benign and solitary. Therefore, they have an excellent prognosis after surgical resection. However, the localization diagnosis of insulinomas still poses a challenge to surgeons and radiologists. Eighty to ninety percent of insulinomas are < 2 cm in size and the lesions are distributed equally throughout the head, body and tail of the pancreas^[1]. Thus, localization diagnosis before operation is important.

In the present case, the tumor was occult and could not be found by either abdominal enhanced spiral computed tomography (CT) or ultrasonography. Therefore, we tried a new method of CT scanning and localized the tumor. This paper introduces the method.

CASE REPORT

A 38-year-old man presented with a typical Whipple's triad. He often suffered from symptoms of hypoglycemia such as hunger, sweating, palpitations, loss of consciousness and syncope. When these symptoms occurred, the blood glucose level was always below 2.48 mmol/L, and the symptoms could be relieved after being given glucose. These symptoms had lasted 14 years. During that time, he had been to many hospitals for treatment, but none of them

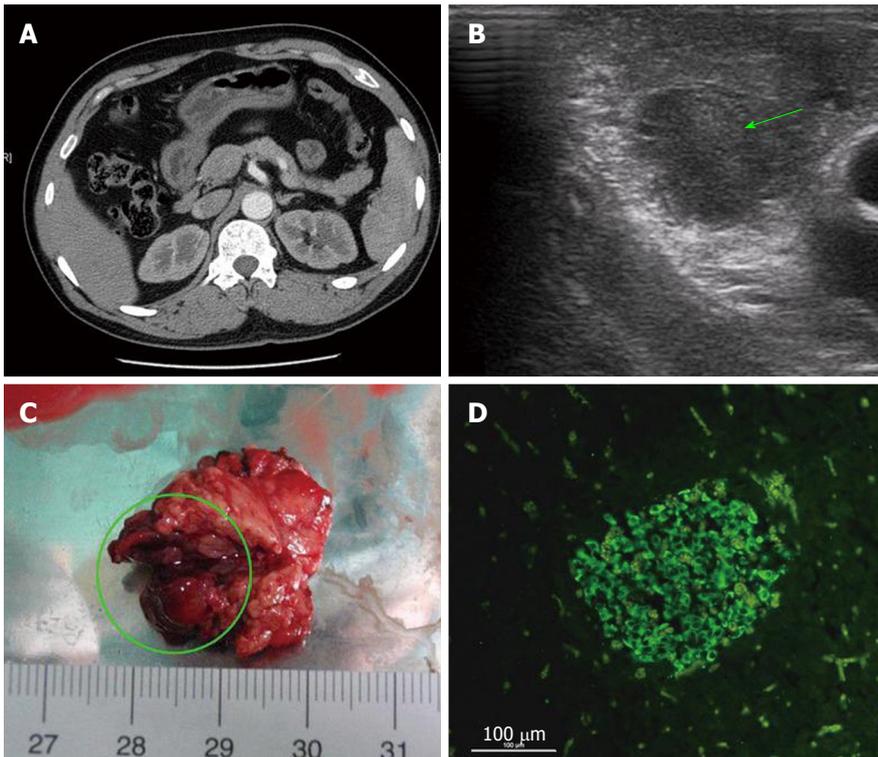

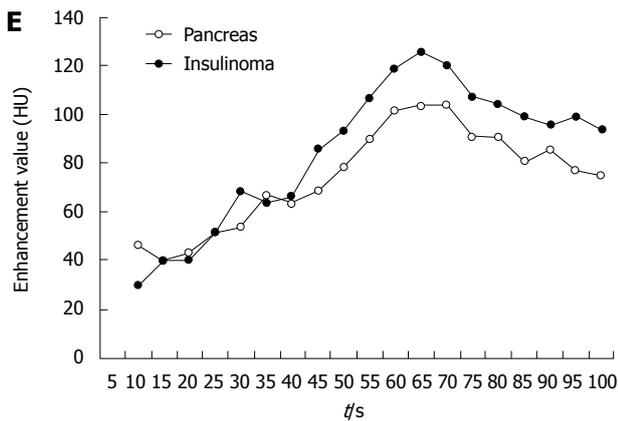

Figure 1 Clinical images related to this case and linear analysis of pancreatic dynamic enhanced spiral CT. A: Negative result of abdominal enhanced spiral CT; B: We used intraoperative ultrasonography to detect the tumor and to determine the location relationship between the tumor and the main pancreatic duct. Fortunately, the tumor (green arrow) did not adjoin the main pancreatic duct. Therefore, we performed simple tumor resection; C: The insulinoma (green circle) (1.4 cm × 1.4 cm × 1.2 cm) was resected; D: Microscopic image of the insulinoma after immunostaining (× 400); E: Enhancement value of the pancreas and insulinoma at each time point after the onset of contrast material injection. The enhancement value peak of the tumor appeared at 65 s. As the interval of tumor-to-pancreas contrast was not obvious (mostly it is < 20 HU), the insulinoma was occult and difficult to find.

could localize the tumor, and no one was willing to perform an exploratory operation. This time in our hospital, we tried abdominal enhanced spiral CT (Figure 1A) and ultrasonography to localize the tumor, but neither was successful. Then, the patient underwent selective arterial calcium stimulation with hepatic venous sampling. The data from the test suggested that the tumor was in the head or neck of the pancreas. Therefore, we designed a new method of CT scanning. The CT machine we used was Lightspeed VCT 64-row detector (GE Healthcare, Milwaukee, WI, USA). We chose the pancreas as the object of scanning. We use non-enhanced CT to define the range of the pancreas. After that, we started to inject contrast material (50 mL in total) by using a technology called intra-arterial infusion^[2]. The injection rate was 4 mL/s. Ten seconds after the onset of injection, the dynamic enhanced CT scanning started. It was designed to scan the whole pancreas from top to bottom in 1 s. This was repeated for 90 s. The slice thickness was 5 mm.

The insulinoma was finally localized in the body of the pancreas (adjoining the neck) (Figure 2). Then, with the help of intraoperative ultrasonography (Figure 1B), we performed the operation successfully. The tumor was about 1.4 cm × 1.4 cm × 1.2 cm in size (Figure 1C) and was proven to be an insulinoma by immunopathology (Figure 1D). After resection of the insulinoma, the patient was followed up for 6 mo. His blood glucose level was in the normal range, and no symptoms of hypoglycemia recurred.

DISCUSSION

Some researchers have advocated that preoperative localization diagnosis is not necessary because most insulinomas can be localized by operative exploration. Others insist that preoperative localization diagnosis is necessary and valuable for surgery^[1,3]. Preoperative localization is very helpful in planning the operation: it allows the sur-

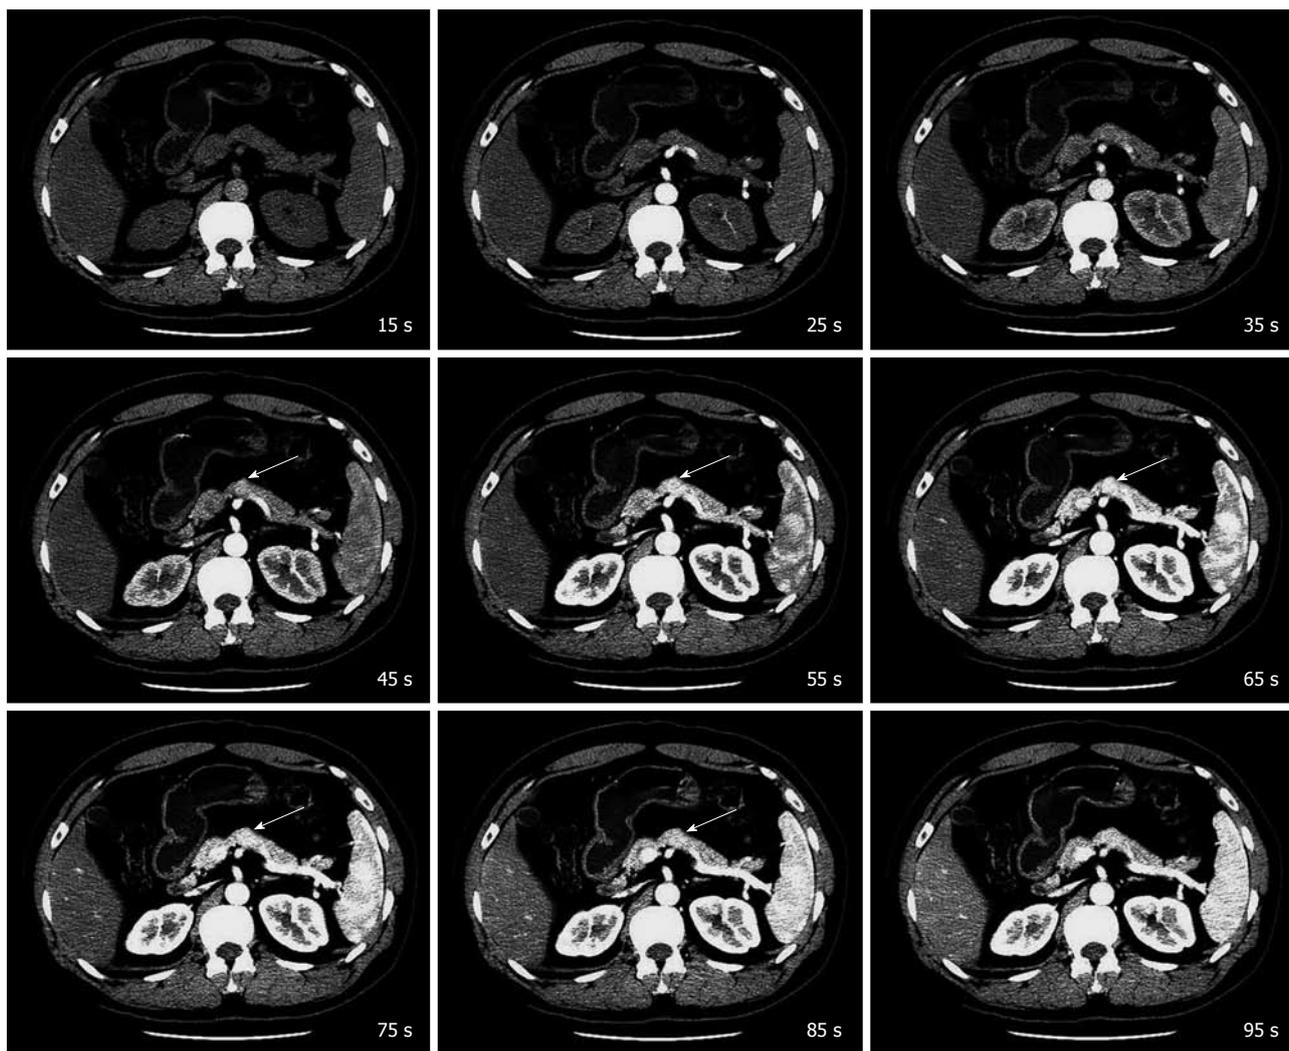

Figure 2 Images of pancreatic dynamic enhanced spiral CT showed the localization of the insulinoma (white arrows). It was in the body of the pancreas (adjoining the neck). The tumor started to enhance from 45 s after the onset of contrast material injection, and could be seen until 85 s. As the contrast between the insulinoma and the pancreas was not obvious, the tumor was difficult to find by other conventional imaging techniques.

geon to determine whether simple tumor resection or partial pancreatectomy is likely to be required. Furthermore, it avoids prolonging the duration of surgery and potential intraoperative damage to major structures.

The advent of spiral CT has improved the detection of insulinomas compared with conventional CT. The sensitivity of CT scanning is significantly higher than it was 15 years ago^[4]. A retrospective study showed that 63% of insulinomas could be detected by multiphasic spiral CT prospectively, and 83% of the lesions could be seen in retrospect^[5]. However, occult insulinomas are not rare. There is still argument about which phase is more sensitive in detecting insulinoma. Some subscribe to the arterial phase, whereas others espouse that the pancreatic phase may be more useful^[5]. Furthermore, different injection rates of contrast material may have great effects on enhancement of tumor and pancreas contrast. Also, the time point of the peak may be different^[6,7].

Therefore, when we are confronted with an occult insulinoma, how should we localize the tumor by CT

scanning? And why is abdominal dual-phase spiral CT not able to find the tumor in these patients? First of all, the interval of occult insulinoma-to-pancreas contrast is not obvious. We know that tumor delineation is based mainly on the interval of tumor-to-pancreas contrast during contrast-enhanced CT. Generally speaking, when the interval of tumor-to-pancreas contrast exceeds 30 HU, it is relatively easier to distinguish the tumor from the surrounding pancreas^[6]. However, in this case, the interval of tumor-to-pancreas contrast was less than 20 HU most of the time. The largest interval was only 21.9 HU, and appeared at 65 s (Figure 1E). Secondly, as with the individual differences, the time point of the enhancement value peak of the tumor is uncertain. Thus, it is possible that abdominal dual-phase spiral CT cannot catch the time point of the peak. For these reasons, we designed the pancreatic dynamic consecutive enhanced CT scanning. It is able to display images of each time point (containing the arterial, pancreatic and portal venous phases). Also, it supplies a large number of images for radiologists

to search the tumor. Therefore, when we are confronted with an occult insulinoma, pancreatic dynamic consecutive enhanced CT scanning may help us to localize the tumor.

Abstract

The authors report a giant hepatocellular carcinoma (HCC) with a diameter over 30 cm and weight over 10 kg that was resected completely. A 62-year-old man was admitted because of continuous abdominal uplift. A computed tomography scan demonstrated that the entire abdomen was filled with a giant tumor containing both cystic and solid components with a size of 29 cm × 22 cm. The huge tumor was successfully resected without any complication, such as massive hemorrhage or visceral injuries. The size and weight of the tumor were 35 cm × 30 cm × 15 cm and 10050 g, respectively. Pathological examination showed that the tumor was a well-differentiated HCC, and α -fetoprotein was positive. Postoperative syndrome, characterized by hypovolemic shock, diarrhea and urine retention, was observed and induced by abdominal decompression. This syndrome was resolved with expectant treatment. The patient was still alive without recurrence after a 27-mo follow-up.

INTRODUCTION

Primary hepatocellular carcinoma (HCC) is the most common malignant tumor in Asia, especially in China. Liver neoplasms with diameters of ≤ 5 cm, 5-10 cm, and > 10 cm are designated as small, big, and giant HCC, respectively^[1]. However, a diameter over 20 cm is extremely rare. Here, we report a giant HCC with a diameter over 30 cm that weighed over 10 kg.

CASE REPORT

A 62-year-old man had a history of progressive abdominal uplift with unknown etiology for 2 years (Figure 1). He was admitted because of difficult defecation. A computed tomography (CT) scan revealed that the entire abdomen was filled with a huge cystic mixed lesion (Figure 2). An enhanced scan demonstrated the poorly-circumscribed lesion under the right lobe of the liver compressing the surrounding organs. The patient had no history of hepatitis, smoking, or drinking. Upon physical examination, no superficial lymphadenectasis, icteric sclera, or liver palm, and spider telangiectasias were observed. Abnormal cardiac and lung function were not observed. Blood serum study showed that the hepatitis

Figure 1 Patient had continuous abdominal uplift.

B surface antibody was positive and hepatitis B surface antigen, hepatitis B e antigen HBeAg, hepatitis B e antibody, and hepatitis B core antibody were all negative. Tumor markers such as α -fetoprotein (AFP), cancer embryonic antigen, carbohydrate antigen 199 (CA199), CA125, and CA724 were detected and their values were all within the normal limits. B-type ultrasonic examination demonstrated a relatively well-circumscribed tumor that measured 30 cm \times 30 cm \times 25 cm. Preoperative glucose tolerance was normal.

Surgical resection under general anesthesia was performed in our hospital on August 30, 2007. Most of the organs in abdominal cavity, including the right kidney, duodenum, abdominal aorta, inferior vena cava, spleen, stomach, small intestine, ascending colon, transverse colon, and urinary bladder were deformed due to the compression by the giant HCC. The right lobe of the liver and diaphragm were adhered closely, the entire right lobe of liver was compressed as thin as a piece of paper. The left lobe of the liver was hypertrophied with normal appearance. Hepatic cirrhosis was not observed. This giant tumor was close to the second portal hepatic vein, and compressed the first and the third portal hepatic vein, blood supply of the tumor was from the hepatic artery, abdominal aorta, renal artery, and collateral circulations. This well-circumscribed tumor was encompassed in a pseudocapsule. The huge tumor and the right lobe of the liver were successfully resected. The injury of abdominal aorta and duodenal serosa was repaired during operation. The intraoperative course was uneventful, which took 185 min, and no intraoperative complication occurred during the operation. Intraoperative blood loss was 600 mL and blood transfusion was 1200 mL. The patient resumed breathing on his own uneventfully. His tracheal intubation was pulled out at the end of operation, and he was sent to ICU for intensive observation and treatment for 48 h.

Postoperative tumor size and weight turned out to be 35 cm \times 30 cm \times 15 cm and 10 050 g, respectively (Figure 3). Grossly, the tumor had cystic degeneration and was encompassed in a pseudocapsule. Histological examination showed that the tumor was infected by a fungus and was a well-differentiated HCC (Figure 4A). Immuno-

Figure 2 Computed tomography of the tumor. A: A huge hepatic carcinoma at the right lobe of the liver. The left lobe of the liver was compensatory hypertrophy; B: A huge hepatic carcinoma above the right lobe of the liver and compression of the surrounding organs.

histochemical staining showed that the tumor was AFP positive (++) (Figure 4B).

Hypovolemic shock was observed 18 h after operation and he recovered 36 h after blood and fluid intravenous transfusions. The patient was treated with fluid intravenous transfusion and total parenteral nutrition after operation in the department of abdominal surgery for 5 d. Postoperative liver function was normal, and no liver failure occurred. His catheter was removed on postoperative day 3 and he urinated without medical aid. However, urinary retention was observed on postoperative day 6, he resumed his self-urination by re-indwelling the catheter, which was pulled out 4 d later. Gastrointestinal function recovered 5 d after operation and he was given semi-liquid diet. Additionally, he had serious diarrhea 9 d after operation, which was relieved by intravenous injections of anisodamine hydrochloride 20 mg once a day and a 9 g oral dose of montmorillonite powder once a day for 4 d. Postoperative acute heart failure (CHF) occurred at day 7 after operation and the patient recovered after treatment with cardiotonics, diuresis and vascular dilation for 2 d. The right pleural effusion occurred 8 d after operation and was treated by CT guided percutaneous drainage. Other postoperative recovery was successful, and surgical incision healed well.

DISCUSSION

Studies on surgical resection of huge hepatic carcinoma have been reported since the 1950s in China. Currently, surgical resection is still the best way to achieve a long-term survival for patients with huge hepatic carcinoma, especially for patients without cardiac, renal, or lung dysfunction or coagulation disturbances^[2,3]. However, the

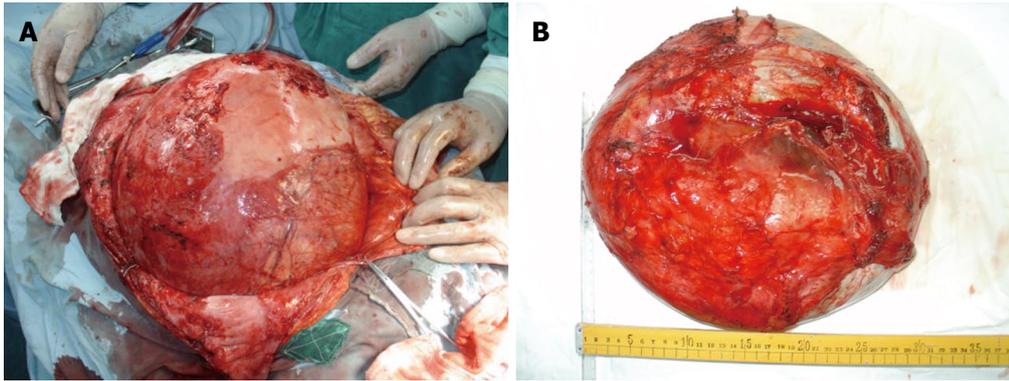

Figure 3 Imaging of the huge tumor. A: The tumor was encompassed by a pseudocapsule and compressed surrounding organs; B: Postoperative measurement of tumor was 35 cm × 30 cm × 15 cm in size and 10 050 g in weight.

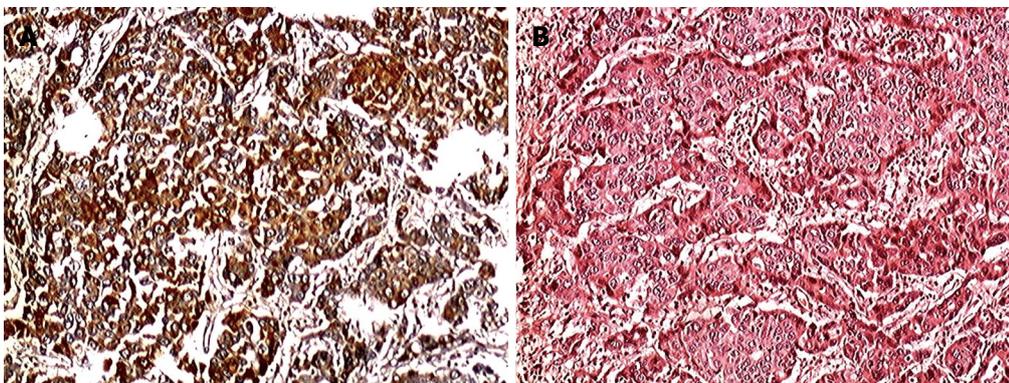

Figure 4 Pathological and biochemical examinations of the huge tumor. A: Pathological examination showed the tumor was a well-differentiated HCC. HE × 400; B: Immunohistochemical staining showed the tumor was α -fetoprotein positive (++) . HE × 400.

prevention of hemorrhages and postoperative hepatic failure are vital for a successful resection of huge hepatic carcinomas. Therefore, surgeons must be skillful at surgical techniques and have a breadth of clinical experience^[2,4,5]. In this case, resection of the huge tumor was performed because the left lobe of the liver was compensatory hypertrophy and liver function was normal.

To complete the operation uneventfully and avoid possible complications during tumor excisions depends on the patient status and clinical experience of surgeons^[2,6]. A higher incidence of complications and mortality were found during mass excisions, including hemorrhage and injury of abdominal aorta, inferior vena cava, portal hepatic vein, small intestine, *etc*^[7,8]. In this case, the surgery was uneventful except some complications.

In this case, postoperative syndromes characterized by hypovolemic shock, urinary retention, CHF, diarrhea, and pleural effusion were observed due to serious intra-abdominal pressure from a huge liver tumor. This syndrome was relieved with expectant treatment. The optimal treatment protocol of syndromes induced by abdominal decompression after surgical resection of huge hepatic carcinomas has not been defined and further studies are needed.

To our knowledge, this tumor 10 050 g in weight is the largest malignant hepatic carcinoma found to date.

Abstract

Liver tumor and other benign liver diseases such as polycystic liver disease can cause massive hepatomegaly and may represent an indication for liver transplantation (LT) in some instances. In this setting, LT can be extremely difficult and challenging due to its decreased mobility and access to vascular supply. Benefit from either a right or a left partial liver resection during the transplant procedure has been advocated to safely accomplish the hepatectomy of the native liver. Although we believe that partial hepatectomy adds some risk to intra-operative bleeding, we alternatively advise a different approach. We have a successful experience with LT in 6 massive hepatomegaly patients due to giant liver lesions. All the transplant procedures were performed without intermediate partial liver resection, showing that selective use of veno-venous bypass can play a significant role in the treatment of massive hepatomegaly.

TO THE EDITOR

We read with great interest the article of Jiang *et al*^[1], published in last October in *World Journal of gastroenterology* 2009 October 28; 15 (40): 5112-5113 regarding a case of liver transplantation (LT) for polycystic liver with massive hepatomegaly. After an unsuccessful attempt to defenestrate the cyst, they performed hepatectomy for the native liver during LT accomplishing a left hepatectomy followed by a right hepatectomy because the massive hepatomegaly resulting from the enlarged liver cysts caused a very small surgical space, thus making the classic dissection of the hilar structures extremely difficult. Although we agree with the authors that the polycystic liver is not only large but also rigid, and consequently the mobility and access to vascular supply are decreased, we think that performing either a right or a left partial liver resection during LT adds some risk to intra-operative bleeding and we alternatively advise a different approach.

Indeed, we have some successful experience with LT in 6 patients with massive hepatomegaly due to giant liver lesions.

The primary indications for LT in 3 patients were polycystic kidneys and liver disease (Figure 1A), and two of them required a combined liver and kidney transplantation (Figure 1B) after bilateral nephrectomy.

LT was performed due to multifocal hepatocellular carcinoma (HCC) (Figure 1C), giant hepatic hemangioma

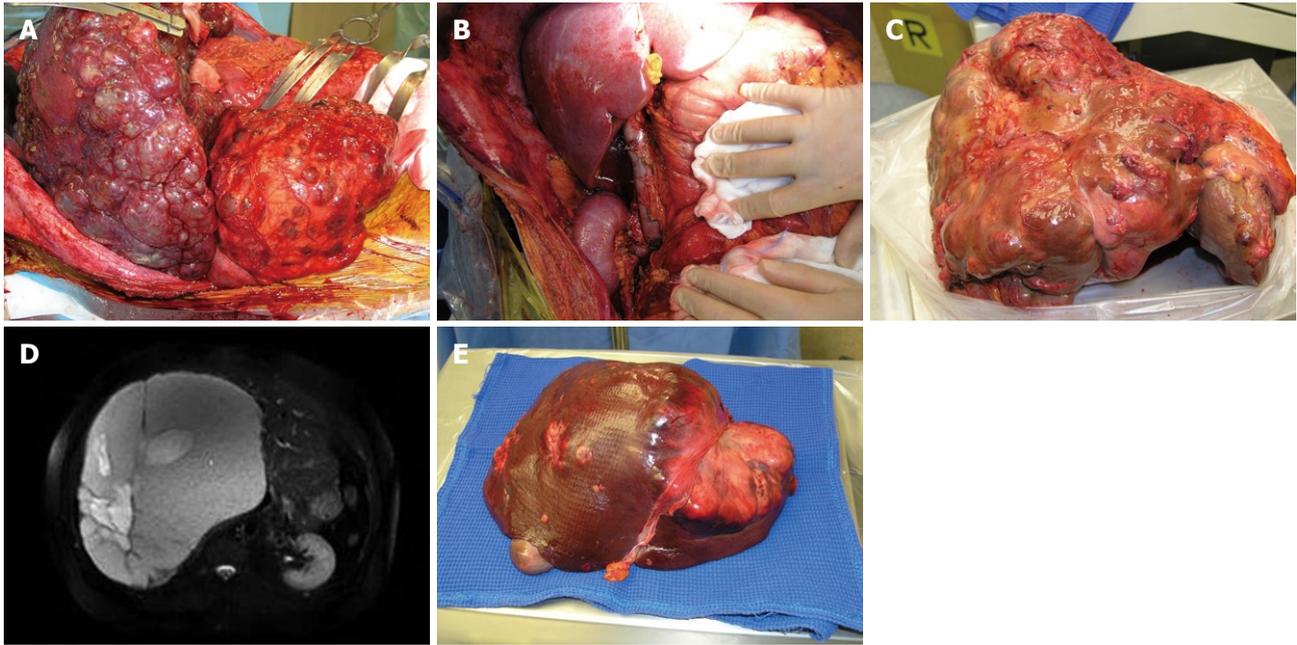

Figure 1 Liver transplantation for hepatomegaly. A: Polycystic kidney and liver disease; B: Combined liver and kidney transplantation after bilateral nephrectomy; C: Multifocal hepatocellular carcinoma (HCC); D: Giant hepatic hemangioma; E: Multiple metastases of carcinoid tumor.

(Figure 1D), and multiple metastases of carcinoid tumor (Figure 1E) for the 3 patients, respectively.

The recipient with giant multifocal HCC was obviously an exception to the Milan criteria (2) for LT in HCC patients.

After consulting our Internal Review Board, this patient was listed in a special list of potential recipients of "liver that nobody uses"^[3]. All LT procedures were performed using cadaveric grafts except in 1 living case of right lobe donation in favor of the recipient with giant hemangioma.

The weight of all the explanted livers was more than 7 kg each (range: 5.440-10.000 g) and all the hepatectomies were extremely difficult because of the massive hepatomegaly.

In the HCC recipient and living donor, venous-venous bypass was performed during hepatectomy^[4] and no systemic anti-coagulation occurred as previously described^[5]. A standard hepatectomy technique instead of venous-venous bypass was used in the other 4 cases. Cystic defenestration was performed in the 6 cases using a large incision instead of thoracotomy for the spaces.

All the recipients had an uneventful post operative course and were alive at the time when they were followed up for 12 mo.

After two-disease free years, the HCC recipient developed a single bone lesion which was treated with selective radiotherapy.

We have never performed intermediate liver resection of massive hepatomegaly, because it may increase the risk of intra-operative bleeding.

We advise venous-venous bypass whether its access to vascular structures is difficult or impossible due to massive hepatomegaly.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article *via* online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board

members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Article: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce Consensus and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Instructions to authors

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/1007-9327/Instructions-toAuthprs.asp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>; Writing requirements of abstract at: <http://www.wjgnet.com/1007-9327/links/Abstract.doc>.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the

main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A...; B...; C...; D...; E...; F...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 $\mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr-A*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-5908-0039

Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/1007-9327/news/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/1007-9327/news/12.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

It is common practice to follow patients with colorectal cancer for some years after resection and/or adjuvant treatment. Data are lacking about how often patients should be seen, what tests should be performed, and what surveillance strategy has a significant impact on patient outcome. Seven randomized trials have addressed this issue, but none had sufficient statistical power. Four published meta-analyses have established that overall survival is significantly improved for patients in the more intensive programs of follow-up. This improvement amounts to a risk difference of 7% (95% CI: 3%-12%, $P = 0.002$) in 5-year survival. This should be partly attributable to more frequent reoperation for cure of asymptomatic recurrence, or more intense follow-up, as well other factors, such increased psychosocial support and well-being, diet and lifestyle optimization, and/or improved treatment of coincidental diseases. A large-scale multicenter European study [Gruppo Italiano di Lavoro per la Diagnosi Anticipata (GILDA)] is underway to answer the question of what constitutes optimal surveillance for patients after primary therapy, based on an adequately powered study.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies and the second leading cause of death related to cancer^[1]. Although about two-thirds of patients undergo radical surgery, up to 30%-50% of them will develop tumor relapse and die of their disease^[2]. This provided a rationale for trying to diagnose recurrence early, while resection is still feasible.

Although there is general agreement about the usefulness of postoperative patient follow-up, no consensus has been reached and there have been no clinical trials to demonstrate effectiveness. Thus, in a survey of members of the American Society of Colon and Rectal Surgeons, it was found that 31% of surgeons request computed tomography (CT) at least once during the first postoperative year after colon cancer surgery, while 53% do not employ CT at all. Similarly, 5% monitor carcinoembryonic antigen (CEA) levels monthly during the first postoperative year, while 4% never check CEA levels^[3]. This poses an important problem because there are many patients at risk and the costs of diagnosis (and treatment, if needed) are high.

OPEN QUESTIONS

An optimal level of follow-up would maximize patient welfare at the least cost. Patients are harmed if a strategy is too intensive, because they are unnecessarily exposed to radiation, and undergo uncomfortable endoscopy and blood tests. If high-intensity surveillance testing provides no improvement in duration or quality of life (QoL), society is also harmed by the waste of resources. If the strategy is not intensive enough, patients who relapse and are potential candidates for effective salvage treatment may die needlessly. Society is also harmed in this case because the costs to treat incurable CRC are high, patients are unable to work, their QoL decreases, and their children grow up without a parent^[4]. How good is the evidence for choosing which follow-up examinations to order?

Early detection of CRC recurrence is seldom useful. In this context, intensive testing leads to anxiety and financial burden, and seldom changes disease outcomes. On the contrary, to wait for signs or symptoms, rather than detecting early disease manifestations is defensible, albeit somewhat paternalistic. Physical examination virtually never discerns early hepatic, lung, or anastomotic recurrence, and CEA is only elevated in 60% of patients with recurrence. Thus, waiting for signs and symptoms seems contrary to the instinct that early detection and prompt disease management is best^[5].

WHAT IS KNOWN ON THIS TOPIC?

In an attempt to rationalize care, the concept of the randomized trial was introduced in the mid-twentieth century. However, very few of these studies have dealt with follow-up of patients with CRC, and no consensus has been reached with respect to the most effective strategy. Indeed, follow-up schedules are highly heterogeneous with regard to procedures (clinical history, physical examination, CEA monitoring, imaging techniques, and colonoscopy) and the frequency with which they are carried out.

Seven randomized controlled trials have addressed this issue, but none had sufficient statistical power^[6-12]. Thus, four meta-analyses have been published to evaluate the impact of various intensities and strategies on the outcome of patients after curative surgery for CRC^[13-16].

Overall survival is significantly improved for patients in the more intensive programs of follow-up. This improvement amounts to a risk difference of 7% (95% CI: 3%-12%, $P = 0.002$) in 5-year survival^[15]. The incidence of asymptomatic recurrence is significantly more common in patients in the more intensive follow-up program. This may explain the more frequent reoperation for recurrence in that group of patients.

The analysis of Renehan *et al*^[13] has found a larger impact on survival in trials using abdominal CT and frequent CEA determinations. The study by Jeffery *et al*^[14] had similar findings. The patients undergoing more intense follow-up have improved survival, earlier diagnosis of recurrence, and more frequent curative resection, as a result of undergoing more tests, especially liver imaging.

However, it is not clear to date which tests or frequency of visits is optimal. Also noted in these overviews are the paucity of data on complications and QoL.

One trial noted two perforations and two episodes of bleeding after polypectomy in 731 colonoscopies: a complication rate of 0.55%^[9]. This complication rate is comparable to that of other colonoscopy studies^[17].

The QoL and attitude of patients participating in follow-up programs have been investigated by Stiggelbout *et al*^[18]. Their results have indicated that regular contact with a physician reassures patients, and that visits and tests cause only slight anticipatory anxiety and other minor inconveniences^[18].

Kjeldsen *et al*^[6] have confirmed these findings in a subgroup of patients participating in a randomized trial that compared minimal to regular follow-up, and which demonstrated similar survival for both follow-up regimens. Patients were mailed the questionnaire to complete at home. Ninety-one percent returned the completed questionnaires. QoL measures and attitudes were almost the same for patients in the minimal and intensive follow-up programs, which indicated that the extra tests or inconveniences were balanced by the more frequent reassurance of health.

Other authors have postulated that improved survival with intensive follow-up is not only due to salvage surgery offering a second chance of cure, but that an additional 4%-11% gain in survival may be attributable to other factors^[19]. The following may be relevant: (1) increased psychosocial support and well-being; (2) cancer survivors tend to optimize their diet and lifestyle, although it is unclear whether these adjustments are self motivated, or a direct consequence of health-care interventions; and (3) improved treatment of coincidental disease.

CONCLUSION

Many doubts about follow-up of CRC patients must be clarified and further well-designed studies with a sufficient number of patients must be carried out. The generation of high-quality evidence for the practice of cancer patient follow-up is an important priority for the medical community, although trials are expensive to mount and take a long time to complete. In this context, two trials of high- vs low-intensity follow-up for breast cancer have been carried out, which indicates that such trials are feasible^[19]. Both employed a randomized two-arm design with a sample size of about 1500 patients. The same is likely to be necessary for trials of CRC patient follow-up; one such trial by Gruppo Italiano di Lavoro per la Diagnosi Anticipata (GILDA) completed patient recruitment in September 2006, and the results should be published during 2010. Major objectives of this study are: overall survival, better timing profile of diagnosis of recurrence, QoL, and program costs. It is hypothesized that the results of high- and low-intensity strategies will be equivalent, and it will answer the question of what constitutes optimal surveillance for patients after primary therapy, based on an adequately powered study.

tained in 3 independent models of mice expressing a COX-2 transgene specifically in the hepatocyte. Upon challenge with pro-inflammatory stimuli, the animals behave very differently, some transgenic models having a protective effect but others enhancing the injury. In addition, one transgene exerts differential effects on normal liver physiology depending on the transgenic animal model used.

COX-2 in liver, from regeneration to hepatocarcinogenesis: What we have learned from animal models? *World J Gastroenterol* 2010; 16(12): 1430-1435 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i12/1430.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i12.1430>

Abstract

The use of animals lacking genes or expressing genes under the control of cell-specific promoters has significantly increased our knowledge of the genetic and molecular basis of physiopathology, allowing testing of functional hypotheses and validation of biochemical and pharmacologic approaches in order to understand cell function. However, with unexpected frequency, gene knockout animals and, more commonly, animal models of transgenesis give experimental support to even opposite conclusions on gene function. Here we summarize what we learned on the role of cyclooxygenase 2 (COX-2) in liver and revise the results ob-

INTRODUCTION

Bioactive lipids, including prostaglandins and thromboxanes - collectively known as prostanoids - are involved in many physiopathological processes ranging from vascular function to gastric mucosa integrity, inflammation and development/progression of various types of oncologic processes including colorectal cancer^[1-5]. These prostanoids are synthesized from arachidonic acid by the sequential action of cyclooxygenase (COX) and a specific prostaglandin or thromboxane synthase. Two isoforms of COX exist: COX-1 that is constitutively expressed in almost all tissues and is responsible for the homeostatic synthesis of prostanoids, and COX-2 that is expressed upon response to cell stressors, such as pro-inflammatory

cytokines, growth factors and hormones^[2,6-8]. Whereas COX-1 exhibits a modest but continuous synthesis of prostanoids, COX-2 is involved in the high throughput synthesis of these bioactive lipids under pathological conditions. Mice lacking COX-1, COX-2 or both isoenzymes have been generated and these animals are fully viable despite the observation of alterations in fertility (the COX-2 deficient females are sterile) and the appearance of nephropathies during aging^[2,9,10]. In adult liver, the expression of COX-2 under rapid response to a pro-inflammatory challenge is almost restricted to the non-hepatocyte cell population. However, under chronic pro-inflammatory conditions hepatocytes express this isoenzyme and the contribution of the increased synthesis of prostanoids to liver pathology is a current subject of research^[11-13]. To better approach the study of COX-2 expression as an early cause of liver pathology, various groups engineered mice that expressed this isoenzyme specifically in the hepatocytes. The results obtained using these animal models are the subject of this review and highlight the need to interpret the data from animal models with a certain caution.

GENE TARGETING IN LIVER INJURY AND REGENERATION

The development of targeted animal models to answer key biological questions in some cases requires appraisal to understand why animals lacking the same gene but generated under different genetic backgrounds or gene-deletion strategies result in different and sometimes even opposite physiopathological conclusions. One case is liver regeneration after partial hepatectomy where only a reduced number of genes appeared to be essential for the survival following resection of two-thirds of the liver^[14-19]. Cumulative studies in this area identified about 70 genes whose expression increased following partial hepatectomy; interestingly, despite the large number of signals controlling the early steps of regeneration only a handful have been described to play a critical role in the successful outcome of the process. Models in which liver regeneration is impaired after partial hepatectomy are animals deficient of insulin-like growth factor-1-binding protein, TAB2 (transforming growth factor- β -activated kinase 1-binding protein 2)-a transforming growth factor-activated kinase-1 interacting protein involved in the early response to interleukin-1 β (IL-1 β), or animals overexpressing transforming growth factor- β (TGF- β)^[20-22]. Examples of relevant genes for regeneration are those controlling commitment to proliferation or inhibiting apoptosis, such as *c-met*, *pdk1*, *p75^{ntr}* (the neurotrophin receptor in stellate cells), and *gadd45b*^[23-26]. Previous studies reported delayed regeneration and sometimes increased death in animals lacking *il-6*, *stat-3*, *cox-2* or *nos-2*^[2,9,27-29], but further studies notably found an attenuated impact of the deficiencies in these genes in terms of liver mass recovery and survival. One extreme example is the requirement of caveolin-1 for regeneration that in one model has been described to be “a gene

essential for liver regeneration”^[30], whereas in the commercially available caveolin-1-deficient mice this gene appears to be absolutely “dispensable” with the peculiarity of an accelerated regeneration and, therefore, being a positive condition for a rapid liver mass recovery^[31]. The reasons for these discrepancies lie with the different genetic backgrounds of both mice strains. Indeed, in those caveolin-1-deficient animals that died after partial hepatectomy, there was partial restoration of the liver mass but they died at day 4-5 post-surgery, a situation that could be overcome after administration of glucose, suggesting that a metabolic problem was the most likely defect in these animals rather than deficient cell replication and growth^[30]. Indeed, in addition to the caveolin-1-deficient mice, there are also gene-targeted animals that exhibit an accelerated early proliferation and liver mass recovery, among them animals deficient in *pai-1*, *timp-1*, *ikk2* or *socs-3*^[32-35]. Finally, there are a few models that, despite being unable to restore liver cellularity because of deficient hepatocyte proliferation/division, show liver growth and fully restored hepatic function through an hypertrophic response with multinucleated and polyploid hepatocytes^[36].

COX-2 TARGETING IN LIVER

As previously mentioned, prostaglandin (PGs) synthesis in mammals is carried out by the expression of 2 forms of cyclooxygenase. COX-1 is constitutively expressed in most tissues and has a narrow specificity for substrates, preferentially using arachidonic acid and releasing PGs that are involved in the physiological action of these lipid mediators. However, for expression of COX-2, the inducible enzyme, in various tissues, a high throughput synthesis of PGs occurs both from arachidonic acid and other polyunsaturated fatty acids. These PGs are involved in the regulation of physiopathological responses as diverse as inflammation, tumor development and progression, and cell growth^[1,3].

One interesting observation in the liver is that normal adult hepatocytes, either in primary culture or *in vivo*, fail to express COX-2 upon challenge with pro-inflammatory stimuli, including toll-like receptor ligands and combinations of tumor necrosis factor- α (TNF- α), IL-1 β and interferon- γ (IFN- γ). This lack of inducibility by pro-inflammatory mediators occurs in adult hepatocytes, but not in hepatocytes from fetal or early newborn animals or in hepatic-derived stable cell lines^[2,11,37]. Previous studies indicated that this behavior resulted from the presence of elevated levels of CCAT/enhancer binding protein- α (C/EBP- α), a transcription factor that is highly expressed in the adult hepatocyte and that interferes with the commitment of the cells to proliferate^[9]. This absence of COX-2 expression has also been observed in *in vivo* models of sepsis, where the production of PGs in the liver is accomplished by the expression of COX-2 in non-hepatocyte cells, mostly Kupffer cells and infiltrating macrophages^[11,13]. These observations reinforce the role of liver infiltration by circulating inflammatory cells

in the release of transcellular mediators, such as PGs. Despite lipopolysaccharide (LPS) or a pro-inflammatory challenge failing to induce the expression of COX-2 in hepatocytes, liver regeneration after partial hepatectomy promotes a rapid expression of COX-2 and synthesis of PGs^[11] that contribute to the regeneration onset as deduced by the impaired recovery observed after administration of selective COX-2 inhibition with COX inhibitors or from animals lacking the *COX-2* gene^[2]. Indeed, COX-2-deficient animals exhibited a full recovery of liver mass and function after partial hepatectomy with a delayed early commitment to proliferation^[2,9,11,38]. The simultaneous absence of COX-2 and other genes relevant for liver regeneration, such as nitric oxide synthase-2 resulted in an impaired liver mass recovery after partial hepatectomy leading to animal death^[39,40]. Dual deficiencies of COX-2 and other genes relevant for liver function and regeneration may help to identify targets critical for hepatocyte survival.

COX-2 TRANSGENESIS AND LIVER INJURY

More intriguing are the models of COX-2 transgenesis that lead to different end-responses without a clear reason. One example came recently when 3 groups engineered mice specifically expressing COX-2 in hepatocytes in order to investigate the role of this inducible enzyme on liver physiopathology. As previously mentioned, hepatocytes only express low levels of COX-1, the constitutive COX enzyme that is responsible for PGE₂ synthesis measured in primary cultures of hepatocytes. However, hepatocytes fail to express COX-2 after onset of inflammation as do typically inflammation-responsive cells, such as Kupffer and stellate cells, macrophages, astrocytes and microglial cells^[2,9]. Interestingly, in the case of hepatocytes, only under time-dependent progression is COX-2 expressed as a result of the drop in C/EBP α levels, among other conditions^[9]. Thus, ectopic expression of COX-2 in hepatocytes constitutes an unphysiological condition ideal for evaluating the role of PGs in liver pathogenesis. Recently, the *COX-2* gene has been expressed under the control of different specific promoters: apolipoprotein E^[38,41], transthyretin^[42,43] or the albumin-enhancer promoter^[44,45], all 3 models giving a high liver-specificity in the expression of the transgene. On analysis, after the selection of the founder colonies, it is remarkable to observe the different intrahepatic levels of PGE₂ reached under each model, as summarized in Table 1. This is despite the observation of a robust expression of the transgene by Western blotting analysis in the 3 models. More tantalizing are the effects upon LPS/D-galactosamine (D-GalN) challenge of the transgenic animals: whereas in the third model^[44], the expression of the COX-2 transgene notably enhanced the injury, in the first model^[41] a clear protection in terms of transaminases release and histological integrity of the tissue was observed. Perhaps the genetic background of the animals was also playing a role in view of the absence

Table 1 Summary of metabolic patterns and liver responses in transgenic mice with a liver-specific expression of the *COX-2* gene

	Model #1 ^[38,41]	Model #2 ^[42,43]	Model #3 ^[44,45]

¹pg/mg of liver; ²pg/mg of protein; ³In animals aged 12-mo. COX-2: Cyclooxygenase 2; ND: Not determined; PG: Prostaglandin; LPS: Lipopolysaccharide; D-GalN: D-galactosamine; MCD: Methionine and choline-deficient diet model; HCC: Hepatocellular carcinoma; WT: Wild type; TG: COX-2 transgenic mice.

of liver apoptosis in the wild-type animals of the third model (C57BL/6) after LPS/D-GalN treatment, whereas those of a C57BL/6XDBA background (first model) exhibited a significant apoptotic response, previously described by many authors. This apoptosis was prevented after the expression of the COX-2 transgene, and was lost upon pharmacological inhibition of COX-2 with selective inhibitors. However, when animal models #1 and #3 were confronted with the Fas/FasL challenge using Jo2 as the stimulus, a very potent protection against liver injury and animal death was observed in those animals that carried the COX-2 transgene, through a mechanism that involved Src/epidermal growth factor receptor signaling^[38,45]. Finally, in a methionine and choline-deficient diet model MCD/CCL₄-induced injury, COX-2 transgenesis failed to exhibit any significant protection on liver injury (animal model #2 and reference 43).

The consequences of transgene expression over time also exhibited different patterns among the animal models: whereas at 12 mo mice of the first model did not exhibit histopathological symptoms of cell infiltration or fibrosis, the animals of model #2 developed significant inflammatory cell infiltration and hepatitis through a mechanism that appears to involve a persistent activation of nuclear factor- κ B. As there is a continuous activity of COX-2 in the hepatocyte in both models, with elevated PGE₂ synthesis, it can be concluded that other factors are required for the development of infiltration and spontaneous hepatitis. Interestingly, COX-2 does not appear to mediate the development of liver fibrosis since similar results were observed in wild-type, COX-2 knockout and COX-2 transgenic mice in an experimental model of induction of liver fibrosis^[43].

At present, there are cumulative studies supporting the proliferative and antiapoptotic role of PGs in different models of liver failure as well as after ischemia/reperfusion injury^[46,47]. This protective role has been observed even in other tissues like cardiomyocytes^[48,49]. Moreover, it is known that PGE₂ inhibits T-cell proliferation,

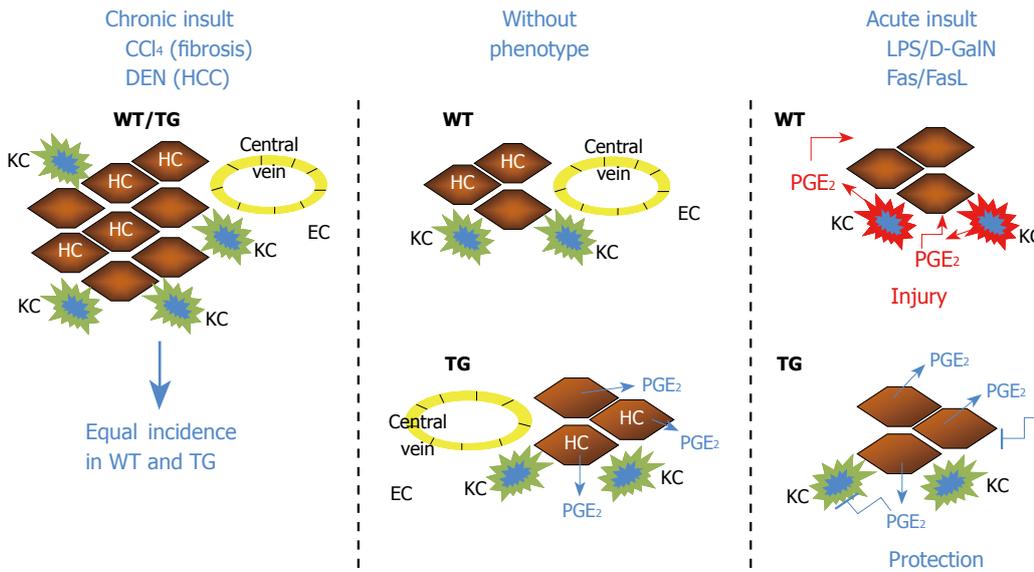

Figure 1 Schematic representation of the effects of transgenic expression of cyclooxygenase 2 (COX-2) in hepatocytes. The transgene protects against acute liver injury, but fails to alter the response to hepatocarcinogens, such as diethylnitrosamine (DEN). and exerts a suppressant effect on type-1 immune responses in macrophages, drastically inhibiting the production of Th1 cytokines, such as IFN- γ and TNF- α and upregulating IL-10^[4,7].

In conclusion, experiments on transgenesis need to take into account the biological activity of the expressed protein. In the case of COX-2, the availability of substrate for this enzyme (arachidonic acid) appears to be a rate-limiting step in the synthesis of PGs. Therefore, different levels of protein expression might result in similar levels of PG synthesis because of substrate restrictions for COX-2. In addition, the time of activation of the ectopic promoter of the transgene, usually after or during the perinatal transition restricts the influence of COX-2 in the embryonic steps of development, but effects on early postnatal development cannot be ruled out among the different COX-2 transgenic models considered. This is in addition to the contribution of the distinct genetic backgrounds used in these animal models. Accordingly, caution must be exercised in deducing conclusions in view of the arbitrary insertion of the transgene and the fact that the biological repercussions of this genetic event may have unexpected effects in the transcriptome, in addition to the specific actions of the protein encoded by the transgene. Scientists are innocent players in this scenario and their work should be well considered, although filtered by evidence coming from ancillary physiopathological data.

COX-2 TRANSGENESIS AND LIVER CARCINOGENESIS

Despite the constitutive presence of COX-2 in hepatocytes in the mice^[38,41-45], they failed to spontaneously develop hepatocellular tumors, and only hepatitis and fibrosis was observed in model #2^[42,43]. This is interesting because COX-2 has been frequently associated

with the presence of hepatocellular tumors (but in the “healthy” portion of the liver) and exacerbated COX-1 and COX-2 expression are frequently observed in hepatoma cell lines^[13]. In addition, targeting of the COX enzymes or the PG receptors (EP1-4) contribute to antiproliferative effects in these cultured cells^[50,51]. Tissue-specific constitutive expression of COX-2 has been reported as a positive factor for the development of carcinogenesis. In mice expressing the enzyme in mammary glands, the continuous release of PGE₂ has been reported to favor angiogenesis and development *per se* of tumorigenic foci in the mammary gland^[52,53]; these data were corroborated by pharmacological approaches based on COX-2 inhibition^[54]. In addition to this, constitutive expression of COX-2 under the control of the keratin 5 promoter markedly sensitized skin to carcinogens; for example, under these conditions the sole challenge of DMBA, without further requirement of phorbol ester administration or other skin tumor promoters was sufficient to induce epidermal hyperplasia and frequent dysplastic lesions in the skin of the transgenic animals^[55,56]. In the gastrointestinal tract, constitutive coexpression of COX-2 and microsomal PGE synthase (mPGES-1; the enzyme that is coupled to COX-2 and directs the prostaglandin synthesis towards PGE₂) under the control of the cytokeratin 19 promoter (that targets the expression of these transgenes in the epithelial cells of gastric mucosa), resulted in animals developing hyperplasia and tumors in the stomach glandular anatomy through a process in which the contribution of infiltrating inflammatory cells, mainly macrophages plays a relevant role^[57,58]. Stable expression of COX-2 in hepatocyte-like cells induced proliferation, with an increase in the proportion of cells in S-phase^[59]. Interestingly, the basal protein levels of pJNK (phosphorylated c-jun-NH2-kinase) and p53, were greater in COX-2 expressing cells

and were induced treatment with diethylnitrosamine (DEN). However, animals of model #1, challenged with DEN did not show an increased sensitivity, compared to the parental strain, in developing hepatic tumors during the following 12 mo of treatment (preliminary results). A schematic representation of these actions of COX-2 in hepatocytes and livers is summarized in Figure 1.

CONCLUSION

The data reported in this review suggest that COX-2 expression provides a continuous supply of bioactive lipids that protect the liver against acute injury. However, attention should be paid to ensure that the substrate for COX-2 is available, since arachidonic acid mobilization requires the activation of phospholipase A₂ isoenzymes, a process that is not usually accomplished under *in vivo* conditions. A noteworthy point is that COX-2 may use other unsaturated fatty acids as substrates, releasing molecules that can activate various nuclear receptors, such as peroxisome proliferator-activated receptors. In addition to this, the fact that COX-2 is not expressed in hepatocytes under pro-inflammatory conditions restricts PG synthesis to other hepatic cells, such as Kupffer cells and activated macrophages. However, in the course of progression of hepatocellular carcinomas, it cannot be excluded that there is a transient expression of COX-2 in transformed cells, as observed in many cell lines derived from hepatocellular carcinomas that express this enzyme either constitutively or after pro-inflammatory induction. Finally, the data from the models of COX-2 transgenesis in hepatocytes support the idea that by itself, COX-2 appears not to contribute to development of tumors in the full life-span of these animals.

Abstract

Recently, nonalcoholic steatohepatitis (NASH) has been considered to be another cause of liver cirrhosis and hepatocellular carcinoma (HCC). The natural history and prognosis of NASH are controversial. Accordingly, we assessed the clinicopathological features of NASH-associated HCC in our experience and reviewed the literature of NASH-associated HCC. We experienced 11 patients with NASH-associated HCC (6 male, 5 female; mean age 73.8 ± 4.9 years) who received curative treatments. Most (91%) patients had been diagnosed with obesity, diabetes, hypertension, or dyslipidemia. Seven patients (64%) also had a non-cirrhotic liver. The recurrence-free survival rates at 1, 3 and 5 years were 72%, 60%, and 60%. We also summarized and reviewed 94 cases of NASH-associated HCC which were reported in the literature (64 male; mean age 66 years). The majority of patients (68%) were obese, 66% of patients had diabetes, and 24% had dyslipidemia. Furthermore, 26% of the HCCs arose from the non-cirrhotic liver. In conclusion, patients with non-cirrhotic NASH may be a high-risk group for HCC, and regular surveillance for

HCC is necessary in non-cirrhotic NASH patients as well as cirrhotic patients.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common malignancy in Asia and South Africa. HCC usually develops in patients with hepatitis B, hepatitis C, and alcoholic liver disease. Recently, nonalcoholic steatohepatitis (NASH) has been considered to be another cause of liver cirrhosis and HCC. Powell *et al*^[1] reported the first case of NASH-associated HCC. Since then, several case series of NASH-associated HCC have been reported^[2-4].

The prevalence of nonalcoholic fatty liver disease (NAFLD) is 10%-30% in adults^[5] and its prevalence is increasing in Japan as well as Western countries because of the epidemic rise in obesity and diabetes mellitus (DM). NASH is part of the spectrum of NAFLD, and 20% of NASH cases are thought to slowly progress to cirrhosis^[6]. According to a previous study^[7], NASH can progress to cirrhosis and result in complications including HCC.

Almost all patients with cryptogenic cirrhosis (CC) had clinical features consistent with NASH, but a diagnosis of NASH could not be confirmed by histology (likely “burnt out NASH”)^[8]. The natural history and prognosis of NASH is controversial, because there are few reports on prospective cohort studies of NASH^[9,10]. Accordingly, it is necessary to clarify an etiology and a prognosis of NASH-associated HCC. Thus, we retrospectively assessed the clinicopathological features of NASH-associated HCC in our experience and reviewed the literature on NASH-associated HCC.

NASH-ASSOCIATED HCC IN OUR EXPERIENCE

We reviewed 797 consecutive patients treated for primary HCC at National Hospital Organization Iwakuni Clinical Center from January 1996 and September 2008. Of these, 445 with HCC initially underwent curative treatment. Curative treatment was defined as complete tumor eradication, with no residual tumor visible by computed tomography (CT), or resection of all evident tumor tissue, and no tumors detected in the remnant liver on CT scan performed 3 to 4 wk after curative treatment. Curative treatment included surgery, percutaneous radiofrequency ablation (RFA), microwave coagulation therapy (MCT), and percutaneous ethanol injection (PEI). Within this group, 11 patients were considered to have NASH based on the histology of the non-cancerous parts of the surgical specimens or biopsy specimens.

NASH was diagnosed using the following criteria^[3]: (1) histological features of steatohepatitis; (2) intake of less than 20 g ethanol per day; (3) absence of other liver diseases such as autoimmune hepatitis, drug-induced liver disease, primary biliary cirrhosis, primary sclerosing cholangitis, and metabolic liver disease such as Wilson’s disease and hemochromatosis; and (4) negative for hepatitis B surface antigen and antibody to hepatitis C virus (HCV) and/or negative for HCV RNA on polymerase chain reaction analysis.

The body mass index (BMI) was calculated as body weight in kilograms divided by the square of the height in meters (kg/m^2). The definition of DM was fasting plasma glucose level ≥ 126 mg/dL on at least two occasions, plasma glucose level of ≥ 200 mg/dL at 2 h in a 75 g oral glucose tolerance test, or the need for insulin or an oral antihyperglycemic drug to control glucose levels. The oral glucose tolerance test was undertaken by patients who had no medical history of DM.

Dyslipidemia was defined as blood total cholesterol concentration > 220 mg/dL or triglyceride > 150 mg/dL or a history of taking oral drugs for dyslipidemia.

The histological status of underlying liver disease was based upon microscopic examination of the non-cancerous part of the surgical specimen or biopsy specimen with hematoxylin-eosin and Azan staining. All liver tissue specimens were evaluated by two senior pathologists who were unaware of the laboratory data and the clinical course. Steatohepatitis was pathologically graded on quantified

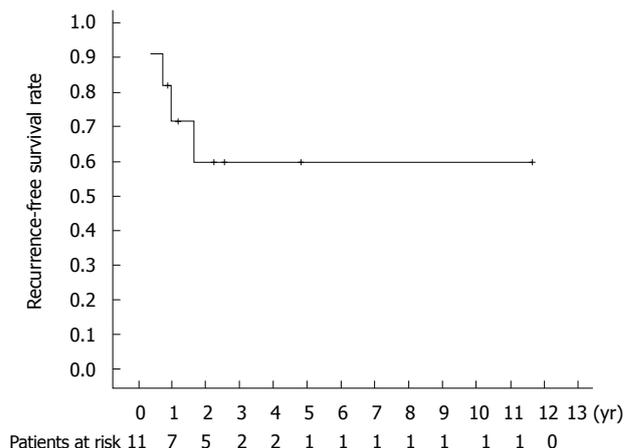

Figure 1 Recurrence-free survival rates in nonalcoholic steatohepatitis (NASH)-associated hepatocellular carcinoma (HCC).

steatosis, ballooning degeneration, and lobular inflammation to produce an NAFLD activity score (NAS)^[11]. When this score is ≥ 5 it is diagnostic for NASH. The extent of fibrosis, established by Desmet *et al.*^[12], is as follows: F0 (no fibrosis), F1 (mild fibrosis), F2 (moderate fibrosis), and F3 (severe fibrosis) were all categorized non-cirrhosis. F4 was categorized as cirrhosis.

A summary of our 11 cases with NASH-associated HCC is shown in Table 1. The mean age of patients with HCC was 73.8 ± 4.9 years. Of the 11 patients, 6 patients (55%) were male, and 5 (45%) were female. The mean BMI was $24.8 \text{ kg}/\text{m}^2$. Six patients (55%) were obese (BMI $\geq 25 \text{ kg}/\text{m}^2$), 6 (55%) had DM, 3 (27%) had dyslipidemia, and 6 (55%) had hypertension. Ten patients (91%) had obesity or at least 1 comorbid illness. The prevalence of positivity of HBV core (HBc) antibodies in our cases was 27% (3 of 11 patients). Ten patients (91%) had Child-Pugh classification A and 1 (9%) was Child-Pugh classification B, and all patients received curative treatments as outlined below. Seven patients (64%) received surgery, 3 patients (27%) received RFA, and 1 patient (9%) received MCT. Four patients (36%) had concomitant liver cirrhosis (F4), and 7 patients (64%) had a non-cirrhotic liver (F1-3). Concerning the characteristics of HCC, 8 patients (73%) had a single nodule, 3 patients (27%) had multinodular lesions, and the mean size of the largest lesion was 3.3 ± 1.3 cm (range 1.7-5.0 cm).

Patients were followed for 41.3 ± 40.0 mo (range, 9.4-151.7 mo), and no patients dropped out. Local tumor progression was not found. The recurrence-free survival rates at 1, 3, and 5 years calculated by Kaplan-Meier method were 72%, 60%, and 60% (Figure 1). All of tumor recurrences were observed within the first 2 years, and no recurrence was observed after 2 years. During the follow-up, 3 patients (27%) died as a result of HCC (2 patients) and hepatic failure (1 patient).

EPIDEMIOLOGIC TRENDS OF NASH AND NASH-ASSOCIATED HCC

HCC is the third leading cause of cancer death in world-

wide; there are an estimated 500 000 to 1 million new cases each year resulting in 600 000 deaths annually^[13]. The major causes of cirrhosis seen in HCC are viral (hepatitis B, hepatitis C), and alcohol. HCV infection is the most prevalent risk factor for HCC in Japan and United States. In United States, the most leading etiology underlying liver disease among the patients with HCC was HCV (51%), and the second most common etiology was CC (29%)^[14].

In the majority of CC cases it is thought to be end-stage NASH because some clinical features such as obesity and diabetes in CC patients are linked to NASH. However, histology often is no longer informative when cirrhosis is already established^[15] because it has been theorized that CC often represents “burned out” NASH. Marrero *et al*^[16] studied the etiology of liver disease in 150 patients with HCC wherein NAFLD-related CC accounted for at least 13% of the cases.

CLINICOPATHOLOGICAL FEATURES

Articles were searched in Medline and Pubmed. The search terms used were NASH, nonalcoholic steatohepatitis, fatty liver, HCC, hepatocellular carcinoma, hepatoma, and liver neoplasms. We summarized and reviewed several studies and numerous case reports which explored NASH-associated HCC^[1-4,17-31]. At least 94 cases of NASH-associated HCC were reported (Table 2). Sixty-four patients were male (64%), and the age at diagnosis ranged from 35 to 89 years (mean, 66 years). The majority of patients (68%) were obese, 66% of patients had DM, and 24% had dyslipidemia. Concerning tumor characteristics, 69% of HCCs were multinodular, maximum tumor size ranged from 1.4-13 cm (mean, 3.5 cm). Furthermore,

26% of cases arose from a non-cirrhotic liver. In a case-controlled study of 34 Japanese NASH-associated HCC patients, those patients were predominantly male, had a median age of 70 years and 88% had advanced fibrosis. Older age, low level of AST, low grade of activity, and advanced fibrosis were independent predictors of developing HCC in NASH^[3].

NATURAL HISTORY AND PROGNOSTIC FACTORS

The natural history and prognosis of NASH is controversial because there are few reports on prospective cohort studies of NASH^[3,9,10].

Yatsuji *et al*^[10] reported that the 5-year HCC rate was 11.3% for NASH-cirrhosis and 30.5% for HCV-cirrhosis in Japanese patients. On the other hand, Hui *et al*^[9] reported that HCC occurred in 8 (17%) of 46 patients with HCV-cirrhosis compared with none of 23 patients with NASH-cirrhosis after 5 years follow-up in Australia.

A prospective cohort study of NASH patients in Japan^[3] showed that the 5-year cumulative incidence of HCC was 7.6%, and the 5-year survival rate was 82.8%. Concerning outcome, 26 of 137 NASH patients died, with death caused by liver failure in 7 patients, HCC in 12 patients and other causes in 7 patients. Liver-related deaths thus accounted for 19 (73%) deaths.

Malik *et al*^[4] reported that the survival rate after liver transplantation for HCC complicated NASH-cirrhosis was 88% at a mean follow-up of 2.5 years. There was no difference in 5-year survival between patients transplanted for NASH-cirrhosis with and without HCC, and no difference in 5-year survival after liver transplantation between

HCC: Hepatocellular carcinoma; DM: Diabetes mellitus; OB: Obesity; DL: Dyslipidemia; LC: Liver cirrhosis; Mul: Multiple; Sol: Solitary; Ope: Surgical operation; PEI: Percutaneous ethanol injection; RFA: Radiofrequency ablation; TAE: Transarterial embolization; LT: Liver transplantation; NR: Not reported.

HCC patients with NASH-cirrhosis and with non-NASH-cirrhosis (HCV, HBV, alcoholic, CC, and otherwise). They concluded that patients with NASH and HCC have a good outcome after liver transplantation.

Giannini *et al*^[32] reported that patients with CC had a significantly greater prevalence of advanced HCC stage, lower amenability to any treatment, and shorter survival times compared with HCV patients, because HCC in CC patients is often diagnosed at an advanced stage owing to lack of surveillance.

MECHANISMS OF NASH-INDUCED HEPATOCARCINOGENESIS

Although the mechanism of carcinogenesis in patients with NASH remains uncertain, insulin resistance and oxidative stress may be involved in carcinogenesis of NASH.

NASH is characterized by insulin resistance with hyperinsulinaemia, and the resistance is thought to be involved in hepatocarcinogenesis. Insulin-like growth factor 1 (IGF-1)^[33] significantly activated mitogen-activated protein kinase (MAPK), and increased overexpression of the c-fos and c-jun proto-oncogenes in cultured hepatoma cells^[34].

Adiponectin and leptin are associated with insulin resistance. Severe liver steatosis and fibrosis were observed in adiponectin knockout (KO) mice as compared with wild type (WT) mice^[35]. Furthermore, liver adenoma and hyperplastic nodules developed in an adiponectin KO mouse, whereas no tumor was detected in WT mice. In animal models, leptin-mediated neovascularization,

which coordinated with VEGF, produced liver fibrosis and hepatocarcinogenesis in NASH^[36].

NASH-associated insulin resistance causes inhibition of hepatic mitochondrial fatty acid oxidation and increased intracellular fatty acids may lead to oxidative DNA damage by stimulating microsomal peroxidases^[37].

Oxidative stress may also promote carcinogenesis. Trans-4-hydroxy-2-nonenal, a major electrophilic by-product of lipid peroxidation caused by oxidative stress may be an important etiological agent for HCC *via* mutation at codon 249 of the *p53* gene^[38].

Reactive oxygen species (ROS) can activate fibrosis^[39]. Furthermore, the major products of lipid peroxidation, malondialdehyde, stimulates DNA mutations^[40]. Therefore, inflammation is a risk factor for various carcinomas^[41]. Oxidative stress has inactivated the expression of *Nrf1* gene that regulates gene transcription encoding enzymatic antioxidants. Recently, in an animal model, oxidative stress inactivation of the *Nrf1* gene in the liver has been reported to spontaneously produce HCC when oxidative injury was present before tumor formation^[42].

Ishii *et al*^[43] reported that in animal models, eicosapentaenoic acid (EPA) ameliorated steatohepatitis with decreasing serum ROS, which consequently inhibited development of HCC. Medical treatment with EPA may minimize the risk of HCC development in patients with NASH.

CONCLUSION

Most (91%) patients with NASH-associated HCC in our experience had been diagnosed with obesity, diabetes,

hypertension, or dyslipidemia. CC patients had these comorbid illnesses, and CC had clinical features consistent with NASH.

Occult HBV infection might be a possible etiologic agent of HCC, and the prevalence of past/occult HBV infection *via* positivity of HBc antibody in our cases was 27%. Negativity of HBc antibody is not necessarily a required item of diagnosis for NASH, and liver specimens of these HBc antibody positive patients had no histological features of chronic hepatitis B.

Although almost NASH-associated HCC was accompanied by liver cirrhosis according to previous reports^[1,17-19], the majority of our case series were accompanied by non-cirrhotic liver.

Furthermore, recent case reports^[2,30] about HCC arising from non-cirrhotic NASH have been accumulating. One possible explanation for this difference between our cases and other previous reports is that almost all patients with CC had clinical features consistent with NASH, but a diagnosis of NASH could not be confirmed by histology (likely “burnt out NASH”).

All cases of tumor recurrence in our series were observed within the first 2 years, no recurrence was observed after 2 years. These recurrence patterns of HCC suggested that the recurrence of HCC might be based on intrahepatic metastasis rather than multicentric carcinogenesis. NASH-associated HCC patients with non-curative treatments were not observed in our cases, because these patients did not receive liver biopsy or surgery. The existence of selection bias is unavoidable.

In conclusion, patients with non-cirrhotic NASH may be a high-risk group for HCC, and regular surveillance for HCC is necessary for non-cirrhotic NASH patients as well as cirrhotic patients.

Abstract

Many studies have looked at connections between diet, etiology, signs and symptoms associated with inflammatory bowel disease (IBD). Although these connections are apparent to clinicians, they are difficult to prove qualitatively or quantitatively. Enteral feeding and polymeric diets are equally effective at bringing about remission in Crohn's disease (CD). Parenteral feeding is also effective, although none of these methods is as effective as corticosteroid therapy. However, enteral feeding is preferred in the pediatric population because linear growth is more adequately maintained *via* this route. Exclusion diets in patients brought into remission using an elemental diet have been shown to maintain remission for longer periods. Studies that aim to isolate culpable food groups have shown that individuals react differently on exposure to or exclusion of various foods. The commonly identified food sensitivities are cereals, milk, eggs, vegetables and citrus fruits. Studies that have looked at gut mucosal antigen behavior have shown higher rectal blood flow, in response to specific food antigens, in those with CD over healthy subjects. Exclusion of sugar shows little evidence of amelioration in CD. Omega 3 fatty acids show promise in the treatment of IBD but await larger randomized controlled trials. Patients frequently notice that specific foods cause

aggravation of their symptoms. Whilst it has been difficult to pinpoint specific foods, with advances in the laboratory tests and food supplements available, the aim is to prolong remission in these patients using dietary measures, and reduce the need for pharmacotherapy and surgical intervention.

INTRODUCTION

The etiology of inflammatory bowel disease (IBD) is considered multifactorial. Genetic, infective and environmental theories exist, as well as those centered around host immunity, intraluminal gut flora, food allergies and hypersensitivity^[1].

Whilst pharmacological therapy plays a major role, many patients prefer to control their symptoms by the most conservative means possible. Our aims in IBD therapy are to downregulate inflammation, and reduce the incidence of relapse and the healing time.

Dietary therapy encompasses dietary modifications suggested by physicians and those that patients make autonomously. The putative mechanisms of action are due to bowel rest, provision of nutrients, alteration of bowel flora or alteration of antigenic stimuli. The gastrointesti-

nal flora and its interaction with nutritional factors has a huge impact on the environment, especially in genetically predisposed individuals. Nutrients as components of cell structure or antigens can induce inflammatory mediator expression and suboptimal levels of nutrients, which may have an impact on tissue repair and other cellular processes^[2]. Other reviews have concluded that nutrients that tend to affect the immune responses of the host (n-3 fatty acids, antioxidants) are likely to play a role in the treatment of IBD^[3].

In this review, we examine the literature for dietary interventions in IBD, such as exclusion/elimination diets, enteral nutrition and total parenteral nutrition (TPN), and review the evidence that they induce and/or maintain remission in patients with IBD.

METHODOLOGY

PubMed, Cochrane and MEDLINE were searched using the broad key words Crohn's disease (CD), ulcerative colitis (UC) and IBD cross-referenced with exclusion diet, elimination diet, diet therapy and nutritional therapy. The results were limited to human studies and those available in English. They were not limited by the type or size of the trial. The search identified 503 papers of interest. When the titles were reviewed, 315 were found to be of interest by two independent reviewers. If there was any doubt, the papers were included. The 315 abstracts were reviewed again by the same two reviewers, out of which 104 were found to be relevant. These 104 were scrutinized for dietary evidence but only 38 of these had a dietary focus or provided evidence for it. Eighty-five secondary references were reviewed by abstract, of which, 45 were obtained and studied. Of these, 10 provided relevant evidence which was included in the review.

INDUCTION OF REMISSION IN CD

Elemental/polymeric diets

Elemental diets were chanced upon as a therapeutic option for CD patients when they were used to bolster their nutritional status and reduce inflammation^[4]. Liquid feeds are thought to work by reducing mucosal antigen exposure, partly due to the nature of the feed and partly to faster transit times. They also alter the fecal flora, which causes local immunomodulation downscaling, which enhances nutritional status and allows relative bowel rest^[5].

Compliance may be poor as elemental diets are not known for their palatability and are often delivered *via* a nasogastric tube, whereas the polymeric drinks are far more palatable. Several trials and meta-analyses have shown no significant difference in the efficacy of elemental diets over polymeric diets^[6,7].

Elemental diets offer a cheaper way of bringing about remission and without the side effect profile of TPN. In both adult^[8] and pediatric populations, elemental^[9] and polymeric^[10] feeds have been shown to be as effective as corticosteroid therapy in treating active CD. However, a

Cochrane review by Zachos *et al*^[11] has shown, in a meta-analysis, that enteral nutrition is not as effective as steroid therapy for inducing remission.

However, enteral therapy for CD has its role in selected cases, in particular, in children in whom steroids may cause growth retardation^[12]. Food exclusion with liquid diet is very difficult to maintain, therefore, these are rarely long-term solutions. Unfortunately, a staged return to normal feeding often leads to relapse.

Exclusion diets

The East Anglia Multicentre Controlled Trial showed that various food intolerances were perceived in individual patients, and among the more common were cereals, dairy produce and yeast^[13]. This work looked at the use of exclusion diets as an intervention in active CD. The exclusion diet was based around daily reintroduction of a single food type. If it caused diarrhea or pain, it was eliminated. All patients were treated initially with an elemental diet, and those who attained remission followed a reduced prednisolone course or the exclusion diet pathway. Jones *et al*^[14] have shown that maintenance of remission, by identification and avoidance of food intolerances, is possible, often without pharmaceutical adjuncts. Testing for these sensitivities has proven difficult, because testing shows a large number of sensitivities in unselected populations, which are of doubtful clinical significance^[15]. Jones *et al*^[14] have tested a diet rich in unrefined carbohydrate against an exclusion diet. Seven out of 10 patients on the exclusion diet stayed in remission for 6 mo, while none of those on the carbohydrate-rich diet remained in remission. Pearson *et al*^[16] have conducted a study of 42 CD patients after induction of remission by elemental diet. Single foods were investigated using open and double blind rechallenge over 5 d. Fourteen patients dropped out due to flare-ups that were thought to be unrelated to food, and caused by inability to comply with the regimen. Twenty of the remaining patients identified food intolerances and eight did not. This research group has concluded that food intolerance is not as frequent as claimed in other studies, and that it is variable in its intensity and occurrence.

Parenteral feeding in CD

TPN allows bowel rest while supplying adequate caloric intake and essential nutrients, and removes antigenic mucosal stimuli. However, TPN is expensive, invasive and has a number of side effects. TPN has been shown to bring about remission in CD^[17,18]. Müller *et al*^[18] have found that, in 30 consecutive complicated CD patients, 3 wk of TPN as an inpatient followed by an additional 9 wk at home, during which time, no medication or oral intake was allowed, 25 patients avoided surgery. These patients returned to work and needed no further medication and ate normal meals subsequently. In a prospective randomized controlled trial (RCT), 51 patients with active CD refractory to medical treatment were treated with TPN and nil by mouth, defined formula diet *via* a nasogastric tube, or partial parenteral nutrition^[17]. Clinical remission was

obtained in 71% of the patients on TPN, 58% on enteral feeding, and 60% on partial parenteral feed.

Enteral vs parenteral feeding

There has been controversy regarding the enteral *vs* parenteral route for feeding in patients with IBD. Comparison of TPN against elemental diet in a group of 36 patients showed no significant difference in the number of days to remission, the drop in Crohn's disease activity index (CDAI) score, the erythrocyte sedimentation rate (ESR), or albumin^[19]. However, in other studies that have agreed with this finding, neither was proven to be as beneficial as corticosteroids, except one study in a pediatric population^[20]. In that study, Sanderson *et al*^[20] entered 17 children into an RCT, in which eight were given an elemental diet for 6 wk *via* a nasogastric tube, and seven were given adrenocorticotrophic hormone injections and oral prednisolone and sulfasalazine. The elemental diet was equally effective at improving the Lloyd-Still disease activity index scores, C-reactive protein (CRP), ESR and albumin. The elemental diet was markedly better at maintaining linear growth. Whilst strong evidence exists supporting the primary use of enteral feeding in children with CD^[21], it is not commonplace in the treatment of adults.

Omega-3 fatty acids

Shoda *et al*^[22] have noted that the gradual replacement of n-3 polyunsaturated fatty acids with n-6 polyunsaturated fatty acids results in an increased incidence of CD. This implies that there is the potential to modulate immune responses by altering the ratio of polyunsaturated fatty acids in favor of n-3 rather than n-6^[23]. Meister and Ghosh have shown that fish-oil-enriched enteral diet, when incubated with intestinal tissue from 11 subjects with IBD and four controls, reduced inflammation modestly in CD and significantly in UC^[24]. Inflammatory improvement was assessed by analyzing the interleukin (IL)-1 receptor antagonist/IL-1 β ratio. The greater the ratio, the less inflamed the tissue. A systematic review of the effects of n-3 fatty acids in IBD by MacLean *et al*^[25] has identified 13 controlled trials that investigated the effects of n-3 fatty acids. The results were mixed but in the three studies that looked at steroid requirements, this was found to be reduced. However, this was statistically significant in just one of these studies^[26].

MAINTENANCE OF REMISSION IN CD

Exclusion diets

Jones has looked at exclusion diets for the maintenance of remission of CD and has shown that, in personalized exclusion diets, 62% of the patients maintained remission at 2 years and 45% at 5 years, with no other medical intervention^[19]. This was compared to the European Cooperative Crohn's Disease Study in 1984 in which the placebo arm of the study had no patient who maintained remission after 2 years of follow-up^[27].

A Cochrane review of the maintenance of remission in CD has suggested that larger, high-powered controlled trials are required to confirm current hypotheses relating to diet and maintenance of remission^[28]. Trials of diet against azathioprine and infliximab also have been suggested to investigate quantitative effects of nutritional supplements and their impact on cost-effectiveness and quality of life.

Enteral feeding

Enteral feeding has been shown to have a role in preventing relapse in inactive CD patients (predominantly in children)^[29], but the effect has also been observed in a Japanese study of adult CD patients^[30]. Esaki *et al*^[31] have demonstrated in a trial of 145 patients with CD (mostly induced into remission with TPN) that, under maintenance with elemental/polymeric nutrition, the risk of recurrence was lower in those with small bowel rather than large bowel involvement.

DIETARY MANAGEMENT IN UC

Maintenance of remission in UC

UC does not seem to be ameliorated by bowel rest and elemental diets in the same way as CD is^[32-34]. However, patients still express concern about specific food types, and there does appear to be an association with a western diet^[35]. In a study that has investigated self-reported food intolerance in chronic IBD, patients with CD and UC have reported that they felt intolerant to specific dietary triggers and restricted their diet accordingly^[36]. The same study has shown that the pattern and frequency of food intolerance did not differ between CD and UC patients. This has been reinforced by work from our own group that has investigated food intolerances detected by measuring IgG4 antibodies to specific food antigens^[37,38]. There is no evidence to support the use of elemental/polymeric feeding in the treatment of UC^[12,23].

Omega-3 fatty acids

Omega-3 fatty acids derived from fish oils have been shown to be of benefit in a double-blind RCT that looked at patients with distal UC. That study found that the group treated with 3.2 g eicosapentaenoic acid or 2.4 g docosahexaenoic acid daily had significantly better clinical and sigmoidoscopic scores compared with the control group who took sunflower oil, after 3 and 6 mo. This supports the idea that omega-3 oils suppress natural cytotoxicity^[39].

ADDITIONAL DIETARY FACTORS

Fiber

Dietary fiber has been investigated as a means of increasing short-chain fatty acid (SCFA) production. IBD has been linked with impaired SCFA production. SCFAs are mainly produced by the anaerobic bacterial fermentation of undigested carbohydrates and fiber polysaccharides.

In 1995, Galvez *et al*^[40] reviewed a number of studies that concluded that dietary fiber confers clinical benefits in patients with IBD because it maintains remission and reduces colonic damage. This is thought to occur by increasing SCFA production and by altering the gut flora towards predominantly non-pathogenic bacteria.

Fats

The properties of omega-3 fatty acids have been discussed elsewhere in this review. Other studies have revealed an inverse correlation between the percentage of energy derived from long-chain triglycerides and the efficacy of enteral feeds in achieving remission^[41,42].

Sugars

A high intake of sugar has been shown to be linked to CD in a number of trials, hence its possible etiological role has led to therapeutic trials of sugar avoidance^[43]. Most of these trials also have promoted a high fiber intake. The only trial to look solely at sugar avoidance has shown no statistically significant benefit^[44].

ANTIGENIC RESPONSE TO FOOD

Van den Bogaerde *et al*^[45] have published a trial in which the reactivity of peripheral lymphocytes to food, yeast and bacterial antigens was studied. They found that 23 out of 31 patients with CD responded to one or more antigens, compared to five out of 22 in the control group. They also correlated *in vitro* sensitization and *in vivo* changes with histological and blood flow changes. Skin testing and rectal exposure to six food antigens and saline were tested in 10 patients and 10 controls. The results showed that CD patients demonstrated *in vitro* and *in vivo* sensitization to food antigens and this was gut specific^[46].

Levo *et al*^[47] have shown that patients with IBD have higher serum concentrations of IgE. They also have shown that the levels are higher still in those with active disease over those in remission. However, this difference is not statistically significant. In 1998, another study was performed to investigate food-specific IgE as well as IgG, and IgE anti-IgE autoantibodies using serum from normal subjects, patients with CD and those with food allergies. They found that food-specific IgE was not detected at all in the CD group but they did have higher levels of IgG and IgE anti-IgE autoantibodies. They concluded that, even if IgE is an autoantigen in CD, it is not thought to take part in the pathophysiology of the adverse food reactions commonly reported by the patients^[48].

Western diets are more strongly associated with CD^[35]. There are several theories as to whether this may relate to the increased intake of sucrose, refined carbohydrate, and omega-6 fatty acids, and reduced intake of fruit and vegetables. Urban diets contain large quantities of microparticles such as natural contaminants like dust, and food additives which may be antigenic. CD patients allocated to a low microparticle diet experienced a reduction in disease activity and in steroid requirement

compared to a control group on a normal diet^[49].

The Table 1 lists the reviewed studies that have investigated dietary exclusion and sensitivity to foods.

SUMMARY

Although many studies have looked at diet therapy and IBD, mixed opinions exist as to the importance that food intolerance plays in the pathophysiology of IBD. In those that have looked at food sensitivity, this was done using different methods. Riordan *et al*^[13] have observed sensitivity to corn in seven patients; wheat, milk and yeast in six; egg, potato, rye, tea and, coffee in four; and apples, mushrooms, oats and chocolate in three. Ballegaard *et al*^[36] have found sensitivity, using questionnaires, to vegetables (particularly onions and cabbage), fruits (apples, strawberries, and citrus fruits) and to meat (especially beef). Van den Bogaerde *et al*^[45] have shown in a case-control study using lymphocyte proliferation that, out of 31 CD patients, 16 reacted to cabbage and peanuts, 14 to cereals, 13 to milk, and nine to citrus fruits.

As observed by Hunter^[50], epidemiologists tend to look at statistical relationships that lead to studies of sugar, sweet, coke and chocolate intake because patients with CD eat and drink more of these substances than control subjects. Clinicians focus on the foods that patients associate with their symptoms and therefore avoid. As a result, exclusion diets have tended to concentrate more on dairy products, cereals and yeast. Other work is being carried out on polyunsaturated fatty acids, especially omega-3 oils, and their anti-inflammatory effects.

Current elemental and polymeric diets have a role to play in the management of CD, particularly in children. Exclusion diets are of use particularly for maintenance of remission. TPN is of value and has been shown to be as effective as elemental diets, but none have proven as effective as corticosteroid therapy. However, TPN remains a crucial method for administering nutrition in patients with severe disease, who are not able to tolerate enteral feeding.

Despite early ideas about the involvement of sugars in the etiology of CD, the omission of sugar has not been found to be of benefit. Omega oil has shown promising results, particularly in reducing inflammation in UC, and to a lesser degree, in CD.

CONCLUSION

IBD has a multifactorial etiology but food sensitivity/intolerance appears to play a role, and the culpable foods vary on an individual basis. Techniques to identify food intolerance require refining. Progress has been made by looking at factors such as IgG4 responses to food antigens, but a large expanse of work exists in trying to determine people's food sensitivities and the degree to which these affect disease activity. Without further research, it remains unclear whether dietary manipulation will continue to have a role solely in symptom control, or

Table 1 Reviewed studies looking at dietary exclusion and sensitivity to foods

Ref.	Trial type	No. of patients	Diets compared	Findings	Outcomes/measures	GRADE rating
Voitk <i>et al</i> ^[4]	Retrospective	13	Elemental diet	Patients with UC. Showed improved weight and positive nitrogen balance	Weight, nitrogen balance and nutritional state	1D
Borrelli <i>et al</i> ^[10]	Open RCT	38	Oral steroid <i>vs</i> polymeric feed only	Clinical remission comparable (67% steroid group, 79% polymeric group). Significantly improved histological and endoscopic scores in the polymeric group	Clinical remission, histological and endoscopic scores at 10 wk	1A
Riordan <i>et al</i> ^[13]	Multicentre double blinded RC	136	Exclusion diet <i>vs</i> steroid treatment	Patients were maintained in remission on exclusion diets	Hemoglobin, albumin, ESR, CRP, remission rates over 2 yr	1A
Jones <i>et al</i> ^[14]	Controlled trial	20	Unrefined carbohydrate rich diet <i>vs</i> exclusion diet	7 out of 10 on the exclusion diet remained in remission for 6 mo <i>vs</i> none of the other group	Clinical remission	
Pearson <i>et al</i> ^[16]	Prospective cohort	42	Food intolerances after remission induced with enteral feeding	20 patients identified food intolerances and eight did not. 14 did not complete the study	Food intolerances were found in CD but were variable and short-lived	2C
Greenberg <i>et al</i> ^[17]	RCT	51	TPN <i>vs</i> formula diet <i>via</i> NG <i>vs</i> partial parenteral and oral food	Clinical remission in 71% of parenteral group, 60% of partial parenteral group and 58% defined formula group	Relapse rates, weight, albumin, arm circumference, triceps skinfold thickness	1B
Jones <i>et al</i> ^[19]	Randomised	36	TPN <i>vs</i> elemental for induction of remission in CD	Both were successful with no significant differences. Elemental diet was cheaper, safer and simpler	CDAI, ESR and serum albumin	2B
Sanderson <i>et al</i> ^[20]	RCT	17 children	Elemental <i>via</i> NG for 6 wk <i>vs</i> high dose steroids	Elemental feed equally effective in children to high dose steroids. Linear growth better in elemental group over 6 mo	Lloyd-Still score, ESR, CRP, albumin, linear growth and body weight	2A
Wilschanski <i>et al</i> ^[29]	Retrospective	65	Nasogastric supplemental feeding	Continued nasogastric feeding post resumption of normal diet maintained remission for longer and showed improved linear growth	Relapse rate, linear growth	1D
Esaki <i>et al</i> ^[31]	Retrospective	145	Enteral <i>vs</i> non enteral (where enteral applies to elemental or polymeric feeds)	Enteral feeding showed a lower relapse rate than non-enteral	Rate of relapse based on CDAI scores	1D
Axelsson <i>et al</i> ^[33]	Cohort	34	Elemental diet for IBD refractory to improvement on high dose steroids	31 had been on high dose steroids prior to trial. 15 went into remission on elemental feed alone. 6 achieved remission with introduction or increase in prednisone dose	Serum iron, transferrin, albumin, creatinine clearance, ESR, urea clearance, fecal volume, number of bowel movements	1B
Ballegaard <i>et al</i> ^[36]	Questionnaire	130		Sensitivity was commonly reported to vegetables (40%), fruit (28%), milk (27%), meat (25%) and bread (23%). No differences were found between the UC and CD groups		1C
Brandes <i>et al</i> ^[44]	RCT	20	Refined sugar rich <i>vs</i> refined sugar excluded	The sugar rich diet was stopped in 4 patients due to flare-ups. In those with mild disease there were no detrimental effects in either group	CDAI	2B
Van den Bogaerde <i>et al</i> ^[45]	Case-control study	31 CD, 22 controls	Peripheral lymphocytes were incubated with food and bacterial antigens	Lymphocyte proliferation to all food and bacterial antigens was higher in CD patients than controls	Lymphocyte proliferation	1C

Abstract

Celiac disease (CD) is now recognized as a common disorder among Middle Eastern (ME) and North African (NA) populations. The aim of this review is to assess the available data regarding CD in the ME and NA and to compare this information with that of Western countries. A literature review was performed using the electronic databases PubMed and Medline (1950-2008) as search engines, and "celiac disease" was used as a Mesh term. The search was limited to ME and NA countries. The prevalence of CD in ME and NA countries among low risk populations is similar to that of Western countries, but is higher in high risk populations such as those with type 1 diabetes. It is underestimated because of lack of clinical suspicion and lack of patient awareness. Clinical presentations in term of gastrointestinal, hematologic, skeletal, and liver mani-

festations are similar between both populations except for a high prevalence of short stature in some ME and NA countries. Few studies have addressed atypical or silent CD. As in the West, diagnosis is initially made by serological tests and is confirmed by small intestinal biopsies. Gluten-free diet is the main mode of treatment with a higher apparent adherence rate than in the West. Most disease complications result from malabsorption. The disease is strongly associated with HLA DQ2 and to a lesser extent with HLA DQ8 alleles. In conclusion, CD prevalence is underestimated, with little data available about its malignant complications. Disease parameters in the ME and NA are otherwise similar to those in Western countries.

INTRODUCTION

Celiac disease (CD) is an autoimmune disorder which affects genetically predisposed individuals upon the ingestion of gluten. Its prevalence has been underestimated, but it is now considered one of the most common genetic disorders in the West with a prevalence of 1%-2.67%^[1-3].

In Middle Eastern (ME) and North African (NA) countries, the literature regarding CD has expanded signif-

icantly. The number of original articles published from the region during the last 30 years is about 120 with around 30, 29, 16, and 10 articles coming from Israel, Turkey, Tunisia, and Iran, respectively. Most studies are epidemiological. The true prevalence of the disease is underestimated and its clinical features have not been fully determined due to small sample size, selection bias, limited knowledge about CD and limited funds available for research.

The aims of this review of CD in ME and NA countries are to compare the disease parameters to those in Western countries, namely its epidemiology in low and high risk populations, its most common clinical presentations, the diagnostic tests used and their reported sensitivity and specificity. In addition, we determine the efficacy of the treatment modalities used, compliance with a gluten-free diet (GFD) and disease complications.

EPIDEMIOLOGY OF CD IN THE MIDDLE EAST AND NORTH AFRICA

Until the 1990s, the prevalence of CD in ME and NA countries was considered low. However, with the introduction of anti-endomysial antibodies (AEA) and anti-gliadin antibodies (AGA) testing, CD has been more readily reported from developing countries^[4], and its prevalence seems similar to that of Western countries^[4-7]. However, this prevalence varies from 0.14% to 1.17% in low risk, and from 2.4% to 44% in high risk populations (Tables 1 and 2). This difference is attributed to the heterogeneity of the studied populations, subject selection, diagnostic strategies used, and whether confirmatory biopsies were performed or not. For example, two studies from Tunisia reported a five-fold difference in CD prevalence, probably due to the use of different screening methods^[8,9].

CD in low risk populations

Prevalence of CD among low risk populations ranges from 0.14% to 1.3% as assessed by serological markers and from 0.033% to 1.17% assessed by biopsies (Table 1). The prevalence was found to be > 1% in two studies from Turkey^[5,6], 0.5%-1% in six reports from Turkey, Egypt, Iran, Tunisia and Israel^[7,8,10-13], and < 0.5% in five reports from Jordan, Lebanon, Tunisia, and Kuwait^[9,14-17].

Most studies screened healthy blood donors^[6,9-11,17], of whom young males represented > 70%. One study screening healthy individuals for CD in Iran, 50% of whom were females, reported a similar disease prevalence of 1% among both men and women^[7]. On the other hand, Green *et al*^[2] reported that the disease was 2 to 3 times more common in women. Another study from Tunisia on healthy blood donors, 30% of whom were females, reported a disease prevalence of 0.4% among women compared to 0.22% among men^[17]. Exclusion of subjects with iron deficiency anemia (IDA), abnormal liver function tests (LFTs) and the low percentage of participating females may have led to the underestimation of disease prevalence. In addition, low suspicion among physicians may have contributed to the low reported incidence of CD^[8,14]. Finally, studies restricted to patients pre-

senting with severe symptoms might have underestimated the true prevalence of the disease by missing asymptomatic and mildly symptomatic individuals^[15].

CD in high risk populations

High risk populations include patients with positive family history, insulin dependent diabetes mellitus (IDDM) and/or thyroiditis, and those with symptoms of malabsorption such as chronic diarrhea, refractory IDA and weight loss. Among these, the prevalence of CD ranges from 2.4% to 44% assessed by serological markers and biopsies (Table 2).

In Western countries, the prevalence of CD among patients with IDDM is 1%-12% assessed by serological markers and 1%-11% by biopsies^[1]. The disease is more common in children than adults with IDDM. In nine reports from ME and NA countries, the prevalence of CD among IDDM patients was 2.4%-20% assessed by serological markers and 2.4%-16.4% by biopsies (Table 2). Small sample size and a high rate of consanguinity may have contributed to the high prevalence. CD and IDDM share many genetic factors including HLA DR3-DQ2 and HLA DR4-DQ8 haplotype^[18,33].

CD is common in patients with autoimmune thyroid diseases. In Western countries a prevalence of 4%-5% is reported^[34,35], with an average of 1.5%-6.7% as assessed by serological markers and 3% by intestinal biopsies^[1]. The prevalence of CD among Tunisian patients with Grave's disease was 3.7% by serological markers and 2.5% by biopsies^[19]. An increased prevalence of autoimmune thyroid antibodies among CD patients on a GFD^[36] has also been reported. In Turkey, 5.9% of patients with autoimmune thyroiditis had positive CD serology^[20]. Autoimmune thyroid disease and CD share a common genetic background (HLA DQ2 and HLA DQ8)^[20].

Prevalence of CD in relatives

In the US, the prevalence of CD was found to be 4.5% and 2.5% in first and second-degree relatives of patients with the disease, respectively^[3]. The National Institutes of Health (NIH) estimates the prevalence of CD among first degree relatives to be 4%-12%, assessed by biopsy.

In two studies from Algeria and Turkey, the prevalence of CD in patients' first degree relatives was 3.4% and 1.7%, respectively^[21,33]. Among 381 first degree relatives, 26 had positive serology, and villous atrophy was present in 13 of 16 who had biopsies performed^[21]. Also, clustering of CD within families has been reported from Jordan and Algeria^[14,21]. There are no twin studies of CD in ME and NA countries. The high rate of consanguinity in these countries might contribute to a higher prevalence of CD and provides an opportunity for studying genotype-phenotype correlations.

CLINICAL PRESENTATION

The clinical presentation of CD varies from silent disease to full-fledged severe intestinal and extra-intestinal manifestations^[1,2,37]. A study comparing Turkish and US

patients found that the former presented mostly with diarrhea and anemia and the latter with atypical symptoms such as fatigue, abdominal pain and bloating^[38]. Whereas some reports from Turkey, Jordan and Iran address silent and atypical CD^[5,14,39], little is known about the prevalence and the clinical, serologic and histopathologic features of patients with atypical or silent CD in this region, the so-called celiac iceberg.

GI manifestations

GI complaints are the most common presenting symptoms. They include diarrhea, abdominal pain, constipation, bloating, flatulence, nausea and vomiting. Lo *et al*^[40] report a drop in the percentage of CD patients presenting initially with diarrhea to 43%, compared to 73% before 1993.

Among six studies assessing chronic diarrhea in ME and NA countries, CD prevalence was 6.5%-21%^[22,23,41-44]. In Iran, Lebanon, Iraq, Saudi Arabia and Kuwait, CD was one of the most common causes of chronic diar-

rhea^[22,41-44]. In Egypt, 4.7% of children presenting with diarrhea and failure to thrive had CD^[13].

The reported prevalence of GI manifestations has varied widely among different studies (Table 3). This may be due to the low number of patients evaluated or a delay in their presentation. For example, al-Hassany^[45] reported 10 cases with advanced CD who all had diarrhea, abdominal distension and weight loss. Diarrhea and abdominal distension were significantly more common in younger children, whereas abdominal pain, failure to thrive and growth retardation were more common among those who were older. This is attributed to the predominance of classical CD among younger children versus atypical CD seen among older children^[14,46].

About one third of children with CD in Western countries develop short stature^[50]. In ME and NA countries, short stature was discovered to be the presenting symptom in 7.7% to 53% of patients. The highest prevalence of short stature was reported from Jordan where 26% of children with CD had rickets. In Turkey, 51% of patients had a

CD: Celiac disease.

height < 2.5 standard deviations below the mean^[47].

Many CD patients are initially diagnosed as having irritable bowel syndrome (IBS). Green *et al*^[51] reported that up to 36% of American patients with CD were previously diagnosed with IBS. In Iran, 12% of IBS labeled patients turned out to have CD^[39].

Hematological manifestations

The prevalence of anemia at the time of CD diagnosis is 12%-69%^[52]. IDA is the most common form and may be the only finding in 45% of patients with sub-clinical CD^[53]. Worldwide prevalence of CD among patients with IDA is 2.8%-8.7% and may be as high as 15%^[54,55]. Folate and B12 deficiency may contribute to anemia in CD, and surprisingly, anemia of chronic disease is relatively common^[52]. In ME and NA countries, anemia occurs in 20%-80% of CD patients and the majority of cases are attributable to iron deficiency^[14,15,22,24-26,33,45-47]. An Egyptian study found that 4% of young IDDM patients with anemia had CD^[56]. Another paper reports a CD prevalence of 44% among 25 Egyptian patients evaluated for refractory IDA^[27].

Osteoporosis

The prevalence of osteopenia and osteoporosis in CD patients is 30%-50% and 3.4%-14%, respectively^[57,58]. In ME and NA countries, 5 studies of CD patients reported a prevalence of hypocalcemia of 3.3%-27.4%^[33,45,46] and of osteoporosis of 13.5%-16.7%^[33,39]. In Saudi Arabia, osteomalacia and IDA were the most common presenting symptoms, accounting for 43.5% of the clinical presentations^[48]. In Tunisian children with CD diagnosed by screening, osteopenia prevalence was 34.7%^[8]. Delay in the diagnosis of CD may account for the high prevalence of osteoporosis^[33].

Abnormal LFTs

Hypertransaminasemia is an early manifestation of liver involvement in CD. Five to 10% of patients with elevated serum aminotransferases end up being diagnosed with

CD^[59]. Liver biopsy may reveal lesions ranging from reactive hepatitis to cirrhosis, which may be partially or totally reversed with a GFD. In ME and NA countries, few studies have reported abnormal LFTs among patients with CD^[21,46]. A Turkish study reported increased transaminases and hypoproteinemia in 38.3% and 4% of CD patients, respectively^[46]. The latter may be attributed to protein-losing enteropathy and/or decreased hepatic synthetic activity^[46]. An Iranian group reported increased transaminases among 25% of CD patients^[22]. Transaminases levels normalized in all patients, except those with cirrhosis, on a GFD^[22,46].

Prevalence of autoimmune diseases among patients with CD

About 30% of patients with CD have other autoimmune disorders such as IDDM and autoimmune thyroiditis^[60,61]. In ME and NA countries, the prevalence of autoimmune diseases among CD patients was demonstrated to be as low as 1.9% in Turkish patients^[46] and as high as 33% in Iranian patients^[28]. Many of these patients were diagnosed with CD after substantial delays^[39]. The prevalence of IDDM in CD patients is 6.7%-18.5% and affected patients are typically older than those with IDDM alone^[33,39,48]. They are mostly females with longer duration of diabetes^[24]. Autoimmune diseases are more common in patients with IDDM and CD than in those with CD or IDDM alone^[28,33,62]. In a Turkish study, adult patients with IDDM and CD had a 33.33% prevalence of other autoimmune diseases such as autoimmune thyroiditis^[28]. This may be an overestimation due to small sample size. Importantly, a French study demonstrated a reduction in the development of autoimmune diseases among CD patients adherent to a GFD compared to those not adherent to such a diet^[63]. This highlights a major role of early diagnosis and therapy of CD in order to reduce the burden of autoimmunity.

DIAGNOSIS

The diagnosis of CD is challenging and requires a high

Table 4 Serological diagnosis of celiac disease in Middle Eastern and North African countries

Country	Population	AGA (%)		AEA (%)		t-TG Ab (%)	
		Sensitivity	Specificity	Sensitivity	Specificity	Sensitivity	Specificity

¹Sensitivity and specificity of all tests simultaneously.

level of suspicion. All screening algorithms start with serological tests and include testing for IgA and IgG anti-gliadin antibodies (AGA), IgA and IgG anti-endomysial antibodies (AEA), IgA and IgG tissue transglutaminase (tTG) and a new generation of anti-gliadin antibodies to deamidated synthetic gliadin peptides (DGP)^[64]. The AEA test is currently the gold standard because of its high sensitivity and almost 100% specificity^[1,65]. Furthermore, high levels of both AEA and tTG have very high sensitivity and specificity^[66]. Small intestinal biopsy remains the gold standard diagnostic test^[1,67].

Diagnosis of CD in ME and developing countries

In 24 out of 28 studies of prevalence of CD in ME and NA countries, patients were initially screened with serological tests. In those testing positive, confirmation of the diagnosis by duodenal biopsy was performed in the majority of cases. In 7 out of 24 studies, confirmation by biopsy was incomplete (Tables 1 and 2). In 4 studies, intestinal biopsies were the initial mode of diagnosis because of the unavailability of serological tests^[14,15,25,29]. Serological marker sensitivity and specificity varied widely because of difference in the choice of gold standard, bias in patient selection, population differences and methodology used, including number of biopsies (Table 4). AEA sensitivity ranges from 20%^[7,11] to > 90%^[17,46,68], with a specificity reaching 100%^[7,11,26,68]. The low AEA sensitivity reported from 2 studies conducted in Iran and Israel is attributed to improper intestinal mucosal sampling, the low power of AEA-immunofluorescence in detecting early CD, and the poor performance of the AEA in the presence of milder degrees of villous atrophy^[11,69]. These factors may have resulted in missing many cases of CD^[7,11]. tTG IgA sensitivity is 70%-100%^[6,7,57], and specificity is 99%^[7]. The sensitivity of IgA AGA is about 80%, while that of IgG AGA is 90%-100%^[17,27,46]. AEA testing was used in 19 out of 24 studies, while t-TGA and AGA testing were used in 12 and 9 studies, respectively (Tables 1 and 2). While the serological tests have shown high sensitivity and specificity for the diagnosis of CD, there are problems including

differences in test kit sensitivity and specificity^[70], as well as an apparent lower performance in the clinical setting compared to research laboratories^[71].

The Marsh classification is a histologic grading system that reflects the varying degrees of intestinal mucosal villous atrophy and inflammatory changes that occur in patients with CD^[1]. Marsh classification is used by almost all investigators in the histological diagnosis and classification of CD severity.

TREATMENT

A GFD remains the mainstay of CD treatment. Adherence to a GFD in Western countries is reported to be less than 50%^[72]. Treatment with a GFD results in improvement of many clinical and serological parameters^[1,73]. Also, adherence to a GFD for five consecutive years or more significantly reduces the incidence of malignancies such as cancer of the mouth, pharynx, esophagus and lymphoma^[74]. Moreover, adherence to a GFD has a protective effect on the development of many autoimmune diseases such as IDDM, inflammatory bowel diseases, hepatitis and hematologic disorders^[63].

Adherence to a GFD in ME and NA countries ranges from 50% to 100%^[10,14,15,18,22,23,39,59,62]. The vast majority of adherent patients have good response ranging from 60% to 100%^[10,14-16,18,22,23,28,39,48,49]. Moreover, patients' level of compliance and response were used interchangeably in some studies^[14,15,48]. The higher level of adherence to a GFD in comparison to Western countries may be due to the limited number of patients studied and the use of less rigorous parameters to assess adherence.

The reasons for poor compliance are not clear. Wheat and barley are major diet constituents with few acceptable alternatives^[22], rendering the convincing of parents that bread is the cause of diarrhea very hard^[15]. Also, convincing patients with atypical CD to adhere to a GFD is difficult^[4]. Finally, lack of information about CD manifestations, lack of benefit from a GFD and lack of encouragement to adhere to such a diet may contribute. More than 10% of adults with CD do not adhere strictly

to long term GFD and more than 30% who believe they are, are actually consuming grams of gluten daily^[4]. Diabetic patients adhering to a GFD will have fewer episodes of hypoglycemia and better diabetes control^[26]. Demir *et al*^[46] report improvement in growth velocity and rapid catch up of height and weight in children with CD who adhere to a GFD. Moreover, adherence to a GFD resulted in improvement of hepatic histopathological changes. In addition to a GFD, supplementation of calcium, vitamin D and iron may accelerate normalization of serological markers and reduce the rate of fractures and complications resulting from anemia^[39].

There are no reports regarding refractory CD or its treatment from ME or NA countries. In addition, no trials of immunosuppressive or immune-modulator drugs have been described. Currently, both a permeability blocker and oral enzyme preparations are in clinical trials in the US and Europe^[75-77]. While the safety and effectiveness of these potential therapies need to be determined, the financial burden of the addition of drugs to a GFD may be prohibitive in developing countries.

COMPLICATIONS

Complications of CD range from malabsorption to cerebellar ataxia, dilated cardiomyopathy^[78], infertility, lymphoma, as well as oropharyngeal, gastrointestinal and thyroid malignancies^[45,79]. Metabolic bone disease, malignancies and autoimmune conditions may develop if treatment is delayed^[80].

In the ME and developing countries, most complications result from malabsorption. Mortality in hospitalized patients with CD is relatively increased in the first 3 years after diagnosis, particularly in patients with malabsorption, those with delayed diagnosis, and those poorly adherent to a GFD^[33]. Prolonged INR due to Vit K malabsorption is found in 25% of patients and improves on a GFD^[81]. However, low levels of serum cholesterol, HDL, LDL and phospholipids in 46 Algerian patients with CD did not improve on a GFD^[82]. Hypocalcemia and hypovitaminosis D contribute to osteoporosis which occurs in 16.7%^[43] of CD patients, similar to what is reported in Western countries^[57,83]. There have been case reports of hepatic vein thrombosis in North African subjects with CD^[84,85].

A mortality rate of 3.3% was reported in 60 Turkish patients with CD, mainly due to malignancies^[33]. In Turkey and Iran, non-Hodgkin lymphomas are the most common CD-associated malignancies^[33,39]. Similar to Western countries, there is an increased prevalence of gastrointestinal malignancies and of non-Hodgkin lymphoma in CD patients. Oropharyngeal malignancies, as well as neurological, cardiac and cutaneous complications of CD, have been described in Western countries^[1,2,37,78,79], but have not been well documented in ME countries. Left ventricular subclinical systolic dysfunction has been reported in Turkish children with CD, with a negative correlation between myocardial systolic wave

and serum IgA AEA level^[86].

Mortality rate among hospitalized patients with CD in Turkey was found to be increased 2-fold^[33], although it is not clear what the control group was in this study. While increased mortality in CD patients has been well documented in the West using standardized mortality ratio (SMR)^[1], which is the ratio of observed deaths in patients with celiac disease to expected deaths on the basis of age- and sex-specific rates in the region under study, no such data has been published from the Middle East.

GENETICS

Most CD patients have HLA DQ2 or HLA DQ8 alleles, which account for 40% of the total genetic predisposition to CD^[1,2]. Moreover, HLA DQ2 and DQ8 are expressed in 30% of the general population, suggesting the presence of additional factors for CD development. One such factor is *CTLA-4* gene polymorphism, a non HLA gene thought to regulate T-cell immune function^[87]. As in the West, CD is found in ME and NA countries to be strongly associated with HLA DQ2 (DQA1*0501 and DQB1*0201)^[88-93]. HLA DQ8 (DQA1*0301 and DQB1*0302) is less strongly associated with CD^[92]. *HLA B8*, a gene expressed in MHC I antigen presenting cells, is found to be associated with CD in Algeria^[89], Iraq^[94,95] and Turkey^[91]. Carriers of this gene are at increased risk of developing CD^[91]. In addition, Saharawi patients with atypical CD were found to over-express the MHC class I chain-related gene A (MICA) allele 5.1^[89]. These associations have been reported in Western countries^[96]. Increased prevalence of HLA-A25(10) in Turkish children with CD is reported, suggesting that this genotype is particularly encountered among this population^[91]. No such association has been described in Western countries.

CONCLUSION

The prevalence of CD disease in ME and NA countries may be underestimated due to lack of awareness and low suspicion of the disease. Whether mass screening for the disease should be done in high risk populations, such as patients with short stature, chronic diarrhea, IDA, IDDM, and those with a positive family history is not clear. The best screening modality is not yet determined, though tTG IgA is probably the most economic.

Large prospective studies are needed to assess the true incidence, the clinical course, the efficacy of treatment modalities employed, patient compliance, disease complications and response to treatment in ME and NA countries. The association of CD with other autoimmune diseases and the presence of specific genetic markers would be areas of interesting future research. The high rate of consanguinity among people of the same ethnic background in this part of the world might provide an opportunity for establishing genotype-phenotype correlations in CD.

Abstract

AIM: To explore the anti-fibrotic effect of *Haobie Yangyin Ruanjian* Decoction (HYRD) on CCl₄-induced hepatic fibrosis in rats and its modulation on the transforming growth factor (TGF) β -Smad signaling pathway.

METHODS: Fifty-six healthy Wistar rats were randomly divided into five groups: normal control group ($n = 6$), CCl₄-induced hepatic fibrosis group ($n = 14$) and three treatment groups (the treated rats received HYRD *via* oral administration at daily dosages of 8.2, 2.5 and 0.82 g/kg, respectively) of HYRD ($n = 12$, respectively). Experimental hepatic fibrosis was induced by subcutaneous injection of carbon tetrachloride solution (CCl₄ dissolved in peanut oil, 4:6, V/V) with 0.5 mL/100 g body weight for the first time, and then 0.3 mL/100 g body weight twice a week for 8 wk. In the former 2 wk, rats were raised by feedstuff I (80% corn meal, 20% lard, 0.5% cholesterol). After 2 wk, they were raised by feedstuff II (corn meal and 0.5% cholesterol). Except for the control group, 30% alcohol solution was given orally to each rat every other day from the beginning, 1 mL for each rat. Liver function

parameters and hepatic hydroxyproline content were detected by chromatometry. Serum levels of hyaluronic acid (HA), type IV collagen (CIV), type III procollagen (PCIII) and laminin (LN) were assayed with radioimmunoassay. Deposition of collagen was observed with hematoxylin-eosin staining and collagen staining. Gene expression of *TGF β 1* and *Smad3* were detected with real-time reverse transcriptase-polymerase chain reaction and Western blotting, respectively.

RESULTS: The serum levels of alanine transaminase and aspartate transaminase were increased in the model group compared with the control group ($P < 0.01$), and they were decreased in the three treatment groups compared with the model group. The serum levels of total protein and albumin were decreased in the model group and increased in the three treatment groups. The hepatic hydroxyproline content and serum levels of PCIII, HA, LN and CIV were markedly increased in the model group compared with the control group, and decreased in the treatment groups. The gene expression of *TGF β 1* and *Smad3* was enhanced in the model group compared with the control group, and HYRD could down regulate their expression.

CONCLUSION: HYRD can inhibit hepatic fibrosis induced by CCl₄ in rats, which is probably associated with its down-regulation on fibrogenic signal transduction of TGF β -Smad pathway.

INTRODUCTION

A variety of pathological factors, including viral hepatitis (especially hepatitis B and C), alcohol and drug abuse, metabolic diseases due to overload of iron or copper, autoimmunity against hepatocytes or bile duct epithelium, and congenital abnormalities can cause hepatic injury. Lifestyle changes (mainly exercise withdrawal and weight gain) have probably raised the prevalence of non-alcoholic fatty liver disease (NAFLD), which is the first cause of chronic liver disease in Western world. All these chronic hepatic diseases can cause hepatic fibrosis (HF)^[1]. If hepatic fibrosis treatment was delayed, hepatic cirrhosis would be developed. Hepatic fibrosis, cirrhosis in particular, is associated with significant morbidity and mortality. Hepatic fibrosis is characterized by imbalance between extracellular matrix synthesis and degradation. Extracellular matrix mainly results from hepatic stellate cells (HSCs) which can be transformed into myofibroblast initially. Transforming growth factor (TGF) β -Smad signal pathway plays an important role in this process^[2], it can activate HSCs and promote collagen synthesis^[3]. Research has shown TGF- β 1 is a key cytokine in determining fatty liver and non-alcoholic steatohepatitis (NASH)^[4]. Therefore, TGF β -Smad signal pathway has become a main target in hepatic fibrosis treatment^[5]. Although new therapeutic approaches have recently been proposed, there is no established therapy for hepatic fibrosis. *Haobie Yangyin Ruanjian* Decoction (HYRD) is a kind of traditional Chinese Medicine. The aim of the present study was to investigate its protective effects and mechanism in a rat model of CCl₄-induced hepatic fibrosis.

MATERIALS AND METHODS

Composition of HYRD

The composition of HYRD include *Herba Artemisiae Annuae*, *Carapax Trionycis*, *Salviae Miltiorrhizae*, *Rhizoma Polygoni Cuspidati*, *Radix Curcumae*.

Animals and experiment protocol

Fifty-six healthy Wistar rats, female and male, weighing 237.8 ± 8.5 g were obtained from the Experimental Animal Center of Academy of Medical Science of Chinese People's Liberation Army (Beijing, China). Animal certificate: SCXK-(Army)2007-004. The rats were randomly divided into normal control group ($n = 6$), model group ($n = 14$), and three treatment groups ($n = 12$, respectively). Except for the normal control group, all the rats were subcutaneously injected with solution of carbon tetrachloride dissolved in peanut oil (CCl₄: peanut oil = 4:6, V/V), 0.5 mL/100 g body weight for the first time, and then 0.3 mL/100 g body weight twice a week for

8 wk. In the former 2 wk, rats were raised with feedstuff I (80% corn meal, 20% lard, 0.5% cholesterol). After 2 wk, they were raised with feedstuff II (corn meal and 0.5% cholesterol). Except for the normal control group, 30% alcohol solution was given orally to each rat every other day from the beginning, 1 mL for each rat. For the normal control group, the peanut oil was injected to each rat subcutaneously.

The rats in the three treatment groups, including a high-dose group (8.2 g/kg per day, calculated as Decoction), a medium-dose group (2.5 g/kg per day), and a low-dose group (0.82 g/kg per day), were given HYRD daily *via* oral administration, 1 mL/100 g body weight. Except for the dead, all the rats were anesthetized with ether. Blood was taken from the abdominal vein, centrifuged at 4°C, 3000 r/min, for 20 min, and serum was kept at -20°C for assay.

Liver laboratory tests

Serum levels of alanine transaminase (ALT), aspartate transaminase (AST), albumin (Alb) and total protein (TP) were measured using commercially available kits (Jiancheng Inst. Biotechnology, Nanjing, China) according to the manufacturer's instructions.

Hepatic hydroxyproline content

Liver tissue (100 mg) was prepared for hydroxyproline (Hyp) determination according to a modified method by Jamall *et al.*^[6]. The Hyp content of the liver as an indirect measure of tissue collagen content was expressed as milligram per gram of dry weight (mg/g).

Serum levels of hyaluronic acid, type IV collagen, type III precollagen and laminin

Serum levels of hyaluronic acid (HA), type IV collagen (CIV), type III precollagen (PCIII) and laminin (LN) were determined by radioimmunoassay (RIA) using commercially available kits (Beifang Inst. Biotechnology, Beijing, China) according to the manufacturer's instructions.

Histological examination

Liver tissues were taken from the left lobe of the liver of each rat, and fixed in 15% buffered paraformaldehyde, and dehydrated in a graded alcohol series. Specimens were embedded in paraffin blocks, cut into 5 μ m-thick sections and placed on glass slides. The sections were stained with hematoxylin-eosin (HE) and ponceau's^[7], respectively. Fibrosis was graded according to the method of Scheuer^[8] as follows: stage 0: no fibrosis; stage 1: an increase of collagen without the formation of septa (small satellite expansion of the portal fields), expansion of portal tracts without linkage; stage 2: formation of incomplete septa not interconnecting with each other, from the portal tract to the central vein; stage 3: complete but thin septa interconnecting with each other, which divide the parenchyma into separate fragments; and stage 4: complete cirrhosis, similar to stage 3 with thicker septa. Pathological examination was performed by the same pathologist who was blinded to the treatment assignment for the rats.

Determination of TGF-β1 mRNA level in liver tissue by real-time reverse transcriptase-polymerase chain reaction (RT-PCR)

Total RNA was extracted from liver tissues of each group with the tissue/cell total RNA isolation kit (Trizol Reagent, Invitrogen, USA) according to the manufacturer's protocol. The quantity and purity of RNA were detected by determining absorbance at 260/280 nm using a spectrophotometer (BECKMAN COULTER Co., USA). Total RNA was reversibly transcribed into complementary DNA (cDNA) using the cDNA synthesis kit [TaKaRa RNA PCR Kit(AMV)Ver 3.0, Dalian, China] according to the manufacturer's protocol. The ABI PRISM 7900 HT Real Time PCR System (ABI Co., USA) and real-time PCR kit (2 × SYBGreen RT-PCR Master Mix, UCL, USA) were employed based on the manufacturer's instructions. The specific primers for the target gene and β-actin were synthesized by Dalian TaKaRa Biotechnology Company. TGF-β1: 5'-TGGCGTTACCTTGGTAACC-3' (forward); 5'-GGTGTGAGCCCTTCCAG-3' (reverse). β-actin: 5'-ACCCITTAAGGCCAACCGTGAAAAG-3' (forward); 5'-TCATGAGGTAGTCTGTCAGGT-3' (reverse).

Two-step PCR procedure was used as follows: pre-denaturation for 30 s at 95°C, 1 cycle; 94°C for 15 s and 56°C for 40 s, 40 cycles. The final products were identified by electrophoresis in 1.5% agarose gel and melt curve analysis. Melt curve detection: 95°C 15 s, 60°C 15 s and 95°C 15 s. The final results were described with the relative values ($2^{-\Delta\Delta C_t}$). The calculation and analysis were performed by the Sequence Detection Software version 2.1 in the ABI PRISM 7900 HT Real Time PCR System (ABI Co., USA).

Determination of Smad3 level in liver tissue by Western blotting

Total protein was extracted from liver tissue and analyzed with bicinchoninic acid (BCA) protein concentration assay kit (Beyotime Inst. Biotechnology, Jiangsu, China). Sample protein was separated by electrophoresis in 12% SDS-PAGE separating gel with Bio-Rad electrophoresis system (Bio Rad Laboratories, Hercules, CA, USA). The primary antibodies (rabbit anti Smad3 antibody, 1:1000 dilution, MILLIPORE Inc., USA) were incubated at 4°C overnight. The corresponding horseradish peroxidase-conjugated secondary antibodies (anti-rabbit IgG, 1:5000 dilution, Zhongshanjinqiao Biotechnology Inc., China) were incubated at room temperature. Immobilon™ Western Chemiluminescent HPR Substrate (MILLIPORE Inc., USA) and Quantity ONE (BIO-RAD) were employed for revealing and quantitative analysis of the blots. β-actin protein was used as the internal control.

Statistical analysis

All values were expressed as mean ± SD. Comparisons were analyzed by one-way ANOVA using the SPSS 12.0 statistical package. Differences were considered statistically significant if the $P < 0.05$.

RESULTS

Effect of HYRD on liver function

The serum levels of ALT and AST were increased in the model group compared with the control group ($P < 0.01$). Compared with the model group, the serum levels of ALT and AST were decreased in the three treatment groups. The serum levels of TP and Alb were decreased in the model group compared with the control group. Compared with the model group, the serum levels of TP and Alb were increased in the treatment groups (Table 1).

Effect of HYRD on hepatic hydroxyproline content

Hepatic hydroxyproline content was markedly increased in the model group compared with the control group ($P < 0.01$). Compared with the model group, the levels of hydroxyproline were significantly decreased in the treatment groups (Table 2).

Effect of HYRD on serum levels of CIV, PCIII, HA and LN

The serum levels of PCIII, HA, LN and CIV were increased in the model group compared with the control group. Compared with the model group, the serum levels of PCIII, HA, LN and CIV were decreased in the treatment groups (Table 3).

Effect of HYRD on hepatic histopathological changes

At the end of the study, normal hepatic lobules, without fibroplasia and inflammatory cell infiltration could be

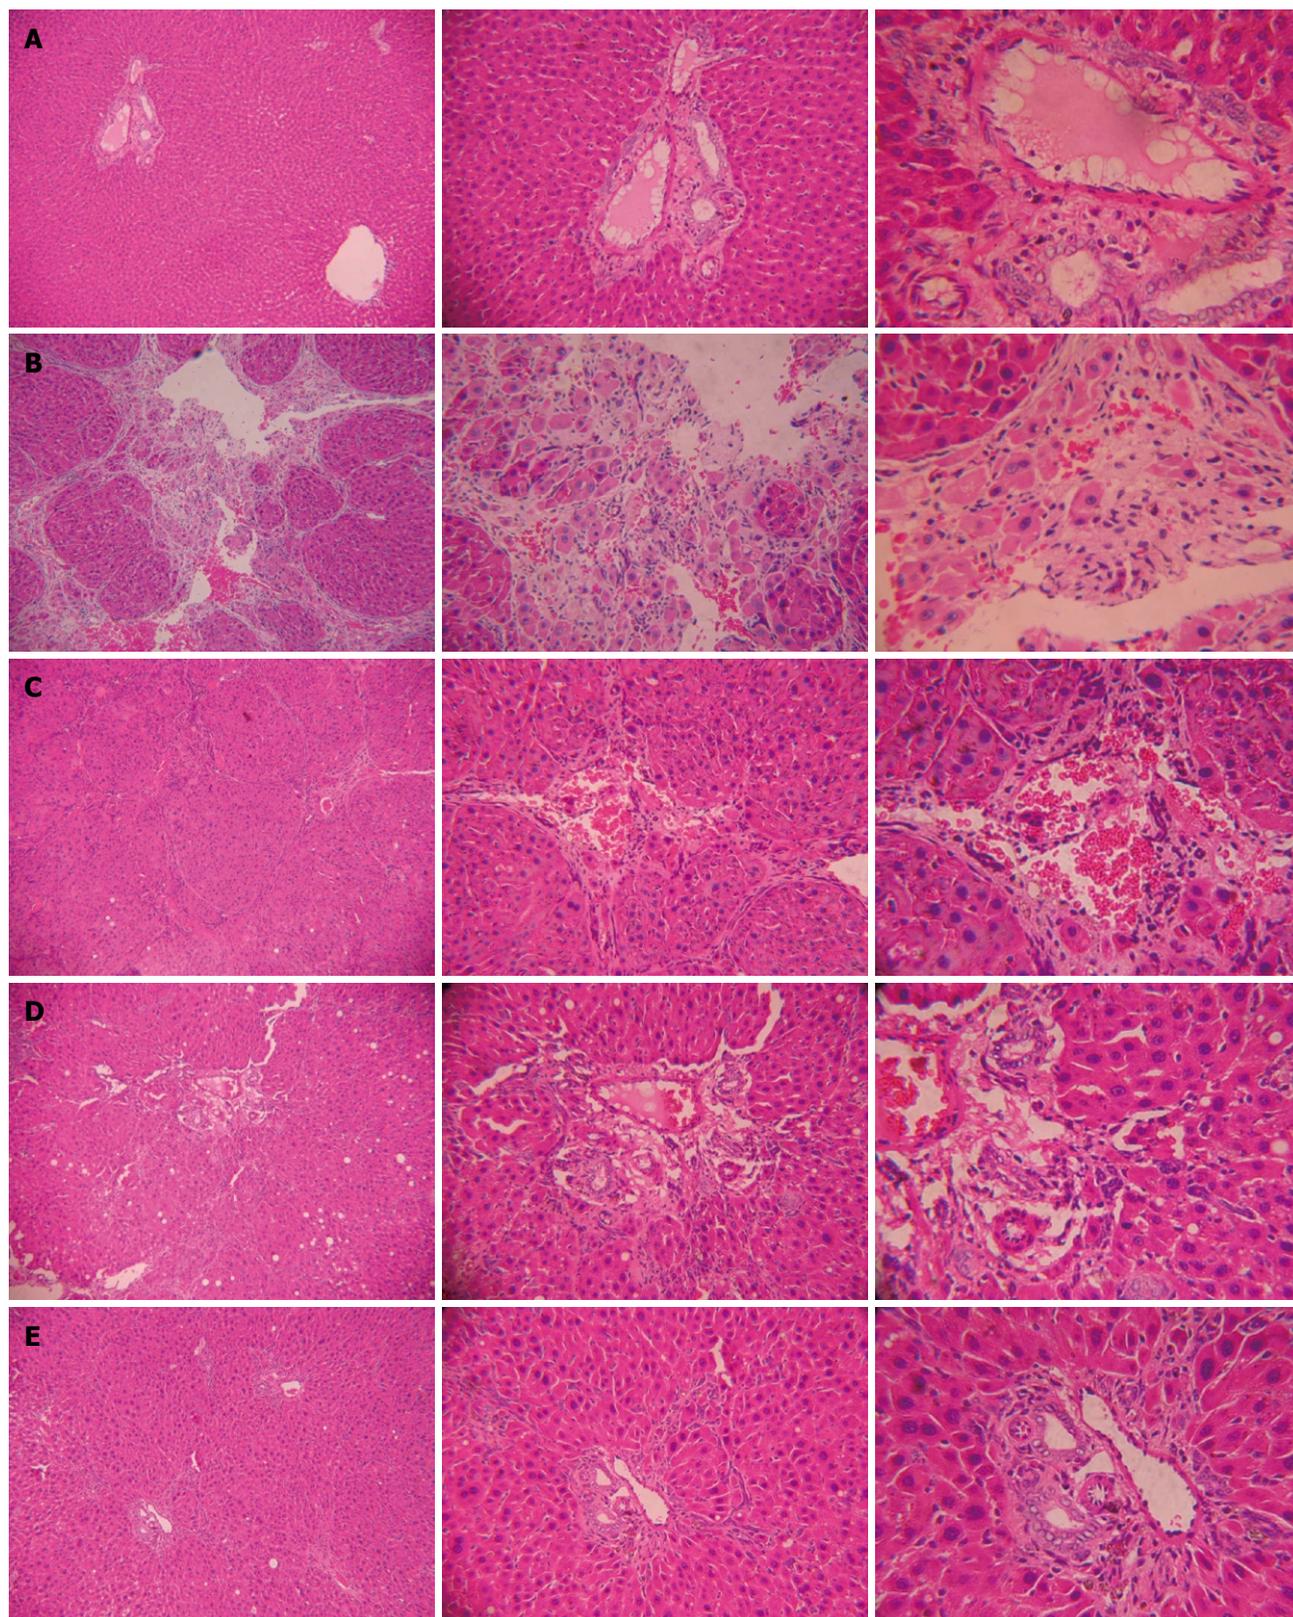

Figure 1 Histological profiles of liver tissues in rats. A: Normal rats; B: Rats with hepatic fibrosis; C: Low-dosage of *Haobie Yangyin Ruanjian* Decoction (HYRD)-treated rats; D: Medium-dosage of HYRD-treated rats; E: High-dosage of HYRD-treated rats. Effect of HYRD on TGF-β1 and Smad3 expression in liver

Expression of TGF-β1 and Smad3 in liver was increased significantly in the model group (*P* < 0.01), and decreased obviously in the treatment groups (Table 5, Figure 3).

DISCUSSION

Hepatic fibrosis is thought to be a reversible disease, CCl₄-induced hepatic fibrosis in rats is a reproducible model for studying the pathogenesis of hepatic fibrosis and cirrhosis^[9]. CCl₄ can cause oxidative stress reaction *via* toxic free radicals. Lipid peroxidation of cytomembrane plays an important role in early stage of hepatic injury, which can activate lipocyte (HSCs). The activation of HSCs “induced by some critical cytokines” is considered to be of great importance during the long period of hepatic fibrosis^[10]. This activated HSC then becomes the main source of most cytokines and collagen proteins. Among the cytokines mediating factors, *TGF-β1* has been demonstrated in most researches to be an essential pro-fibrogenesis factor^[11-15]. In addition to that, *TGF-β-Smad* signaling pathway is the main pathway of *TGF-β*^[16-18], which transfers the stimulating signal from outside into the affected cells. The *Smad* proteins consist of a large family of transcription factors. *Smads* are *TGF-β* receptor substrates with a demonstrated ability to propagate signals. Briefly, two different transmembrane protein serine/threonine kinases, named *TGF-β* receptor type I and II, respectively, are brought together by the ligand, which acts as a receptor assembly factor^[19]. Before this occurs, receptor I is inactive. During the *TGF-β* signal transduction, receptor II is activated first. *TGF-β* and its receptor then form an activated complex. In the ligand-induced complex, active receptor II activates the receptor I kinase. The type I receptors specifically recognize the *Smad* subgroup known as receptor-activated *Smads* (R-*Smads*), which are *Smad 2* and *Smad 3*^[20]. Then R-*Smads* are activated and form a complex consisting of R-*Smads* and *Smad 4*, which belong to Co-*Smad*. The *Smads*-complex then is accumulated in the nucleus. This procedure leads to the formation of the functional transcriptional complexes. Both the R-*Smads* and the Co-*Smads* in this complex may participate in DNA-binding and recruitment of transcriptional cofactors^[21,22]. After transferring into the nucleus, the transcriptional complex binds to the certain domain of the target gene and cause the gene expression such as collagen production. The excess collagen production would lead to collagen deposition in liver tissue and hepatic fibrosis or cirrhosis at last. Thus, the down-regulation of *TGF-β* expression, modulation of *TGF-β-Smad* signaling and inhibition of the accumulation of activated HSCs by modulating either their activation and/or proliferation or promoting their apoptosis are important therapeutic strategy.

According to the Chinese Medicine theories, hepatic fibrosis is caused by internal damp (Shi), heat (Re), poison (Du), blood stasis (Yu), and both Qi and Yin asthenia. In this study, not only CCl₄ but also cholesterol, lard and alcohol were used to establish a hepatic fibrosis model. CCl₄ is poison, cholesterol, lard and alcohol produce damp and heat, which cause healthy energy asthenia, blood stasis exacerbation, unrelievable damp and heat, and induce hepatic fibrosis. Thus, the main Chinese Medicine approach to hepatic fibrosis is to eliminate heat, dispel damp, activate blood, promote Qi and cultivate

Yin^[23,24]. HYRD is composed of *Herba Artemisiae Annuae*, *Carapax Trionycis*, *Salviae Miltiorrhizae*, *Rhizoma Polygoni Cuspidati*, *Radix Curcumae*. The Decoction can activate blood and remove stasis, clear heat and eliminate damp, soften hard lumps and dispel nodes.

Herba Artemisiae Annuae can improve immunocyte activity, whose derivative artesunate can inhibit hepatic fibrosis^[25], and *Carapax Trionycis* can inhibit hepatic collagen deposition, promote collagen degradation^[26]. *Salviae Miltiorrhizae* and *Rhizoma Polygoni Cuspidati* can inhibit lipid peroxidation, reinforce organism immunity, improve hepatic microcirculation, inhibit adhesion of leucocyte and platelet to endotheliocyte, promote hepatocyte regeneration and collagen degradation^[27,28]. *Radix Curcumae* can activate blood and remove stasis, clear heat and eliminate damp^[29].

In conclusion, HYRD can inhibit lipid peroxidation, improve hepatic function, lessen collagen deposition, and prevent hepatic fibrosis *via* modulating *TGF-β-Smad* signaling pathway.

COMMENTS

Background

In China, the incidence of hepatic cirrhosis is still high. If treated properly at fibrosis stage, cirrhosis can be prevented. However, no effective antifibrotic drugs are available at present. According to the Chinese Medicine theories, hepatic fibrosis is caused by internal damp (Shi), heat (Re), poison (Du), blood stasis (Yu), and both Qi and Yin asthenia. *Haobie Yangyin Ruanjian* Decoction (HYRD) can activate blood and remove stasis, clear heat and eliminate damp, soften hard lumps and dispel nodes.

Research frontiers

Recent research showed hepatic fibrosis can be reversed by regulating collagen metabolism, inhibiting hepatic stellate cell (HSC) activation or by promoting HSC apoptosis. Hepatic extracellular matrix mainly results from HSC, which can be activated by fibrogenesis signal pathway.

Innovations and breakthroughs

This study has confirmed that HYRD can improve liver function, alleviate hepatic fibrosis, which is probably associated with its down-regulation on fibrogenic signal transduction of transforming growth factor (TGF) β -Smad pathway.

Applications

The HYRD can prevent hepatic fibrosis, which implies that it will be a good medicine for patients with chronic hepatic injury, this article can provide some scientific data for its application and development.

Peer review

This paper has reinforced my conviction that there is some good in this therapeutic approach. The study is statistically well-managed. Data are clear and convincing.

Abstract

AIM: To investigate the role of platelet-derived growth factor receptor-like gene (*PDGFRL*) in the anti-cancer therapy for colorectal cancers (CRC).

METHODS: *PDGFRL* mRNA and protein levels were measured by reverse transcription-polymerase chain reaction (RT-PCR) and immunohistochemistry in CRC and colorectal normal tissues. *PDGFRL* prokaryotic expression vector was carried out in *Escherichia coli* (*E. coli*), and purified by immobilized metal affinity chromatography. The effect of *PDGFRL* protein on CRC HCT-116 cells was detected by 3-(4,5-dimethylthiazolyl-2)-2,5-diphenyltetrazolium bromide (MTT), clone counting, cell cycle, and wound healing assay.

RESULTS: Both RT-PCR and immunohistochemistry showed that the expression of *PDGFRL* in colorectal normal tissues was higher than in cancer tissues. Recombinant *pET22b-PDGFRL* prokaryotic expression

vector was successfully expressed in *E. coli*, and the target protein was expressed in the form of inclusion bodies. After purification and refolding, recombinant human *PDGFRL* (*rhPDGFRL*) could efficiently inhibit the proliferation and invasion of CRC HCT-116 cells detected by MTT, clone counting and wound healing assay. Moreover, *rhPDGFRL* arrested HCT-116 cell cycling at the G0/G1 phase.

CONCLUSION: *PDGFRL* is a potential gene for application in the anti-cancer therapy for CRC.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignant tumors in the world. It is estimated that 783 000 new cases are diagnosed each year, and the number has increased rapidly since 1975^[1]. CRC is the third most common cancer and the second leading cause

of cancer related mortality in the Western world. The incidence of CRC in China has increased rapidly over the past few decades^[2]. The molecular mechanism of carcinogenesis and development of CRC is still not fully understood.

Tumor suppressor genes are genes that can slow down cell division, repair DNA errors, and tell cells when to die (a process known as apoptosis or programmed cell death). When tumor suppressor genes do not work properly, cells can grow out of control, leading to cancer. About 30 tumor suppressor genes have been identified, including *p53*, *BRCA1*, *BRCA2*, *APC*, *RB1*, and platelet-derived growth factor receptor-like gene (*PDGFRL*). Tumor suppressor genes cause cancers when they are inactivated, and encode proteins that normally serve as a brake on cell growth. When such genes are mutated, the brake may be lifted, resulting in the runaway cell growth known as cancer. Gain of oncogene function associated with loss of tumor suppressors is now widely accepted as a hallmark of cancer initiation and progression^[3].

PDGFRL is located in chromosome 8p21.3-8p22, which is commonly deleted in sporadic hepatocellular carcinoma, CRC, breast cancer, and non-small cell lung cancers^[4,5]. While its precise biological function is not known, *PDGFRL* encodes a 375aa product with significant sequence similarity to the ligand-binding domain of platelet-derived growth factor receptor β . Mutations in *PDGFRL* have been found in individual cancer samples^[6-9]. An in-depth study using micro-cell-mediated chromosome transfer found that *PDGFRL* expression is decreased in the majority of breast cancer cells^[10]. Recently, *PDGFRL* is identified to play a central role in the tumor suppressor network by adopting a network perspective^[11]. Furthermore, *PDGFRL* was found to be involved in the suppression of the tumor metastatic phenotype as a strong candidate gene^[12].

To further identify new genes involved in the pathogenesis of CRC, we analyzed the expression of *PDGFRL* in CRC tissues and normal tissues by both reverse transcription-polymerase chain reaction (RT-PCR) and immunohistochemistry, and found that *PDGFRL* was expressed at higher levels in normal tissues than in CRC tissues. We constructed *pET22b-PDGFRL* recombinant prokaryotic expression vector before expression and purification of the *PDGFRL* recombinant protein were completed. The biological features of protein were identified to inhibit the proliferation and invasion of CRC HCT-116 cells by 3-(4,5-dimethylthiazolyl-2)-2,5-diphenyltetrazolium bromide (MTT), clone counting, and wound healing assay. In addition, *rhPDGFRL* arrested HCT-116 cell cycling at the G0/G1 phase.

MATERIALS AND METHODS

Cell culture

HCT-116 CRC cells and human umbilical vein endothelial cells (HUVEC) were maintained by our lab and cultured in Dulbecco-modified Eagle medium (DMEM; Gibco) supplemented with 10% bovine calf serum (BCS)

(Gibco). Cells were maintained at 37°C in an atmosphere of humidified air with 50 mL/L CO₂.

Collection of tissues

Fifteen samples of CRC tissues and paired non-cancerous tissues (5 cm away from tumor) were obtained from the First Hospital of Changsha. Written consent was obtained from the patients, who agreed with the collection of tissue samples. The resected tissue samples were immediately cut into small pieces, and snap frozen in liquid nitrogen until use. All tumor tissue and paired non-cancerous tissue samples were pathologically confirmed.

RT-PCR

RNA isolated from tissues and cells was reversibly transcribed and amplified using the RT-PCR System (Fermentas). Primer sequences used were sense 5'-CAAGAAGGTGAAGCCCAAAAT-3' and antisense 5'-ACAAGGAACCACAGCCTGTCT-3' for *PDGFRL*. A 587-bp Glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) fragment was amplified as an internal control. For *GAPDH*, the forward primer 5'-AATCCCA TCACCATCTTCCA-3', and the reverse primer 5'-CC TGCTTCACCACCTTCTTG-3' were used. After heating at 95°C for 1 min, PCRs were exposed to 30 cycles (*GAPDH*, 25 cycles) of 95°C for 30 s, 60°C for 30 s, and 68°C for 1 min and 30 s with a final extension at 68°C for 10 min. The relative mRNA levels were normalized to that of *GAPDH* and the ratio of *PDGFRL* to *GAPDH* was calculated.

Immunohistochemistry

Paraffin sections were deparaffinized with xylene and rehydrated in graded alcohol. Endogenous peroxidase activity was blocked by incubation in 3% hydrogen peroxide at reverse transcription (RT) for 10 min. Non-specific binding was blocked with phosphate buffered saline Tween-20 (PBST) containing 10% goat serum for 2 h at RT. *PDGFRL* antibody (Abcam) was added to each slide and incubated at 4°C overnight. Following three washes, slides were incubated with Envision (DAKO) for 40 min at RT. Diaminobenzidine was used as a chromogen. Sections were counterstained with hematoxylin, dehydrated, and mounted. Evaluation of immunohistochemical slides was done with a Nikon Eclipse E800 microscope at $\times 100$ magnification. The intensity of the staining was scored on a scale of 0 to 3+ where 0, 1, 2 and 3 represented no staining and weak, moderate or strong staining, respectively. The mean staining scores for tissues and the mean fold change in protein expression was calculated.

Plasmid construction

A DNA fragment encoding the gene *PDGFRL* was amplified by PCR using a sense primer, 5'-TGAG CCATGGATCAACACCTTCC-3', and an anti-sense primer, 5'-AAGCTCGAGGGAAAACCTCAACAGT-3'. The primers were introduced to an *NcoI* site (sense) and an *XbaI* site (anti-sense), respectively. The amplification

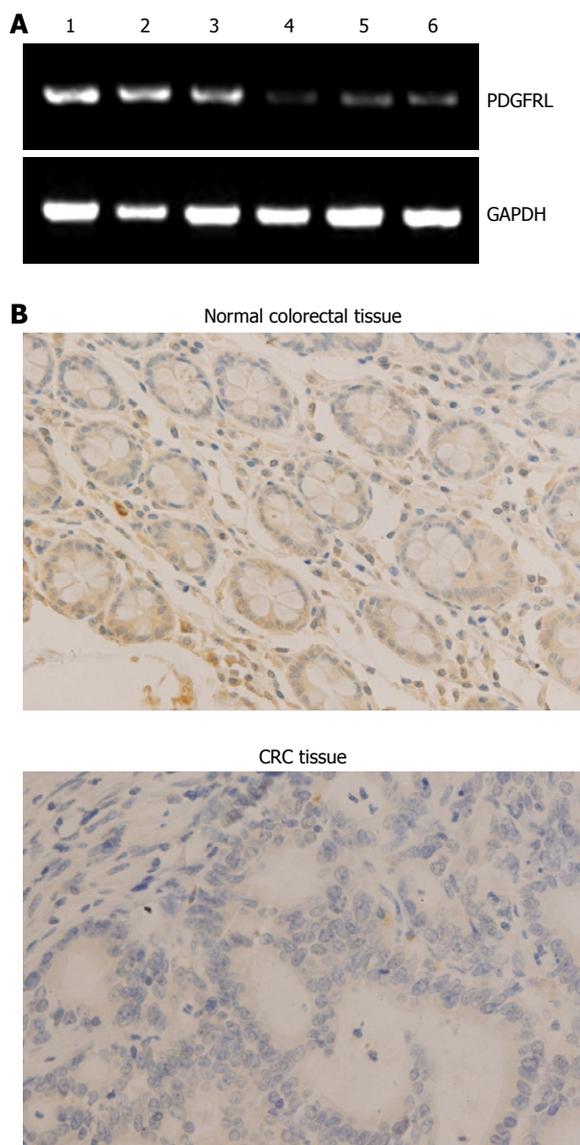

Figure 1 Expression of platelet-derived growth factor receptor-like gene (*PDGFRL*) in colorectal cancer and normal tissues. was performed using $2 \times$ pfu PCR MasterMix (MBI Fermentas) on an Eppendorf PCR instrument. The PCR products were purified by 1% agarose gel electrophoresis and double digested and ligated into the expression vector pET22b(+), resulting in a *pET22b-PDGFRL* plasmid with the sequence encoding the gene *PDGFRL*. The constructed plasmid was transformed into competent *Escherichia coli* (*E. coli*). DH5 α cells and the transformed strains were grown in Luria-Bertani (LB) broth supplemented with ampicillin (100 μ g/mL). All strains were incubated at 37°C with constant shaking (220 r/min). The recombinant was identified by PCR, double endonuclease digestion and DNA sequencing.

M: DNA ladder; 1: Double digestion with *NcoI/XhoI*; 2: *pET22b-PDGFRL* without digestion.

Bacterial expression of recombinant human PDGFRL (*rhPDGFRL*)

The recombinant plasmid *pET22b-PDGFRL* was transformed into *E. coli* expression strain BL21 (DE3) cells. One colony was picked up and was grown in 3 mL LB rich medium containing 100 mg/L ampicillin. After 8 h, 1 mL of the BL21 (DE3) cells were introduced into 100 mL of LB medium containing 100 mg/L ampicillin. Bacteria were grown at 37°C until an A_{600} of 0.6 was reached. Then, isopropyl-b-D-thiogalactopyranoside (IPTG) was added to induce protein expression at 30°C. To check the expression of *pET22b-PDGFRL*, *E. coli* were induced at different final concentrations of IPTG such as 0.1, 0.5, 1.0, 1.5 and 2.0 mmol/L, and different time points such as 1, 2, 4 and 6 h, respectively. The cells were harvested by centrifugation at $4800 \times g$ for 30 min and the pellet was resuspended in 50 mmol/L sodium phosphate, 0.3 mol/L NaCl, pH 8.0. The resuspended cells were lysed by sonication. The cells after lysis were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).

Purification of *rhPDGFRL*

The protein was further purified by immobilized metal affinity chromatography (MagExtractor[®] His-tag protein purification kit, TOYOBO). The extracts were fractionated by gel filtration column chromatography (AKTA explorer 10S with HiLoad 16/60 Superdex 75 pg column, GE Healthcare) in 50 mmol/L Tris-HCl (pH 7.5) and 100 mmol/L NaCl. These fractionated extracts were desalinated using Slide-A-Lyzer[®] dialysis cassettes (Pierce Biotechnology), separated by denaturing SDS-PAGE, and stained with Coomassie brilliant blue (CBB). Western blotting was performed using an anti-His antibody (Abcam)^[13].

MTT assay

MTT assay was performed to measure cell viability and proliferation in external factors. The 3rd generation

human HUVEC and HCT-116 cells were made into cell suspension with a density of $1 \times 10^4/\text{mL}$, which was inoculated into 96-well plates separately. The purified *rhPDGFRL* with different concentrations (0, 0.5, 1.0, 1.5 and 2.0 $\mu\text{g/mL}$, suspended in DMEM plus 1% BCS) was added to HUVEC and HCT-116 cells. After two days, 5 mg/mL MTT was added into the wells and incubated at 37°C for 3 h. The supernatant was blotted and added with DMSO (dimethyl sulfoxide). Absorbance of the dye was measured at a wavelength of 490 nm on a Microplate Reader. HCT-116 cells were then treated with *rhPDGFRL* or bovine serum albumin (BSA) (suspended in DMEM plus 1% BCS) and MTT assay was performed.

Colony formation assay

Crystal violet (CV) staining of cells and clone counting were used to measure cell proliferation. Dilute the HCT-116 cells into a 6-well plate separately and each pole contained 1000 cells. The *rhPDGFRL* or BSA (1.5 $\mu\text{g/mL}$) was added to HCT-116 cells. After 2 wk, 0.05% CV was added into the plates. The cells were fixed for 10 min with 4% Paraformaldehyde (PFA) and stained for 30 min with 0.05% CV. The plates were carefully rinsed in ddH₂O until

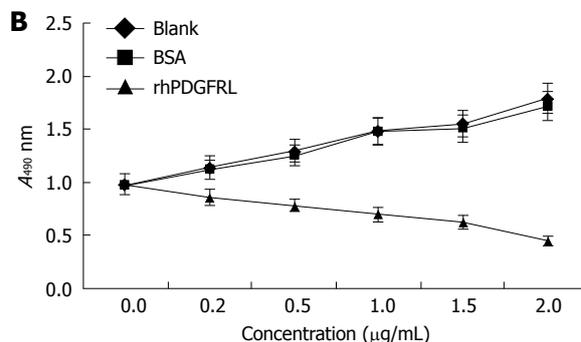

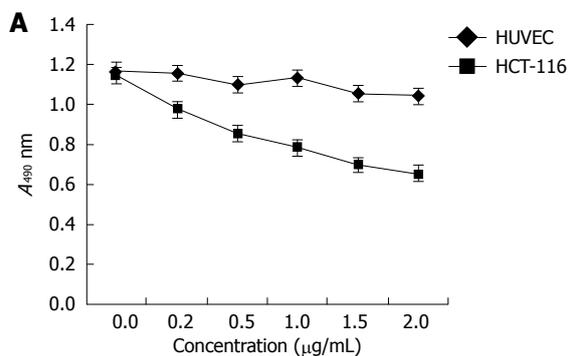

Figure 5 PDGFRL inhibits HCT-116 cell proliferation. A: MTT assay shows that HCT-116 cells grew slowly compared with human umbilical vein endothelial cells (HUVEC) cells after PDGFRL protein treatment, $P < 0.05$, HCT116 vs HUVEC; B: HCT-116 cells were treated with *rhPDGFRL* (HCT-116/*rhPDGFRL*) or bovine serum albumin (BSA) (HCT-116/BSA), $P < 0.05$, *rhPDGFRL* vs BSA. Data are expressed as mean \pm SD of three independent experiments.

no color appeared. Clone forming efficiency for individual type of cells was calculated according to the number of colonies/number of inoculated cells \times 100%.

Flow cytometry of cell cycle

The impact of *rhPDGFRL* on the HCT-116 cell cycling was examined by flow cytometry. HCT-116 cells indicated were seeded into a 6-well plate at a density of 3.5×10^5 cell/well. Once the cells were grown at 70%-80% confluence, HCT-116 cells were treated with the *rhPDGFRL* or BSA (1.5 $\mu\text{g/mL}$). Cells were harvested at 48 h and resuspended in fixation fluid at a density of $10^6/\text{mL}$, 1500 μL propidium iodide (PI) solution was added, and

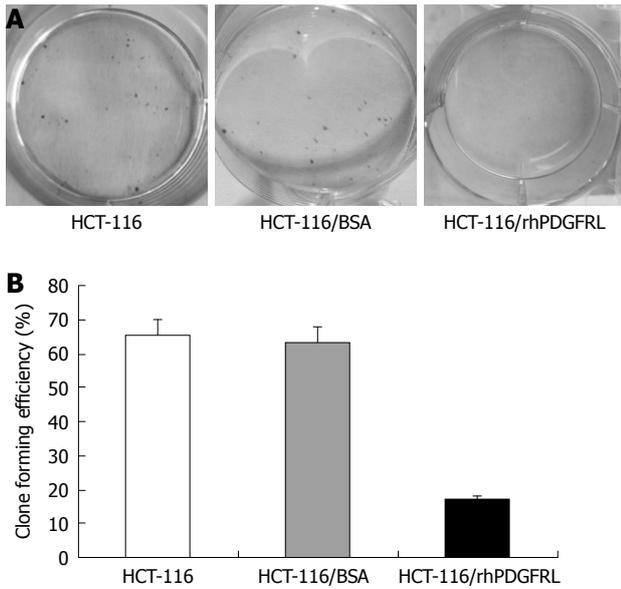

Figure 6 Crystal violet (CV) staining of cells and clone counting assay. A: CV staining of HCT-116 cells; B: Quantitative analysis of colony formation. Data are expressed as the efficiency of colony formation (%) and expressed as the mean \pm SD of three separated experiments, $P < 0.05$, HCT-116/rhPDGFRL vs HCT-116/BSA.

the cell cycle was detected by FACS Caliber (Becton Dickinson).

Monolayer wound healing assay

Wound healing assay was applied to measure cell invasion. HCT-116 cells indicated were seeded into a 6-well plate at a density of 3.5×10^5 cell/well. Once the cells were grown to a monolayer, a wound was made and the rhPDGFRL or BSA (1.5 $\mu\text{g}/\text{mL}$) was added to the HCT-116 cells. The distance of cell migration was calculated by subtracting the distance between the lesion edges at 48 h from the distance measured at 0 h. The relative migrating distance of cells was measured by the distance of cell migration/the distance measured at 0 h.

RESULTS

Expression of PDGFRL in CRC and normal tissues

To verify PDGFRL in CRC and normal tissues, we did RT-PCR and immunohistochemical analysis in 15 human CRC and adjacent normal tissue samples. In RT-PCR analysis, mRNA levels in CRC tissues were lower than in normal tissues (Figure 1A). By immunohistochemical analysis, immunoreaction signal of PDGFRL in cancer tissues was weak compared with normal tissues (Figure 1B). Semi-quantitative analysis of mRNA and protein expression for PDGFRL was performed in CRC and adjacent normal tissue samples. The relative mRNA expression of PDGFRL in CRC tissues was 0.11, but the one in the adjacent normal tissues was 0.78. Likewise, the relative protein level of PDGFRL in adjacent normal tissues was 8.2, but the one in CRC tissues was only 1.3. Both RT-PCR and immunohistochemistry showed that the expression of PDGFRL in colorec-

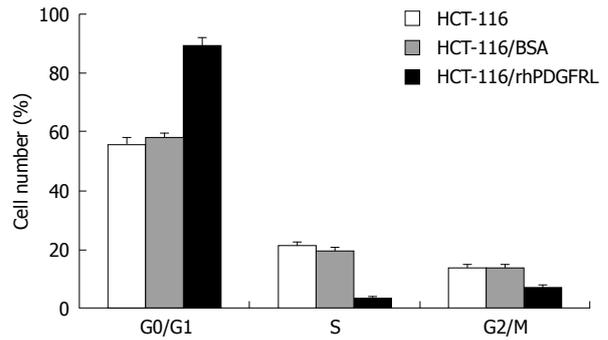

Figure 7 Analysis of cell cycle. HCT-116, HCT-116/BSA, and HCT-116/rhPDGFRL cells were fixed with 70% ethanol and stained with PI, followed by FACS analysis. Data are expressed as mean \pm SD of three independent experiments, $P < 0.05$, HCT-116/rhPDGFRL vs HCT-116/BSA.

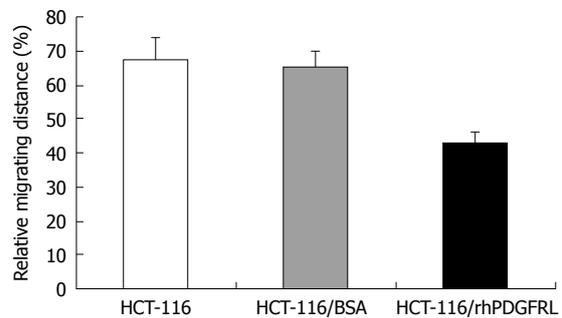

Figure 8 Measurement of migration distance in HCT-116, HCT-116/BSA, and HCT-116/rhPDGFRL cells. Data are expressed as the mean \pm SD of three independent experiments, $P < 0.05$, HCT-116/rhPDGFRL vs HCT-116/BSA.

tal normal tissues was higher than in cancer tissues based on the identification of PDGFRL as a tumor suppressor.

Construction of pET22b-PDGFRL

As shown in Figure 2, the prokaryotic expression recombinant pET22b-PDGFRL was successfully constructed using bacterial colony PCR (Figure 2A), restriction enzyme digestions (Figure 2B) and complete sequencing (data not shown).

Expression and purification of pET22b-PDGFRL recombinant protein

The prokaryotic expressive vector pET22b-PDGFRL was transformed into the *E. coli* BL21 (DE3) expression host strain for protein over-expression. Several potential clones were identified with DNA sequencing (data not shown). The expression and purification were identified by, respectively, running the crude lysate and the elution fractions on a 12% SDS-PAGE gel and subsequently staining with Coomassie brilliant blue. Experiments of IPTG concentration and time course were performed to determine the kinetics of protein expression in the bacterial culture (Figure 3). As a result, the cells should be harvested 4 h after 0.1 mmol/L IPTG induction, as the largest amount of the correct 42 kDa size pET22b-PDGFRL protein was produced at this time and concentration point.

The expressed protein at 0.1 mmol/L IPTG for 4 h

Figure 9 PDGFRL protein contains a putative signal peptide of 21aa. A: *PDGFRL* cDNA sequences contain an open reading frame (ORF) of 1128-base pairs that is matched in bold; B: ORF encodes a protein of 375 amino acids (aa) with a putative signal peptide of 21aa.

was further purified by immobilized metal affinity chromatography. The electrophoretic analysis revealed that the His-tagged His-*PDGFRL* recombinant protein was purified to near homogeneity and migrated as a 42 kDa band (Figure 4A). Moreover, the purification of the recombinant protein was confirmed by immunoblotting using anti-His-Tag antibody (Figure 4B).

PDGFRL inhibits HCT-116 cell proliferation

MTT assay was performed to measure the effect on cell viability. HCT-116 cells were found to grow slowly compared with HUVEC cells after *PDGFRL* protein was added (Figure 5A). The proliferating ability of HCT-116 cells decreased gradually with an increasing concentration of *PDGFRL*, but normal cell line HUVEC had no evident change in proliferation. Next, we treated HCT-116 cells with *rhPDGFRL* or BSA, and found that the cell viability of HCT-116 treated with *rhPDGFRL* (HCT-116/*rhPDGFRL*) decreased compared with that treated with BSA (HCT-116/BSA), which was not distinguishable from blank group (Figure 5B). A similar pattern of inhibitory effect of *rhPDGFRL* in HCT-116 cells was achieved in colony formation assay (Figure 6). Following incubation for 2 wk, a few colonies from HCT-116/*rhPDGFRL* cells were generated compared with HCT-116 or HCT-116/BSA. Therefore, the low MTT activity and a small number of cell colonies from HCT-116/*rhPDGFRL* cells demon-

strated that *rhPDGFRL* inhibited the growth of HCT-116 cells *in vitro*.

Impact of PDGFRL on HCT-116 cell cycle

To further explore the cause of the decrease in cell viability, we examined the effects of *PDGFRL* on cell cycle. As illustrated in Figure 7, HCT-116 cells treated with *PDGFRL* blocked the cell cycle in G1 phase. The G0/G1-phase fraction increased from 57.8% (HCT-116/BSA) to 89.4% (HCT-116/*rhPDGFRL*). These data indicated that *PDGFRL* arrested HCT-116 cell cycling at the G0/G1 phase, which may inhibit the growth of HCT-116 cells.

Effects of PDGFRL on the migration of HCT-116 cells

We examined the impact of *PDGFRL* on the migration of HCT-116 cells by the wound healing assay as shown in Figure 8. Following incubation of physically wounded cells for 48 h, the mobile distance of HCT-116/*rhPDGFRL* cells was found significantly shorter than that of controls.

DISCUSSION

Despite curative surgery, nearly 4 out of 10 patients with CRC experience disease relapse, 1 of 5 will develop liver metastases, and 1 of 12 will develop pulmonary

metastases^[14]. The survival of CRC patients is still a key issue to address and the need for drugs curing CRC is urgent.

The tools and concept of gene therapy are being applied to the development of new effective treatment strategies for human cancer^[15]. Most human cancers are associated with multiple interacting and cooperating mutations in protooncogenes and tumor suppressor genes. Cancer therapies that target oncogenes usually seek to block or reduce their action, while those aimed at tumor suppressor genes seek to restore or increase their action. In several model systems, some features of the tumor phenotype can be suppressed *in vitro* through the restoration of expression of tumor suppressor genes such as *Rb* and *p53*^[16,17]. It is interesting that most investigators have found that pVHL suppresses tumorigenicity in a nude mouse assay but not *in vitro*^[18,19]. Protein phosphatase-2A (PP2A) has progressively been considered as a potential tumor suppressor. PP2A activation by forskolin, 1,9-di-deoxy-forskolin and FTY720 effectively antagonize leukemogenesis in both *in vitro* and *in vivo* models of these cancers^[20-22]. PP2A is now a highly promising target for developing a new series of anticancer agents potentially capable of overcoming the drug-resistance^[23]. It is necessary to identify new genes applied in the treatment for CRC.

In this study, both RT-PCR and immunohistochemistry showed that the expression of *PDGFRL* in colorectal normal tissues was higher than in cancer tissues based on the identification of *PDGFRL* as a tumor suppressor. To investigate the role of *PDGFRL* in the anti-cancer therapy for CRC, pET-22b (+) prokaryotic expression vector was used to construct *rhPDGFRL*.

The pET-22b (+) vector carries an N-terminal pelB signal sequence for potential periplasmic localization, plus optional C-terminal His-tag sequence. However, in our study, periplasmic secretion of *PDGFRL* protein was too small to collect the purified protein, and most of expressive proteins were produced in an insoluble form in *E. coli* (data not shown).

PDGFRL cDNA sequences contain an open reading frame (ORF) of 1128-base pairs encoding a protein of 375 amino acids (aa) with a putative signal peptide of 21aa (Figure 9). The signal peptide could not be expressed stably in prokaryotic expression vector in high yield, and therefore the signal peptide was deleted in the construction of the recombinant *pET22b-PDGFRL*^[24,25].

In this report, *in vitro* bioactivity of *PDGFRL* was determined by MTT, clone counting, cell cycle and wound healing assay. When *PDGFRL* protein was added to HCT-116 cells, MTT, clone counting and wound healing assay showed that proliferation and invasion of HCT-116 cells decreased. This result indicated that *PDGFRL* as a tumor suppressor inhibited the growth of CRC cells. In addition, *PDGFRL* arrested HCT-116 cell cycling at the G0/G1 phase. The results of this study extended our previous knowledge of *PDGFRL* as a tumor suppressor in CRC. Further characterization of *PDGFRL* will provide new insights into the role of *PDGFRL* in the molecular pathogenesis and therapy of CRC.

COMMENTS

Background

Colorectal cancer (CRC) is the third most common cancer and the second leading cause of cancer related mortality in the Western world. The incidence of CRC in China has increased rapidly over the past few decades. The molecular mechanism of human carcinogenesis and development of CRC is still not clear.

Research frontiers

Mutations in platelet-derived growth factor receptor-like gene (*PDGFRL*) as a tumor suppressor have been found in individual cancer samples and *PDGFRL* expression is decreased in the majority of breast cancer cells. Recently *PDGFRL* is identified to play a central role in the tumor suppressor network by adopting a network perspective. Furthermore, *PDGFRL* was found to be involved in the suppression of the tumor metastatic phenotype as a strong candidate gene.

Innovations and breakthroughs

This study extended the previous knowledge of *PDGFRL* as a tumor suppressor in CRC.

Applications

Further characterization of *PDGFRL* will provide new insights into the role of *PDGFRL* in the molecular pathogenesis and therapy of CRC.

Terminology

PDGFRL is located in chromosome 8p21.3-8p22, which is commonly deleted in sporadic hepatocellular carcinoma, CRC, breast cancer, and non-small cell lung cancer.

Peer review

By different methods, the authors analyzed the role of platelet-derived growth factor receptor-like gene in CRC and its possible application in anti-cancer therapy. The manuscript is well-written and the study is conducted appropriately.

Abstract

AIM: To investigate whether Melatonin has synergistic effects with Doxorubicin in the growth-inhibition and apoptosis-induction of human hepatoma cell lines HepG2 and Bel-7402.

METHODS: The synergism of Melatonin and Doxorubicin inhibited the cell growth and induced cell apoptosis in human hepatoma cell lines HepG2 and Bel-7402. Cell viability was analyzed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) assay. Cell apoptosis was evaluated using TUNEL method and flow cytometry. Apoptosis-related protein Bax, Bcl-2 and caspase-3 expressions were measured by immunohistochemical staining.

RESULTS: Treatment with Melatonin (10^{-8} - 10^{-5} mol/L) alone had a dose-related inhibitory effect on cell proliferation but no cytotoxic effect on hepatoma cell lines HepG2 and Bel-7402. Interestingly, when combined with Doxorubicin, Melatonin significantly increased the effects of cell growth inhibition and cell apoptosis. Furthermore, TUNEL staining and flow cytometry revealed that cooperative apoptosis induction was associated with decreased expression of Bcl-2 as well as increased expression of Bax and Caspase3.

CONCLUSION: The synergism of Melatonin and Doxorubicin inhibits hepatoma cell growth and induces cell apoptosis.

INTRODUCTION

Melatonin, a chief secretory product of the pineal gland, has diverse physiological functions. It plays a crucial role in regulating circadian rhythm, and is involved in immunomodulation, hematopoiesis, and antioxidative

processes^[1-5]. A large number of studies have demonstrated that Melatonin has important oncostatic properties^[6,7]. It inhibits cell proliferation in several cancer cell lines including human B-lymphoma cells^[8], human myeloid leukemia cells HL-60^[9] and human neuroblastoma cancer cells^[10]. Melatonin decreased the growth rates of tumors *in vivo* both in transplantable animal model and the animal model induced by the administration of carcinogens^[11,12].

Hepatocellular carcinoma (HCC) is the fifth most common cancer in the worldwide, and more than half a million new cases occur annually^[13]. In some areas of Asia and the Middle East, HCC ranks as the first cause of death from cancer. The incidence of HCC is also increasing in Europe and the United States^[14]. Chemotherapy is one of the common strategies in HCC treatment, especially for unresectable tumors. Conventional chemotherapeutic drugs such as Doxorubicin often have severe side effects that limit their efficacy. Combined therapy with multiple drugs or modalities is a common practice in the treatment of cancer, which can achieve better therapeutic effects than a single drug or modality, and can reduce the side effects and resistance to drugs as well. Thus it is imperative to develop new agents which can help enhance the drug effectiveness as well as reduce the toxicity.

The present study was designed to investigate the growth-inhibiting and apoptosis-inducing effects of Melatonin alone or combined with Doxorubicin in order to develop a new adjuvant therapy for HCC.

MATERIALS AND METHODS

Cell culture

Human hepatoma cells HepG2 and Bel-7402 were purchased from Shanghai cell bank, Chinese Academy of Sciences, cultured in Dulbecco's modified Eagles's medium and RPMI-1640 medium respectively. Each was supplemented with 10% (v/v) heat-inactivated fetal bovine serum and antibiotics and incubated at 37°C in a humid atmosphere with 50 mL/L CO₂.

Drugs and chemicals

The Doxorubicin injection was purchased from Shenzhen Main Luck Pharmaceuticals Inc. (Shenzhen, China, Cat-NO0407E1, 10 mg/ampoule); Melatonin, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetra-zolium bromide (MTT) and Rnase A was from Sigma (St Louis, MO, USA). DMEM and RPMI-1640 medium was from Gibco BRL Life Technologies Inc. (Grand Island, New York, USA); Rabbit polyclonal antibodies against human Bcl-2, Bax and caspase-3 were all purchased from Lab Vision Corporation (Fremont, California, USA) and the streptavidin-biotin-peroxidase (S-P) reagents kit was obtained from Fuzhou Maxim Biotech, Ltd. (Fuzhou, China). Cell Apoptosis PI Detection Kit was provided by Nanjing KeyGen Biotech Co. Ltd. (Nanjing, China). DeadEnd™ Colorimetric TUNEL System was from Promega Biotech Co. Ltd. (Madison, WI, USA).

In vitro cytotoxicity examination

Cytotoxicity was measured using MTT assay. HepG2 and

Bel-7402 cells in exponentially growth phase were cultured at a density of 1×10^4 cells/well in a 96-well plate. After treatment with various concentrations of drug for 48 h, MTT solution (5.0 mg/mL in phosphate-buffered saline) was added (20.0 μL/well), and the plates were incubated for another 4 h at 37°C. The purple formazan crystals were dissolved in 150.0 μL Dimethyl Sulfoxide DMSO per well. After 10 min, the plates were read on microplate reader (American Bio-Tek) at 490 nm. The cells without drugs were used as control. Assays were performed in three independent experiments. The percentage of cytotoxicity was calculated as follows: Cytotoxicity (%) = $(1 - A_{490} \text{ of experimental well}) / A_{490} \text{ of control well}$. The median inhibitory concentration (IC₅₀) (defined as the drug concentration at which cell growth was inhibited by 50%) was assessed from the dose-response curves.

Analysis of in vitro drug interaction

The coefficient of drug interaction (CDI) was used to analyze the synergistical inhibitory effect of drug combination. CDI is calculated as follows: $CDI = AB / (A \times B)$. According to the absorbance of each group, AB is the ratio of the combination groups to control group in A_{490} ; A or B is the ratio of the single agent groups to control group in A_{490} . Thus CDI value less than, equal to or greater than 1 indicates that the drugs are synergistic, additive or antagonistic, respectively. CDI less than 0.7 indicates that the drugs are significantly synergistic.

TUNEL assay

The cells were cultured in 6-well plates containing cover slips overnight. After treatment with various concentrations of Melatonin or Doxorubicin or in combination for 48 h, the cover slips were washed twice with PBS and fixed in 4% paraformaldehyde solution for 25 min at room temperature. Apoptotic cells were detected by terminal deoxynucleotidyl-transferase-mediated dUTP nick end-labeling (TUNEL) assay using DeadEnd™ Colorimetric TUNEL System Kit from Promega (Madison, WI), following the manufacturer's instructions. The TUNEL assay results were quantitatively analyzed by biological image analysis system which consists of Nikon ECLIPSE 80i biology microscope, Nikon Digital Camera DXM 1200F, ACT-1 version 2.63 software (Japan).

Immunocytochemistry

Cells were seeded onto glass coverslips overnight. After incubation with various concentrations of the drugs for 48 h, the cover slips were washed twice with PBS and added 4% paraformaldehyde solution for 30 min at room temperature. Immunohistochemical staining for Bcl-2, Bax and caspase-3 was measured using the standard S-P method. The detailed manipulation was conducted according to the manufacturer's instructions. As negative control, PBS was used instead of primary antibody, and other steps were followed in the same way. The immunocytochemical results were quantitatively analyzed by biological image analysis system which consists of Nikon

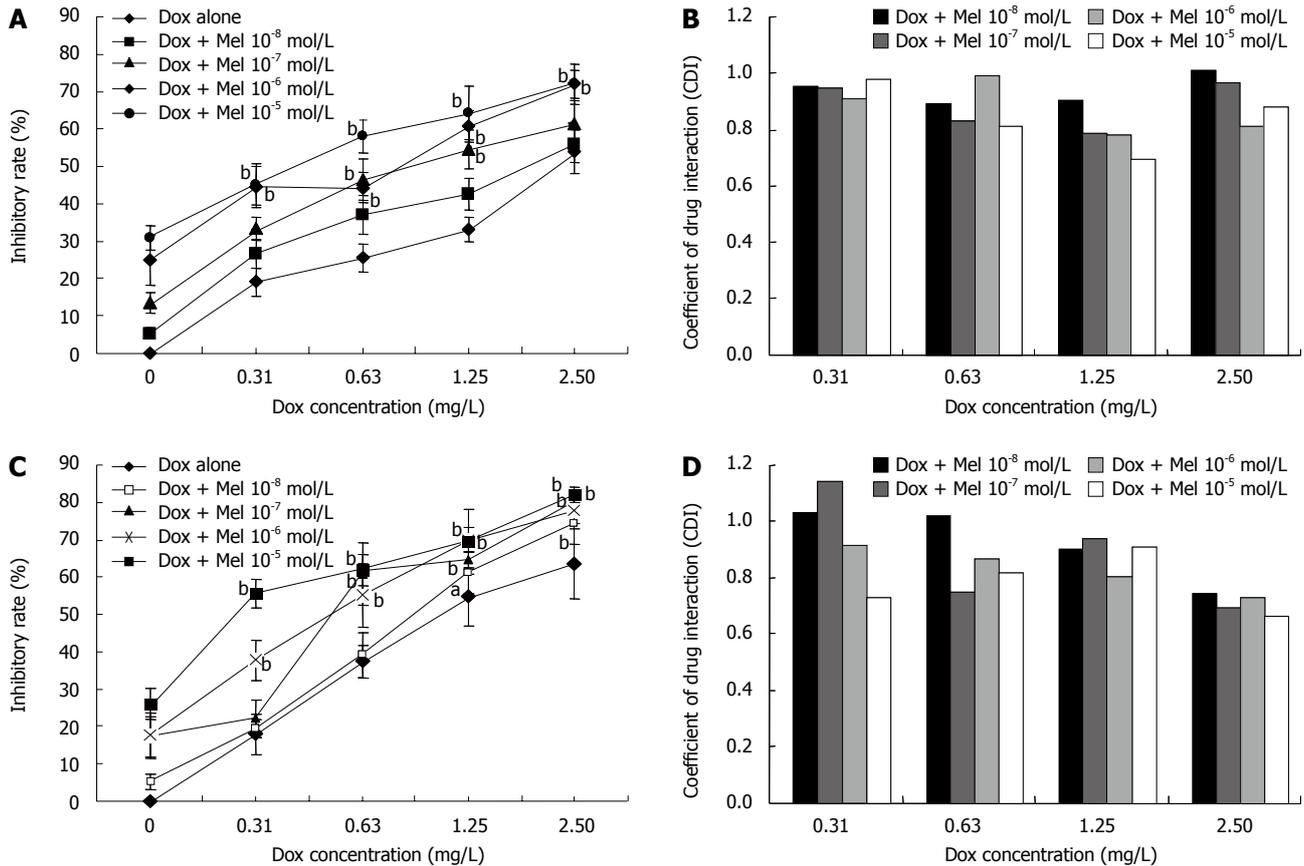

Figure 1 Synergistic effects and CDI of Melatonin and Doxorubicin on HepG2 and Bel-7402 cells. HepG2 cells (A) and Bel-7402 cells (C) were treated with 10⁻⁸, 10⁻⁷, 10⁻⁶ and 10⁻⁵ mol/L Melatonin and 0.31, 0.63, 1.25 and 2.50 g/L Doxorubicin for 48 h; CDI values of the combination group in HepG2 cells (B) and Bel-7402 cells (D). Data are presented as mean ± SE (error bar) of triplicate cultures. ^aP < 0.05, ^bP < 0.01 vs Dox treated alone.

ECLIPSE 80i biology microscope, Nikon Digital Camera DXM 1200F, ACT-1 version 2.63 software (Japan), and JEOA 801D morphological biological image analysis software version 6.0 (Jie Da Technologies, Inc., China). The average absorbance value was analyzed by 5 randomly selected optical fields under microscopy (× 400).

Flow cytometry

The cells were grown in 6-well plates and then treated with Melatonin and/or Doxorubicin at the desired concentrations. After exposure to drugs for 48 h, cells were trypsinized, washed twice with cold PBS and centrifuged. The cell pellet was resuspended in 1 mL cold PBS and fixed in 9 mL of 70% ethanol at -20°C for at least 12 h. Then cells were centrifuged and resuspended in 500 μL PBS, RNase A was added and the cells were incubated at 37°C for 30 min. Propidium iodide (PI) staining buffer was added in the dark at room temperature for 30 min (according to the procedure program of the Cell Apoptosis PI Detection Kit). A minimum of 1 × 10⁶/mL cells for each group was analyzed using an EPICS XL-MCL model counter (Beckman Coulter, Fullerton, CA, USA).

Statistical analysis

Biostatistical analyses were done using the SPSS 11.5 software package. All experiments were repeated at least three times. The results of multiple experiments are

given as the mean ± SE. Non-parametric Kruskal-Wallis test was used to detect differences among the different experimental groups. The Mann-Whitney U-test was subsequently used for statistical evaluation in two-group comparisons. Pearson correlation coefficient was used for continuous independent and dependent variables. A level of P < 0.05 was accepted as statistically significant.

RESULTS

Inhibitory effect of Melatonin on hepatoma cell proliferation

HepG2 and Bel-7402 cells incubated with various concentrations of Melatonin alone for 48 h showed a dose-dependent reduction of cell proliferation. The inhibitory rate of Melatonin (10⁻⁸, 10⁻⁷, 10⁻⁶ and 10⁻⁵ mol/L) on HepG2 cells was 5.27% ± 1.53%, 13.53% ± 2.73%, 24.91% ± 6.60%, and 30.78% ± 3.28%, (r = 0.993, P < 0.01) and that on Bel-7402 cells was 5.35% ± 2.05%, 17.06% ± 5.51%, 17.73% ± 5.91%, and 26.09% ± 4.23%, respectively (r = 0.952, P < 0.05). The IC₅₀ of Melatonin on HepG2 and Bel-7402 cells were 7.623 × 10⁻⁵ and 4.693 × 10⁻⁴, respectively.

Synergistic cytotoxicity of combined Melatonin and Doxorubicin

To investigate the synergistic inhibitory effects of Mela-

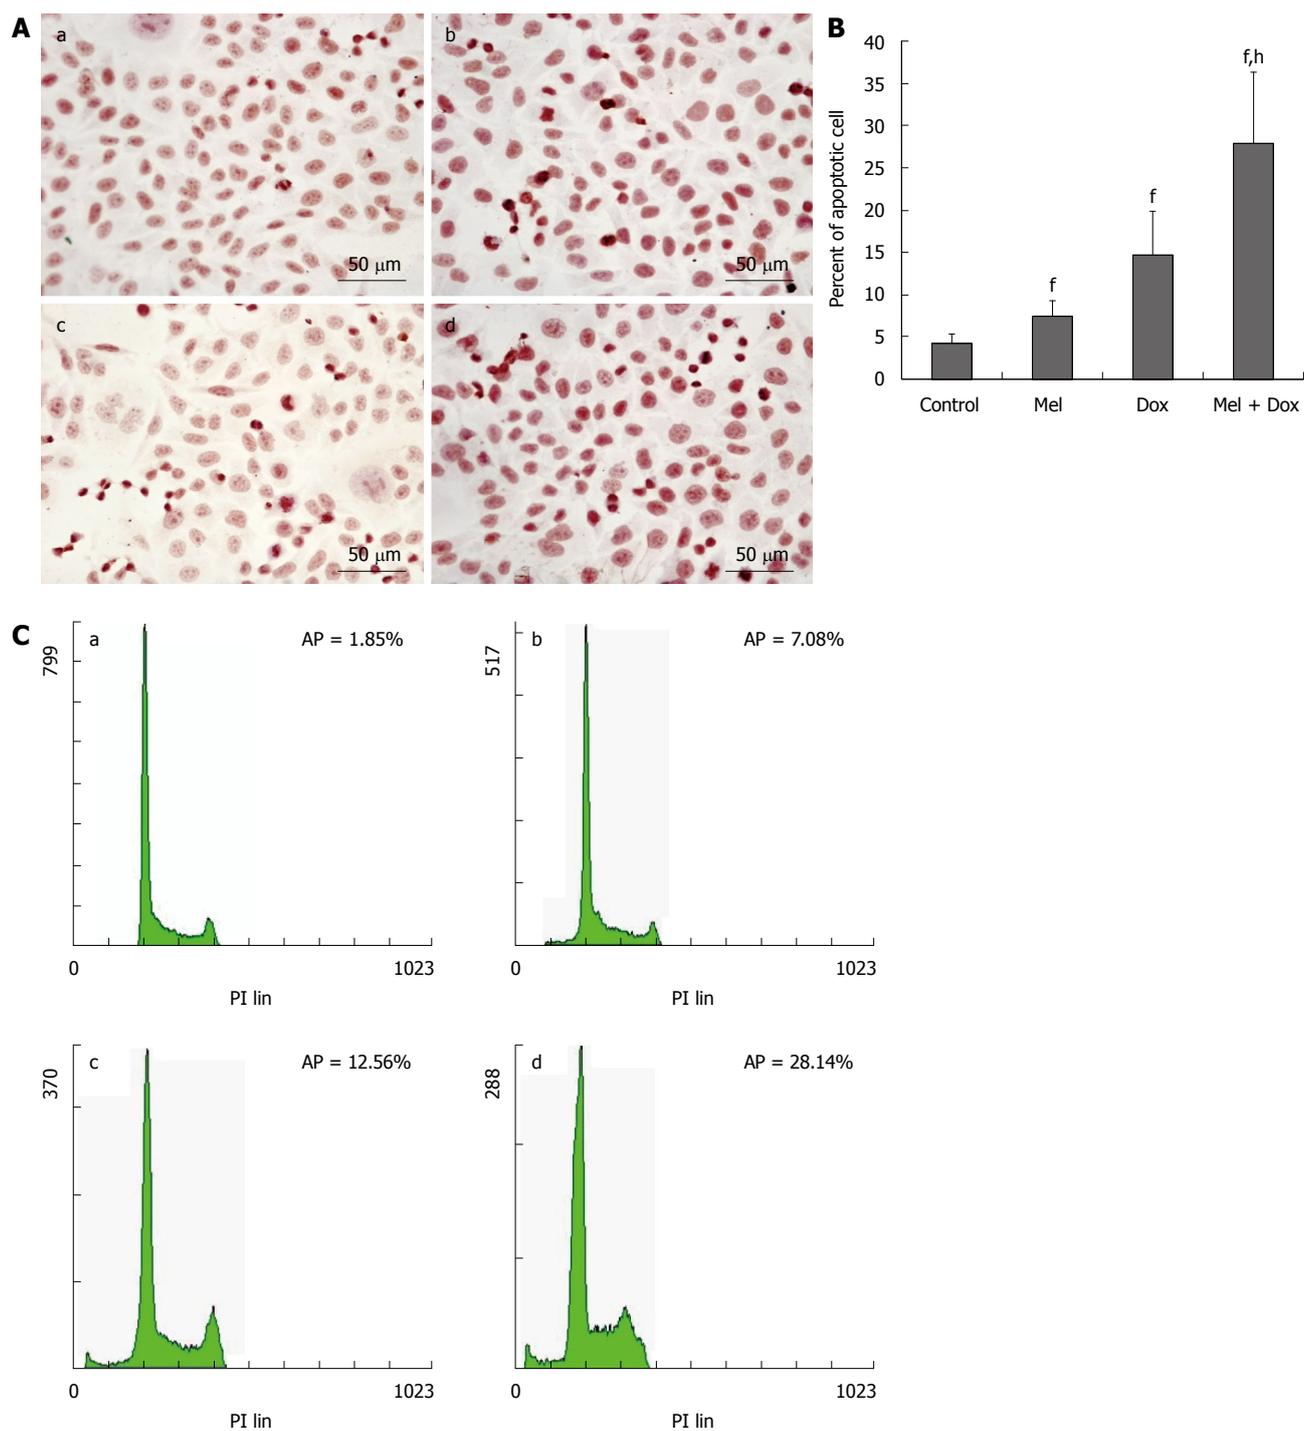

Figure 2 Effects of Melatonin and/or Doxorubicin on apoptosis of HepG2. A: Morphological changes of HepG2 cells treated with Mel and Dox. a: Untreated cells; b: 10^{-5} mol/L Mel; c: 1.25 mg/L Dox; d: 10^{-5} mol/L Mel plus 1.25 mg/L Dox; B: Percentage of apoptotic cells by TUNEL assay. Data are presented as mean \pm SD (error bar) of triplicate cultures. ⁱ $P < 0.01$ vs control, ^h $P < 0.01$ vs Dox treated alone; C: Apoptotic cells determined by FCM assay. a: Untreated cells; b: 10^{-5} mol/L Mel; c: 1.25 mg/L Dox; d: 10^{-5} mol/L Mel plus 1.25 mg/L Dox.

tonin and Doxorubicin, four different doses of Melatonin (10^{-8} , 10^{-7} , 10^{-6} and 10^{-5} mol/L) and four different concentrations of Doxorubicin (0.31, 0.63, 1.25 and 2.5 mg/L) were chosen and assessed. As depicted in Figure 1, Melatonin increased the cytotoxicity of Doxorubicin on HepG2 (Figure 1A and B) and Bel-7402 cells (Figure 1C and D). CDI was used to evaluate the nature of the interaction. When 10^{-5} mol/L Melatonin was combined with 1.25 mg/L Doxorubicin, the synergistic inhibitory effects

is the strongest on HepG2 (Figure 1B). Doxorubicin and Melatonin had the strongest synergism on Bel-7402 when 10^{-5} mol/L Melatonin was combined with 2.5 mg/L Doxorubicin (Figure 1D).

Proapoptotic effect of combined Melatonin and Doxorubicin

HepG2 and Bel-7402 cells were treated with different concentrations of Melatonin, Doxorubicin or a combination

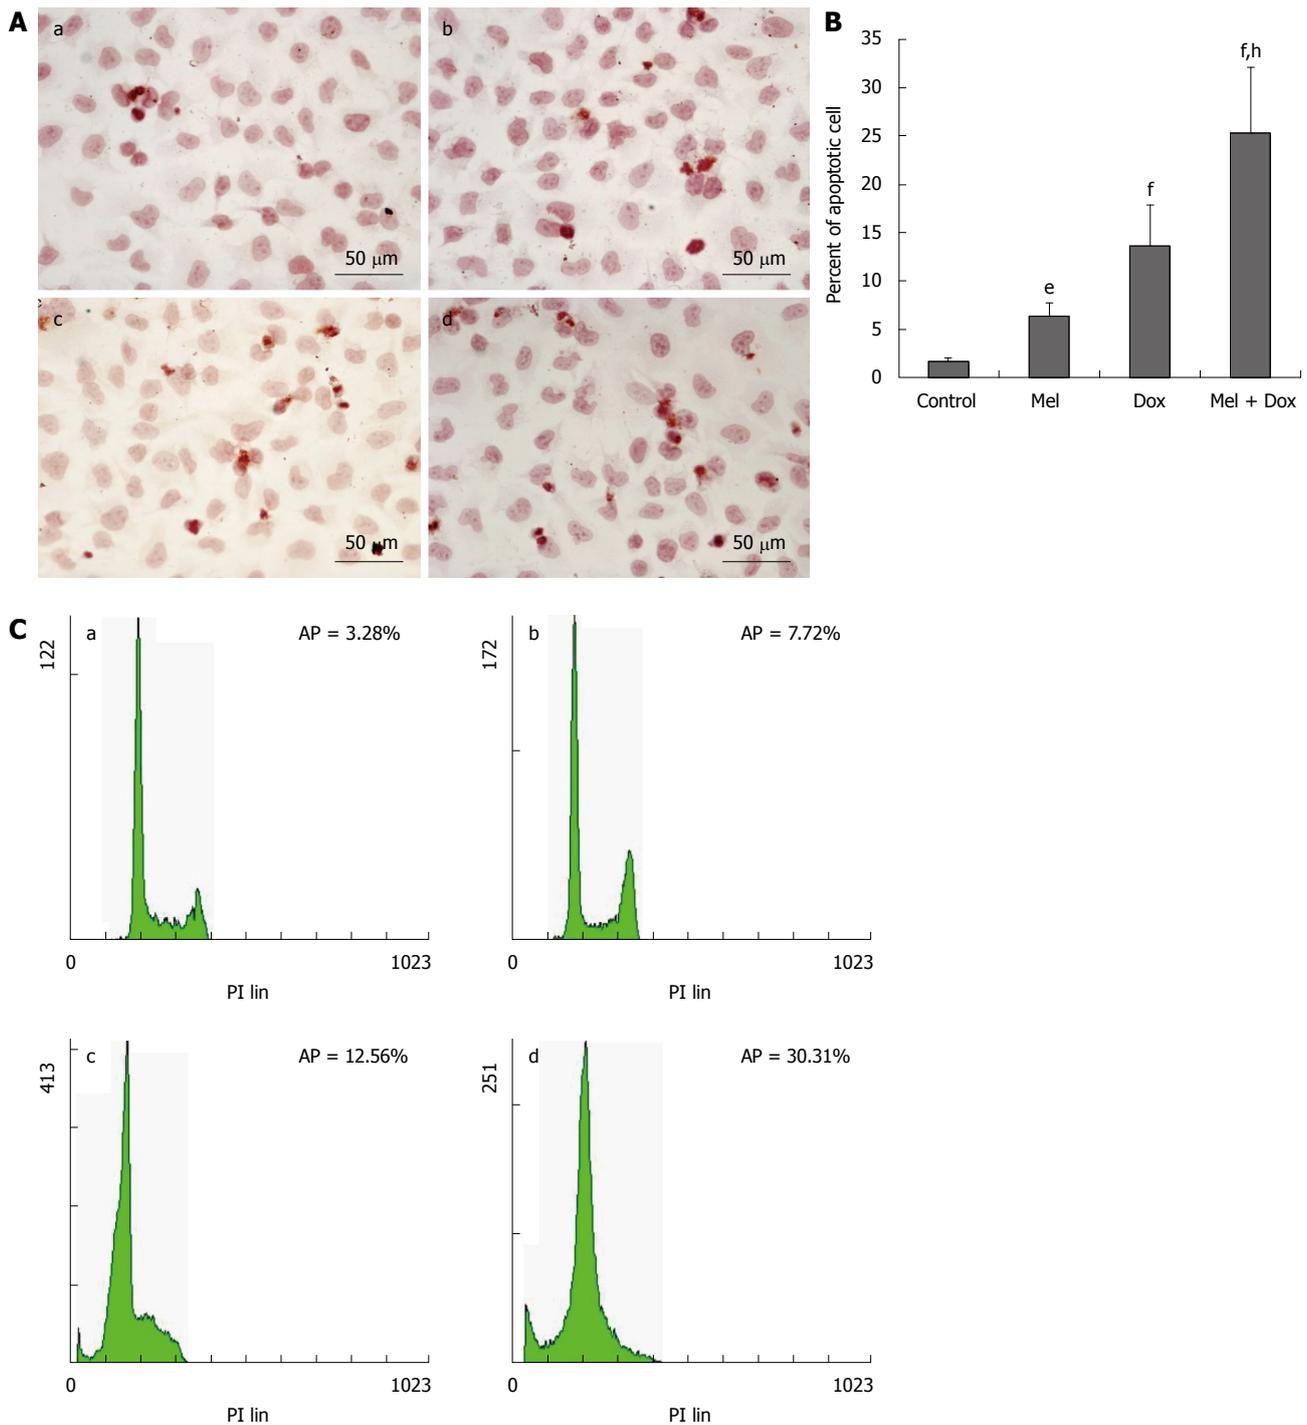

Figure 3 Effects of Melatonin and/or Doxorubicin on apoptosis of Bel-7402. A: Morphological changes of Bel-7402 cells treated with Mel and Dox. a: Untreated cells; b: 10⁻⁵ mol/L Mel; c: 2.5 mg/L Dox; d: 10⁻⁵ mol/L Mel plus 2.5 mg/L Dox; B: Percentage of apoptotic cells by TUNEL test. Data are presented as mean ± SD (error bar) of triplicate cultures. ^cP < 0.05, ^fP < 0.01 vs control, ^hP < 0.01 vs Dox treated alone; C: Apoptotic cells determined by FCM assay. a: Untreated cells; b: 10⁻⁵ mol/L Mel; c: 2.5 mg/L Dox; d: 10⁻⁵ mol/L Mel plus 2.5 mg/L Dox.

of both for 48 h, respectively, and apoptosis was assessed by TUNEL and FACS methods. We found that in the combination treatment group, there was a greater degree of induction of apoptosis than that caused by either agent alone. In HepG2 cells, the number of apoptosis cells in Melatonin (10⁻⁵ mol/L) or Doxorubicin (1.25 mg/L) alone treatment group was only slightly increased when compared with the cell control group. However, the apoptotic rate

increased greatly when the cells were treated with combined Doxorubicin and Melatonin (Figure 2A and B). Similar results were found in Bel-7402 cells (Figure 3A and B). These results were confirmed by FCM assay. As shown in Figure 2C and Figure 3C, the sub-G1 peak, which appeared before the G1 phase that represents apoptotic cell population, was slightly increased in these two cell lines treated with Doxorubicin or Melatonin alone. The

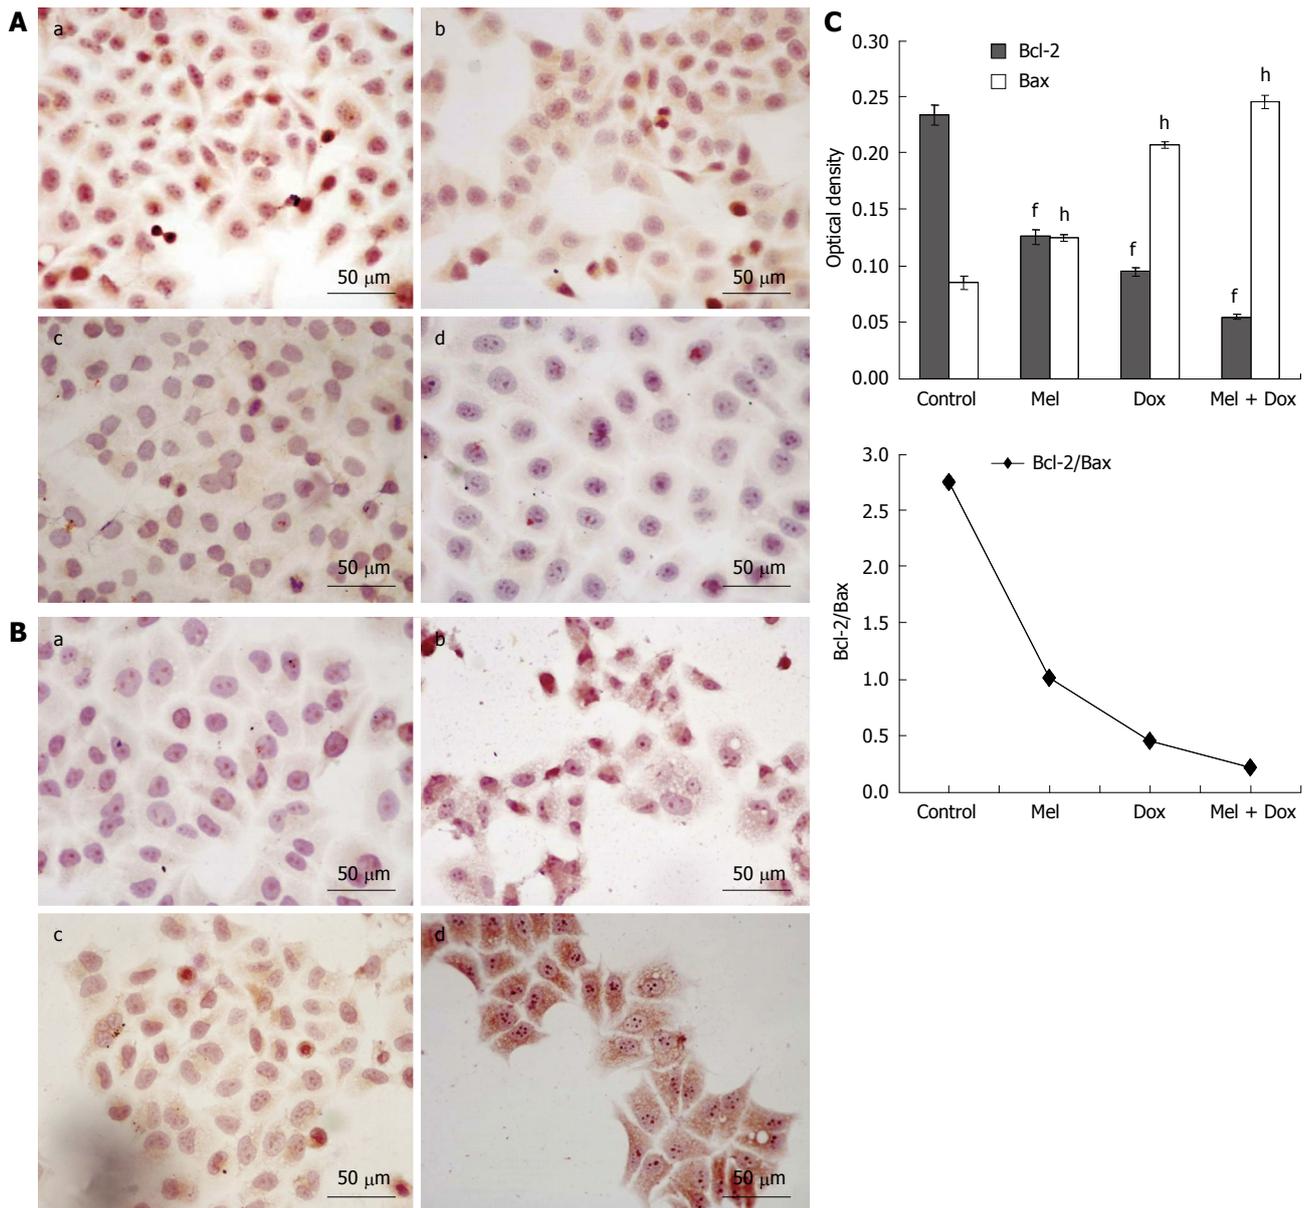

Figure 4 Effect of Melatonin and/or Doxorubicin on the expression of Bcl-2 (A) and Bax (B) in HepG2 cells, the quantitative analysis (C) of Bcl-2 and Bax. Quantitative analysis of Bcl-2 and Bax, expression by Biological Image Analysis System. Data are presented as mean ± SD (error bar). a: Untreated cells; b: 10^{-5} mol/L Mel; c: 1.25 mg/L Dox; d: 10^{-5} mol/L Mel plus 1.25 mg/L Dox. S-P ($\times 400$). ^f $P < 0.01$ vs control of Bcl-2, ^h $P < 0.01$ vs control of Bax.

apoptotic peak was dramatically increased when the cells were exposed to combined Melatonin and Doxorubicin.

The standard positive Bcl-2 and Bax expressions were stained brown or yellow mainly in cytoplasm or membrane. After treatment for 48 h, the expression of Bcl-2 decreased (Figure 4A and Figure 5A) and in contrast, there was a significant increase of Bax expression, especially in the combination groups (Figure 4B and Figure 5B). The results were quantitatively analyzed by biological image analysis system and the ratio of Bcl-2/Bax decreased correspondingly (Figure 4C and Figure 5C).

To determine whether caspase-3 plays a role in Melatonin and/or Doxorubicin mediated apoptosis of HepG2 and Bel-7402 cells, we assessed the activated caspase-3 protein level of the two cell lines before and after treatment with Melatonin and/or Doxorubicin using

S-P method. The standard positive caspase-3 expressions were stained brown or yellow mainly in cytoplasm or nucleus. As shown in Figure 6, the expression of activated caspase-3 increased especially in the combination group after the two cell lines were exposed to drugs for 48 h.

DISCUSSION

Our results in the present study indicate that Melatonin inhibits growth of HepG2 and Bel-7402 cells in a dose-dependent manner. Meanwhile, combinations of Melatonin and Doxorubicin results in enhanced growth inhibitory effect and induction of cell apoptosis when compared with Melatonin or Doxorubicin used alone. These results suggest that chemotherapy combined with Melatonin may increase the therapeutic effect of anti-

cancer drugs. Our results demonstrated that Melatonin had a synergetic effect with Doxorubicin in inhibiting the proliferation of non-small cell lung cancer (A-549)^[15]. Moreover, combining with the study of Martin-Renedo *et al*^[16], our observation extend the possibility that Melatonin may provide a potential approach for the development of agents for the treatment and prevention of HCC.

Although the exact mechanism of the cytotoxicity of Melatonin against tumor cells is not very clear, many potential mechanisms have been proposed for the growth inhibition by Melatonin on cultured cells and animal models. These mechanisms include the induction of apoptosis^[17], the direct augmentation of natural killer (NK) cell activity^[17], which increases immunosurveillance, as well as the stimulation of cytokine production, e.g interleukin IL-2, IL-6, IL-12 and interferon IFN γ ^[18]. Apoptosis or

programmed cell death is an essential physiological process that plays a critical role in development and tissue homeostasis. However, apoptosis is also involved in a wide range of pathological conditions^[19]. Apoptotic defects are a common event in oncogenesis and contribute to drug resistance^[20,21]. It is therefore interesting to search for ways to facilitate this apoptotic process after the use of chemotherapeutic drugs. Many studies have demonstrated that Melatonin could induce apoptosis *in vitro* and *in vivo*. To investigate the apoptosis-inducing effect of Melatonin as a single agent and combined Melatonin and Doxorubicin in hepatoma cells, the morphological changes and apoptotic rate were detected. The cells treated with the drugs showed the typical characteristics of apoptosis, which were more prominent in the combination group. Similarly, an apoptotic peak appeared before G1 phase when treated

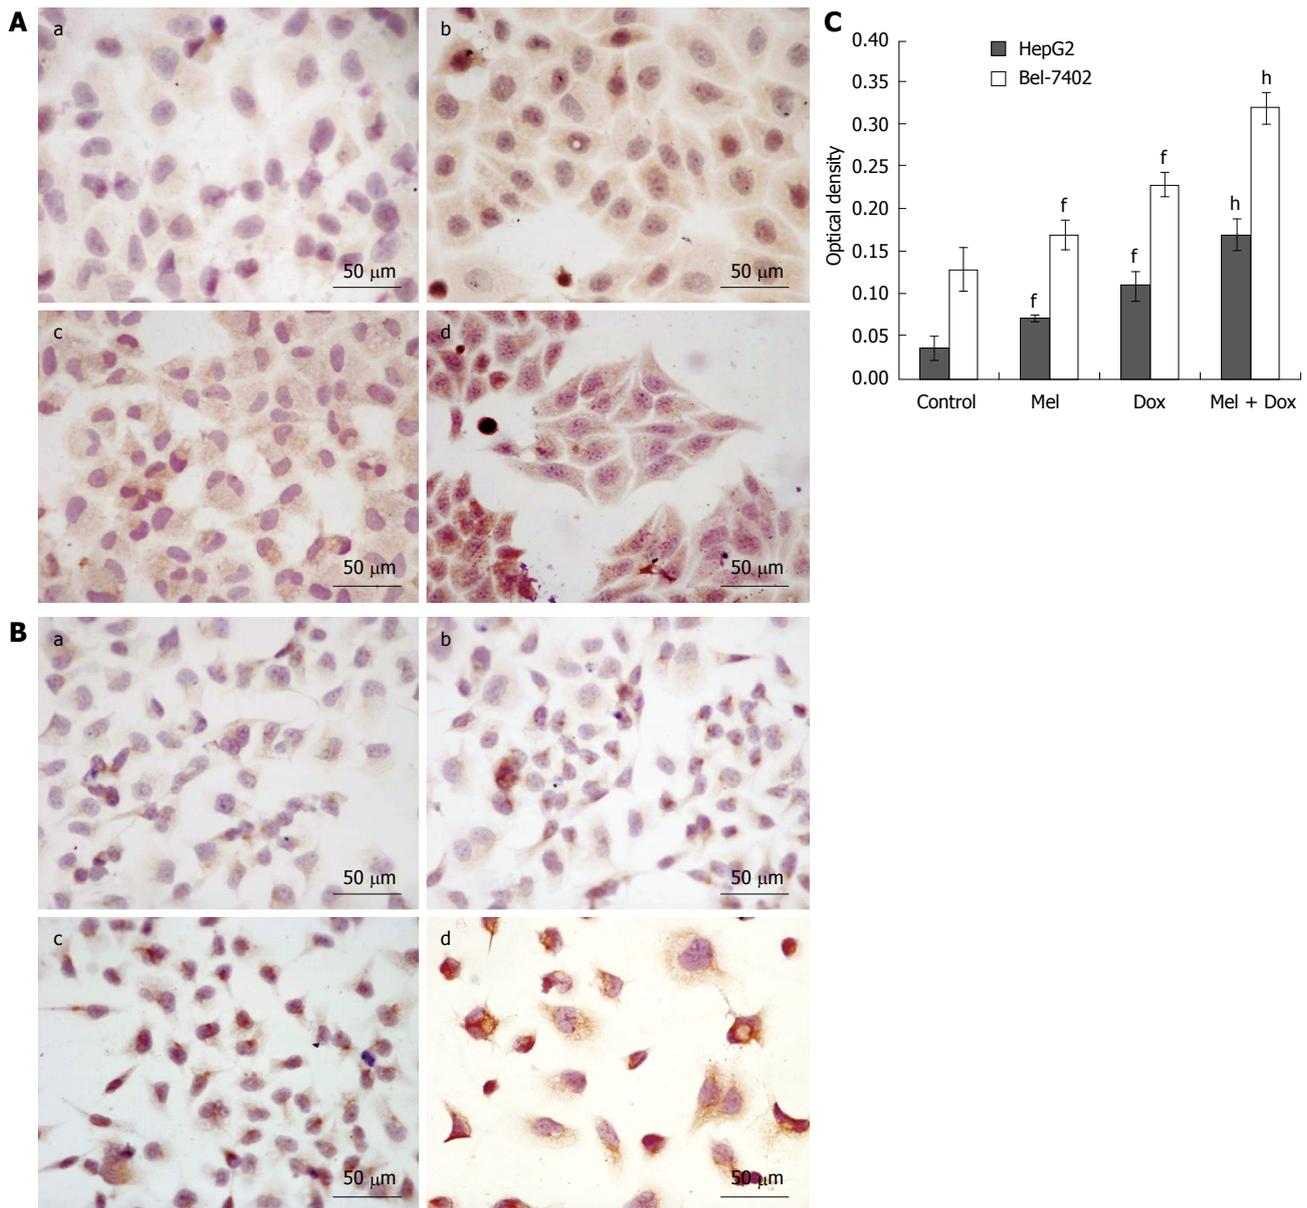

Figure 6 Effect of Melatonin and/or Doxorubicin on the expression of Caspase-3 in HepG2 (A) and Bel-7402 cells (B), and the quantitative analysis (C) of Caspase-3 expression. with Melatonin or Doxorubicin alone, and a significant synergistic effect on the induction of apoptosis was observed in the combination group.

Several factors contribute to apoptosis, but the key elements are categorized into two main families of proteins including caspase enzymes and Bcl-2 family^[22]. Bcl-2 family is a set of cytoplasmic protein members that regulate apoptosis. The two main groups of this family, Bcl-2 and Bax proteins, are functionally opposed: Bcl-2 acts to inhibit apoptosis, whereas Bax counteracts this effect^[23,24]. Caspases are crucial mediators of programmed cell death (apoptosis). Among them, caspase-3 is a frequently activated death protease, catalyzing the specific cleavage of many key cellular proteins^[23,25]. Thus, we studied bcl-2

and bax and caspase-3 protein in hepatoma cell lines. The current findings show that Melatonin and/or Doxorubicin increased the expression of Bax and caspase-3, decreased the expression of Bcl-2. Furthermore, a significant decrease in the ratio of Bcl-2/Bax was observed when Melatonin was treated in combination with Doxorubicin, which was correlated with the incidence of apoptosis.

In conclusion, these results indicate that Melatonin in combination with Doxorubicin has significantly synergistic growth-inhibitory and apoptosis-including effects on the human hepatoma cell lines HepG2 and Bel-7402, which may be related to down-regulation of Bcl-2, up-regulation of Bax, and activation of caspase-3. Melatonin is expected to be an adjuvant drug in HCC treatment in the future.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is a major contributor to cancer incidence and mortality in the world. Currently, No effective treatment is available. Therefore, there is a critical need to develop effective chemotherapeutic strategies for hepatomas.

Research frontiers

Melatonin, the chief secretory product of the pineal gland has shown anti-neoplastic activities in both cell lines and animal models. However, studies on the oncostatic effects of Melatonin in the treatment of hepatocarcinoma are limited. In this study, the authors demonstrate that Melatonin has synergistic effects with Doxorubicin on the growth-inhibition and apoptosis-induction of human hepatoma cell lines.

Innovations and breakthroughs

This is the first report on the anti-proliferation, induction of apoptosis by Melatonin and Doxorubicin synergistically in human hepatoma cell lines.

Applications

Melatonin might be useful as an adjuvant drug in hepatocarcinoma treatment.

Terminology

Melatonin is a small lipophile molecule that is essentially secreted by the pineal gland and its synthesis shows a circadian pattern. Melatonin plays an important role in biological rhythm resynchronization, sleep induction, immunomodulation and tumor inhibition.

Peer review

The study puts forward an interesting point in Melatonin-related chemotherapy and provides some experimental evidence that Melatonin can be of interest in treatment of hepatocellular carcinoma. This cell culture-based study focused on the molecular synergism of Melatonin and Doxorubicin in apoptosis of hepatoma cells. The main limit of the study is that cultured cell lines were exclusively used.

Abstract

AIM: To investigate whether Recq15, a DNA helicase that plays an important role in the maintenance of genome integrity, is a tumor suppressor in the gastrointestinal tract in mice.

METHODS: We generated cohorts of both *Recq15*-proficient and *Recq15*-deficient *Apc^{min/+}* mice and compared the tumor susceptibility in their gastrointestinal tracts.

RESULTS: Recq15 deficiency in *Apc^{min/+}* mice resulted in a significant increase in the tumor incidence in both the colon ($P = 0.0162$) and the small intestine ($P < 0.01$). These findings have provided the first genetic evidence for a tumor suppression role of Recq15 in the gastrointestinal tract of mice. Importantly, since mouse Recq15 and human RECQL5 are highly conserved, these findings also suggest that RECQL5 may be a tumor suppressor for human colon cancer.

INTRODUCTION

Cancer is a complicated genetic disorder, which may result from a myriad of deleterious oncogenic events induced by both endogenous and environmental insults, which perturb the normal growth control and physiological functions of cells^[1,2]. Most tumors are found to harbor genetic changes of either activation of proto-oncogenes, or inactivation of tumor suppressor genes (TSGs), or both^[3]. In particular, inactivation of TSGs represents an important early event of carcinogenesis in colorectal cancer. Generally, TSGs can be categorized into two major types, so-called “gatekeeper” and “caretaker” genes^[4,5]. Gatekeepers, such as the Retinoblastoma gene and the Adenomatous polyposis coli (*APC*) gene, have pivotal roles in cell proliferation by regulating cell cycle checkpoints, apoptosis and signaling transduction^[6,7]. It has been hypothesized that the loss of caretakers

provides the initial changes for the initiation of carcinogenesis, whereas mutations in gatekeepers provide the necessary “promotion” effect for the fully fledged development of cancer.

Chromosome instability (CIN) is one of the hallmarks of many cancer cells, and it has been suggested that CIN, both structural and numerical, contributes to the development of malignancies, and in particular, colorectal cancer^[8,9]. CIN may occur through many different mechanisms, such as DNA breaks, centrosome amplification, chromatid cohesion instability and cell cycle checkpoint defects^[9,10]. We have reported recently that deletion of Recq15, a member of the RecQ DNA helicase family, in mice resulted in a rearrangement type of CIN and an increased susceptibility to cancer in a number of organs and tissues, but not in the intestinal tract^[11]. Nonetheless, given that CIN is known to play an important role in the development of colorectal cancer, we suspected that Recq15 might have a role in tumor suppression in the gastrointestinal (GI) tract but that such an effect could not be readily detected in our previous study using straight *Recq15* knockout mice. *Apc^{min}* mice have been widely used as a sensitizing background for assessing the potential oncogenic effect in the GI tract of specific genetic alterations^[12]. *Apc^{min}* mice carry a spontaneous point mutation in one of the two copies of the *Apc*, the mouse homologue of the human *APC* TSG. In humans, mutations in this *APC* TSG give rise to familial adenomatous polyposis syndrome^[13]. In adult *Apc^{min}* mice, the loss of the remaining wild-type copy of the *Apc* gene in the colonic epithelium predisposes these cells to tumorigenesis, leading to development of adenomas both in the small intestine and colon. The number of tumors developed per mouse as well as the size of these tumors can be affected by the genetic background of the animals. Thus, they have been used extensively for assessing the potential oncogenic effects of specific genetic alterations^[12].

In the current study, we have examined the potential effect of Recq15 deficiency on tumorigenesis within the gastrointestinal tract in *Apc^{min/+}* mice, taking advantage of the sensitized genetic background for analyzing tumorigenesis in the GI tract provided by this well established model^[14].

MATERIALS AND METHODS

Mouse work

Recq15^{+/+} and *Recq15^{+/-}* mice were generated from crossings between *Recq15^{+/-}* mice, which were maintained in a mixed genetic background (87.5% C57BL/6 and 12.5% 129sv) as described previously^[15]. C57BL/6J (B6) and C57BL/6J-*Apc^{Min}*/J (*Apc^{Min/+}*) mice were purchased from the Jackson Laboratory (Bar Harbor, ME). All mice were propagated in the Case Western Reserve University American Association of Laboratory Animals accredited barrier-free facility. Mice were fed a commercially available rodent breeder diet, 5010 (PMI LabDiet). All cages, food, bedding, and water were autoclaved before

use. All procedures were approved by the Case Western Reserve University Institutional Animal Care and Use Committee.

Analysis of intestinal adenomas in *Apc^{Min/+}* mice

Recq15^{+/-} female mice were mated with B6-*Apc^{Min/+}* male mice. The resulting *Recq15^{+/-}Apc^{Min/+}* progeny were intercrossed to obtain both *Recq15^{+/+}Apc^{Min/+}* and *Recq15^{-/-}Apc^{Min/+}* mice. Genotyping was carried out by standard PCR methods^[16]. At 90 d of age, *Recq15^{+/+}Apc^{Min/+}* and *Recq15^{-/-}Apc^{Min/+}* mice were euthanized by CO₂ asphyxiation for quantitative analysis of intestinal adenomas. The entire intestine tract from duodenum to anus was removed, washed in phosphate buffered saline (PBS), opened longitudinally and pinned luminal side up on a wax dissection plate. Intestinal adenomas (macroadenomas with maximal diameters ≥ 1 mm, microadenomas < 1 mm) along the entire intestine were counted by microscopic examination at 10 \times magnification followed by fixation with 10% formalin in PBS (Fisher Scientific). Digital images of polyps and a metric ruler were captured using SPOT software 3.2.5 for Macintosh and an RT color SPOT camera mounted on a Leica MZFLIII workstation (Diagnostic Instruments). The percentages were calculated by dividing numbers of mice with more than 100 macroadenomas against total numbers of mice.

Statistical analysis

Statistical analyses were performed with the two-sample student's *t*-test using the Prism software package (Graph-Pad Software).

RESULTS

To investigate whether Recq15 deficiency may affect the adenoma multiplicity by either accelerating the loss of wild type *Apc* or by promoting the progression of tumors, we introduced the *Recq15* knockout allele into the *Apc^{Min/+}* background and analyzed the phenotype of intestinal adenomas at 90 d of age when mice are not severely affected by other complications, such as anemia.

We found that under our specific experimental conditions and a C57BL/6J \times 129Sv mixed genetic background, *Recq15^{+/+}Apc^{Min/+}* mice developed 72.9 ± 12.7 (mean \pm SE) macroadenomas (diameter ≥ 1 mm) along the entire intestinal tract at 90 d (Figure 1A and C). Remarkably, *Recq15^{-/-}Apc^{Min/+}* littermates developed 142.5 ± 9.4 macroadenomas at the same age, which is significantly higher than that observed in their *Recq15^{+/+}Apc^{Min/+}* littermates ($P = 0.0032$) (Figure 1A and C, Table 1). In particular, 15 out of 19 *Recq15^{-/-}Apc^{Min/+}* mice (78.9%) had more than 100 macroadenomas (Figure 1B and C) compared with only 1 out of 7 (14.2%) of such individuals in the *Recq15^{+/+}Apc^{Min/+}* cohort. Interestingly, however, although the average number of microadenomas (diameter < 1 mm) was higher in the *Recq15^{-/-}Apc^{Min/+}* cohort than in mice of the corresponding *Recq15^{+/+}Apc^{Min/+}* cohort, the difference did not reach a signifi-

Table 1 Effect of *Recq15* status on the intestine polyp multiplicity (\pm SE) of *Apc^{Min/+}* mice at age 90 d

Genotype	Size	Upper small intestine (duodenum and jejunum)	Lower small intestine (ileum)	Large intestine (colon)
<i>Recq15^{+/+}Apc^{Min/+}</i>	Macroadenoma (\geq 1 mm)	23.70 \pm 4.04	52.20 \pm 10.90	1.20 \pm 0.65
	Microadenoma (< 1 mm)	10.80 \pm 2.57	25.20 \pm 7.77	0.80 \pm 0.65
<i>Recq15^{-/-}Apc^{Min/+}</i>	Macroadenoma (\geq 1 mm)	28.20 \pm 3.38 ($P = 0.270$)	108.00 \pm 11.50 ($P = 0.006$)	2.80 \pm 0.47 ($P = 0.041$)
	Microadenoma (< 1 mm)	13.10 \pm 2.04 ($P = 0.360$)	41.40 \pm 4.82 ($P = 0.070$)	0.90 \pm 0.33 ($P = 0.450$)

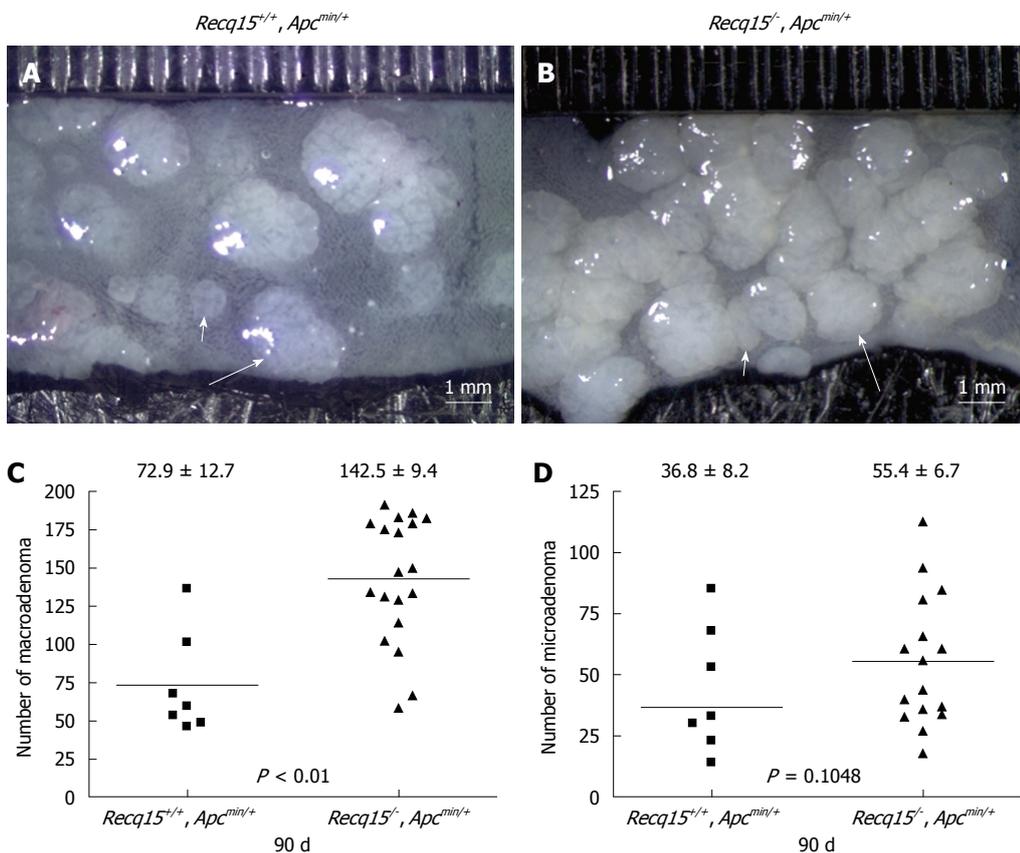

Figure 1 Effects of *Recq15* deficiency in the development of intestinal adenomas in the *Apc^{Min/+}* mice. *Recq15^{+/+}Apc^{Min/+}* and *Recq15^{-/-}Apc^{Min/+}* mice were monitored and sacrificed at 90 d of age. A, B: Representative microscopic images of sections from the ileum of a *Recq15^{+/+}Apc^{Min/+}* (A) and a *Recq15^{-/-}Apc^{Min/+}* (B) mouse. A microadenoma (diameter < 1 mm, short arrows) and a macroadenoma (diameter \geq 1 mm, long arrows) are indicated in (A, B); C, D: Multiplicity of macroadenomas (C) and microadenomas (D) in the intestine of individual mice at 90 d of age. Mean and SE are also shown at the top of each column. Each data point represents the total number of macroadenomas (C) or microadenomas (D) in a single mouse.

cant level ($P = 0.1048$, Figure 1D, Table 1).

Previous studies have shown that although *Apc^{Min/+}* mice are highly prone to intestinal adenomas, colonic tumors were relatively infrequent (< 50% penetrance) in these mice^[16]. We found, however, that *Recq15* deficiency had a significant impact on the incidence of colonic tumors in these mice. It resulted in an increase of the colonic tumor incidence to 94.1% (16 out of 17 mice) (Figure 2). Moreover, microscopic examination revealed that some *Recq15^{+/+}Apc^{Min/+}* mice developed only small polyp-like nodules in their colons (Figure 2A, Table 1), whereas most *Recq15^{-/-}Apc^{Min/+}* mice had multiple macroadenomas in each colon (Figure 2B, Table 1). Together, this data clearly indicate that *Recq15* deficiency could play an important role in the development of intestinal adenomas in *Apc^{Min/+}* mice.

DISCUSSION

Previous studies have shown that *Apc^{Min/+}* mice on a congenic C57BL/6 background develop 30 to 50 macroadenomas at 90 to 120 d of age, respectively^[16]. We found that under the mixed genetic background resulting from intercrossing between *B6/129.Recq15^{-/-}* and *B6.Apc^{Min/+}* mice, *Recq15^{+/+}Apc^{Min/+}* mice developed 72.9 \pm 12.7 macroadenomas (diameter > 1 mm) along the entire intestinal tract at 90 d. This elevated adenoma development in *Recq15^{+/+}Apc^{Min/+}* mice suggests the existence of possible modifier(s) in this particular genetic background or a difference in environmental factors, such as diet. Importantly, comparing with cohorts of mice that were selected based on sibling pairs allows us to clearly show that the loss of *Recq15* in *Apc^{Min/+}* mice has a great impact

COMMENTS

Background

Colorectal cancer is a major type of human cancer. Knowledge regarding the molecular basis for the etiology of this disease can help in identifying novel biomarkers for its early diagnosis or in improving the efficacy of intervention regimens.

Research frontiers

This is the first report about the role of Recq15, a DNA helicase that plays an important role in the maintenance of genome integrity, in suppressing tumorigenesis in the gastrointestinal (GI) tract in mice.

Innovations and breakthroughs

In this article, the authors reported that Recq15 has a role in suppressing tumorigenesis in the GI tract in mice. Since mouse Recq15 and its human homologue (RECQL5) are highly conserved, these new findings have implicated RECQL5 as a suppressor for colorectal cancer in humans. Thus, RECQL5 may be used as a biomarker for this disease. Moreover, they have recently shown that mutations in *Recq15* resulted in a significantly enhanced sensitivity to anticancer drug camptothecin, the prototype of irinotecan that is currently used to treat colorectal cancer patients. Thus, the expression of RECQL5 could be used as a criterion for selecting patients for irinotecan-based chemotherapies.

Applications

No direct application may be derived based on the findings from this study. However, these findings should justify further investigation of the potential role of RECQL5 mutations in human GI cancers and the potential use of RECQL5 as a colorectal cancer biomarker or drug target.

Peer review

This is a well conceived, concisely written article, which certainly deserves publication.

METHODS: We report a group of 12 WD patients treated with zinc and/or penicillamine who underwent multiple follow-up liver biopsies. Demographic, clinical and laboratory data were gathered and all patients underwent an initial biopsy and at least one repeat biopsy.

RESULTS: Time to repeat biopsy ranged from 2 to 12 years. Six patients (non-progressors) showed stable hepatic histology or improvement. In one case, we observed improvement of fibrosis from stage 2 to 0. Six patients (progressors) had worsening of fibrosis. There was no significant correlation between the histological findings and serum aminotransferases or copper metabolism parameters. The hepatic copper concentration reached normal levels in only two patients: one from the non-progressors and one from the progressors group. The estimated rate of progression of hepatic fibrosis in the entire group was 0 units per year in the time frame between the first and the second liver biopsy (4 years), and 0.25 between the second and the third (3 years). In the progressors group, the rate of progression of liver fibrosis was estimated at 0.11 fibrosis units per year between the first and second biopsy and, 0.6 fibrosis units between the second and third biopsy.

CONCLUSION: The inability of clinical tools to detect fibrosis progression in WD suggests that a liver biopsy with hepatic copper quantification every 3 years should be considered.

INTRODUCTION

Wilson disease (WD) is an inherited, autosomal recessive disorder of copper accumulation that affects about one individual per 30 000 population^[1]. It is due to the dysfunction of a copper-transporting P-type ATPase that has a crucial role in copper excretion into the bile. The gene that encodes this P-type ATPase, ATP7B, is located on chromosome 13q14.3, and numerous gene mutations can impair the protein's function^[2,3], which leads to copper accumulation mainly in the liver, but also in the brain, cornea, and kidney. The most frequent clinical presentation of WD is liver involvement^[4]. Hepatic manifestations may vary from hepatomegaly and fatty liver, to acute hepatitis, with high serum aminotransferases, liver failure, jaundice, and cirrhosis. The earliest morphological features of WD are represented by micro- and macrovesicular hepatic steatosis, glycogenated nuclei in the periportal hepatocytes, and focal hepatocellular necrosis. With the progression of parenchymal damage and inflammation, fibrosis, and subsequently cirrhosis, invariably develop. Cirrhosis can have either a micronodular or a mixed macro-micronodular pattern, and it is rarely complicated by hepatocellular carcinoma or cholangiocarcinoma^[5]. Regarding the timing of the disease progression, cirrhosis is often diagnosed by the second decade, but there are some individuals who do not develop cirrhosis even after the fourth decade of life^[6,7]. The ultrastructural analysis is characterized typically by mitochondrial abnormalities, including variability in size and shape, increased density of the matrix material, and numerous inclusions of lipid and fine granular material, which may be copper^[8]. With adequate treatment, these changes may not occur. WD is a treatable disorder and early diagnosis is essential: the goal of therapy is to reduce copper accumulation by enhancing its urinary excretion (with chelating agents) and by decreasing its intestinal absorption (with zinc salts)^[9-11]. As a result of the rarity of the disease and the fact that the liver biopsy is not performed routinely during the follow-up of WD, unless clinically indicated, the progression and timing of the liver pathology and its correlation with different anti-copper treatments or with aminotransferase levels are poorly characterized. Previous studies have shown the possibility of improvement of the steatosis and inflammation grade^[12], and the fibrosis stage^[13,14] during long-term follow-up. However, studies on serial liver biopsies, as well as studies on the correlation between hepatic histology and clinical parameters, are lacking.

The overall objective of this study was to describe the evolution of liver histology in WD patients during penicillamine (PCA) and zinc treatment, to define the rate of progression of the liver damage, and to correlate the clinical and biochemical parameters of liver injury with hepatic copper concentration.

MATERIALS AND METHODS

We included 12 patients with WD from the Division of Gastroenterology and Hepatology, Padua University Hospital (Italy), who were followed from 1981 to 2006 and who underwent serial liver biopsies. The mean follow-up was 5 ± 3 years (range: 1-12 years). Patients with history of alcohol abuse, positive serology for hepatitis B and C, and features of the metabolic syndrome were excluded. The study was conducted according to the principles of the Declaration of Helsinki, and all patients gave informed consent before undergoing liver biopsy. WD was diagnosed when 24-h urine copper excretion was $> 100 \mu\text{g}/24 \text{ h}$, hepatic copper concentration was $> 250 \mu\text{g}/\text{g}$ dry weight, and serum ceruloplasmin was $< 20 \text{ mg}/\text{dL}$. All patients were treated with either PCA or zinc sulfate following the initial biopsy. Liver biopsy samples were obtained by the percutaneous route, using the Menghini method. Liver copper concentrations in dried liver tissue were measured by flame atomic absorption spectrophotometry. Demographic, clinical, and laboratory data were gathered, and all patients underwent an initial and at least one repeat biopsy. Selected laboratory values were recorded at the time of initial and repeat biopsies: serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST), 24-h urinary copper excretion, and hepatic copper concentration. Slides of formalin-fixed, paraffin-embedded tissue were stained with hematoxylin and eosin (HE), and with the histochemical stains Perls for hemosiderin and Van Gieson for fibrosis. Two experienced pathologists who scored the biopsies were blinded to all clinical and biochemical information, and to the order of execution of the biopsies. The biopsies were semi-quantitatively graded on three main parameters (inflammation, steatosis, and fibrosis). The grading of portal and lobular inflammation was 0, none; 1, mild; 2, moderate; and 3, severe. The grading of steatosis was 0, none; 1, up to 25%; 2, 25%-50%; 3, 50%-75%; and 4, 75%-100%. The staging of fibrosis was 0, none; 1, expansion of portal fibrous tissue; 2, early bridging, no nodules; 3, bridging fibrosis, early nodule formation; and 4, cirrhosis. Iron deposits were graded by a standard method, from 0 to 4, where grade 1 represents minimal iron deposition and grade 4 represents iron deposition throughout all zones^[15]. Patients were separated into two groups. We considered as progressors the patients who presented worsening of at least one unit of fibrosis. Inflammation and steatosis were described separately. Non-progressors presented stable or improved fibrosis scores. The rate of the fibrosis progression was calculated as the result of the mean difference in fibrosis scores divided by the mean interval in years between the first and second liver biopsies.

Statistical analysis

Data are expressed as mean \pm SD or as proportions. The goodness-of-fit test was used to determine whether the distributions of continuous variables were normal prior to analysis^[16]. Measurements were log-transformed as necessary to improve the normality of residuals and homoscedasticity (or homogeneity of variance) of errors before analysis. Paired *t* test was used to compare the underlying mean differences in response between follow-up and baseline. Separate analyses were performed for each variable and each follow-up time. Analysis of variance (ANOVA) was performed to assess: (1) whether there was a significant mean difference in each response between two independent samples (i.e. treatment groups); and (2) whether there was a significant mean difference between progressors and non-progressors, after controlling the potential effects of other variables. Pearson (Spearman) correlation coefficients were estimated to assess the magnitude and direction of a linear association between two given continuous (ranked) variables. Individual trajectories of serum measurement changes in response level over the follow-up time were estimated from linear random-effect models. Each response level was entered as the dependent variable and treatment, follow-up time, and treatment \times follow-up time interaction were entered as the independent variables. To account for inter-subject heterogeneity in the change of response level, intercept and time were modeled as random effects. A two-side *P* value of 0.05 was considered significant. All statistical analyses were performed using SAS, Version 9.1 (SAS Institute, Cary, NC, USA).

RESULTS

Clinical features

Table 1 summarizes the clinical features for progressors *vs* non-progressors. The mean age of the 12 patients at diagnosis was 17.3 years (range: 6-35 years), and three (25%) were female. Ten patients presented with different degrees of hepatic symptoms and two with mixed hepatic and neurological disease, mainly characterized by rigidity, tremors, and dystonia. At baseline, before anti-copper treatment, 24-h urinary copper concentration was $994 \pm 1293 \mu\text{g}/24 \text{ h}$, and mean hepatic copper concentration was $491 \pm 260 \mu\text{g}/\text{g dry liver}$. Five patients were started on PCA after the diagnosis, and the remaining seven on zinc salts. Most patients remained on the same drug during follow-up. One patient began zinc treatment that was later changed to PCA, and the therapy switch was indicated by the lack of improvement of liver enzymes. At diagnosis, the mean ALT was $84.1 \pm 50.9 \text{ U/L}$, and AST was $62.8 \pm 50.5 \text{ U/L}$. During follow-up, we observed a significant improvement of aminotransferase levels, with mean ALT $37.3 \pm 20.6 \text{ U/L}$ and AST $35.3 \pm 34.8 \text{ U/L}$ ($P = 0.01$ and 0.03 , compared to baseline) at the time of the second liver biopsy and mean ALT $38.3 \pm 17 \text{ U/L}$ and AST $27.9 \pm 9.9 \text{ U/L}$ at the time of the third liver biopsy. There was no significant change in hepatic copper concentration over time (Figure 1), and

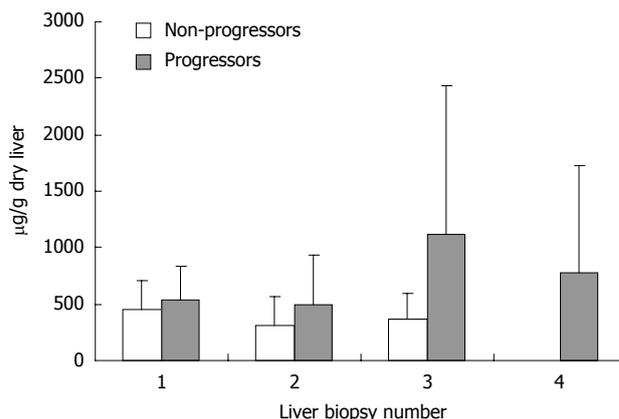

Figure 1 Evolution of the hepatic copper concentration in patients who presented with progression and without progression of the total histological score. Progressors had a higher hepatic copper concentration at all time points, but the difference between the two groups was not significant.

there was no significant difference in terms of laboratory data improvement between progressors and non-progressors (Table 1).

Hepatic histology

All patients underwent at least two liver biopsies. The average number of portal tracts was 14.9 ± 7.5 (range: 4-34). The mean interval between the first and the second liver biopsy was 4 years (range: 2-12 years) (12 patients). The mean interval between the second and third biopsy was 3 years (range: 2-4 years) (four patients). Two patients underwent a fourth liver biopsy after 2 and 3 years, respectively. None of the patients was on anti-copper treatment at the time of the first liver biopsy. The follow-up liver biopsies were indicated by an increase in the aminotransferase levels, or change of therapy, or were performed to monitor the potential disease progression. At baseline, five patients had grade 0 steatosis, three had grade 1, three had grade 2, and one presented with grade 3. Regarding the stage of fibrosis, seven had stage 0, three had stage 1, and two had stage 2. There were no cirrhotic patients. Three patients (two on zinc and one on PCA) showed overall improvement of the histological severity (patients 2, 3 and 6), with decreased steatosis (Figure 2A and B), and in one case, significant improvement of fibrosis, from stage 2 to 0 over 6 years of follow-up (Figure 2C and D). Three patients (one on zinc and two on PCA) showed no significant change in histology, although initial biopsies in this group showed mild lesions (patients 1, 4 and 5; Table 2). The patients with mixed neurological and hepatic phenotype were both included in the non-progressors group (patients 1 and 2). The six patients who manifested histological progression (patients 7-12) demonstrated worsening of inflammation and/or fibrosis (Figure 2E and F). Of these six patients, four had been started on zinc and two on PCA, and one was switched from zinc to PCA. One patient (#10) who showed an overall progression underwent the second liver biopsy 12 years after the first one, and over this time, the grade of steatosis and inflammation and the stage of fibrosis increased (Table 2).

Table 1 Baseline characteristics of patients who showed progression of the histologic score (progressors) *vs* those who showed overall improvement or no progression in histology (non-progressors)

	Progressors	Non-progressors
Age at diagnosis (mean \pm SD) (yr)	18.0 \pm 8.8	16.6 \pm 9.8
Phenotype	All hepatic phenotype	4 with hepatic phenotype; 2 with mixed hepatic and neurological phenotype
AST U/L (baseline) (normal range 15-43)	60.0 \pm 56.8 (range 18-44) (6)	64.6 \pm 51.3 (range 15-129) (6)
AST U/L (time of 2nd biopsy)	45.1 \pm 48.2 (range 20-143) (6)	25.5 \pm 9.7 (range 13-39) (6)
AST U/L (time of 3rd biopsy)	27.3 \pm 10.2 (range 13-44) (6)	28.7 \pm 10.8 (range 15-41) (3)
AST U/L (time of 4th biopsy)	24 and 28 (2)	
ALT U/L (baseline) (normal range 6-43)	83.5 \pm 40.2 (range 45-137) (6)	84.5 \pm 60.7 (range 15-164) (6)
ALT U/L (time of 2nd biopsy)	48.5 \pm 21.8 (range 24-80) (6)	26.1 \pm 12.3 (range 10-46) (6)
ALT U/L (time of 3rd biopsy)	42.0 \pm 17.2 (22 and 68) (2)	32.7 \pm 17.2 (range 8-48) (3)
ALT U/L (time of 4th biopsy)	47.0 \pm 7.0 (42 and 52) (2)	
24 h urinary Cu μ g/24 h (baseline)	679.7 \pm 504.0 (6)	1245.0 \pm 1649.0 (6)
Hepatic Cu mg/g dry liver (baseline)	534.4 \pm 298.7 (6)	455.0 \pm 245.3 (6)
Type of treatment	2 = penicillamine; 4 = zinc One patient switched to penicillamine during follow up	3 = penicillamine; 3 = zinc No change of treatment during follow up

The numbers in brackets represent the number of patients included in the analysis.

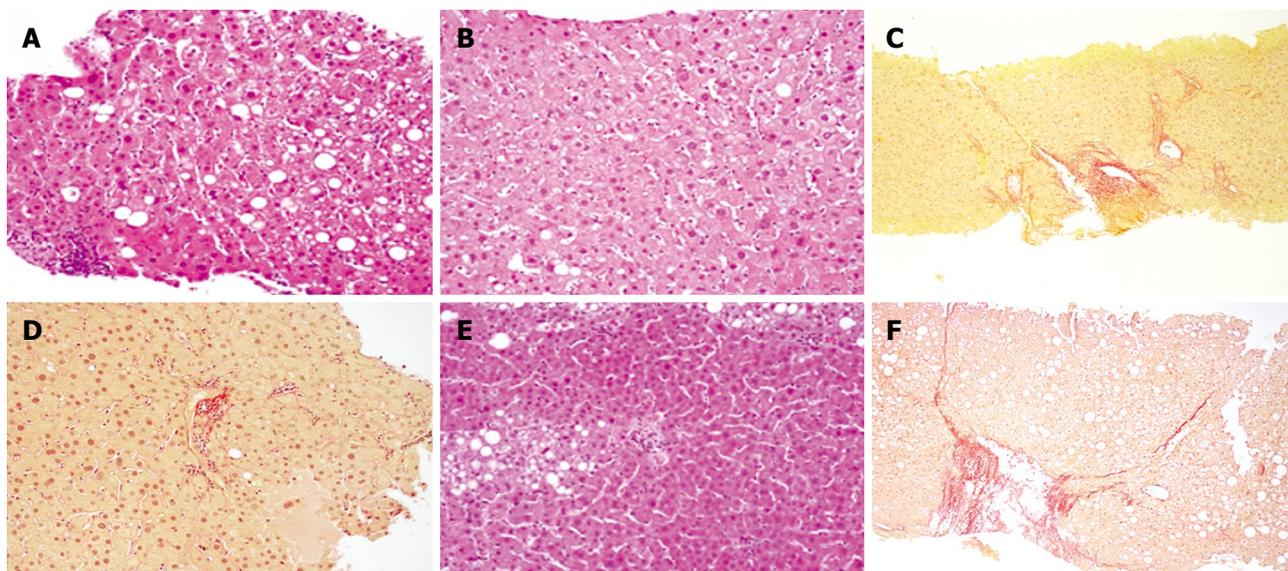

Figure 2 Biopsy of patients 3 and 9. A: Patient 3, initial biopsy, showing steatosis and focal inflammation (HE stain, 200 \times); B: Patient 3, third biopsy, 6 years after diagnosis, showing only rare steatosis and no inflammation (HE stain, 200 \times); C: Patient 3, initial biopsy, with bridging fibrosis (HE stain, 100 \times); D: Patient 3, second biopsy, without portal fibrosis (HE stain, 100 \times). Patient 3 was treated with zinc; E: Patient 9, initial biopsy, showing focal steatosis (HE stain, 200 \times); F: Patient 9, fourth biopsy, 8 years after diagnosis, showing bridging fibrosis and mild inflammation (Van Gieson stain, 100 \times). Patient 9 was treated with zinc.

Hepatic copper concentration was variable in the two groups, and did not correlate with histological findings. Progressors showed a mean hepatic copper concentration higher than non-progressors at all time points, but the result was not significant due to the small sample and high variability of the hepatic copper content (Figure 1). In our study, the hepatic copper concentration reached normal levels ($< 50 \mu\text{g/g}$ dry weight liver) in only two patients: one from the non-progressors group and one from the progressors group. The patients who did not show any change in histology also had consistent decreases in hepatic copper concentration, although levels were still elevated above normal. Iron staining was positive at baseline in two progressors and in one non-progressor. In one non-progressor the iron staining was positive after

4 years of anti-copper treatment (Table 2). There was no correlation between iron staining results and the severity of inflammation and fibrosis.

The histological progression did not correlate with subsequent aminotransferase levels or with the type of therapy. The estimated rate of progression of hepatic fibrosis (as result of the mean difference in fibrosis scores divided by the mean interval in years between the first and second liver biopsies) in the entire group was 0 units per year in the time frame between the first and the second liver biopsies, and 0.25 between the second and the third. However, among progressors, the rate of progression of fibrosis was estimated at 0.23 fibrosis units per year between the first and the second biopsy, and 0.6 units between the second and the third.

Grade of inflammation and steatosis are also described. ¹Indicates the two patients who presented with mixed hepatic and neurological phenotype. NP: Non-progressors; P: Progressors; Zinc: Zinc sulfate; PCA: Penicillamine.

DISCUSSION

While our study confirms that, in WD, the clinical laboratory parameters do not correlate with the progression of hepatic histopathology, our newest finding is the rate of progression of fibrosis of 0 fibrosis units per year over a mean follow-up of 4 years after the diagnosis, and of 0.25 over 3 years between the second and third liver biopsy. We also observed improvement of the stage of fibrosis in two patients. Although some patients have been followed for several years, the overall amount of fibrosis in our study was low, with no patients demonstrating cirrhosis, even after long-term follow-up. However, our study covered a maximum of 12 years of follow-up, which might not be a sufficient time to observe the development of advanced-stage fibrosis in WD. A large study from Germany on 163 patients, 78 of whom underwent liver biopsy, showed variable hepatic involvement, with 37% patients presenting with cirrhosis, 36% with unspecified stage of fibrosis, and 54% with steatosis. Similar to our data, the hepatic copper concentration was highly variable, with a range from 95 to 3776 $\mu\text{g/g}$ dry weight^[17].

Our finding that anti-copper treatments, zinc and PCA, were equally distributed between progressors and non-progressors is in agreement with previous studies that have demonstrated various responses to different type of treatments, including PCA, trientine, and zinc. There are six main previous studies on follow-up liver biopsies including a total of 42 WD patients (Table 3). The effect of PCA in the long-term progression of liver damage in WD has been described in three small groups of patients: four pediatric patients showed improvement or stable hepatic fibrosis after 2-7 years of treatment^[18], and seven adult patients showed marked improvement or disappearance of steatosis and improvement of mitochondrial morphological abnormalities after 3-5 years of PCA^[19]. Shiono *et al*^[20] have described an improvement in chronic active hepatitis in one patient after 6 years of PCA treatment, while in two patients with cirrhosis, there was no significant change in histopathology after 3-8.5 years of follow-up. Marcellini *et al*^[12] have described a pediatric population of 22 subjects that underwent a follow-up liver biopsy 10 years after diagnosis, and all subjects were treated with zinc sulfate. The

authors observed an improvement in all parameters of histological damage (inflammation, steatosis, and fibrosis) and an overall decrease in hepatic copper concentration; however, the level remained higher than normal in all patients^[12]. Askari *et al*^[13] have shown various degrees of improvement of fibrosis in three WD patients with cirrhosis, who were treated first with zinc and trientine and later only with zinc as maintenance treatment. One patient showed persistent stage 3-4 fibrosis; a second patient showed stage 2-3 and only one showed stage 1. Linn *et al*^[14] have described 17 patients who were followed for a median of 14 years and treated with zinc. In two cases, a second liver biopsy was performed after the baseline, which showed resolution of the initial mild fibrosis in one case and development of cirrhosis in the other. Although the data are heterogeneous and the progression of histopathological features is described following different criteria, it seems that there was an improvement in histology in most of the described patients, while we observed improvement or no progression only in 50% of cases. The explanation of our findings may be that we performed the liver biopsies when clinically indicated by the failure to respond to anti-copper agents, which potentially selected worse cases.

In previous work on WD, there have been variable changes in serum aminotransferases upon initiation of either PCA or zinc therapy, as well as persistently high levels resistant to either PCA or zinc therapy^[10,21]. In none of these studies was there a significant correlation between aminotransferase level and histological progression, which confirms the observation made by us and others that, in WD, an elevation of aminotransferase level is common and does not correspond to clinical worsening^[22]. The discovery of a higher hepatic copper concentration in progressors, as compared to non-progressors, is certainly not surprising and it may underline the importance of measuring hepatic copper during follow-up. Only one post-treatment specimen became positive for iron staining, and there was no correlation with fibrosis progression, which prevented us making any comparison with the results of Shiono *et al*^[20], which showed hepatic iron accumulation after long-term anti-copper treatment. Our study was limited by the relatively small number of patients; however, this was still one of the largest studies conducted on serial biopsies of this rare condition. The limited statistical power did not allow us to find significant correlations or predictive factors of histological progression, but we were able to derive important observations that might contribute to the long-term management of WD, considering that the timing and the indication for follow-up liver biopsy in WD has not been established yet. Our patients were recruited in the hepatology setting and were selected for this study according to the availability of serial liver biopsies. Nevertheless these patients' varied histopathology appears representative of the WD hepatic presentation. Our study focused on the role of liver biopsy in WD follow-up. However, liver biopsy, even as a fundamental diagnostic tool in WD and in chronic liver diseases, is limited by sampling error, which can affect both histologi-

cal evaluation and hepatic copper concentration, which is known to be significantly variable over time and among regenerative nodules in WD cirrhosis^[23,24]. Despite these limitations, our data are particularly valuable because of the rarity of WD and the infrequency of serial liver biopsies in this disease. Our observation of the inability of clinical tools to detect the progression of fibrosis despite treatment suggests that a liver biopsy with hepatic copper quantification every 3 years should be considered.

COMMENTS

Background

The earliest morphological features of Wilson disease (WD) are represented by micro- and macrovesicular hepatic steatosis, glycogenated nuclei in the periportal hepatocytes, and focal hepatocellular necrosis. With the progression of parenchymal damage and inflammation, fibrosis, and subsequently, cirrhosis invariably develop. As a result of the rarity of WD and the fact that liver biopsy is not performed routinely during follow-up of WD, unless clinically indicated, the progression and timing of the liver pathology is characterized poorly. Previous studies have shown the possibility of improvement during long-term follow-up of the steatosis and inflammation grade, and of the fibrosis stage. Studies on serial liver biopsies, as well as studies on the correlation between hepatic histology and clinical parameters are lacking.

Research frontiers

The research hotspots are: (1) what is the rate of hepatic fibrosis progression in WD; and (2) when is the best time to perform follow-up liver biopsies in WD patients?

Innovations and breakthroughs

The results indicate that the estimated rate of progression of hepatic fibrosis (as result of the mean difference in fibrosis scores divided by the mean interval in years between the first and second liver biopsies) in the entire WD group was 0 units per year between the first and second liver biopsy (4 years), and 0.25 between the second and third (3 years). However, among progressors the rate of progression of liver fibrosis was estimated as 0.23 and 0.6 fibrosis units per year between the first and second biopsy and between the second and third, respectively.

Applications

The results suggest that liver biopsy with hepatic copper quantification every 3 years should be considered.

Peer review

This paper investigate the progression of hepatic histopathology in serial liver biopsies from WD patients. The manuscript is well written, and it can be published in current form.

Abstract

AIM: To establish a quantitative method to measure the amount of lipids.

METHODS: The livers of 53 male Wistar rats (225 g) with different degrees of hepatic steatosis were studied. This model of hepatic steatosis was based on a high carbohydrate, fat-free modified diet. Biopsies were classified into four grades depending on fat accumulation, using the Kleiner and Brunt classification. Total fat was studied by the Soxtec method (Soxtec™ 2050 Auto Fat Extraction System), and agreement be-

tween both assays was assessed by calculating the κ coefficient.

RESULTS: According to the histological classification, 38% of rats presented grade 0, 21% grade 1, 22% grade 2 and 20% grade 3. The amount of fat per 100 g tissue was 2.60 ± 0.64 g for grade 0, 3.87 ± 1.59 g for grade 1, 5.82 ± 1.37 g for grade 2 and 8.68 ± 2.30 g for grade 3. Statistically significant differences were found between the mean values for each of the histological grades ($P < 0.05$). The correlation for the quantification of fat in the liver between both assays was moderate ($\kappa = 0.60$).

CONCLUSION: The biochemical quantification of fat in liver tissue by the Soxtec method was correlated with the histological classification, although the agreement between the two tests was only moderate.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) covers a wide spectrum that ranges from fatty liver alone to steatohep-

atitis, fibrosis or cirrhosis. Fatty liver alone is the most common histological lesion in patients with NAFLD^[1], and liver biopsy is the only diagnostic test that can reliably identify and quantify the degree of steatosis^[2,3].

The gold standard for detecting steatosis is the histopathological analysis of a liver sample collected by biopsy. The biopsy procedure is invasive and painful and presents a risk for patients^[4]. Actually, most hospitals use the histological method to determine the degree of steatosis. However, this method is subjective as it can vary, depending on the criteria for each pathologist. It is therefore necessary to develop a new method that is capable of determining the exact amount of fat in the liver.

Our aim was to compare a simple method for the isolation and purification of total lipids with the histological classification for quantifying fat deposits in a simple steatosis model in rats.

MATERIALS AND METHODS

Animals and diets

Male Wistar [CRL:Wi (Han)] rats (Charles River Laboratories) weighing approximately 225 g were studied. All experiments were conducted in accordance with the Guide for the Care and Use of Laboratory Animals published by the United States Public Health Service. Animals were kept in separate cages with a regular 12-h light regime at a controlled temperature ($25 \pm 2^\circ\text{C}$). The modified diet (high carbohydrate, fat-free) consisted of carbohydrates (80%, as starch), protein (16%, as casein), and vitamins and minerals (4%) (PANLAB, Barcelona, Spain). The standard diet consisted of a balanced diet that contained carbohydrates (51%), protein (16%), vitamins and minerals (4%), and lipids (3%). The standard diet contained 2.9 kcal/g, and the modified diet 3.58 kcal/g. This model was based on that reported by Delzenne *et al.*^[5] and Bujanda *et al.*^[6].

Experimental procedures

The rats were separated into two groups: control (20 rats) and steatosis (33 rats). The control group was given free access to food and drink and was fed a standard diet during 28 d. The steatosis group was given free access to food and water 4 d/wk and fasted for the remaining 3 d (only access to water was allowed). They were fed a modified diet during the dietary restriction cycles (Figure 1).

All rats were killed after completing four cycles of feeding and fasting, i.e. 28 d after study start. The amount of food taken by the rats and the weight of the animals were controlled. At the end of the study, all rats were anesthetized using isoflurane (Forane[®]). The animals were placed in an induction chamber with 5% isoflurane and administered 0.2 mL/200 g buprenorphine (Buprex[®]) as an analgesic. Once asleep, they were maintained with 3% isoflurane and 0.5-0.75 L oxygen.

Pathological evaluation

A histological study was performed following a midline laparotomy to remove the liver. The hepatic index was obtained by dividing the liver weight by rat weight and mul-

tiplying by 100. Liver tissue samples taken at the time the rat was killed were immediately placed in 10% buffered formalin and subsequently embedded in paraffin. Liver sections were stained with hematoxylin and eosin using standard techniques. The sections were viewed without prior knowledge of the treatment group to which each animal belonged. Biopsies were classified into four grades, depending on fat accumulation, using the classification proposed by Kleiner *et al.*^[2], whereby a patient is classified as grade 0 when < 5% of hepatocytes are affected by fat vacuoles, grade 1 when fat vacuoles are seen in 5%-33% of hepatocytes, grade 2 when 33%-66% of hepatocytes are affected by fat vacuoles, and grade 3 when fat vacuoles are found in > 66% of hepatocytes. Two experienced pathologists blinded to the experiment evaluated all samples, and agreement between both pathologists was determined. In case of discrepancy, the opinion of a third histopathologist reviewed the biopsies.

Quantitative determination of total fat in liver

The Soxtec[™] 2050 Auto Fat Extraction (Foss[®] Analytical, Hilleroed, Denmark) apparatus consisted of an extraction unit, a control unit and a drive unit. One gram of liver tissue was inserted into the extraction unit, solvent was added to the extraction cups in a closed system, and the cups were heated with an electric heating plate. The four-step extraction consisted of boiling, rinsing, solvent recovery and pre-drying. The results were calculated as total amount of fat (g) per 100 g tissue.

Samples were classified into four grades, according to the amount of fat detected in the steatosis group, using the data obtained for the control group and the maximum amount of fat detected in the steatosis rats as a reference.

Statistical analysis

Quantitative data were expressed as the mean \pm SD for the different animals in each group, and comparisons were made using a two-sided Student's *t* test. $P < 0.05$ was considered statistically significant. The agreement between biochemical assessments (grades) and histological steatosis grades (gold standard) was assessed by calculating the κ coefficient, which assessed how much better the agreement was than it would have been by chance alone ($\kappa = 1$ indicates perfect agreement; $0.80 < \kappa < 1$, excellent; $0.60 < \kappa < 0.80$, good; $0.40 < \kappa < 0.60$, moderate; $0.20 < \kappa < 0.40$, fair; $0 < \kappa < 0.20$, poor agreement). Weighted κ coefficients were calculated for ordered categorical data, whereas simple κ values were determined for other data.

RESULTS

Rat weight increased significantly in the control group (221 ± 10 to 355 ± 16 g), but remained similar in the group with fatty liver disease (222 ± 12 to 226 ± 14 g). The rats in the control group ate 31.11 ± 10.1 g/d and rats in the steatosis group ate 14.78 ± 3.2 g/d. The hepatic index was 4.47 ± 0.63 and 3.9 ± 0.31 in the steatosis and control groups, respectively.

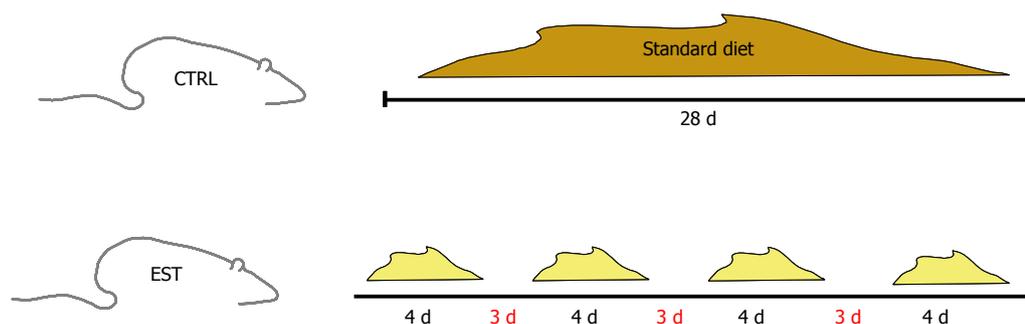

Figure 1 Summary of animal model.

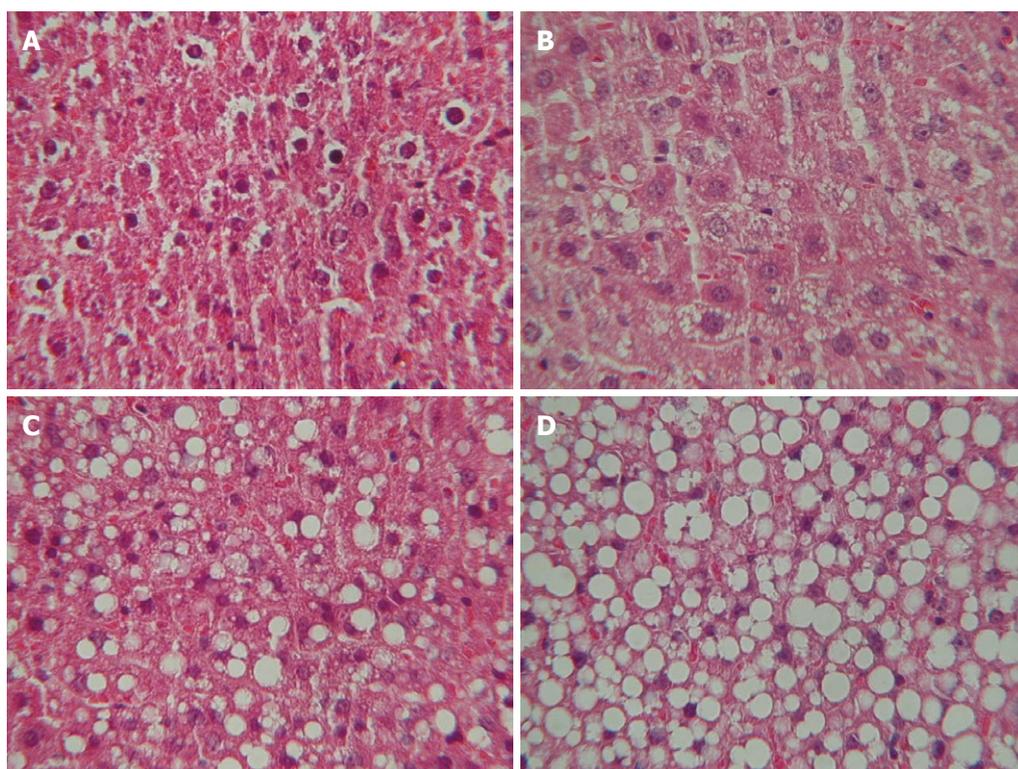

Figure 2 Different histological grades observed in the group of rats with steatosis. A: Grade 0; B: Grade 1; C: Grade 2; D: Grade 3.

Histological evaluation

No fatty infiltration was seen in the control group (Figure 1). Eleven rats (34%) in the steatosis group presented histological grade 1, 12 (36%) grade 2, and 10 (30%) grade 3. Inter-observer agreement was 0.89 and intra-observer agreement 0.92 (Figure 2).

Quantitative determination of total lipids

The amount of fat per 100 g tissue was 2.60 ± 0.64 g for histological grade 0, 3.87 ± 1.59 g for grade 1, 5.82 ± 1.37 g for grade 2, and 8.68 ± 2.30 g for grade 3. Statistically significant differences were found between the mean values for each of the histological grades ($P < 0.05$), except between grades 0 and 1 (Figure 2). The following biochemical classification was proposed on the basis of the amount of fat observed in the control group (2.6 g/100 g tissue) and the maximum amounts of fat observed in the steatosis group (11.16 g/100 g tissue). If we group

the rats for each histological grade and the average and SD we obtain the cut-off. The animals were classified as grade 0, when the amount of fat per 100 g tissue was < 2.6 g; grade 1, when the amount of fat was 2.6-5 g; grade 2, when the amount of fat was 5.1-8 g; and grade 3, when the amount of fat was > 8.1 g (Figure 3). The κ correlation between the histological and biochemical classifications was calculated to be 0.6 (moderate).

DISCUSSION

The amount of total fat determined by the Soxhlet method correlates well with the Kleiner and Brunt histological classification^[2,3]. Quantifying fat biochemically is a more objective and accurate method of determining the fat content in liver tissue. In the Soxhlet method, the crude fat is extracted from the liver by the Randall method^[7], a two-step extraction procedure that reduces fat-extraction

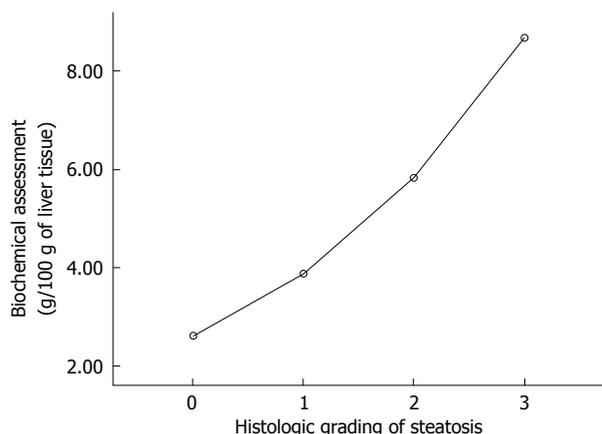

Figure 3 Biochemical determination of fat in liver tissue by the Soxtec method is correlated with the Kleiner and Brunt histological classification.

times to < 1 h per sample. This method for fat extraction has previously been used for meat and meat products and is accepted as an Association of Analytical Communities Official Method of Analysis (991.36)^[8]. It is recommended for Official First Action. This method is now automated and allows several samples to be analyzed simultaneously and rapidly (< 1 h). The approximate cost per sample is low, at around 22 euros. The Soxtec method is easier to perform than the classical biochemical method described by Folch in 1957 and is automated, which in our opinion, means it is the method of choice.

The diagnostic gold standard in another cumulative liver disease, namely hemochromatosis, is to determine the amount of iron present in a tissue sample obtained by liver biopsy. Other techniques, such as magnetic resonance imaging (MRI), which allow iron to be determined without the need for a liver biopsy, have been established based on this gold standard. In light of this, we are of the opinion that the best method for determining the amount of fat deposited in the liver is the biochemical method described herein, and that all other techniques, especially histological classification, are less accurate.

One of the main limitations of this biochemical technique, which is also inherent to histological classification, is that the amount of fat detected depends on the region where the biopsy is taken, which means that incorrect results can be obtained in cases of localized steatosis. Another limitation of biochemical determination is that it does not provide any information regarding other types of lesion that may be present, such as fibrosis or inflammation. The main limitations of histological classification include the subjective evaluation of the tissue sample by a pathologist, which can lead to incorrect results in the case of localized hepatic steatosis, and the higher cost with respect to biochemical analysis. The main advantage of histological classification with respect to biochemical analysis is that it provides information regarding other types of liver lesions. Despite its subjective nature, the majority of studies concerning the histological classification of fat in the liver have reported a good ($\kappa = 0.60-0.80$) or excellent ($\kappa > 0.80$) inter- and intra-individual cor-

relation^[2,9]. Indeed, the correlation between the pathologists in our hospital was excellent ($\kappa = 0.89$). Another limitation for both tests is that both techniques (Soxtec method and histological) are invasive and therefore need a liver biopsy.

Several noninvasive imaging techniques, including ultrasonography, computed tomography, and MRI, can identify hepatic steatosis and have been advocated as diagnostic tests for NAFLD^[10-15] but sometimes cannot distinguish between simple steatosis and steatohepatitis, or stage degree of fibrosis accurately^[16]. However, the gold standard for diagnosing hepatic steatosis is still liver biopsy, and the most objective technique is biochemical determination.

In the not too distant future, we must be able to diagnose steatosis, without using invasive methods. Today, for the diagnosis, liver biopsy is used, but it would be very interesting to be able to perform diagnosis using noninvasive techniques. For example, determining the amount of liver fat by magnetic resonance techniques. It would be very useful to perform a predictive test, but for this, we need much more research about the interaction of different factors, molecules and genes^[17]. The identification of the molecular mechanism that leads to fat accumulation and oxidative imbalance in steatotic liver, as well as genome and proteome studies from patients at various stages of the disease, is expected to improve the diagnostic and therapeutic approaches. In this way, attractive pharmacological designs include new molecules that can decrease lipid levels in the liver and improve insulin sensitivity.

In summary, the biochemical determination of fat in liver tissue by the Soxtec method is the most objective and direct technique available and should therefore be considered the gold standard for this assay. The results obtained by this method complement those obtained from histological studies. Further studies are needed to confirm our findings and their application in humans.

We thank Koro Berasarte, Iñaki Martínez and Mariasun Zabala for technical assistance.

COMMENTS

Background

The prevalence of nonalcoholic fatty liver disease is high, and histological classification is currently considered to be the gold standard for quantifying fat deposits in the liver.

Research frontiers

Histological analysis is the gold standard to determine the amount of fat in the liver. However, this method is subjective because it can vary depending on the pathologist's criteria. We therefore propose a new biochemical method, the Soxtec method, to determine exactly the amount of fat in the liver.

Innovations and breakthroughs

This is the first study to report the comparison of histological and biochemical (Soxtec) methods in steatosis. This report highlights the importance of the new method to determine exactly the fat content.

Applications

Being able to determine the exact amount of fat is important because it can

be very useful in the treatment of these patients. This represents a future therapeutic intervention.

Peer review

The authors have proposed a novel biochemical method for evaluating hepatic steatosis. Its reliability was assessed compared with that of histopathological analysis. This study is interesting and significant, although more clinical and laboratory data are needed to determine whether the Soxtec method is practically available.

Abstract

AIM: To assess expression of matrix metalloproteinases 2 (*MMP2*) and *MMP9* in gastric cancer, superficial gastritis and normal mucosa, and to measure metalloproteinase activity.

METHODS: *MMP2* and *MMP9* mRNA expression was determined by quantitative real-time polymerase chain reaction. Normalization was carried out using three different factors. Proteins were analyzed by quantitative gelatin zymography (qGZ).

RESULTS: 18S ribosomal RNA (*18SRNA*) was very highly expressed, while hypoxanthine ribosyltransferase-1 (*HPRT-1*) was moderately expressed. *MMP2* was highly expressed, while *MMP9* was not detected or

lowly expressed in normal tissues, moderately or highly expressed in gastritis and highly expressed in cancer. Relative expression of *18SRNA* and *HPRT-1* showed no significant differences. Significant differences in *MMP2* and *MMP9* were found between cancer and normal tissue, but not between gastritis and normal tissue. Absolute quantification of *MMP9* echoed this pattern, but differential expression of *MMP2* proved conflictive. Analysis by qGZ indicated significant differences between cancer and normal tissue in *MMP-2*, total *MMP-9*, 250 and 110 kDa bands.

CONCLUSION: *MMP9* expression is enhanced in gastric cancer compared to normal mucosa; interpretation of differential expression of *MMP2* is difficult to establish.

INTRODUCTION

The matrix metalloproteinase (MMP) family is a group of 24 zinc-dependent endopeptidases in humans that degrade components of extracellular matrix (ECM), and are noteworthy due to their involvement in a great

number of physiological and pathological processes, including stomach diseases such as gastritis and gastric cancer^[1-3]. Hence MMPs, besides their ability to degrade ECM, participate in regulating growth, angiogenesis, invasion, immune response, survival and epithelial mesenchymal transition^[3]. As a result proteolytic parameters may be suitable as prognosis tools in gastric cancer.

The group of gelatinases comprises MMP-2 (gelatinase A) and MMP-9 (gelatinase B), both of which cleave proteins, solubilize pericellular matrix components such as chemokines, shed cellular ectodomains and have been implicated in angiogenesis stimulation by means of integrin- $\alpha\text{v}\beta^3$ ^[4]. Both MMP-2 and MMP-9 gelatinolytic activities can be studied by means of quantitative gelatin zymography (qGZ)^[5]. These proteases are synthesized predominantly by stromal cells rather than cancer cells, and it has been proposed that both contribute to cancer progression^[3]. Studies show that high levels of *MMP2* and/or *MMP9* have a significant correlation with gastric cancer invasion^[6,7] and moreover are associated with poor prognosis^[7,8]. This is important; hence both proteases could participate during invasion into the gastric wall and metastasis, which are key clinical parameters in defining patient treatment in gastric cancer.

Quantitative real-time polymerase chain reaction (qRT-PCR) is a highly specific and sensitive technique for gene expression analysis^[9]; it can provide the quantification of transcripts in many different tissues and cell lines for a limited number of genes, and is particularly suitable when availability of cells is limited, such as in microdissected or biopsy tissue studies^[10,11]. Gene expression analysis is increasingly important in the study of complex regulatory networks and in the understanding of disease pathogenesis. Multiple assays based on qRT-PCR have been developed for diagnosis, prognosis and monitoring of chronic and infectious diseases^[12,13]. In these assays, it is essential to relate gene expression to quantity of tissue analyzed. Ideally, the RNA target employed as an endogenous control gene should be expressed at a similar level between tissue samples at all stages of development and remain unaffected by experimental treatments^[14]. In general, housekeeping genes are selected to normalize for the variability between samples, which can occur due to constitutive expression. Unfortunately, there is no single RNA molecule for which expression is constant in all biological conditions and tissues samples^[14,15]. Therefore, the constant expression of an endogenous control gene, selected for each particular set of experimental samples, requires testing and validation before reliable data can be obtained. In this study we used qRT-PCR to assess genetic expression of two commonly used housekeeping genes: 18S ribosomal RNA (*18SRNA*) and hypoxanthine ribosyltransferase-1 (*HPRT-1*), and two members of the MMP family, *MMP2* and *MMP9*, in two related gastric diseases: gastritis and cancer^[16]. The variances of each gene and their correlation coefficients were analyzed. In addition, we used qGZ^[5] to determine the metalloproteinase activity of MMP-2 and MMP-9.

MATERIALS AND METHODS

Ethics

This study was given approval by the Hospital Ethics Committee which, from April 2007 to April 2008, permitted the recruitment of patients undergoing upper gastrointestinal endoscopy. This study complied with the code of ethics of the World Medical Association (Helsinki Declaration of 1964, as revised in 2002).

Clinical samples and histological analysis

Antral gastrointestinal biopsies from 28 patients were analyzed: 11 normal (7 females, 4 males: mean age 52 ± 14.86 years; range 28-72 years); 11 cases of superficial gastritis (9 females, 2 males: mean age 52 ± 12.56 years; range 29-72 years), and 6 cases of advanced gastric cancer (3 females, 3 males: mean age 58 ± 8.73 years; range 49-69 years). All gastrointestinal endoscopies were performed using an EVIS EXERA Video Gastroscope Olympus GIF-Q145 (Olympus, Wendenstr, HRB, DE). Biopsy specimens were collected from each patient for routine histological examination and for RNA/protein isolation.

RNA isolation

Antral gastric biopsy specimens were collected in phosphate buffered saline (PBS) solution and immediately immersed in a tissue stabilization solution (RNAlater[®], Applied Biosystems, Foster City, CA, US). Tissues were homogenized in 1 mL of TRI reagent (Molecular Research Center, INC, Cincinnati, OH, US). RNA isolation was performed following the TRI reagent protocol. gDNA was digested using DNase I (Applied Biosystems). Quality and quantity of RNA were established by measuring the optical density of each sample at 260 and 280 nm.

Reverse transcription

RNA was pre-incubated with random primers and the reverse transcription reaction was performed at 42°C for 60 min. Expression levels of *18SRNA*, *HPRT-1*, *MMP2* and *MMP9* were assessed by qRT-PCR in 28 antral gastric mucosa tissue samples: 11 normal, 11 cases of superficial gastritis and 6 cases of advanced gastric cancer.

qRT-PCR

The qRT-PCR was performed using ABI PRISM 7500 Real-time PCR System as described by Nuttall *et al.*^[17]. All qRT-PCR reagents, plates, optical adhesives covers, primer and probe for *18SRNA*, *HPRT-1*, *MMP2* and *MMP9* were from Applied Biosystems (assay ID: 4308329, Hs99999909_m1, Hs00234579_m1 and Hs00234422_m1, respectively). Standard curves were prepared for each gene by serial dilution. The number of PCR cycles, termed cycle threshold (C_T), at which amplification entered the exponential phase was determined and this number was used as an indicator of the amount of target RNA in each sample. C_T values were used to classify genetic expression as very high ($C_T \leq 25$), high ($C_T = 26-30$), moderate ($C_T = 31-35$), low ($C_T = 36-39$) or not detected ($C_T = 40$) as

validated by Nuttall *et al.*¹⁷. The absolute quantity of the clinical samples was determined from comparison with the standard curve divided by three different factors: *18SRNA* C_T values; *HPRT-1* C_T values and geometric mean of *18SRNA/HPRT-1* C_T values.

Zymography

From the homogenized samples, the lower organic phase was transferred into fresh tubes and proteins were isolated following the protocol of the supplier (TRI reagent, Research Organic). Proteins were normalized and electrophoresed under non-reducing conditions. The gQZ was performed as described by Peake *et al.*⁵. Electrophoresis was performed using 5% polyacrylamide stacking gel and 10% resolving polyacrylamide co-polymerized with 1 mg/mL gelatin. MMP-2/MMP-9, human zymography standards (Millipore, Billerica, MA, US), were simultaneously loaded onto the gel. Gels were run in standard Tris-glycine-SDS running buffer. Gelatin gels were washed overnight by gentle shaking at room temperature in rinse buffer [50 mmol/L Tris-HCl pH 8.0, 5 mmol/L CaCl₂ and 2.5% (v/v) Triton X-100], incubated in 50 mmol/L Tris-HCl pH7.5, 5 mmol/L CaCl₂ for 18 h. Parallel gels of gelatin zymography were incubated in buffers containing 10 mmol/L EDTA to inhibit metalloproteinase activity. Gelatinolytic activity appeared as a clear band over a blue background. Using a 170-8170 Molecular Imager Gel Doc XR System and Quantity one software (Bio-Rad) images taken at the same magnification were quantified by densitometry, on the basis of their contour quantity after background subtraction. The arbitrary densitometry units were correlated with a standard curve prepared by serial dilutions of human recombinant gelatinases across a linear range (0.039-1.25 ng/mL). A total of 19 samples were randomly selected for qGZ studies: 7 of 11 normal gastric mucosa; 7 of 11 gastritis cases, and 5 of 6 gastric cancer samples.

Statistical analysis

Statistical analyses were carried out using Sigma Stat (SPSS Inc.). C_T values were expressed as mean ± SD and the variances of each gene were calculated. A Spearman correlation was used to compare *18SRNA* and *HPRT-1* expression patterns between normal, gastritis and cancer biopsies. A positive correlation coefficient $r > 0.5$ with $P < 0.05$ was considered significant. A Kruskal-Wallis test was used to examine differences observed, in both qRT-PCR and qGZ, between normal and gastritis tissue samples, and between normal and cancer tissue samples, where $P < 0.05$ was considered significant.

RESULTS

Relative expression of *18SRNA*, *HPRT-1*, *MMP2* and *MMP9*

The qRT-PCR analysis showed that in all samples the endogenous levels of *18SRNA* and *HPRT-1* were very high (C_T ≤ 25) and moderate (C_T = 31-35), respectively. *MMP2* was highly expressed (C_T = 26-30) in all samples.

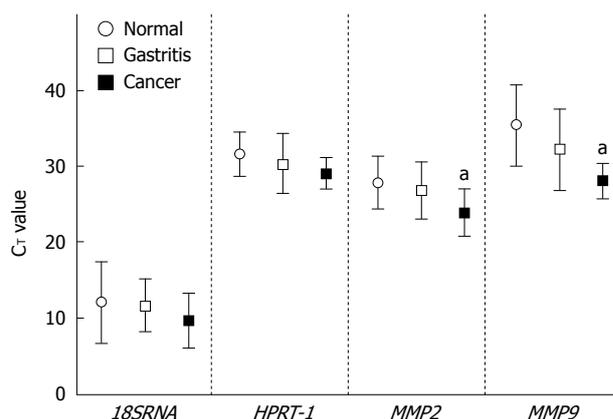

Figure 1 Relative mRNA expression of 18S ribosomal RNA (*18SRNA*), hypoxanthine ribosyltransferase-1 (*HPRT-1*), matrix metalloproteinases 2 (*MMP2*) and *MMP9* in three different groups of gastric mucosa tissues. Error bars represent the mean ± SD. ^a $P < 0.05$ vs normal condition.

MMP9 was either not detected (C_T = 40, 3 samples) or lowly expressed in normal tissues (C_T = 36-39, 8 samples), while in gastritis it was not detected in 1 sample, moderately expressed in 5, and highly expressed in the remaining 5. In cancer samples, *MMP9* was moderately and highly expressed in 2 and 4 samples respectively. Using a Kruskal-Wallis test we found, as expected, for *18SRNA* and *HPRT-1* no significant differences between relative expression in gastric cancer and normal tissue, and between gastritis and normal tissue. For *MMP2* ($P = 0.039$) and *MMP9* ($P = 0.018$) there were significant differences between cancer and normal tissue samples (Figure 1).

The mean C_T value across all clinical samples of the endogenous control genes tested was 18.48 (SD 3.05) for *18SRNA* and 32.92 (SD 2.49) for *HPRT-1*. *HPRT-1* was the gene with the lowest C_T variance (5.98) in comparison with *18SRNA* (8.96). Analysis by Spearman rank correlation showed a high correlation between genetic expression of the *18SRNA* and *HPRT-1* genes in normal, gastritis and cancer clinical samples ($r = 0.800$, $P < 0.001$, data not shown).

Absolute quantification of *MMP2* and *MMP9* transcripts using different normalization factors

We subsequently determined the absolute mRNA levels of *MMP2* and *MMP9* using *18SRNA*, *HPRT-1* and the geometric mean of *18SRNA/HPRT-1* C_T values as normalization factors. We believed that the geometric mean of *18SRNA/HPRT-1* would indicate the central tendency of the expression of these commonly used endogenous genes in gastric mucosa tissue samples. In accordance with relative expression, we found significant differences ($P = 0.039$) for *MMP2* between gastric cancer and normal tissue, but not between gastritis and normal tissue, using *HPRT-1* as the normalization factor (data not shown). However, in the estimation of absolute expression of *MMP2* employing *18SRNA* and the geometric mean of *18SRNA/HPRT-1* as normalization factors, there were no significant differences found between gastric cancer and normal tissue, which is in

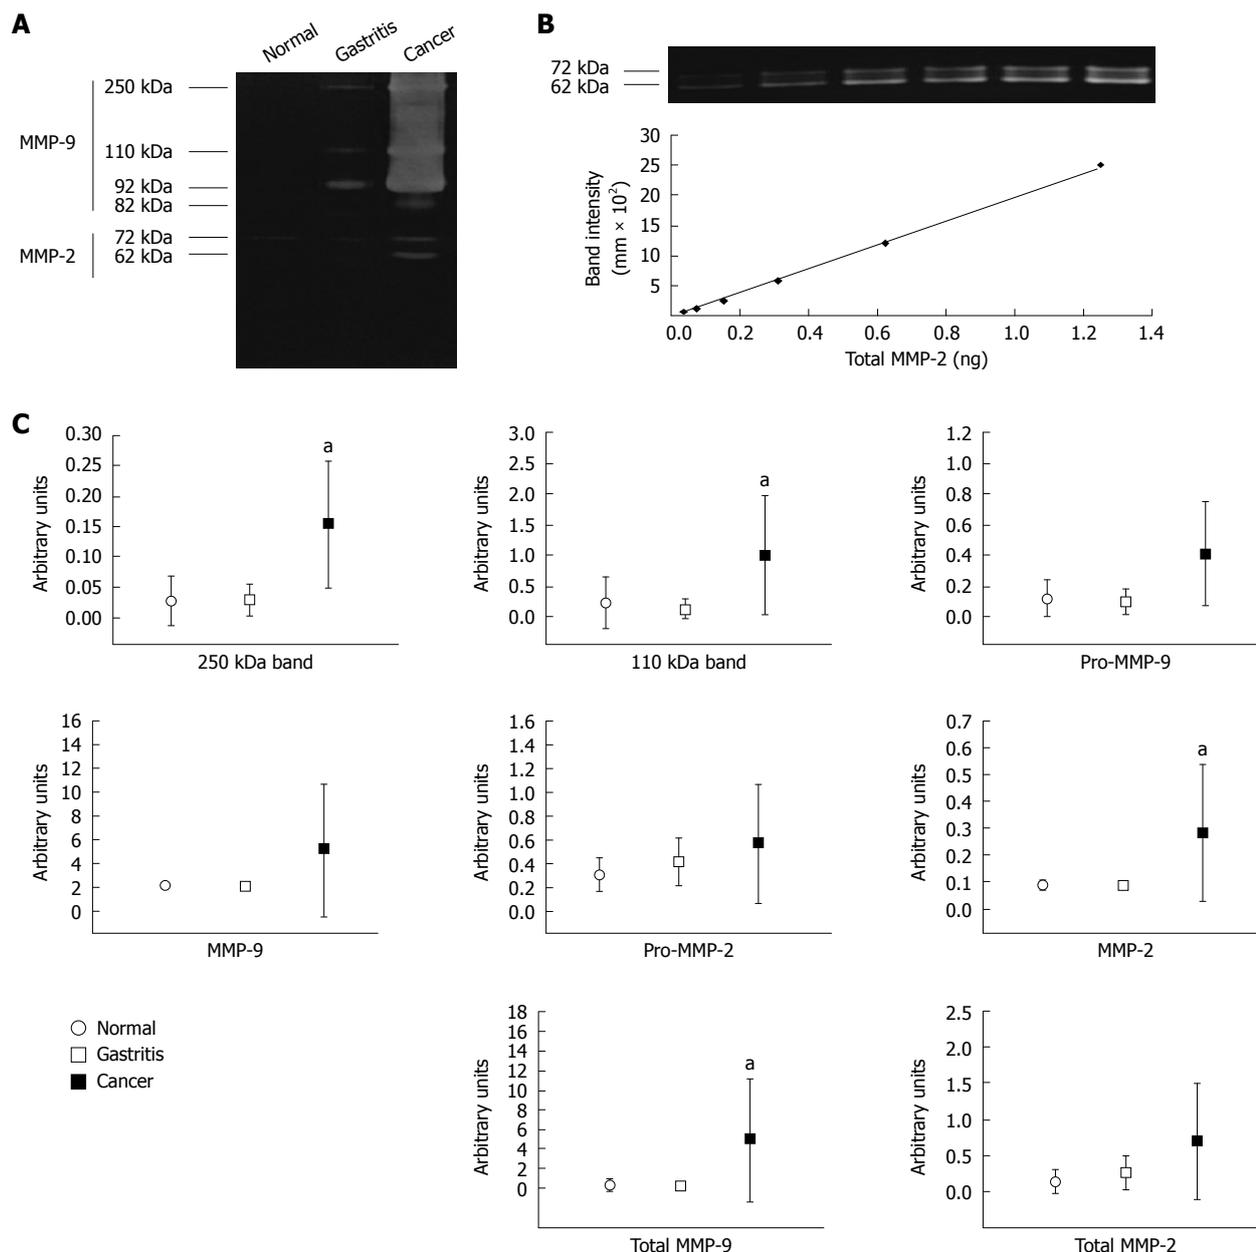

Figure 2 Validation of quantitative gelatin zymography (qGZ) of human mucosal biopsy homogenates. A: Representative zymogram of tested samples; B: Representative standard curve generated from human recombinant MMP-2 across linear range of 0.039-1.25 ng/mL, used to generate arbitrary units from densitometric data; C: Differential gelatinase activity of each of the six bands activity detected in normal (open circle), gastritis (open square) and gastric cancer (close square). Error bars represent the mean \pm SD. ^a $P < 0.05$ vs normal condition.

discordance with the relative expression data (data not shown). However, the P value for absolute expression of *MMP2* using geometric mean of *18SRNA/HPRT-1* was marginally significant ($P = 0.063$). In agreement with the relative expression data, there was a significant difference for *MMP9* between cancer and normal tissue, but not between gastritis and normal tissue, using all normalization factors (data not shown).

Gelatinase activity in gastritis, gastric cancer and gastric normal mucosa biopsies

Samples chosen for qGZ studies were analyzed by densitometry of each of the six bands activity: 250 kDa reported as MMP-9 homodimer^[18]; 110 kDa reported

as MMP-9/lipocalin-2^[19]; 92 kDa (Pro-MMP-9); 82 kDa (MMP-9); 72 kDa (Pro-MMP-2) and 62 kDa (MMP-2), see representative test samples in Figure 2A. Total MMP-9 was calculated by adding the 250, 110, 92 and 82 kDa band activities, and total MMP-2 by adding 82 and 72 kDa band activities. Arbitrary values for each individual band, total MMP-2 and total MMP-9 were determined from the standard curve; see representative standard curve generated from human recombinant MMP-2 on Figure 2B.

Using a Kruskal-Wallis test, we found no significant differences between gastritis and normal tissue in all bands. In addition, no significant differences were found for Pro-MMP-9, MMP-9, Pro-MMP-2 total MMP-2, between cancer and normal tissue (data not shown). However,

significant differences were found between cancer and normal tissue for 250 kDa ($P = 0.01$), 110 kDa ($P = 0.01$), MMP-2 ($P = 0.01$) and total MMP-9 ($P = 0.01$) (Figure 2C).

DISCUSSION

Various studies have reported high levels of MMP-2 and MMP-9^[6,20], and lipocalin-2^[6,21,22] in human gastrointestinal cancers, detected mainly by immune and zymography assays. In accordance with these, this study shows that the absolute quantity of *MMP9* mRNA is significantly enhanced in gastric cancer compared to normal mucosa, but interpretation of the differential mRNA expression among gastric cancer and normal mucosa of *MMP2* is conflictive, and appears to depend on the normalization factor employed. Our findings would suggest that the commonly used housekeeping genes *18SRNA* and *HPRT-1* are constitutively expressed at different levels in normal mucosa, gastritis and gastric cancer samples, although further studies with larger numbers of samples are required to confirm these findings. In addition, this study found that minor differences of the highly expressed gene *MMP2* between normal and cancer tissues could be obscured when using the equally highly expressed gene *18SRNA* as a normalization factor. Kubben and collaborators first reported that MMP-9 in complex with lipocalin-2 is increased in human gastric cancers compared to adjacent control tissue following detection by zymograms and immunoblotting^[23]. Our qGZ analysis reveals that MMP-9 homodimers, MMP-9/lipocalin-2 complexes, MMP-2 and total MMP-9 are significantly enhanced in gastric cancer compared to normal gastric mucosa. The formation of MMP-9/lipocalin-2 complexes has potential clinical value, as this action has been shown to protect MMP-9 from degradation *in vitro*^[24]. This may lead to the maintenance of an extracellular pool of latent MMP-9^[23]. Enhanced levels of these complexes are associated with poor prognosis in comparison to enhanced levels of MMP-9 alone. This study does not investigate the existence of possible ternary complexes of MMP-9/lipocalin-2/TIMP-1, which have been reported previously and show low gelatinase activity^[25]. Enhanced expression of MMP-2 and MMP-9 in human gastritis mucosal biopsy homogenates which are *Helicobacter pylori* (*H. pylori*)-positive has been reported using semiquantitative gelatin zymography^[19]; MMP-9 in serum samples from patients with gastritis *H. pylori*-positive^[26] and MMP-9 in infiltrative human gastric mucosal lymphocytes of *H. pylori*-associated gastritis are detected by flow cytometry^[27]. Interestingly, it has been shown by immunochemistry that Mmp-9 is increased in the murine *H. felis*-associated gastritis model and it has been associated with infection response and recruitment of immune cells^[28]. However, using qRT-PCR and qGZ technology we did not find significant differences in levels of *MMP2* and *MMP9* in gastritis biopsies compared to normal mucosa. There are several reasons which may account for this: (1) employment of different technology, qRT-PCR and qGZ, *vs* flow cytometry immunochemistry and semiquantitative gelatin zymography; (2) existence of

multiple levels of regulation of MMP expression and activity; and (3) our model was human superficial gastritis in which, at least initially, inflammation is confined to the portion of mucosa occupied by foveolae and the basal membrane is intact^[29]. In this regard it would be interesting to determine MMP expression and activity in gastritis characterized by strong tissue remodeling and degradation of the basal membrane, such as erosive gastritis^[29]. We would anticipate enhanced activity of MMPs in erosive gastritis compared to superficial gastritis.

In summary, we have shown that *MMP9* mRNA is significantly enhanced in gastric cancer compared to normal mucosa, while interpretation of the differential of *MMP2* transcripts among cancer and normal gastric mucosa is conflictive. The commonly used housekeeping genes *18SRNA* and *HPRT-1* appear to be constitutively expressed at different levels in normal mucosa, gastritis and gastric cancer tissues, although further studies are required. qGZ analysis reveals that MMP-9 homodimers, MMP-9/lipocalin-2 complexes, MMP-2 and total MMP-9 are significantly enhanced in gastric cancer compared to normal gastric mucosa. The potential clinical value of these findings should be fully explored in larger groups of gastritis and cancer patients.

COMMENTS

Background

Gastric cancer in Mexico is the most frequent gastrointestinal malignant neoplasm and mortality due to this disease has been reported to be steady during the past three decades. Several precursor conditions, such as chronic gastritis, have been associated with the development of gastric cancer. Proteolysis represents an important mechanism for achieving precise cellular control of biological processes, through the highly specific hydrolysis of peptide bonds. Proteases such as matrix metalloproteinases 2 (MMP-2) and MMP-9 degrade basement membrane, cleave chemokines, shed cellular ectodomains and have been implicated in different gastrointestinal diseases, such as gastritis and cancer.

Research frontiers

MMP-2 and MMP-9 are fundamental enzymes in extracellular matrix (ECM) homeostasis. In this study the authors demonstrate differences in *MMP9* mRNA between gastric cancer and to normal mucosa; interpretation of differential expression of *MMP2* among cancer and normal gastric mucosa is conflictive. No differences for both genes were detected between gastritis and normal mucosa. Analysis of metalloproteinase activity has shown that MMP-9 homodimers, MMP-9/lipocalin-2 complexes, MMP-2 and total MMP-9 are significantly enhanced in gastric cancer compared to normal gastric mucosa but no differences were found among gastritis and normal condition.

Innovations and breakthroughs

Besides the ability of MMPs to degrade extracellular matrix components, they participate in regulating immune response, inflammation, invasion, angiogenesis, survival and epithelial mesenchymal transition; hence proteolytic parameters may be suitable as prognosis tools in gastrointestinal diseases. In the Mexican population, this is the first study to report *MMP2* and *MMP9* expression in two related gastric diseases: gastritis and cancer.

Applications

Knowledge about proteolytic profiles between normal gastric mucosa, precursor conditions and malignant mucosa is central to elucidation of regulatory pathways

involved in cancer development and progression. Combination of proteolytic gene expression profile and clinicopathological factors may provide insight into biology of these diseases.

Terminology

The MMPs are a family of zinc-dependent endopeptidases that consists of at least 24 members. These enzymes are able to degrade most components of ECM. The ECM is all secreted molecules that are outside cells. This network supports adhesion of cells and transmits signals through cell-surface adhesion receptors. The group of gelatinases comprises MMP-2 and MMP-9 both is noteworthy because they are involved in a great number of physiological and pathological processes including cancer.

Peer review

The authors investigated differential expression of *MMP2* and *MMP9* in gastric tumor and gastritis tissues using a population from Mexico, a high risk population of gastric cancer. They observed a significantly increased expression of *MMP9* in tumor tissues. Results of this study were supported by previous studies. Strengths of this study are (1) biologically plausible mechanism, and (2) two different approaches for assessing expression of enzymes.

Abstract

AIM: To investigate the efficacy of short-term peg-interferon (PEG-IFN) monotherapy for chronic hepatitis C patients who achieved an immediate virological response.

METHODS: Defining an "immediate virological response (IVR)" as the loss of serum hepatitis C virus (HCV) RNA 7 d after the first administration of PEG-IFN α , we conducted a 12-wk course of PEG-IFN α 2a monotherapy without the addition of ribavirin for 38 patients who had low pretreatment HCV RNA load and exhibited IVR. The patients included 21 men and 17 women, whose ages ranged from 22 to 77 years (mean \pm SD: 52.0 \pm 17.8 years). There were 4 patients with HCV genotype 1b, 23 patients with genotype 2a and 4 patients with genotype 2b. HCV genotype was not determined for the remaining 7 patients. Patients were categorized into a sustained virological response (SVR) group, if serum HCV RNA remained negative for 24 wk after the end of treatment, or into a relapse group.

RESULTS: Based on the intention-to-treat analysis, 35 patients (92.1%) achieved SVR. One patient (2.6%)

relapsed with serum HCV RNA 12 wk after the end of treatment. Two patients (5.3%) withdrew from the study during the 24-wk follow-up period. With regard to the HCV RNA genotype, the SVR rates were 100% (4/4) for genotype 1b, 95.7% (22/23) for genotype 2a and 100% (4/4) for genotype 2b. The SVR rate in 7 patients, whose HCV RNA genotypes were not determined, was 71.4% (5/7).

CONCLUSION: Short-term PEG-IFN α 2a monotherapy is highly effective for chronic hepatitis C patients who have low pretreatment HCV RNA load and exhibit IVR.

INTRODUCTION

Hepatitis C virus (HCV) infection is a leading cause of chronic hepatitis, liver cirrhosis and hepatocellular carcinoma. About 170 million patients are chronically infected with HCV worldwide. Interferon (IFN) therapy is important for suppressing the progression of chronic liver disease derived from HCV infection. Currently,

combination therapy with peg-interferon α (PEG-IFN α) and ribavirin (RBV) is the first-line therapy used to eliminate HCV in patients with chronic hepatitis C. The duration of treatment is determined based on the viral genotype, with treatment administered for 48 wk in patients with genotype 1 and 24 wk in patients with genotypes 2 or 3^[1,2]. However, long-term administration of IFN and RBV increases the cost of treatment and the risk of severe adverse events.

The efficacy of IFN therapy depends on the HCV genotype, pretreatment viral load and early viral kinetics^[3-7]. Thus, IFN therapy must be individualized and optimized according to the virological and clinical status of each patient. Several studies have shown that the duration of IFN therapy could be shortened in patients who achieve serum HCV RNA negativity during the early stages of treatment^[7-9]. Therefore, it is essential that we reduce the treatment duration for patients who exhibit a quick virological response to IFN therapy. In the present study, we focused on the initial response to PEG-IFN α administration and studied the efficacy of short-term PEG-IFN α 2a monotherapy for patients who had low pretreatment HCV RNA load.

MATERIALS AND METHODS

Definition of IVR and protocol for PEG-IFN α 2a therapy

We defined an "immediate virological response (IVR)" as the loss of serum HCV RNA 7 d after the first administration of PEG-IFN α . Patients with low pretreatment HCV RNA load ($< 1.0 \times 10^5$ IU/mL) were monitored for HCV RNA in the serum 7 d after the first administration of PEG-IFN α 2a. We scheduled a 12-wk treatment course of PEG-IFN α 2a without the addition of RBV for patients who achieved IVR. The patients received subcutaneous injection of 180 μ g of PEG-IFN α 2a (Pegasys, Roche) once per week. According to the circumstance of each patient, the dose was reduced to 90 μ g or the treatment course was terminated.

Patients

We administered PEG-IFN α 2a without the addition of RBV to a total of 59 patients with low HCV RNA load from December 2004 to November 2007. They were monitored for serum HCV RNA 7 d after the first administration of PEG-IFN α 2a. Among these, 38 patients who achieved IVR were enrolled in this study. The age, gender, HCV genotype, serum HCV RNA level, ALT level, hemoglobin (Hb), and the neutrophil and platelet (PLT) counts before treatment are shown in Table 1. The patients included 21 men and 17 women, whose ages ranged from 22 to 77 years (mean \pm SD: 52.0 \pm 17.8 years). There were 4 patients with genotype 1b, 23 patients with genotype 2a and 4 patients with genotype 2b. HCV genotype was not determined for the remaining 7 patients. Among the 38 patients enrolled in this study, 37 received IFN therapy for the first time for HCV infection. Pt. 16 is the same patient as Pt. 3, who

received the same treatment course for HCV genotype 2a infection at 26 years of age. After the initial successful treatment, the patient was infected with genotype 2b HCV and re-treated at 28 years of age. Pt. 25 had been treated for hepatocellular carcinoma prior to this IFN treatment course.

Determination of serum HCV RNA load and the HCV genotype

Pretreatment serum HCV RNA levels were determined by RT-PCR using an Amplicor HCV monitor v2.0 series kit (Roche Diagnostics Co.), which had a detection limit of 5.0×10^3 IU/mL. When the serum HCV RNA level was below the detection limit, qualitative analysis of the HCV RNA was performed by RT-PCR using a COBAS Amplicor HCV test kit v2.0 (Roche Diagnostics Co.), which had a detection limit of 50 IU/mL. Qualitative analysis of HCV RNA was performed 7 d after the first administration for the evaluation of IVR, and at 24 wk after the end of treatment for the evaluation of the SVR. HCV genotype was determined using an HCV Genotyping SMITEST kit (Roche Diagnostics Co.).

Evaluation of the efficacy of PEG-IFN α 2a therapy

Patients were categorized into the sustained virological response (SVR) group, if serum HCV RNA remained negative for 24 wk after the end of PEG-IFN α 2a therapy. Patients were categorized into the relapse group if serum HCV RNA reappeared after the end of the treatment course.

Informed consent

All patients provided informed consent prior to their participation in this study. The study was conducted in accordance with the ethical guidelines of the Declaration of Helsinki and the International Conference on Harmonization Guidelines for Good Clinical Practice.

RESULTS

Completion of treatment

Figure 1 presents the dose and duration of PEG-IFN α 2a administration for each patient. Of 38 patients enrolled in this study, 26 (Pts. 1-26, 68.4%) completed a 12-wk treatment course. It was necessary to reduce the dose of PEG-IFN α 2a in 5 (Pts. 22-26) of these 26 patients. Twelve patients (Pts. 27-38, 31.6%) discontinued treatment prior to completion of the 12-wk course. In 6 (Pts. 30, 31 and 35-38, 15.8%) of these 12 patients, either self-withdrawal or financial problem was the cause for discontinuation. In 3 cases (Pts. 27, 28 and 32), the dose was reduced during the treatment, but the treatment was discontinued before completion of the 12-wk course.

Efficacy of the therapy

An intention-to-treat analysis was performed. Two patients (Pts. 27 and 35, 5.3%) withdrew from this study

during the 24-wk follow-up period because they did not attend the hospital appointments. Thirty-five patients (92.1%) were negative for serum HCV RNA 24 wk after the end of treatment and were categorized into the SVR group (Figure 2). One patient (Pt. 6, 2.6%) was positive for serum HCV RNA 24 wk after the end of treatment and was categorized into the relapse group.

With regard to the HCV RNA genotype, the SVR rates were 100% (4/4) for genotype 1b, 95.7% (22/23) for genotype 2a and 100% (4/4) for genotype 2b (Figure 2). The SVR rate in 7 patients, whose HCV RNA genotypes were not determined, was 71.4% (5/7), as we could not evaluate the treatment effect for 2 patients because of self-withdrawal during the follow-up period.

Adverse events

The most frequent adverse events were flu-like symptoms, such as fever and pain. Fatigue appeared as the second most frequent. Other adverse events are sum-

marized in Table 2. Some patients who complained of insomnia were treated with hypnotics. Thrombocytopenia ($< 50\,000/\text{mm}^3$) occurred in 1 case (Pt. 23) and the dose was reduced for the 4th and 5th administration during the treatment course. Neutropenia ($< 750/\text{mm}^3$) appeared in 3 cases, and in 1 case (Pt. 32) it was necessary to reduce the dose of PEG-IFN $\alpha 2a$ from the 2nd to 5th administration. Anemia (Hb < 8.5 g/dL) did not occur in any of the patients. In 6 cases, it was necessary to reduce the dose of PEG-IFN $\alpha 2a$ because of fatigue (Pts. 22, 25 and 28), emotional lability (Pts. 26 and 27) or vertigo (Pt. 24). None of the patients discontinued the treatment course because of bone marrow suppression. In 5 cases it was necessary to discontinue the treatment course for the following reasons: 2 with fatigue (Pts. 28 and 34), 1 with stomatitis (Pt. 27), 1 with skin symptoms and diarrhea (Pt. 29) and the other with viral influenza infection (Pt. 32). These adverse events were not particularly severe. One case (Pt. 33) discontinued the treatment

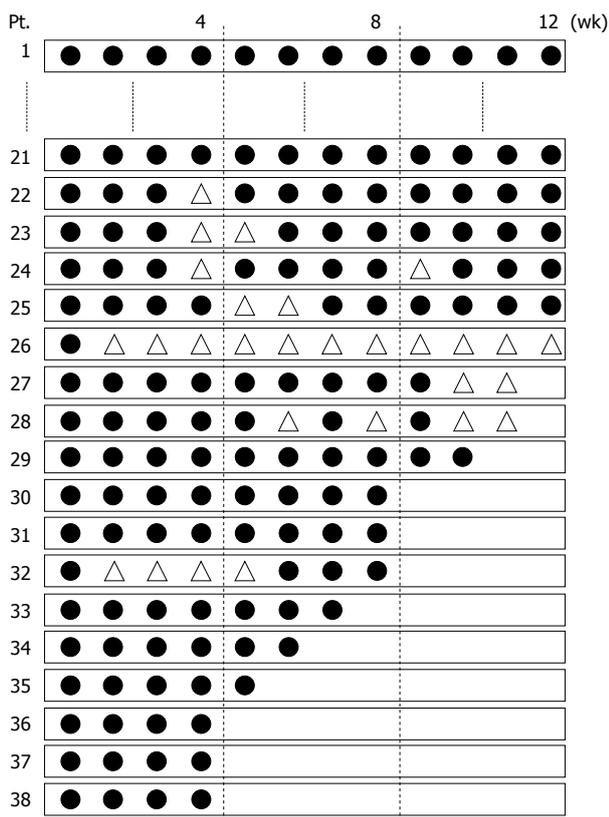

Figure 1 Administration of peg-interferon (PEG-IFN) α 2a. The patients received subcutaneous injections of 180 μ g of PEG-IFN α 2a (rotundity) once per week. Twenty-one patients (Pts. 1-21) completed a 12-wk treatment course without dose reduction. In 17 patients (Pts. 22-38), the dose was reduced to 90 μ g (triangle) or the treatment was terminated before completion of the 12-wk course.

course because of bacterial pneumonia, and recovered after antibiotic administration.

DISCUSSION

In the present study, we defined an “immediate virological response (IVR)” as the loss of serum HCV RNA 7 d after the first administration of PEG-IFN α . We then conducted a 12-wk treatment course of PEG-IFN α 2a in a population of patients who had low pretreatment HCV RNA load and who achieved IVR. This short-term PEG-IFN α 2a monotherapy without the addition of RBV exhibited an extremely high SVR rate.

The current standard therapy to eliminate HCV in patients with chronic hepatitis C is combination therapy with PEG-IFN α and RBV. While the SVR rate for 24 wk of PEG-IFN α /RBV therapy in patients with genotypes 2 and 3 is 78%-93%, the SVR rate for 48 wk of treatment for genotype 1 is 40%-51%^[1,2,10-13]. New methods of determining the adequate dose and duration of PEG-IFN α /RBV administration have been devised to increase the probability of SVR in the treatment for patients with genotype 1 and high pretreatment viral load^[9,14]. High dose and long-term IFN treatments, however, are expensive and contribute to additional risk for many adverse events.

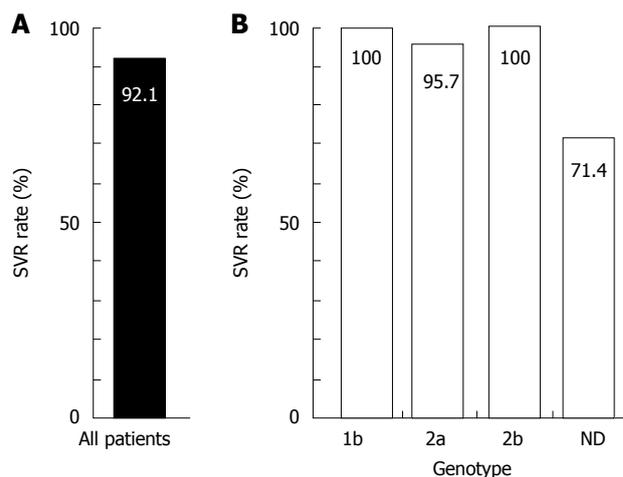

Figure 2 Efficacy of the therapy. A: The sustained virological response (SVR) rate in all patients; B: The efficacy of the therapy for each genotype.

Major contributory factors for SVR are viral genotype (except genotype 1), low pretreatment viral load (< 1.0 × 10⁵ IU/mL) and early loss of serum HCV RNA^[5-7]. Early virological response (EVR) and rapid virological response (RVR), which are indicated by loss of serum HCV RNA at weeks 12 and 4, respectively, are closely related to the SVR rate^[6,7,15,16]. Furthermore, Mangia *et al.*^[8] have reported that 12 wk of administration of PEG-IFN α /RBV to patients with HCV genotype 2 or 3 and who achieve RVR, results in a high probability of SVR. Tabaru *et al.*^[17] reported that the SVR rate was 100% after treatment with IFN α 2b for 6 wk for patients infected with HCV genotype 2a and low viral load. Establishing the minimum, and yet sufficient, IFN therapy period is important in terms of financial efficiency and for reduction of the risk of adverse events. Therefore, it is essential to establish a guideline to make the treatment period shorter than the standard length for patients who have a high probability of achieving SVR. For patients with low pretreatment HCV RNA load, the current standard IFN therapy which is allowed by Japanese National Medical Insurance, is 24-48 wk of PEG-IFN α 2a monotherapy without the addition of

RBV. RBV causes hemolytic anemia, and severe anemic symptoms sometimes appear in PEG-IFN α /RBV combination treatment^[18]. PEG-IFN α monotherapy can avoid these adverse events induced by RBV.

Thus, in the current study, we studied the efficacy of short-term PEG-IFN α 2a monotherapy for patients who had a low pretreatment HCV RNA load and exhibited IVR. Remarkably, 35 (97.2%) out of 36 cases that we were able to follow up to 24 wk after the last administration, were categorized into the SVR group. With regard to the HCV RNA genotype, SVR rates were 100% (4/4) for genotype 1b, 95.7% (22/23) for genotype 2a and 100% (4/4) for genotype 2b (Figure 2). These data might suggest that the efficacy of short-term PEG-IFN α 2a monotherapy for patients exhibiting IVR is independent of HCV genotype. Further analyses with a large population of patients should be conducted for each genotype of HCV, because the number of patients enrolled in this study, especially for genotype 1b, was small.

The patient (Pt. 6) who relapsed during this treatment course subsequently received 24 wk of PEG-IFN α 2a therapy and succeeded in achieving SVR. We consider that if short-term treatment failed to induce SVR, those non-SVR patients could be re-treated with long-term PEG-IFN α monotherapy (24-48 wk) or PEG-IFN α /RBV combination therapy. Thus, it is suggested that we should select short-term monotherapy at the first approach for patients with low pretreatment HCV RNA load and IVR.

Nine out of 35 cases who achieved SVR received less than 9 wk (4-8 wk) of drug administration. Therefore, there is the possibility that the treatment period could be shortened to less than 12 wk for a certain group of patients. Further analyses in randomized controlled trials with a large population of patients should be conducted to examine the efficacy of shorter treatment courses, such as 4 wk or 8 wk.

Frequent adverse events that generally appear during IFN therapy were seen in this study group of patients. However, no severe events were observed. None of the patients required discontinuation of therapy because of bone marrow suppression. While 1 case exhibited bacterial pneumonia as a severe complication, the patient recovered with antibiotic treatment. Thus, we consider that short-term monotherapy is safe.

PEG-IFN α monotherapy clearly has the advantage of avoiding adverse events induced by RBV. However, we have to consider the possibility that adding RBV to this short term PEG-IFN α therapy could offer shorter treatment duration or higher SVR rates. This option should be investigated in larger studies.

In conclusion, short-term PEG-IFN α 2a monotherapy is highly effective for chronic hepatitis C patients who have low pretreatment HCV RNA load and exhibit IVR. IVR is a simple and useful indicator of early viral kinetics to predict the high probability of SVR.

hepatitis C virus (HCV) genotype, pretreatment viral load and early viral kinetics. Therefore, IFN therapy must be individualized and optimized according to the virological and clinical status of each patient.

Research frontiers

Focusing on the initial response to PEG-IFN α administration, the authors proposed a new concept, the "immediate virological response (IVR)". Then the efficacy of short-term PEG-IFN α 2a monotherapy was investigated for patients who had low pretreatment HCV RNA load and exhibited IVR.

Innovations and breakthroughs

A 12-wk treatment course of PEG-IFN α 2a without the addition of RBV was highly effective for patients who achieved IVR. SVR rate for all patients in this study was 92.1% (35/38).

Applications

The present study has shown that short-term PEG-IFN α 2a monotherapy is an excellent treatment regimen for chronic hepatitis C patients who have low pretreatment HCV RNA load and exhibit IVR. It is also suggested that IVR is a simple and useful indicator of early viral kinetics to predict the high probability of SVR.

Terminology

An "IVR" was defined as the loss of serum HCV RNA 7 d after the first administration of PEG-IFN α .

Peer review

Yada *et al* reported that a 12-wk treatment course of PEG-IFN α 2a alone in a population of patients who had low pretreatment HCV RNA load and achieved immediate virological response results in extremely high SVR rates. The data are encouraging and important from a cost-effectiveness point of view.

Abstract

AIM: To determine the glycemic index (GI) and glycemic load (GL) values of Chinese traditional foods in Hong Kong.

METHODS: Fifteen healthy subjects (8 males and 7 females) volunteered to consume either glucose or one of 23 test foods after 10-14 h overnight fast. The blood glucose concentrations were analyzed immediately before, 15, 30, 45, 60, 90 and 120 min after food consumption using capillary blood samples. The GI value of each test food was calculated by expressing the incremental area under the blood glucose response curve (IAUC) value for the test food as a percentage of each subject's average IAUC value for the glucose. The GL value of each test food was calculated as the GI value of the food multiplied by the amount of the available carbohydrate in a usual portion size, divided by 100.

RESULTS: Among all the 23 Chinese traditional foods tested, 6 of them belonged to low GI foods (Tuna Fish

Bun, Egg Tart, Green Bean Dessert, Chinese Herbal Jelly, Fried Rice Vermicelli in Singapore-style, and Spring Roll), 10 of them belonged to moderate GI foods (Baked Barbecued Pork Puff, Fried Fritter, "Mai-Lai" Cake, "Pine-apple" Bun, Fried Rice Noodles with Sliced Beef, Barbecue Pork Bun, Moon Cakes, Glutinous Rice Ball, Instant Sweet Milky Bun, and Salted Meat Rice Dumpling), the others belonged to high GI foods (Fried Rice in Yangzhou-Style, Sticky Rice Wrapped in Lotus Leaf, Steamed Glutinous Rice Roll, Jam and Peanut Butter Toast, Plain Steamed Vermicelli Roll, Red Bean Dessert, and Frozen Sweet Milky Bun).

CONCLUSION: The GI and GL values for these Chinese traditional foods will provide some valuable information to both researchers and public on their food preference.

INTRODUCTION

The glycemic index (GI) was firstly introduced by Jenkins *et al*^[1]. It was defined as the incremental area under the blood glucose response curve (IAUC) after a portion of food containing 50 g available carbohydrate expressed as a percentage of that after the same amount of carbohydrate

from a reference food, usually glucose or white bread, taken by the same subject. The glycemic load (GL) was more recently introduced to reflect overall glucose response^[2,3], and it was calculated as the GI value of the food multiplied by the amount of the available carbohydrate in a usual portion size, divided by 100. GI and GL of foods have been shown to related to some chronic diseases, such as diabetes^[2,3], metabolic syndrome^[4], cardiovascular disease^[5] and even some types of cancers^[6]. Low GI and GL diets could contribute to a reduction in body mass in overweight, obese adolescents^[7], or coronary heart disease (CHD)^[8] and have a small but clinically useful effect on medium-term glycemic control in patients with diabetes^[9].

The relevance of dietary GI and GL is still debated^[10] and the availability of a reliable table of GI is critical for continuing research and resolution of the controversy. The GI and GL values of over 2480 individual food items were listed in the more recent edition of the international GI and GL tables^[10], among which there were only about 50 Chinese foods. Chinese traditional foods, although some styles are very popular and well-known worldwide, are very different from western foods with recipes followed strictly as laboratory instructions.

In some studies investigating the effect of food intake on local people^[11,12], there were no precise GI and GL values for many local Chinese foods. They had to use international GI tables to find similar foods or seek for a “best estimate” from experts in this field. These studies indicated that there might be some differences between the estimated GI values and the real values. Furthermore, during recent years the GI and GL values of different local foods have been reported^[13-15]. Therefore, it was worthwhile to determine the GI and GL values of Chinese traditional foods so as to advise local individuals on their daily diets and provide tools to undertake related studies in this area. The purpose of this study was to determine GI and GL values of some Chinese traditional foods in Hong Kong, which would be preliminary information which may act as the basis for the development of a GI and GL database for Chinese traditional foods.

MATERIALS AND METHODS

Participants

Fifteen healthy adults (8 males and 7 females, mean \pm SE: age, 25.4 \pm 1.2 years; BMI, 21.2 \pm 0.6 kg/m²) volunteered to participate in the study. All subjects reported no history of diabetes and all female subjects were non-pregnant and non-lactating. The present study was approved by the University Clinical Research Ethical Committee and all subjects gave written informed consent.

Procedures

The GI values of 23 Chinese traditional foods were determined by using the Food and Agriculture Organization (FAO) recommended methods^[16]. All subjects were required to refrain from alcohol consumption and vigorous physical activities 24 h before test. They were

required not to consume unusually large meals and have balanced diets on the previous day. After 10-14 h overnight fast, the subjects were required to report to the lab between 8 am and 10 am. On arrival, the subjects rested for around 15 min and the baseline finger-prick capillary samples were collected. Then the subjects consumed either reference (50 g anhydrous glucose) or test foods containing 50 g of available carbohydrate, based on the information from the label of food or from the food nutrition content table provided by the Center of Food Safety, the Government of the Hong Kong Special Administrative Region^[17]. Each subject was given 50 g anhydrous glucose 3 times and 25 g anhydrous glucose twice as a reference. Among all the selected foods, 2 foods, which contained both 50 g and 25 g available carbohydrate, were tested twice to compare whether the different portion sizes gave the same result. Only one food contained 25 g available carbohydrate for size limitation.

The intervals between two tests were at least two days. Foods for testing were randomized in blocks of 4 foods^[18]. A drink of 250 mL water was served with test food in each test and all foods were required to be consumed within 10 min. Further blood samples were collected at 15, 30, 45, 60, 90, and 120 min after starting to eat. All the blood samples were analyzed with YSI glucose analyzer (YSI 1500, USA; YSI).

The food items included Baked Barbecued Pork Puff (BBPP), Fried Rice in Yangzhou-style (FRYS), Fried Fritter (FF), “Mai-Lai” Cake (MLC), Tuna Fish Bun (TFB), Sticky Rice Wrapped in Lotus Leaf (SRWLL), Steamed Glutinous Rice Roll (SGRR), “Pineapple” Bun (PAB), Jam and Peanut Butter Toast (JPBT), Fried Rice Noodles with Sliced Beef (FRNSB), Egg Tart (ET), Plain Steamed Vermicelli Roll (PSVR), Green Bean Dessert (GBD), Barbecue Pork Bun (BPB), Red Bean Dessert (RBD), Moon Cakes (MC), Glutinous Rice Ball (GRB), Chinese Herbal Jelly (CHJ), Instant Sweet Milky Bun (ISMB), Frozen Sweet Milky Bun (FSMB), Fried Rice Vermicelli in Singapore-style (FRVSS), Salted Meat Rice Dumpling (SMRD) and Spring Roll (SR). All foods were prepared on the test morning or the day before the test; when necessary the foods were steamed by hot water. Because of special cooking methods and habits, some Chinese traditional foods were actually mixed meals. However, they were very popular in China and all of them were prepared by fixed methods. Therefore, the GI value of the same kind of food produced in different places was expected to be similar. The detailed information of each food was listed in Table 1.

Statistical analysis

The individual GI value was calculated by expressing the IAUC for each test food as a percentage of each subject's average IAUC for the glucose. IAUC were calculated ignoring area beneath the fasting level^[16,19]. The mean of all the individual GI values for each test food calculated from all subjects was the GI value for that food. GL values were calculated by multiplying GI values of a food by the carbohydrate content of the usual portion

sizes of this food, divided by 100. The usual portion sizes of different foods were taken from manufacturers' information or from mean values of testing foods.

The differences in IAUC and GI values between male and female subjects were compared with independent samples *t*-test. The differences in IAUC and GI values between FRVS (50 g) and FRVS (25 g), SMRD (50 g) and SMRD (25 g) were compared with paired *t*-test. The differences in the mean IAUC value and within-subject coefficient of variation for repeated references (CVref) between Reference (50 g) and Reference (25 g) were also compared with paired *t*-test. The results were analyzed using the SPSS for Windows version 12.0 (SPSS, Chicago, IL) software package. The values were presented as mean \pm SE and the significance level was set at $P < 0.05$.

RESULTS

All subjects completed the experiment except one subject who did not consume the foods containing 25 g available carbohydrate for individual reasons. The determined GI and GL values of test foods were shown in Table 2.

The mean IAUC value of all the test foods calculated from male subjects (IAUC_{male}) was lower than that from female subjects (IAUC_{female}) (91.10 ± 3.09 mmol min⁻¹ L⁻¹ *vs* 118.60 ± 4.05 mmol min⁻¹ L⁻¹, $P < 0.001$), however there were no differences between the mean GI value of all the test foods determined from data of male subjects (GI_{male}) and that from female subjects (GI_{female}) (64 ± 2 *vs* 67 ± 2 , $P = 0.224$). When grouped by each test food, there were no differences either in the mean IAUC or GI value between male and female subjects.

The mean IAUC value calculated from the data elicited by 50 g anhydrous glucose (IAUC_{ref50}) was higher than that from the data elicited by 25 g anhydrous glucose (IAUC_{ref25}) (167.54 ± 14.54 mmol min⁻¹ L⁻¹ *vs* 108.40 ± 8.86 mmol min⁻¹ L⁻¹, $P < 0.001$). However, there were no differences in the mean within-subject CVref (CVref = $100\% \times \text{SD}/\text{mean}$) ($28.00\% \pm 3.55\%$ *vs* $21.56\% \pm 3.74\%$, $P = 0.163$) for the 14 subjects between 50 g and 25 g anhydrous glucose.

The mean IAUC value calculated from the food containing 50 g carbohydrate was higher than that elicited by the same food containing 25 g carbohydrate (FRVS: 89.24

Table 2 Determined GI and GL values of test foods (mean \pm SE)

DISCUSSION

The availability of reliable GI values of different foods is critical for not only researchers but also common people. The University of Sydney has determined the glycemic and insulin responses to more than 1750 foods and shown that the GI is a reproducible measure of day-long postprandial glycemia^[9]. In the more recent edition of international tables of GI and GL^[10], over 2480 GI values of individual food items were listed. Because of the close relationship between the food GI and human health, labeling of GI on foods has been proposed or is occurring in Australia, South Africa, Sweden, United Kingdom, and Germany, with several commercial laboratories measuring the GI of foods^[20].

During recent years, the GI values of some local foods have been measured in different countries prior to their utilization in research and clinical settings among the local population^[13-15]. Since there was little information about GI values of Chinese traditional foods in Hong Kong in the literature, and that had limited the related research in this area^[11,12], it was worthwhile to setup a GI and GL database for Chinese traditional foods. However, there are so many traditional and special Chinese foods, according to folk culture, district,

religion, and festival. For the famous classes divided by district, there are styles of Guangdong, Beijing, Shanghai, Sichuan, North-West, *etc.* These all above mentioned styles are well-known worldwide. Quite different from Western cooking whose recipes are followed strictly like laboratory instructions, Chinese cooking allows for a creative and stylistic touch to it and it is also one important reason why Chinese foods are always absent in the international GI and GL tables. In this study, by using a recommended standard method, GI and GL values of 23 Chinese traditional foods were determined.

Although GI was a classification of the blood glucose raising potential of carbohydrate foods, many other factors such as food form, particle size, cooking methods, presence of other macronutrients and starch structure, might affect the GI of foods^[14,21]. Fat and protein added to carbohydrate foods have been suggested to reduce the postprandial glycemic responses which occurred by different mechanisms, such as delaying gastric emptying^[22]; however, most of the studies found that the amount of protein or fat in commonly consumed foods did not affect the glycemic responses^[23,24]. It was also found in the present study that no relation existed between the amounts of fats or protein in foods and their GI values.

Though there was a recommended standard protocol for the determination of GI^[16,25], there were still some methodological factors which will influence the accuracy in GI determination. According to an inter-laboratory study^[21], the GI values of foods were more precisely determined using capillary than venous blood sampling. A recent study^[20] also found that the CV of the IAUC val-

ues was significantly lower for capillary than for venous blood. So in the present study, capillary blood samples were selected for determining the GI values of foods.

One study suggested that the composition and characteristics of the evening meal might influence glucose tolerance the next morning^[27]. However, no difference was found in another study on within-individual variation influenced by subject preparation between controlled trials and uncontrolled trials^[28]. Furthermore, a more recent report suggested that simply advising subjects to avoid certain types of foods was almost as good and might be more cost-effective^[20]. Thus, in the present study all the subjects were just advised to have a balanced dinner each night before the test. Furthermore, all subjects in the present study were also required to refrain from alcohol consumption and vigorous physical activities 24 h before test, foods for testing were randomized in blocks of 4 foods, and the intervals between two tests were at least two days^[16,18].

The FAO recommended the reference food test should be repeated at least three times in each subject^[16]. A recent study suggested that no evidence to justify doing 3 tests rather than 2 tests was found because the difference was small and not significant^[20]. In our study, the reference of 50 g anhydrous glucose was tested three times to determine the GI and GL values for 20 of the 23 foods.

In the present study, though the mean IAUC values calculated from female subjects were higher than that calculated from male subjects, there were no differences in the mean GI values between them, which is consistent with a previous study^[20].

One study showed that GI value was negatively related to the within-individual CVref, and low within-subject variation (CVref < 30%) was required for accuracy in GI determination^[20]. Another study also found that most of the variation of GI values was due to within-subject variation, and in normal subjects the mean CVref was about 25.0%^[22]. In the present study, both CVref of 50 g glucose and that of 25 g glucose were less than 30%, and there were no differences between the two values. This result might indicate that the determined GI values were accurate in some extent.

No differences were found between the two GI values determined for the same food containing different amounts of available carbohydrate (50 g and 25 g) in this study. It might suggest that when the portion of one food containing 50 g available carbohydrate was too large for subjects to consume, it was appropriate to select the portion of the food containing 25 g available carbohydrate to determine the GI values. The result was consistent with a previous study which showed that the relative glycemic responses to the foods containing different levels of available carbohydrate intake were the same, at least between 25 g and 100 g^[29].

In conclusion, the GI and GL values for these Chinese traditional foods in the present study provide some valuable information both to researchers and to common individuals on their food preference and they are

also preliminary references on the setup of a GI and GL database for Chinese traditional foods later.

COMMENTS

Background

The glycemic index (GI) and glycemic load (GL) are closely related to some chronic diseases, however, little was known about the GI and GL values of Chinese traditional foods even in the latest international GI and GL tables.

Research frontiers

Previous studies have shown that GI is a reproducible measure of day-long postprandial glycemia and over 2480 GI values of individual food items were listed in the more recent edition of international tables of GI and GL. The relationship between food GI and human health has been largely investigated and is still one of the research hotspots in this research field. During recent years, the GI values of some local foods have been measured in different countries because most of the published GI data are based on analysis carried out in western countries, while this has limited the application of GI tables to local researchers or common people.

Innovations and breakthroughs

The present study determined the GI and GL values of some selected Chinese traditional foods which are very popular in Hong Kong. The results will provide some preliminary information which may act as the basis for the development of a GI and GL database for Chinese traditional foods.

Applications

The availability of reliable GI values of different foods is critical for not only researchers but also common people. Therefore, the results of this study will provide some valuable information both to researchers and to common individuals on their food preference.

Terminology

GI: GI was defined as the incremental area under the blood glucose response curve after a portion of food containing 50 g available carbohydrate expressed as a percentage of that after the same amount of carbohydrate from a reference food, usually glucose or white bread, taken by the same subject. The differences in the food GI values are mainly related to differences in the rate at which the carbohydrates are digested and absorbed. GL: GL was calculated as the GI value of the food multiplied by the amount of the available carbohydrate in a usual portion size, divided by 100.

Peer review

Blood glucose response to intake of traditional Chinese foods was investigated in this study. The aim of the study is interesting and the study design is good.

METHODS: This is a multi-center, hospital-based, case-control study. Case patients consisted of women who were newly diagnosed and pathology-proven to have esophageal squamous cell carcinoma (ESCC) from three large medical centers (one from Northern and two from Southern Taiwan, respectively) between August 2000 and December 2008. Each ESCC patient was matched with 4 healthy women based on age (within 3 years) and hospital of origin, from the Department of Preventive Medicine in each hospital. A total of 51 case patients and 204 controls, all women, were studied.

RESULTS: Frequencies of smokers and drinkers among ESCC patients were 19.6% and 21.6%, respectively, which were significantly higher than smokers (4.4%) and drinkers (4.4%) among controls (OR = 4.07, 95% CI: 1.36-12.16, $P = 0.01$; OR = 3.55, 95% CI: 1.03-12.27, $P = 0.04$). Women who drank an amount of alcohol more than 158 g per week had a 20.58-fold greater risk (95% CI: 1.72-245.62, $P = 0.02$) of ESCC than those who never drank alcohol after adjusting for other covariates, although the sample size was small.

CONCLUSION: Cigarette smoking and alcohol drinking, especially heavy drinking, are the major risks for developing ESCC in Taiwanese women.

Abstract

AIM: To investigate the etiology of esophageal cancer among Taiwanese women.

Tai SY, Wu IC, Wu DC, Su HJ, Huang JL, Tsai HJ, Lu CY, Lee JM, Wu MT. Cigarette smoking and alcohol drinking and esophageal cancer risk in Taiwanese women. *World J Gastroenterol* 2010; 16(12): 1518-1521 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i12/1518.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i12.1518>

INTRODUCTION

Esophageal cancer, predominately esophageal squamous cell carcinoma (ESCC), was the 9th leading cause of cancer deaths in Taiwan in 2006^[1]. The age-adjusted mortality rate was 0.54 per 100 000 persons for females, much lower than for males (9.04 per 100 000 persons), due to low incidence rate of esophageal cancer in females (0.77 per 100 000 persons in females and 11.99 per 100 000 persons in males).

Most epidemiological studies, including ours, regarding the etiology of ESCC have been conducted in men or both combined genders^[2-6], but very few have only focused on the effect of risk/protective factors on esophageal cancer among women^[7,8]. Cheng *et al*^[7] conducted a population-based, case-control study in four regions in England and Scotland. They found that high body mass index in early adulthood and low consumption of fruit are the most important risk factors, but that breastfeeding may confer a protective effect, for esophageal adenocarcinoma^[7]. In the same group led by Sharp *et al*^[8], the researchers found that cigarette smoking and consumption of hot food and tea are significant risk factors for ESCC in the same four regions of the previous study^[7]. Since, in Taiwan, no study has examined the determinants of ESCC occurrence in women, we conducted a multicenter, hospital-based, case-control study to investigate this issue.

MATERIALS AND METHODS

Selection of cases and controls

Case patients were women who were newly diagnosed and pathology-proven to have ESCC from three large medical centers: National Taiwan University Hospital (NTUH) located in northern Taiwan, Kaohsiung Medical University Hospital (KMUH) and Kaohsiung Veterans General Hospital located in southern Taiwan. These three hospitals are the main medical centers in their geographic areas and are accessible to patients from all socioeconomic groups in Taiwan. We matched each case patient with 4 healthy women based on their age (within 3 years) and hospital of origin, from the Department of Preventive Medicine. In total, 51 cases and 204 controls, all women, were recruited for interview between August 2000 and December 2008. During the same period, we recruited 530 male ESCC patients from these three medical centers. The study women were interviewed to collect demographic and substance use information by trained interviewers using a standardized questionnaire which was used earlier in an esophageal cancer study of

Taiwanese men^[2,3]. This study was approved by the Human Subjects Committee of KMUH; informed consent was obtained from all subjects.

Questionnaire

The information collected regarding substance-use habits included whether the subject had been a habitual areca chewer, cigarette smoker or alcoholic beverage drinker in her lifetime. Subjects who had smoked more than 10 cigarettes per week for at least 6 mo were defined as cigarette smokers. Those who reported regularly chewing betel quid for at least 6 mo were defined as areca chewers. For those who were cigarette smokers or areca chewers, the amount of consumed tobacco or areca per week was also collected. For alcohol drinking, subjects who had drunk beer, wine or distilled spirits more than once a week for at least 6 mo were defined as alcoholic beverage drinkers. For those who had ever consumed alcohol, detailed information was collected as to percentage of alcohol content (categorized as < 10%, 10%-19%, 20%-49%, and \geq 50%) and number of alcohol drinks consumed per week. One drink was defined as a bottle or can of beer, a medium glass of wine, a small glass of port/sherry, or a nip of spirits/liqueur.

Statistical analysis

Descriptive analysis was applied to demographic data to determine respective distributions. The averaged alcohol intake (in grams) per week for each type of beverage was estimated by multiplying the midpoint value for each intake frequency by the standard drink volume per week and median percentage of alcohol content (categorized as < 10%, 10%-19%, 20%-49%, and \geq 50%). Unconditional logistic regression was used to assess the association between case/control status and use of substances (tobacco, alcohol, and areca) and other covariates. Data were analyzed using the SAS 9.1 statistical package; all *P*-values were two-sided.

RESULTS

The distributions of age, tea consumption, and educational level were comparable between case patients and controls (Table 1). The frequencies of smokers, drinkers, and areca chewers were higher in case patients than in controls. After adjusting for other covariates, the status of smoking and drinking remained significant. Compared to non-smokers, smokers had a 4.07-fold (95% CI: 1.36-12.16, *P* = 0.01) greater risk of developing ESCC in women. Compared to non-drinkers, drinkers had a 3.55-fold (95% CI: 1.03-12.27, *P* = 0.04) greater risk of developing ESCC (Table 1). Since smoking and drinking alcohol are the significant risk factors for ESCC, we further examined their dose-response effect by dichotomizing the average amount of alcohol intake per week by the median (cigarette smoking: 3.5 packs/wk; alcohol drinking: 158 g/wk). We found that women who drank an amount of alcohol more than 158 g per week had a 20.58-fold greater disease risk (95% CI: 1.72-245.62, *P* = 0.02) than those who

¹After adjusting for age (≤ 65 years *vs* > 65 years old), educational level (≤ 9 y *vs* > 9 yr), tea consumption (yes *vs* no), and status of smoking, areca chewing, and alcohol consumption (yes *vs* no); ²We got missing data with the educational level and tea consumption of cases.

never drank alcohol after adjusting for age, educational level, cigarette smoking, and areca chewing. Women who drank less than 158 g per week had a slightly elevated risk of ESCC, but not significantly, compared to non-drinkers (Adjusted OR = 2.06, 95% CI: 0.44-9.63). In contrast, we did not find any significant dose-response effect of smoking on the risk of developing ESCC (Table 1).

DISCUSSION

This multi-center hospital-based case-control study shows that cigarette smoking and alcohol drinking are the major risk factors for ESCC in Taiwanese women. The effect of alcohol drinking on ESCC risk is mainly confined to heavy drinkers (> 158 g/wk). Tobacco and alcohol are classified as class 1 carcinogens by the International Agency for Research on Cancer^[9]. Although cigarette smoking and alcohol drinking are well-known risk factors for ESCC^[10-15], the majority of findings have been from studies among men.

To our knowledge, only two papers have been published which solely investigate the risk/protective factors of esophageal cancer in women^[7,8]. Cheng *et al*^[7] first conducted a multi-center, population-based, case-control study in four regions in England and Scotland. They collected 74 incident cases of women with histologically confirmed diagnoses of esophageal adenocarcinoma, and 74 female controls matched by age. They found that high body mass index in early adulthood and low consumption of fruit are important risk factors for esophageal adenocarcinoma. In contrast, breastfeeding may confer a protective effect, but this needs further confirmation as suggested by the authors^[7]. In the same group

led by Sharp *et al*^[8], the researchers conducted another population-based, matched case-control study of histologically confirmed ESCC in women in the same four regions. There were 159 case-control pairs. They found that cigarette smoking and the consumption of hot food and tea are significant risk factors. However, they did not find that alcohol drinking was a significant risk factor for ESCC, a result which is different from our findings.

Tobacco contains numerous carcinogens and many studies have demonstrated its link to esophageal cancer^[8,12-14,16-19]. In point of fact, the likelihood that cigarette smoking is more of a promoter than a mutagenic initiator is seen epidemiologically, as when heavy smokers stop smoking their risk of developing lung cancer is greatly diminished. Moreover, the most predominant chemicals in cigarette smoke are known promoters as they share mechanistic properties of known tumor promoters (i.e. they have threshold levels of action; they are reversible in action; their biological effects can be overridden by anti-tumor promoters, anti-oxidants and chemopreventive agents in the diet, *etc.*)^[20-23]. However, for alcoholic beverages, it is not clear what exact mechanisms cause the increased risk of esophageal cancer. The commonest ingredient of all beverages is ethanol. Although ethanol has not been shown as carcinogenic in laboratory animals, it may act through its major metabolite, acetaldehyde, which is a carcinogen in animal models^[24,25]. Alternatively, ethanol could exert a promoting effect by either solubilizing tobacco-specific carcinogens or enhancing their penetration into the esophageal mucosa to cause direct toxicity or oxidative damage on the epithelial mucosa^[18,26]. In addition, alcoholic beverages may activate other carcinogenic compounds, such

as N-nitrosamines and urethane, to increase the risk of malignancies of the upper aerodigestive tract^[9,17,26].

A relatively small sample size was the major limitation in this study. Since the incidence rate of ESCC in Taiwanese women is extremely low (average 0.81 per 100 000 for the preceding 5 years), a large effort was made in this study to recruit all incident cases of ESCC from three medical centers in Taiwan. Because of small sample size, we are unable to investigate other factors, such as fruit and vegetable intake, which may have a modest protective effect on ESCC in women. In conclusion, our results suggest that cigarette smoking and alcohol drinking, especially heavy drinking, are the major risks affecting the development of ESCC in Taiwanese women.

COMMENTS

Background

Esophageal cancer, predominately esophageal squamous cell carcinoma (ESCC), was the 9th leading cause of cancer deaths in Taiwan in 2006. While most epidemiological studies regarding the etiology of ESCC have been conducted in men or both combined genders, very few have solely focused on the effect of risk/protective factors on esophageal cancer among women.

Research frontiers

Since, in Taiwan, no study has examined the determinants of ESCC occurrence in women, the authors conducted a multi-center, hospital-based, case-control study to investigate this issue.

Innovations and breakthroughs

The results of this study suggest that cigarette smoking and alcohol drinking, especially heavy drinking, are the major risk factors for developing ESCC in Taiwanese women.

Applications

This study suggests that to abstain from smoking and drinking can prevent the development of ESCC in women.

Peer review

This manuscript is a well-written article. It is a quite interesting study by mainly being held on women population. The authors investigated the etiology of esophageal cancer among women in Taiwan. It is a multi-center hospital-based case-control study which concluded that cigarette smoking and alcohol drinking, especially for heavy drinkers, are the major risk factors for developing ESCC in Taiwanese women.

Abstract

AIM: To study the characteristics of *APC* (adenomatous polyposis coli) gene germline mutation in Chinese patients with familial adenomatous polyposis (FAP).

METHODS: *APC* gene from 14 FAP families was amplified by polymerase chain reaction (PCR) and underwent direct sequencing to determine the micromutation type. For the samples without micromutation, the large fragment deletion of *APC* gene was examined by multiplex ligation-dependent probe amplification (MLPA).

RESULTS: There were gene micromutations in 9 families with a micromutation detection rate of 64.3% (9/14), including 6 frameshift mutations (66.7%), 1 nonsense mutation (11.1%) and 2 splicing mutations

(22.2%). Large fragment deletions were detected by MLPA in 2 families. The total mutation detection rate of micromutations and large fragment deletions was 78.6% (11/14).

CONCLUSION: The detection rate of *APC* gene germline mutation can be improved by direct sequencing combined with MLPA large fragment deletion detection.

INTRODUCTION

Familial adenomatous polyposis (FAP) is a rare autosomal dominant genetic disease, with an approximate incidence rate of 1/10000. Clinical manifestations are mainly multiple adenomatous polyps in the large intestine (more than 100 polyps in total), and most of these patients fall ill in adolescence. Adenomatous polyps are a type of precancerous lesions. Thereby, cancerization will occur before the age of 40 years in almost 100% of patients without treatment. It was shown that the occurrence of FAP was related to *APC* (adenomatous polyposis coli) gene

mutations located at 5q21-q22^[1]. APC gene micromutations were identified in about 60%-70% of FAP patients^[2], while large fragment deletion mutations of APC gene were identified in 10%-15%^[3,4]. APC gene mutation screening in FAP patients and their family members cannot only further explore the pathogenesis of FAP and understand the APC gene mutation spectrum of Chinese FAP, but also predict the risk of FAP in "healthy members" of their families. It is also helpful for monitoring and in the clinical treatment of high-risk individuals with mutant genes, and can effectively decrease the incidence and mortality of FAP^[5]. At present, only a few studies of Chinese FAP have been reported, and smaller sample size and lower detection rate (mostly at 50%) were the main problems in these studies. In order to further understand APC gene mutations in Chinese patients with FAP, a total of 14 FAP families were detected by direct sequencing combined with large fragment deletion detection in this study.

MATERIALS AND METHODS

Patients

From 2002 to 2008, 14 patients from FAP families diagnosed and treated in the General Hospital of Beijing Military Region were enrolled in this study. Diagnostic criteria were as follows: (1) more than 100 adenomatous polypi in total; (2) more than 20 adenomatous polypi in patients with a family history of FAP. The patients which included 7 males and 7 females were from Beijing, Hebei, Henan, Anhui, Inner Mongolia, Shan'xi, Fujian Provinces and other regions, and were aged 12-57 years (mean 35.21 years) with an onset age of 8-57 years (mean 28.14 years). All patients gave written informed consent.

Genomic DNA extraction

Ten milliliter peripheral venous blood was drawn from FAP patients and genomic DNA was extracted by the phenol/chloroform/isoamyl alcohol method.

Primer synthesis

Primer sequences for APC gene exons 1-15 were synthesized by Shanghai Sangon Biological Engineering Technology & Services Co. Ltd, as previously described^[6].

PCR

Twenty microlitre PCR amplification reaction system contained 100 ng template DNA, 0.2 mmol/L of dNTP, 1.5 mmol/L of Mg²⁺, 0.1-0.2 μmol/L of upstream and downstream exon primers and 1-1.5 U TaqDNA polymerase. PCR reaction conditions were as follows: initial denaturation at 94°C for 5 min, followed by 35-40 cycles of denaturation at 94°C for 30 s, annealing for 30 s and extension at 72°C for 30 s, and a final extension at 72°C for 5 min, preservation was carried out at 4°C. After 1.5% agarose gel electrophoresis (containing EB dye), PCR products were observed by a gel imaging instrument. Fragment sizes of PCR products were indicated with DL2000 DNA Marker.

DNA sequencing

PCR reaction products were purified, and sequencing was performed by a DNA automatic sequencer (ABI PRISM 3730XL, USA). Changes in base sequence were confirmed by reverse sequencing.

Biological analyses

Sequence analyses were performed by BioEdit software. For the changed base sequences, the mutational site and type were determined in NCBI, and then the mutations were identified as new by referring to the mutations reported in the Human Gene Mutation Database (<http://www.hgmd.cf.ac.uk/ac/gene.php?gene=APC>) and the UMD-APC mutations database (<http://www.umd.be/APC/>).

Detection of large fragment deletions

Large fragment deletions were detected by multiplex ligation-dependent probe amplification (MLPA) only in samples without micromutations, and the experimental procedures followed the instruction manual of the MLPA kit (SALSA MLPA kit P043 APC, MRC-Holland, Amsterdam, the Netherlands). One hundred nanogram template DNA was denatured at 98°C for 5 min and hybridized with the probe liquid at 60°C overnight, subsequently, with thermal stability enzyme ligase 65, and spliced with long and short probes with the same sequences at 54°C for 15 min. Finally, the spliced probes were amplified by PCR with universal primers. Electrophoresis and collection of PCR amplification products were finished in an ABI 3700 sequenator, and the results were analyzed by GeneMapper software to obtain a peak map and peak area.

RESULTS

A total of 9 micromutations were identified by direct sequencing among these 14 unrelated FAP families with a mutation rate of 64.3%, including 6 frameshift mutations (66.7%), 2 splicing mutations (22.2%) and 1 nonsense mutation (11.1%), of which 4 mutations including c.2336-2337insT, c.3923-3929delAAGAAAA, c.532-2A>T and c.4179-4180GAdelinsT have not previously been reported (Table 1 and Figure 1). Among the 5 patients without micromutations identified by direct sequencing, large fragment deletions were identified by the MLPA method in 2 patients, including large fragment deletions of exon 11 and 10A (Alternative exon) in one patient and a large fragment deletion of exon 15 start in another patient (three probes included start, middle and end in the MLPA detection of exon 15), and these two large fragment deletions have not previously been reported (Table 1 and Figure 2).

The detection rate of large fragment deletions in APC mutation-negative patients was 40%, while the total mutation rate of micromutations and large fragment deletions was 78.6%. Meanwhile, 7 Snp sites were detected in 14 families (Table 2). Missense mutations including c.2753C>A, c.4007G>C and c.3964C>T were found in

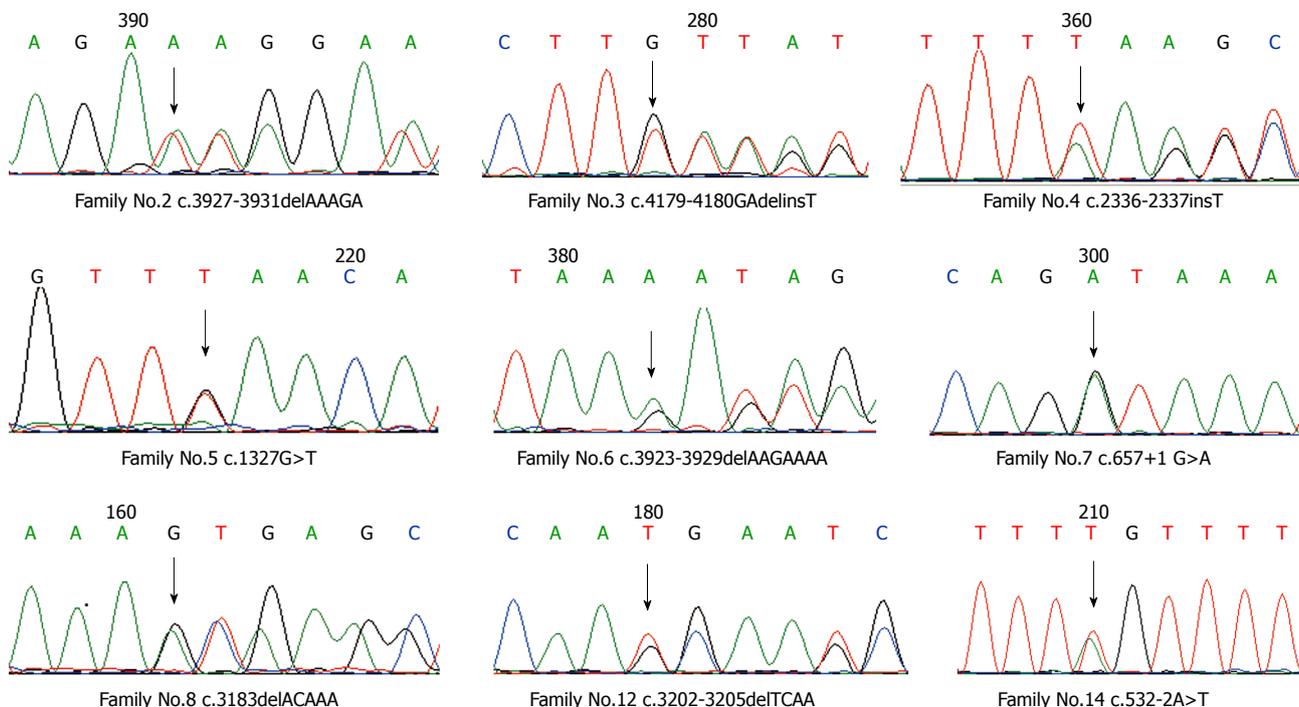

Figure 1 DNA sequencing of micromutations.

families 3, 11 and 14 besides frameshift mutations, large fragment deletions and splicing mutations, respectively. Due to difficulty in assessing pathopoiesis of missense mutations, these 3 missense mutations were excluded in the calculation of the mutation detection rate during analyses of the results. Moreover, one base substitution of intron 14 (c.653+8T>C) was found in family 13. Due to unknown effects of intron mutation, this was also excluded in the calculation of the mutation detection rate.

DISCUSSION

APC gene, a tumor suppressor gene, is the key gene in FAP. It is located at 5q21-q22 and contains an 8538 bp open reading-frame and a total of 15 exons. The *APC* gene product, APC protein, is a multi-regional binding

protein containing 2843 amino acids. The majority of *APC* gene mutations will result in the earlier formation of terminal codons in downstream. APC protein will lose biological activities due to its truncated change. Although there are numerous methods for detecting *APC* gene micromutations, direct sequencing is the most direct and accurate method. MLPA is a new method for detecting large fragment deletions which is rapid, sensitive, specific and reliable and has other advantages. In order to improve the detection rate of *APC* gene mutations, direct sequencing and the MLPA method for detecting large fragment deletions were combined in this study.

Direct sequencing showed that the *APC* gene mutation rate in Chinese FAP patients (Mainland) was 64.3%, which was significantly higher than that in Taiwan (50%)^[6], Hong Kong (50%)^[6] and other reports in the Mainland

(48.39%^[7] and 50%^[8]). This difference in Chinese *APC* gene mutation rates might result from different human subjects and detection methods and small sample sizes. The detection rate in this study was close to that in Japan (67%^[9] and 64.67%^[10]), lower than that in Greece (83%^[6]) and Chile (87.5%^[11]), and slightly higher than that in the Czech Republic (59.3%^[12]), Slovakia (61.5%^[12]) and South Korea (61%^[13]). Combined with the MLPA method for detecting large fragment deletions, the total detection rate of *APC* gene mutations was up to 78.6%, which was higher than that reported in Czechoslovakia (67.6%^[9]).

Among the 9 micromutations detected, the majority were frameshift mutations (66.7%) located at exon 15 (66.7%). Eventually, 77.8% of the mutations including nonsense mutations and frameshift mutations resulted in the earlier formation of terminal codons, and truncated changes were found in APC proteins. Substitution of bases in site +1 of exon 7 splicing district in family 7 and in site -2 of exon 5 splicing district in family 14 might lead to abnormal mRNA splicing. Therefore, the synthesized proteins were different from the wild-type. Four new micromutations found in this study were located at codon 779, 1308, 1394 and c.532-2, respectively.

With the exception of the above-mentioned 9 micromutations, 7 Snp sites were identified in this study, which was consistent with NCBI reports. Base substitution located at c.653+8 in intron 14 was found in family 13. However, the mechanisms of intron mutation are not yet understood. Therefore, the relationship between the mutation at c.653+8 and the onset of FAP should be studied further.

We also found two mutations in one family, including: (1) a frameshift mutation c.4179-4180GAdelinsT and a missense mutation c.2753C>A in family 3; (2) large fragment deletions of exon 10A and exon 11 and a missense mutation c.4007G>C in family 11; and (3) splicing mutations c.532-2A>T and a missense mutation c.3964C>T in family 14. Because the frameshift mutation in family 3, large fragment deletion in family 11 and splicing mutation in family 14 were definite pathogenic mutations, it was difficult to identify the pathopoiesis of simultaneous missense mutations, indicating that undetected definite

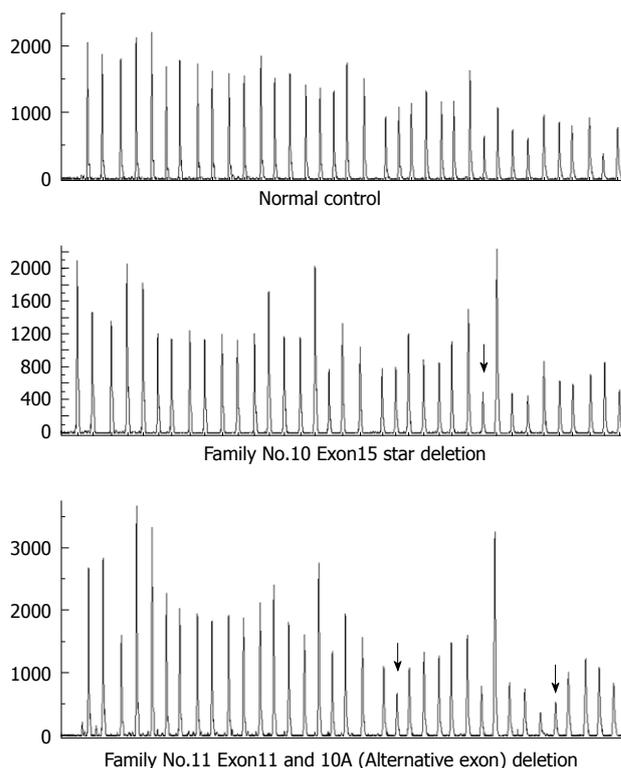

Figure 2 Peak of large fragment deletion detected by multiplex ligation-dependent probe amplification (MLPA). Arrows show the reduced relative peak area of the amplification product of that probe which means heterozygous deletions of corresponding exons.

pathogenic mutations would decrease after comprehensive screening for all exons of *APC* genes combined with large fragment deletion detection. Therefore, functional experiments should be carried out to identify the pathopoiesis of missense mutations and understand the causal relation with occurrence of diseases.

Two large fragment deletions were found by the MLPA method in patients without micromutations detected by direct sequencing. Deletions of 10A and exon 11 were found in one case. Because 10A was located at 1.6 kb in the downstream of exon 10, this indicated that deletions of exon 10A and exon 11 including some parts of intron 10 existed in this case. Deletion of exon 15 start was found in another case. These two large fragment deletions have not been reported in the Human Gene Mutation Database (<http://www.hgmd.cf.ac.uk/ac/gene.php?gene=APC>). MLPA showed that the detection rate of large fragment deletions in patients without *APC* gene mutations was 40% (2/5), which was higher than that in Belgium (15%^[3]) and the Netherlands (6.4%^[14]). Because of the small sample size in the research on large fragment deletions (5 cases) and few reports on *APC* gene large fragment deletions in Chinese patients, studies on *APC* gene large fragment deletions in Chinese FAP need to be carried out with a larger sample size.

In addition, 10A, an additional *APC* gene exon, was found recently located at 1.6 kb in the downstream of exon 10. 10A consisted of 54 bases encoding 18 amino acids^[15]. One case of 10A deletion was detected in this

study. Therefore, APC gene screening should include exon 10A. Recently, the studies on MYH genes and MYH associated polyposis (MAP) revealed that MAP accounted for 5%-7.5 % of FAP. It was found by Sieber *et al*^[6] that diallelic MYH mutations accounted for 6.6 % of polyposis families without APC gene mutations, and accounted for almost one third of FAP in families with attenuation-type familial adenomatous polyposis. Detection of MYH gene mutations should be performed in patients who have no mutations shown by mutation detection and large fragment deletion detection of APC genes.

In conclusion, there were a variety of APC gene mutations in Chinese FAP, and mutation detection rates were relatively high. Four new micromutations and 2 new large fragment deletions were found in this study. APC gene mutation detection rates could be improved effectively by direct sequencing combined with the MLPA method for large fragment deletions. Therefore, it was very necessary to add large fragment deletion detection to conventional detection of molecular genetics.

COMMENTS

Background

Familial adenomatous polyposis (FAP) is a rare autosomal dominant genetic disease. Clinical manifestations are mainly multiple adenomatous polyps in large intestine, and most patients fall ill in adolescence. Cancerization will occur before the age of 40 years in almost 100% of patients without treatment. FAP is related to APC (adenomatous polyposis coli) gene mutations located at 5q21-q22.

Research frontiers

APC gene micromutations were identified in about 60%-70% of FAP patients, while large fragment deletions were identified in 10%-15%. Direct sequencing is the most accurate method for detecting APC gene micromutations. Multiplex ligation-dependent probe amplification (MLPA) is a new method for detecting large fragment deletions.

Innovations and breakthroughs

In order to improve the detection rate of APC gene mutations, direct sequencing and the MLPA method for large fragment deletion detection were combined in this study. The total detection rate of APC gene mutations was up to 78.6%. Moreover, 4 novel micromutations and 2 novel large fragment deletions were found in this study.

Applications

APC gene mutation detection rates could be improved effectively by direct sequencing combined with the MLPA method for large fragment deletions. Therefore, it was very necessary to add large fragment deletion detection to conventional detection of molecular genetics.

Terminology

Multiplex ligation-dependent probe amplification (MLPA) is a variation of PCR that permits multiple targets to be amplified with only a single primer pair. Each probe consists of a two oligonucleotides which recognise adjacent target sites on the DNA. One probe oligonucleotide contains the sequence recognised by the forward primer, the other sequence is recognised by the reverse primer. Only when both probe oligonucleotides are hybridized to their respective targets, can they be ligated into a complete probe.

Peer review

The work described in this report is a service to the community concerned with APC gene mutations. The discovery of new mutations in an important gene and disease sometimes can qualify for a publication, especially in a relevant journal. This article is well written and the work done properly.

Abstract

AIM: To evaluate the clinical presentation, treatment and survival of patients with primary malignant tumor of small bowel (PMTSB).

METHODS: Clinicopathologic data about 141 surgically treated PMTSB patients (91 males and 50 females) at the median age of 53.5 years (range 23-79 years) were retrospectively analyzed.

RESULTS: The most common initial clinical features of the patients were intermittent abdominal discomfort or vague abdominal pain (67.4%), abdominal mass (31.2%), bowel obstruction (24.1%), hematochezia (21.3%), jaundice (16.3%), fever (14.2%), coexistence of bowel perforation and peritonitis (5.7%), coexistence of gastrointestinal bleeding and shock (5.0%), and intraabdominal bleeding (1.4%). Ileum was the most common site of tumor (44.7%), followed by jejunum (30.5%) and duodenum (24.8%). PMTSB had a nonspecific clinical presentation. Segmental bowel resection ($n = 81$) was the most common surgical procedure, followed by right hemi-

colectomy ($n = 15$), pancreaticoduodenectomy ($n = 10$), and others ($n = 19$). Twenty-seven adenocarcinoma patients and 13 malignant lymphoma patients received adjuvant chemotherapy with 5-fluorouracil and cyclophosphamide, adriamycin, vincristine and prednisone, respectively. Information about 120 patients was obtained during the follow-up. The median survival time of PMTSB patients was 20.3 mo. The 1-, 3- and 5-year survival rate was 75.0% (90/120), 40.0% (48/120) and 20.8% (25/120), respectively. Adenocarcinoma was found in 73.7% (42/57), 21.1% (12/57) and 15.8% (9/57) of the patients, respectively. Gastrointestinal stromal tumor was observed in 80.0% (20/25), 72.0% (18/25) and 36.0% (9/25) of the patients, respectively. Carcinoid was detected in 100.0% (15/15), 80.0% (12/15) and 46.7% (7/15) of the patients, respectively. Malignant lymphoma was demonstrated in 69.2% (9/13), 30.8% (4/13) and 0% (0/13) of the patients, respectively.

CONCLUSION: *En bloc* resection is the principal therapy for most PMTSB and chemotherapy is the important treatment modality for malignant lymphoma and other malignant tumors of small bowel which cannot be radically removed.

INTRODUCTION

Primary malignant tumor of the small bowel (PMTSB) accounts for 2% of all gastrointestinal (GI) tumors and 1% of GI tumor-related deaths^[1-5]. The small bowel is relatively resistant to carcinogenesis although it is considerably long (accounting for 70% of the whole digestive tract) and exposed to a wide variety of potentially noxious substances. In a review of over 11 000 primary GI malignant tumors, Martin^[6] found that only 2.4%, 10.8%, 16.4%, and 70.3% of primary malignancies are originated from the small bowel, esophagus, stomach, and colorectum, respectively. However, the diagnosis of PMTSB is difficult, because its symptoms and signs are nonspecific at presentation. Therefore, it is usually discovered at its advanced stage and often needs a surgical intervention due to acute complications. Sometimes, it is occasionally found during other surgical procedures^[6-11]. This retrospective study was to evaluate the clinical presentation, treatment and survival of PMTSB patients.

MATERIALS AND METHODS

Medical records of PMTSB patients at the tumor registry of our hospital between January 1988 and December 2007 were analyzed. Patients with tumor at the ampulla of Vater, pancreatic head, and ileocecal valve and metastatic cancer were excluded from the study. Only those with primary tumor arising from the duodenum, jejunum, or ileum were included.

One hundred and forty-one patients entered the study. Data on demography, clinical presentation, diagnosis, surgical treatment, histopathological findings, postoperative course, and survival time were collected from each patient. The TNM staging classification (AJCC system, 6th edition)^[12] was used to classify the extent of adenocarcinoma and carcinoid based on the histopathological and surgical reports. Stage I (T1-2, N0) was defined as tumor extending to muscularis propria, stage II (T3-4, N0) as tumor extending to subserosa, mesentery, and adjacent viscera, stage III (any T, N1) as tumor with regional lymph node metastasis, and stage IV (any T, any N, M1) as tumor with distant metastasis. Adenocarcinoma at stages I-IV was detected in 3, 14, 37 and 7 patients, respectively. Carcinoid at stages I-IV was found in 4, 8, 5 and 2 patients, respectively. Operation reports on the type, extent, and necessity of *en bloc* resection were reviewed. Operation was defined as radical if the tumor was completely removed both grossly and microscopically, and as palliative if the patients had distant metastasis at presentation, gross residual tumor at surgery, or positive margins microscopically. The World Health Organization standard grading system (well differentiated, moderately differentiated, poorly differentiated, and undifferentiated) was used to classify the histological types^[12]. In addition, Ann Arbor staging classification^[13] was used to classify the extent of malignant lymphoma. The diagnosis of gastrointestinal stromal tumor (GIST) was made as previously described^[14-16].

Statistical analysis

Data were analyzed using the SPSS software (version 13.0; SPSS, Inc., Chicago, IL). Patient records were reviewed during the follow-up or by direct contact with the patients, their relatives, or office visit. Survival rate was calculated on the day of histological diagnosis until death or last follow-up with the Kaplan-Meier method for analysis of censored data. Cox regression analysis was performed to assess the independent prognostic significance of parameters. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical and diagnostic features

Of the 141 PMTSB patients, 91 were male and 50 were female. Their median age was 53.5 years (range 23-79 years). Ileum was the most common site of PMTSB (44.7%), followed by jejunum (30.5%) and duodenum (24.8%). The most common clinical features of PMTSB patients at initial presentation were intermittent abdominal discomfort or vague abdominal pain (67.4%), abdominal mass (31.2%), bowel obstruction (24.1%), hematochezia (21.3%), jaundice (16.3%), fever (14.2%), coexistence of bowel perforation and peritonitis (5.7%), coexistence of gastrointestinal bleeding and shock (5.0%), and intraabdominal bleeding (1.4%). Other symptoms were loss of appetite, diarrhea, anemia and loss of bodyweight (Table 1). The median time of symptoms was 2 mo (range 0-41 mo).

The preoperative diagnostic rate was decreased to 91.7% (11/12) at the duodenum, 70.6% (36/51) at the jejunum, and 60.3% (47/78) at the ileum, respectively. The most commonly used diagnostic techniques were ultrasonography (US) of the abdomen (90.1%), followed by computed tomography (CT) of the abdomen (80.1%), upper gastrointestinal radiography (31.9%) and upper endoscopy (25.5%). Additional techniques included ultrasonography, endoscopic retrograde cholangiopancreatography (ERCP), superior mesenteric arteriography, colonoscopy and bone scanning.

All the patients were diagnosed histopathologically after operation. Of the 141 patients, 61 (43.3%) were diagnosed as adenocarcinoma, 28 (19.8%) as GIST, 17 (12.1%) as carcinoid, 14 (9.9%) as malignant lymphoma, 10 (7.1%) as leiomyosarcoma, 6 (4.3%) as malignant melanoma, 3 (2.1%) as malignant neurilemmoma, and 2 (1.4%) as fibrosarcoma, respectively (Table 2). Twenty-three of the 61 patients (37.7%) who underwent curative resection were found to have lymph node metastases after surgery, which were not suspected before operation.

Surgical procedures

Of the 141 patients who underwent surgical intervention, 31 (22.0%) had emergency operation and 110 (78.0%) had selective operation. The emergency indications included bowel obstruction ($n = 24$), gastrointestinal bleeding ($n = 4$) and bowel perforation ($n = 3$). The most commonly used surgical procedure was segmental bowel resection

Table 1 Clinical symptoms and signs of PMTSB patients

Symptoms	n (%)
Abdominal pain	95 (67.4)
Abdominal mass	44 (31.2)
Bowel obstruction	34 (24.1)
Hematochezia	30 (21.3)
Jaundice	23 (16.3)
Fever	20 (14.2)
Bowel perforation coexistent peritonitis	8 (5.7)
Gastrointestinal bleeding and coexistent Shock	7 (5.0)
Intraabdominal bleeding	2 (1.4)

Others symptoms: Loss of appetite, diarrhea, anemia and loss of body-weight. PMTSB: Primary malignant tumor of small bowel.

Table 3 Surgical procedure for PMTSB patients

Procedure	n (%)
Operative intervention	
Emergent procedure	31 (22.0)
Elective procedure	110 (78.0)
Disease for emergent procedure	
Bowel obstruction	24 (77.4)
Gastrointestinal bleeding	4 (12.9)
Bowel perforation	3 (9.6)
Surgical procedure	
Segmental bowel resection	92 (65.3)
Right hemi-colectomy	15 (10.6)
Pancreaticoduodenectomy	10 (7.1)
Gastric bypass	13 (9.2)
Biopsy at laparotomy	5 (3.6)
Feeding jejunostomy	2 (1.4)
Biliary bypass	2 (1.4)
Enteric bypass	2 (1.4)
Radicality of procedure	
Radical ¹	104 (73.8)
Palliative ²	37 (26.2)

¹Radical resection: Negative margin, resection of all gross diseases, *en bloc* local resection when indicated; ²Palliative resection: Positive margin, gross residual disease.

(65.3%), followed by right hemicolectomy (10.6%), and pancreaticoduodenectomy (7.1%). Other procedures included gastric bypass ($n = 13$), biopsy only ($n = 5$), feeding jejunostomy ($n = 2$), biliary bypass ($n = 2$), and enteric bypass ($n = 2$).

Of the 141 PMTSB patients, 104 (73.8%) received a radical resection, 37 (26.2%) underwent diagnostic or palliative operation. Of the 32 patients who underwent a palliative resection, 15 had synchronous distant metastasis (liver metastasis in 10 and peritoneal dissemination in 5) in small bowel and its mesentery ($n = 11$), retroperitoneum ($n = 5$) and ovary ($n = 1$) (Table 3).

Postoperative complications

Postoperative complications occurred in 21 (14.9%) patients, including pancreatic anastomotic leak in 7 (5.0%), wound infection in 6 (4.3%), prolonged gastric emptying in 3 (2.1%), subphrenic abscess in 3 (2.1%), and gastrointestinal bleeding from gastrojejunostomy in 2 (1.4%) as shown in Table 4. The median hospital stay time of patients was 13.2 d (range 8-60 d).

Table 2 Histopathological type of PMTSB ($n = 141$)

Histopathological type	n (%)
Adenocarcinoma	61 (43.3)
GIST	28 (19.8)
Carcinoid	17 (12.1)
Malignant lymphoma	14 (9.9)
Leiomyosarcoma	10 (7.1)
Malignant melanoma	6 (4.3)
Malignant neurilemmoma	3 (2.1)
Fibrosarcoma	2 (1.4)

GIST: Gastrointestinal stromal tumor.

Table 4 Complications after operation

Complications	n (%)
Pancreatic anastomotic leak	7 (5.0)
Wound infection	6 (4.3)
Prolonged gastric emptying	3 (2.1)
Subphrenic abscess	3 (2.1)
Gastrointestinal bleeding	2 (1.4)
Total	21 (14.9)

Postoperative adjuvant therapy

Of the 141 PMTSB patients, 40 (28.4%) received adjuvant chemotherapy after operation. However, adenocarcinoma was treated with 5-fluorouracil (5-FU) and malignant lymphoma was treated with cyclophosphamide, adriamycin, vincristine and prednisone (CHOP).

Recurrence patterns

Recurrence of the tumor was found in 32 (22.7%) of the 104 patients after radical resection (at a single site in 13 and at multiple sites in 19). The most common sites of recurrence were liver and lung (65.6%), peritoneal carcinomatosis (21.9%) and intestinal mesentery (12.5%). Nine patients (28.1%) underwent further operative intervention, 8 (25.0%) received chemotherapy and/or radiotherapy, and 4 (12.5%) received no further treatment. Of the 9 patients who underwent a second operation, 7 received a palliative procedure and died of the disease progression at a median time of 10 mo (range 2-18 mo) after operation.

Survival rate of PMTSB patients according to histology

Information was obtained during the follow-up of 120 patients with PMTSB including adenocarcinoma ($n = 57$), GIST ($n = 25$), carcinoid ($n = 17$), malignant lymphoma ($n = 17$), leiomyosarcoma ($n = 3$) and malignant melanoma ($n = 1$). The median survival time of PMTSB patients was 20.3 mo. The 1-, 3- and 5-year survival rate was 75.0% (90/120), 40.0% (48/120) and 20.8% (25/120), respectively. Adenocarcinoma was detected in 73.7% (42/57), 21.1% (12/57), and 15.8% (9/57) of the patients, respectively. GIST was observed in 80.0% (20/25), 72.0% (18/25) and 36.0% (9/25) of the patients, respectively. Carcinoid was found in 100.0% (15/15), 80.0% (12/15) and 46.7% (7/15) of the patients, respectively. Malignant lymphoma was shown in 69.2% (9/13), 30.8% (4/13) and 0% (0/13) of the patients, respectively. In addition,

Table 5 Survival rate of PMTSB patients *n* (%)

Histopathological type	Loss of follow-up cases (<i>n</i>)	1-yr survival rate	3-yr survival rate	5-yr survival rate
Adenocarcinoma (<i>n</i> = 61)	4	42 (73.7)	12 (21.0)	9 (15.8)
GIST (<i>n</i> = 28)	3	20 (80.0)	18 (72.0)	9 (36.0)
Carcinoid (<i>n</i> = 17)	2	15 (100.0)	12 (80.0)	7 (46.7)
Lymphoma (<i>n</i> = 14)	1	9 (9.25)	4 (30.8)	0
Other tumors(<i>n</i> = 21)	11	3 cases of leiomyosarcoma survived (15, 39 and 71 mo, respectively) and 1 case of malignant melanoma survived 18 mo		

3 leiomyosarcoma patients had a survived time of 15, 39 and 71 mo, respectively. One malignant melanoma patient survived for 18 mo (Table 5).

DISCUSSION

Presentation and diagnosis of PMTSB

PMTSB is a rare malignancy. Most PMTSB patients have nonspecific clinical symptoms and signs^[1-6]. In this series, the most frequent symptoms were abdominal pain (67.4%), abdominal mass (31.2%) and bowel obstruction (24.1%), followed by hematochezia (21.3%), jaundice (16.3%), fever (14.2%), coexistence of bowel perforation and peritonitis (5.7%), coexistence of gastrointestinal bleeding and shock (5.0%), and intraabdominal bleeding (1.4%). The symptoms are similar to the reported findings^[1-3,10,11]. The median time of delayed diagnosis in our series was 2 mo.

Preoperative diagnosis of PMTSB is often difficult. In our series, the preoperative diagnostic rate was decreased to 91.7% at the duodenum, 70.6% at the jejunum, and 60.3% at the ileum, respectively. The most commonly used diagnostic techniques were US, CT, upper gastrointestinal radiography and upper endoscopy. Endoscopic biopsy proved that most duodenal tumors (91.7%) in our study were malignant before surgery, suggesting that the more distal the tumor is, the more difficult the preoperative diagnosis is^[16,17]. Since the accuracy of CT staging for small bowel adenocarcinoma is 47%-61%, it is only used in the detection of mesenteric infiltration and regional lymphadenopathy^[16-20].

Hatzaras *et al*^[1] showed that carcinoid tumor is the most common intestinal cancer, followed by adenocarcinoma. Our data demonstrate that ileum is the most common site (44.7%), followed by jejunum (30.5%), duodenum (24.8%), and that the most prevalent histological type is adenocarcinoma (43.3%), followed by GIST (19.8%), carcinoid (12.1%), malignant lymphoma (9.9%), leiomyosarcoma (7.1%), malignant melanoma (4.3%), malignant neurilemmoma (2.1%) and fibrosarcoma (1.4%), indicating that carcinoid tumor is more frequently found in ileum than adenocarcinoma in duodenum^[1,8,21-23].

Laparoscopy can help to stage small bowel malignant tumor; serosal infiltration, retroperitoneal fixation, lymph node metastasis and ascites^[23]. Laparoscopy can accurately assess and stage gastric adenocarcinoma^[24,25], thus avoiding unnecessary laparotomy for those with no indication for palliative surgery. However, laparoscopy is not appropriate for patients with obstruction or bleeding.

Treatment strategy and surgical procedure

Treatment of PMTSB is mainly based on its histopathological type, location and extent. If the tumor is located at jejunum or ileum, an aggressive segmental resection and primary anastomosis are indicated^[2]. If the tumor is located at ileum around the ileocolon junction, ileocolonic resection or right hemi-colectomy is indicated^[3]. The optimal resection extent of duodenal tumor has not been defined. Some authors advocate pancreaticoduodenectomy (PD) for all patients with malignant tumor of the duodenum, including those located at the third and fourth portions to ensure adequate *en bloc* resection^[6]. If the tumor is an adenocarcinoma or a carcinoid, *en bloc* resection and systemic lymph node dissection are indicated^[7]. If the tumor is a histopathologically proven malignant lymphoma before operation, systemic chemotherapy is the first choice of treatment and surgery selection is only indicated for those with bowel obstruction, perforation and bleeding^[26-29]. The value for routine extensive resection of adenocarcinoma or carcinoid has been recently challenged^[2,3,7,8,26,27]. Others support PD for proximal duodenal carcinoma, but segmental resection for tumor of the third and fourth portions^[27-29]. In our patients, the most commonly used surgical procedure was segmental bowel resection (65.3%), followed by right hemicolectomy (10.6%), PD (7.1%) and others.

Of the 61 patients (37.7%) who underwent curative resection, 23 were found to have lymph node metastasis after surgery, which was not suspected before operation. It has been shown that laparoscopy can help to stage GI cancer, thus avoiding unnecessary laparotomies. However, laparoscopy is not appropriate for patients with obstruction or bleeding or for those with no indication for palliative surgery^[24,25]. In this series, 31 (22.0%) patients required urgent laparotomy for intestinal obstruction, gastrointestinal bleeding, or perforation.

It has been reported that chemotherapy may be beneficial for PMTSB, but optimal chemotherapy and the degree of benefit remain to be defined^[27,30,31]. Bakaen *et al*^[30] showed that chemotherapy with lomustine (CCNU), 5-FU, either alone or in combination with other therapies, can considerably improve symptoms and hormone level, and moderately inhibit tumor regression, particularly in patients with metastatic gastroenteropancreatic neuroendocrine tumors with minimal adverse effects^[30,31]. In our study, 40 patients (28.4%) received adjuvant chemotherapy after operation. However, adenocarcinoma and malignant lymphoma were treated with 5-FU and CHOP, respectively.

Surgical outcome

It has been reported that the 5-year survival rate of PMTSB patients after curative resection is 32%-47%^[1,20-22,32,33]. Howe *et al.*^[31] have reported that the 5-year survival rate of patients after curative resection of localized, regional and distant metastatic PMTSB is 47.6%, 31% and 3.9%, respectively, which is similar to that of our patients. The median survival time of the 141 PMTSB patients was 20.3 mo. The 1-, 3- and 5-year survival rate was 75.0%, 40.0% and 20.8%, respectively. Adenocarcinoma was detected in 73.7%, 21.1% and 15.8% of the patients, respectively. GIST was found in 80.0%, 72.0% and 36.0% of the patients, respectively. Carcinoid was observed in 100.0%, 80.0% and 46.7% of the patients, respectively. Malignant lymphoma was demonstrated in 69.2%, 30.8% and 0% of the patients, respectively.

The site, clinical stage, and histological type do not influence the survival time of PMTSB patients. Howe *et al.*^[31] reported that the median survival time of patients with tumors of duodenum, jejunum and ileum is 16.9 and 28-31 mo, respectively. In our study, 32 of 104 patients (22.7%) had distant metastasis or intra-abdominal carcinomatosis at presentation, which is consistent with the reported findings^[1,5,7,11,26]. Ito *et al.*^[7] reported that the 5-year survival rate of T1/T2 and T3/T4 tumor patients is 82% and 58%, respectively ($P < 0.05$). In contrast, Bakaeen *et al.*^[30] found that T stage can not predict the survival time of PMTSB patients. Curative resection, however, may not be possible owing to the late diagnosis of PMTSB. Dabaja *et al.*^[29] also reported that the 5-year survival rate of patients with PMTSB at stage IV is 5%, which is much lower than that of those with PMTSB at stages I-III (36%). Although carcinoid is usually silent and diagnosed at its advanced stage, carcinoid patients have a good prognosis and a long survival time after effective treatment^[2,5,7,34,35].

In summary, *en bloc* resection is the principal procedure for most PMTSB patients and chemotherapy is the important treatment modality for malignant lymphoma and other small bowel malignant tumors with no indication for radical resection.

COMMENTS

Background

Although small bowel is considerably long and exposed to a wide variety of potentially noxious substances, it is relatively resistant to carcinogenesis. Primary malignant tumor of the small bowel (PMTSB) accounts for 2% of gastrointestinal (GI) tumors and 1% of gastrointestinal tract cancer-related deaths. In a review of over 11 000 primary GI malignant tumors, Martin found that only 2.4%, 10.8%, 16.4% and 16.4% are originated from the small bowel, esophagus, stomach, and colorectum, respectively. However, the diagnosis of PMTSB is difficult, because its symptoms and signs are nonspecific at presentation. Therefore, PMTSB is usually discovered at its advanced stage and often needs surgical intervention due to acute complications. Sometimes, it is occasionally found during other

surgical procedures. The objective of this study was to evaluate the clinical presentation, treatment and survival of PMTSB patients.

Research frontiers

How to improve the early diagnosis and treatment of PMTSB is a hotspot in recent studies.

Innovations and breakthroughs

This study evaluated the clinical presentation, treatment and survival time of PMTSB patients.

Applications

The retrospective analysis of the clinical presentation, treatment and survival time of PMTSB patients showed that PMTSB can be made early diagnosed and can thus be rationally treated.

Peer review

This is a rather large series of PMTSB patients from a single center. The data provided in this study contribute to the early diagnosis and treatment of PMTSB.

Abstract

The surgical management of gallstone ileus is complex and potentially highly morbid. Initial management requires enterolithotomy and is generally followed by fistula resection at a later date. There have been reports of gallstone extraction using various endoscopic modalities to relieve the obstruction, however, to date, there has never been a published case of endoscopic stone extraction from the colon using electrohydraulic lithotripsy. In this report, we present the technique employed to successfully perform an electrohydraulic lithotripsy for removal of a large gallstone impacted in the sigmoid colon. A cavity was excavated in an obstructing 4.1 cm lamellated stone in the sigmoid colon using electrohydraulic lithotripsy. A screw stent retractor and stent extractor bored a larger lumen which allowed for guidewire advancement and stone fracture *via* serial pneumatic balloon dilatation. The stone fragments were removed. Electrohydraulic lithotripsy is a safe and effective method to treat colonic obstruction in the setting of gallstone ileus.

INTRODUCTION

Gallstone obstruction of the colon is a rare event^[1]. The traditional approach has been an initial enterolithotomy followed by fistula resection as indicated^[2]. Although this has been shown to be successful, endoscopic therapies offer a less invasive approach. Non-surgical treatment of gallstone(s) impacted in the colon has been described using extracorporeal lithotripsy, dormia baskets and polypectomy snares^[3-6]. These techniques, while successful in situations where the gallstone is small enough to be endoscopically extracted or where it yields enough to be broken with less radical endoscopic methods, can be inadequate for management of large stones. We encountered a large calcified stone impacted in the sigmoid colon that required localized disintegration by use of intracolonic electrohydraulic lithotripsy (EHL).

CASE REPORT

A 92-year-old man presented with a 5-d history of obstruction followed by nausea and vomiting. His abdomen was mildly distended with left lower quadrant tenderness. His past medical history was significant for diverticulo-

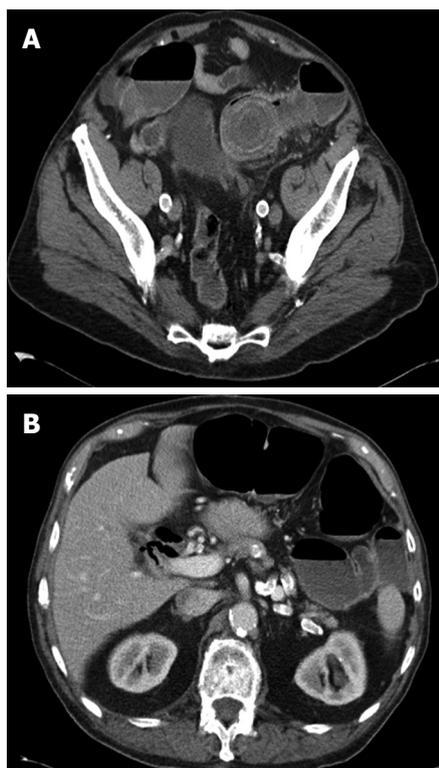

Figure 1 Computed tomography. A: Gallstone impacted in the sigmoid colon; B: Pneumobilia.

sis, coronary artery disease, severe aortic stenosis and an attack of right upper quadrant pain with nausea and vomiting 6 mo previously. Computed tomography demonstrated dilated loops of small and large intestine proximal to a 4.1 cm lamellated stone impacted in the sigmoid colon (Figure 1A), in addition to a separate 3.8 cm stone within the gallbladder lumen. There was fistulous communication between the gallbladder fundus and the transverse colon with resultant pneumobilia (Figure 1B). Due to his advanced age and extensive comorbidities, endoscopic intervention was recommended. In the endoscopy suite, the patient was placed in the left lateral decubitus position. An Olympus gastroscope (Olympus America Inc., Center Valley, PA) was advanced transanally to the impacted piston-shaped stone which was found to be lodged within the distal sigmoid colon at an area of narrowing, likely from prior diverticulitis. A 1.9 French EHL probe (Northgate Research Inc., Arlington Heights, IL) was passed through the biopsy channel of the gastroscope. Continuous normal saline instillation was used to provide a medium for EHL. EHL was performed by applying shocks to the center of the impacted stone using the Northgate SD-100 EHL generator with shock delivery at a setting of 70 to 100 watts (Figure 2A). A total of nine EHL probes were required to excavate a cavity through the core of the stone after 2200 cumulative shocks. The shocks did not produce fragmentation but rather a “tunnel” through the stone. Due to poor visualization, when a small amount of blood was seen exiting from the proximal end of the tunnel it was assumed

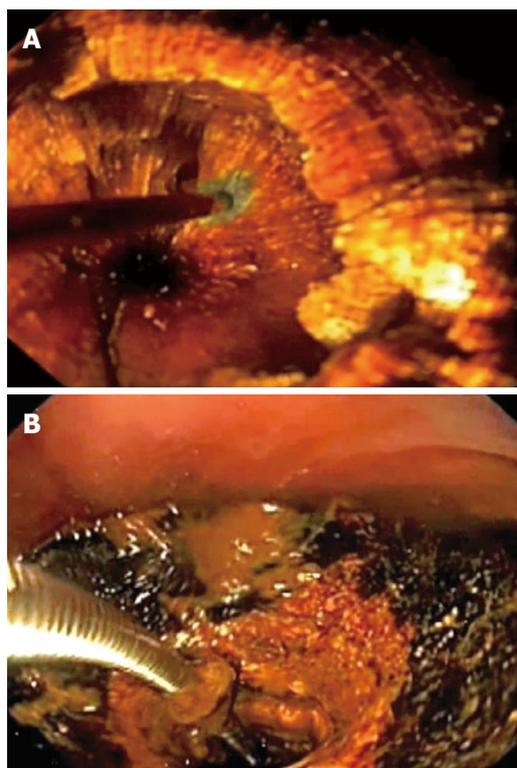

Figure 2 Endoscopy images. A: Electrohydraulic lithotripsy (EHL) shock to the center of the gallstone; B: Soehendra screw retractor in place for dilation of the gallstone lumen.

Figure 3 Four gallstone fragments after balloon fracture.

a complete lumen was created within the stone. A guidewire was advanced through the cavity into the proximal colon. A 7 French Soehendra screw stent retractor and a 10 French Soehendra screw stent extractor (Cook Medical, Winston-Salem, NC) were used to enlarge the proximal lumen (Figure 2B). This allowed passage of a dilating balloon to enable the stone to be fractured from within. Dilation using 18, 19 and 20 mm balloons inflated to maximum PSI was performed within the stone neolumen, causing it to fracture into four large pieces (Figure 3). These were retrieved using a Roth basket (US Endoscopy, Mentor, OH) and a large polypectomy snare. Concerns over the duration of the manipulation and resulting colonic wall edema necessitated termination of the procedure after a colonic decompression tube was placed over a guidewire that extended to the descending

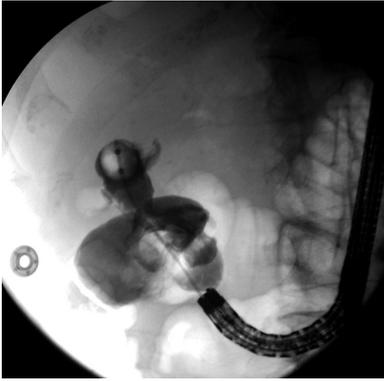

Figure 4 Endoscopically assisted contrast evaluation of the cholecystocolonic fistula with cholelithiasis.

colon. We were able to reconstruct the gallstone into its whole form, confirming that no potentially obstructing stone fragment was retained.

Due to concerns of biliary tract infection and recurrent gallstone ileus, an attempt at extraction of the existing gallstone within the gallbladder was attempted the following day. An Olympus IT gastroscope was advanced to the hepatic flexure where a large cholecystocolonic fistula was encountered. We advanced the endoscope through the fistula into the gallbladder fundus but no gallstone was encountered. Fluoroscopy and contrast injection through a biliary occlusion balloon (Olympus America, Inc.) demonstrated a stricture within the fundus and a large filling defect wedged within the gallbladder infundibulum consistent with the known retained gallstone (Figure 4). The stricture prevented further endoscopic manipulation. Therefore, the patient underwent resection of the fistulous tract with en bloc cholecystectomy and segmental colonic resection *via* a right subcostal incision. This confirmed a 4 cm long cholecystocolonic fistula from the fundus of the gallbladder to the hepatic flexure. The known retained stone plus an additional 1 cm stone were found within the infundibulum. This was walled off from the fundus due to the stricture. An intra-operative cholangiogram confirmed patency of the patient's biliary system without evidence of bile leak.

The patient recovered from a gastrointestinal standpoint without any complications related to the endoscopic procedures. Post-operatively, he developed decompensated congestive heart failure and pulmonary hypertension in addition to atrial fibrillation. He was discharged on post-operative day 25 after optimization of his cardiac function. The patient died at home 12 mo later secondary to aspiration pneumonia.

DISCUSSION

Gallstone ileus is a rare clinical entity accounting for 1% to 3% of intestinal obstruction and is more common in the elderly population^[1]. Gallstones most commonly impact in the terminal ileum (61%) followed by the jejunum (16%), stomach (14%), and large intestine (4%) at the rectosigmoid junction. The classic signs on imaging studies include di-

lated bowel and pneumobilia. Aberrantly located gallstones are present in about 50% of patients^[7]. Initial surgical enterolithotomy is the traditional treatment and this allows for relief of the obstruction in the short term. Fistula resection can be safely performed during a second surgical procedure if indicated^[2]. As this condition is predominantly encountered in an elderly population with a high incidence of comorbid conditions, the complication and mortality rates of surgical treatment are substantial^[1,2]. Endoscopically accessible impacted gallstones are amenable to less invasive alternative therapeutic options including EHL, extracorporeal shock wave lithotripsy, intracorporeal laser lithotripsy and endoscopic mechanical lithotripsy for fragmentation. To date, there have been a few case reports of the successful use of EHL in patients with gallstones impacted within the stomach and small intestine, but to our knowledge, this is the first report of the successful and safe use of EHL to remove an impacted gallstone within the sigmoid colon^[8-12]. The EHL technique allows for fragmentation of large, calcified stones that would not otherwise be amenable to other endoscopic modalities. Advanced endoscopic skills, in addition to the proper equipment, are necessary as the technique has the potential to be long and complicated, but can ultimately be successful.

The patient's retained gallstone posed a high risk for biliary infection and recurrent gallstone ileus and therefore the patient underwent an attempt at endoscopic retrieval of the retained gallstone within the gallbladder. Due to the stricture at the infundibulum, we were unable to manage this without operative intervention. However, the endoscopic extraction of the obstructing gallstone was able to eliminate an enterolithotomy procedure. This simplified his initial management and allowed him to undergo fistula resection under optimal conditions.

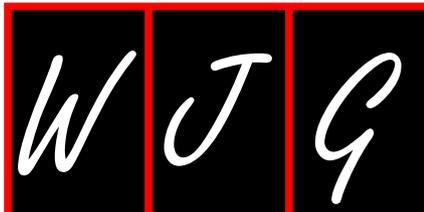

In summary, we present our technique for the first reported use of EHL to endoscopically extract an impacted gallstone within the lumen of the colon and believe that this is a safe and effective method to treat colonic obstruction in the setting of gallstone ileus.

Abstract

Mesotherapy and anti-obesity medications are gradually gaining worldwide popularity for purposes of body contouring and weight loss. Their adverse effects are various, but there is a tendency to disregard them. Ischemic colitis is one of the most common diseases associated with non-obstructive blood vessel disorders. However, there have been no case reports about the adverse effects resulting from mesotherapy only or in combination with anti-obesity medications. We report on an interesting case of ischemic colitis after mesotherapy combined with anti-obesity medications in a 39-year-old female who had no risk factors.

INTRODUCTION

Mesotherapy and anti-obesity medications are gradually gaining in popularity for purposes of body contouring and weight loss. However, there is a tendency to disregard their various adverse effects. Adverse effects of mesotherapy include bruising, edema, skin necrosis, abdominal hematoma at the site of injection, liver toxicity, demyelination of nerves, and atypical mycobacterial infection^[1]. Adverse effects of anti-obesity medications include increase of blood pressure, headache, constipation, and insomnia^[2-5].

Until now, there have been no case reports on the intestinal ischemia resulting from mesotherapy only or in combination with anti-obesity medications. We report on an interesting case of ischemic colitis after mesotherapy combined with anti-obesity medications in a 39-year-old female who had no risk factors.

CASE REPORT

A 39-year-old female was admitted to our hospital due to hematochezia persisting for 12 h. She had no previous history of disease. Eight days before admission, she visited an outside anti-obesity clinic where she underwent two days of injection therapy once per day into the sub-

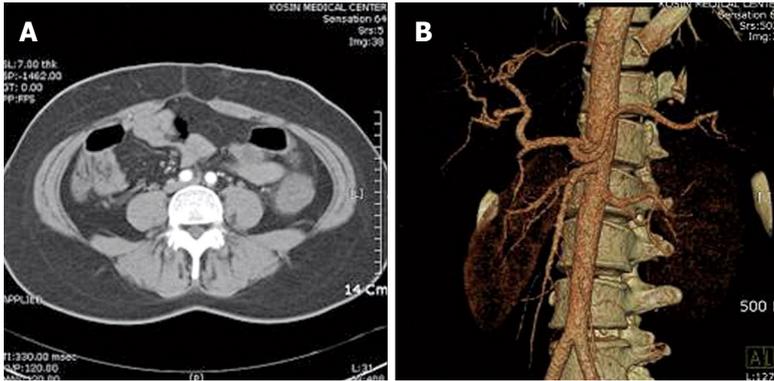

Figure 1 Abdominal computed tomography and angiography. A: Computed tomography showed diffuse bowel wall edema in the descending colon; B: Angiography showed no evidence of obstruction or stenosis in mesenteric vessels.

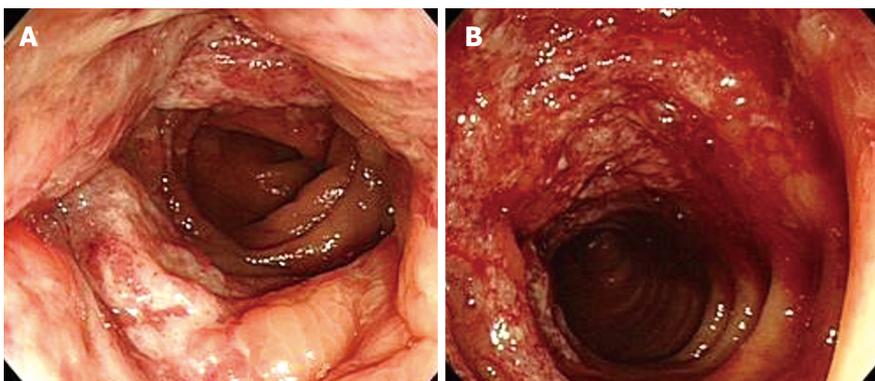

Figure 2 Sigmoidoscopic findings. Diffuse mucosal edema, erythema (A), friability and submucosal hemorrhage (B) from the splenic flexure to the sigmoid colon are shown.

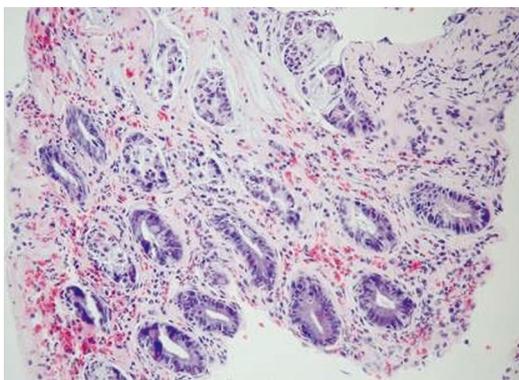

Figure 3 Microscopic findings of colonoscopic biopsy. Sections showed portions of colonic mucosa revealing sloughing of the surface epithelium and infiltration of mononuclear inflammatory cells in hyalinized lamina propria. (HE, $\times 200$).

cutaneous fat of the lower abdomen as mesotherapy, and took oral anti-obesity medications twice per day for two days. Medications for mesotherapy were aminophylline, epinephrine, and lidocaine at doses that could not be obtained outside the anti-obesity clinic. Oral anti-obesity medications were fluoxetine 10 mg, ephedrine hydrochloride 10 mg, anhydrous caffeine 50 mg, and green tea powder 250 mg per dose. Six days before admission, the patient stopped taking the mesotherapy and anti-obesity medications due to lower abdominal discomfort and nausea and vomiting. She nearly fasted, except for a small amount of liquid diet, until her admission to our hospital. A sudden onset of hematochezia and lower abdominal pain developed about 12 h prior to admission. She had no

history of any medication other than recent mesotherapy and anti-obesity medications. Her vital signs were within normal limits, including normal systolic and diastolic blood pressure. Physical examinations were normal, except for mild tenderness of the left lower abdomen, and fresh bloody stool was revealed with digital rectal examination. Height and body weight were 162 cm and 76.7 kg, respectively, with BMI 29.2 kg/m². Laboratory test results were within normal limits, including a hemoglobin 14 g/dL, platelet 351 000/uL, prothrombin time 11.3 s, protein C antigen 96% (normal range: 72%-160%), protein S antigen 81% (normal range: 60%-150%), B-type natriuretic peptide 35 pg/mL (normal range: less than 100 pg/mL), except for mildly elevated white blood cells 15 400/mm³. Electrocardiogram, 24-h Holter monitoring, and transthoracic echocardiography all had normal findings. Abdominal CT and CT angiography showed a markedly edematous wall of the entire descending colon and intact abdominal vasculature, including the superior and inferior mesenteric arteries (Figure 1). Colonoscopy showed diffuse edema, erythema, friability, and intramural hemorrhage with multiple active ulcers from the splenic flexure to the sigmoid colon, which were clearly demarcated with adjacent normal segments of colon (Figure 2). Microscopic findings showed portions of colonic mucosa revealing sloughing of the surface epithelium and infiltration of mononuclear inflammatory cells in hyalinized lamina propria (Figure 3). Two days after conservative management with intravenous fluids, electrolytes, and antibiotics composed of ciprofloxacin and metronidazole, bloody stool and abdominal pain markedly decreased and disappeared 6 d later, with complete normalization of

leukocytosis. The patient has been followed for 2 years on an outpatient basis without recurrence of specific symptoms.

DISCUSSION

Ischemic colitis is one of the most common diseases associated with non-obstructive blood vessel disorders. Ischemic colitis is common in people over 50 years old. However, it can develop rarely in women younger than 40 years old through use of oral contraceptives, vasoconstrictors, diuretics, cocaine and anti-depressants, or as a result of irritable bowel syndrome^[6-9].

Potential cardiac sources of embolism (CSE) (arrhythmia, structural cardiac abnormality such as valvular heart disease and structural aortic abnormality) were relatively common in patients with ischemic colitis^[10,11]. This suggests that when ambulatory ischemic colitis occurs, it is necessary to perform an exhaustive cardiovascular evaluation similar to those performed in other ischemic diseases^[11]. The optimal way to detect potential CSE was the combination of electrocardiogram, 24-h Holter monitoring, and transthoracic echocardiography^[11,12]. Anticoagulation therapy should also be considered for patients who have CSE^[10].

Cases of ischemic colitis in young patients have been reported^[12,13] to be associated with hereditary factors such as deficiencies of protein C, protein S, and antithrombin, factor V Leiden mutation, and prothrombin 20210G/A mutation, as well as acquired factors such as antiphospholipid antibodies^[13]. The mechanism of ischemic colitis is more often multifactorial^[11,12]. Therefore, an interaction between hereditary and acquired factors including the drugs which are used in mesotherapy and anti-obesity medication, is possibly the key to understanding why certain persons develop colonic ischemia at a specific time point especially at a young age^[12]. Accordingly, when ischemic colitis develops in young people, we should examine whether such hereditary and acquired factors as causes of it exist or not.

Mesotherapy is a recently introduced treatment that involves delivery of pharmacologic drugs into the mesoderm, which is the layer of fat or connective tissue under the skin. It is commonly used for purposes of body contouring and weight loss. Aminophylline is a common ingredient in mesotherapy that is used for lipolysis. It inhibits phosphodiesterase and activates hydrolysis of adipose tissue^[14]. Systemically, it stimulates the medullary respiratory center to induce diuresis and induces catecholamine release from the adrenal medulla^[15]. Epinephrine and lidocaine are not commonly used ingredients in mesotherapy. However, we think that they were administered for the purpose of causing local vasoconstriction and for pain relief at the subcutaneous injection site of the lower abdomen, respectively. Although the mesotherapy solution was injected locally into the subcutaneous fat, we think that its systemic effect could not be completely ignored.

Some oral agents are approved by the U.S. FDA as

anti-obesity medications for the purpose of long-term use: sibutramine, orlistat, and rimonabant. In addition, anti-obesity medications for short-term use include sympathomimetic amines, selective serotonin reuptake inhibitors (SSRI), ephedrine, and caffeine^[2,10,16]. Fluoxetine is an anti-depressant belonging to the SSRIs. Blockage of serotonin uptake in the nerve terminal and amplification of signals sent by serotonin neurons result in decreased food intake^[5]. There have been no reported cases of intestinal ischemia induced by use of fluoxetine as a single agent; however, three cases of intestinal ischemia induced by use of fluoxetine in combination with sumatriptan have been reported^[3]. Pseudoephedrine is an α -adrenergic agonist and potent vasoconstrictor. It inhibits appetite through release of noradrenaline in sympathetic nerve, and exerts a synergistic action when administered with caffeine^[2,10]. Dowd *et al*^[4] reported on 4 female patients aged 37 to 50 who developed ischemic colitis after taking pseudoephedrine. Caffeine promotes secretion of catecholamine and inhibits appetite. Green tea contains caffeine, and therefore exerts effects similar to those of caffeine^[17].

In this case, a second colonoscopy during the follow-up period could not be performed due to the patient's pregnancy and this is a weakness since we don't know if the findings of the first colonoscopy were resolved or not, although symptoms have completely disappeared.

We think that the potential important environmental factors for ischemic colitis in our patient were aminophylline (by increasing noradrenaline activity and inducing catecholamine release from the adrenal medulla), epinephrine (by acting as a direct vasoconstrictor), fluoxetine (by blocking serotonin uptake and so decreasing food intake and causing dehydration), ephedrine (by releasing noradrenaline in sympathetic nerves), caffeine (by exerting a synergistic action when administered with ephedrine), green tea (by caffeine effects and increasing the action and release of catecholamines), and unidentified hereditary and/or acquired factors might have contributed to the development of ischemic colitis. In addition, reduced body fluid caused by relative fasting and vomiting can be considered as aggravating factors in the development of ischemic colitis. Although two cases of ischemic colitis associated with anti-obesity medications with fenfluramine and phentermine have been reported^[18,19], they were not related to the agents prescribed for our patient. Therefore, to the best of our knowledge, our case is the first report in the world on ischemic colitis after mesotherapy combined with anti-obesity medications.

In conclusion, mesotherapy should be taken with great care by both the young and the old, particularly when combined with anti-obesity medications, because it can cause systemic vasoconstriction and result in various side effects, such as ischemic colitis. In addition, dehydration by relative fasting should be avoided during therapy because it can aggravate development of ischemic colitis.

Abstract

Endoscopic therapy of pancreatic duct (PD) strictures using balloon dilation and pancreatic duct stent (PS) placement has been reported to improve the severity of abdominal pain in selected patients with chronic pancreatitis (CP). However, some strictures are refractory and require frequent PS exchange to control symptoms. We describe two cases of successful endoscopic PD incision for difficult PD stricture using a wire-guided snare. The snare is partially opened within the strictured pancreatic duct while applying current, thus incising the duct. Although both cases were successful without complications we do not advocate that this method be used routinely because of the potential for severe complications, e.g. bleeding, ductal perforation or pancreatic parenchymal damage. In order to prevent these complications, we developed a wire-guided technique under fluoroscopic control. We think this procedure may be useful in patients with short, straight PD strictures. Although further study is required, this approach may have potential for selected patients with refractory PD strictures due to CP.

INTRODUCTION

Endoscopic therapy of pancreatic duct (PD) strictures using balloon dilation and pancreatic duct stent placement has been reported to improve the severity of abdominal pain in selected patients with chronic pancreatitis (CP)^[1-6]. However, some strictures are refractory and require frequent stent exchange to control symptoms. We describe two cases of successful endoscopic PD incisions for difficult PD strictures using a wire-guided snare. The snare is partially opened within the strictured pancreatic duct while applying electrical current, to incise the duct.

CASE REPORT

Case 1

A 35-year-old man with a 2-year history of acute chronic pancreatitis required repeated initial placement of a 7-Fr stent, followed by 10-Fr pancreatic duct stent exchange

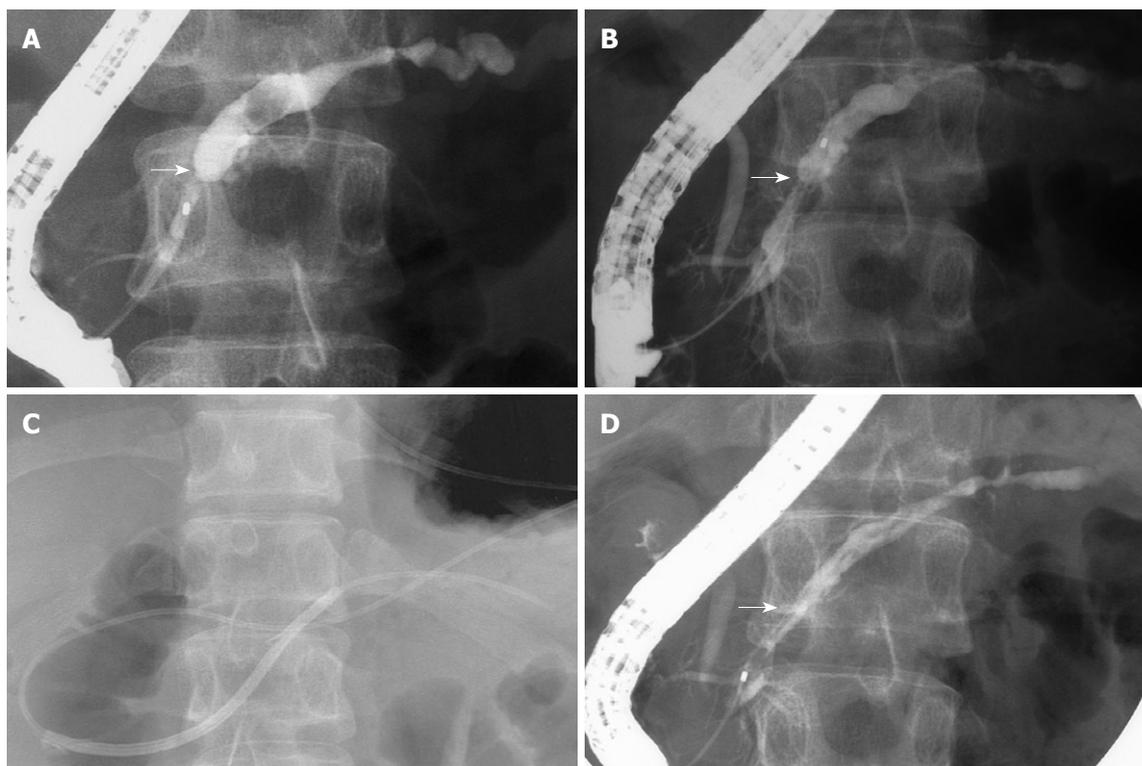

Figure 1 Pancreatic duct incision of a refractory pancreatic duct stricture. A: Pancreatography reveals a short pancreatic duct stricture (arrow) and upstream ductal dilation; B: Pancreatography after removal of a 10-Fr stent shows a stricture (arrow) still remaining; C: Wire-guided snare forceps are advanced into the pancreatic duct through the major papilla; D: Pancreatography reveals resolution of pancreatic duct stricture (arrow).

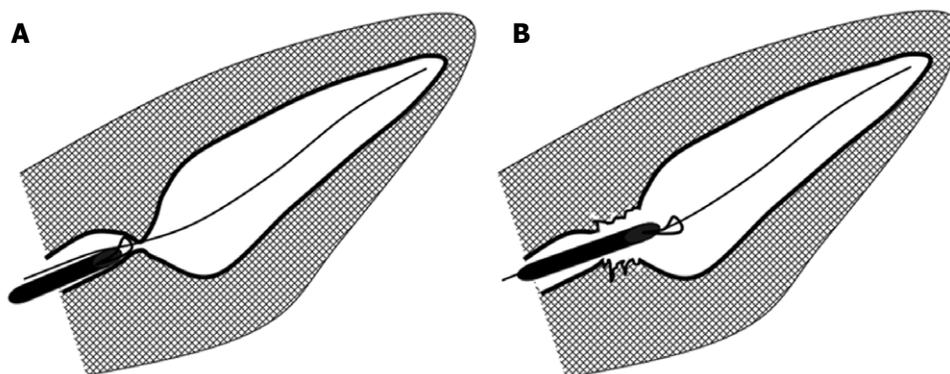

Figure 2 Diagram of pancreatic duct incision using snare forceps. A: Snare forceps are advanced into the pancreatic duct stricture; B: Pancreatic duct incision is performed with an electrocautery snare.

after a major papillotomy for management of a tight, short PD stricture (Figure 1A). Pancreatography after removal of the 10-Fr stent still showed a PD stricture (Figure 1B); the PD stent removal had been performed 6 mo previously at the patient's request. He was subsequently admitted with severe epigastric pain and recurrent pancreatitis. Pancreatography revealed obstruction of the PD and a 7-Fr stent was placed. We again recommended regular stent exchange or surgical therapy, but he refused. One month later, a transpapillary PD incision was performed in an attempt to produce stricture resolution without a stent. A guidewire was inserted across the stricture, and a standard snare (SD-5U-1, 6U-1, Olympus Medical Systems, Tokyo, Japan) was advanced over the

wire to the level of the stricture (Figure 1C). A PD incision was performed using an electrocautery generator (ICC200; ERBE Elektromedizin GmbH, Tübingen, Germany) (Figure 2A and B). The patient experienced pain during the incision. A 10-Fr stent was placed without any serious complications such as bleeding or pancreatitis. Two weeks later the stent was removed (Figure 1D). The patient remains asymptomatic 3 years later.

Case 2

A 37-year-old woman had undergone regular replacement of 7-Fr and 10-Fr stents with a minor papillotomy across the minor papilla for management of a PD stricture (Figure 3A) due to pancreas divisum for the past

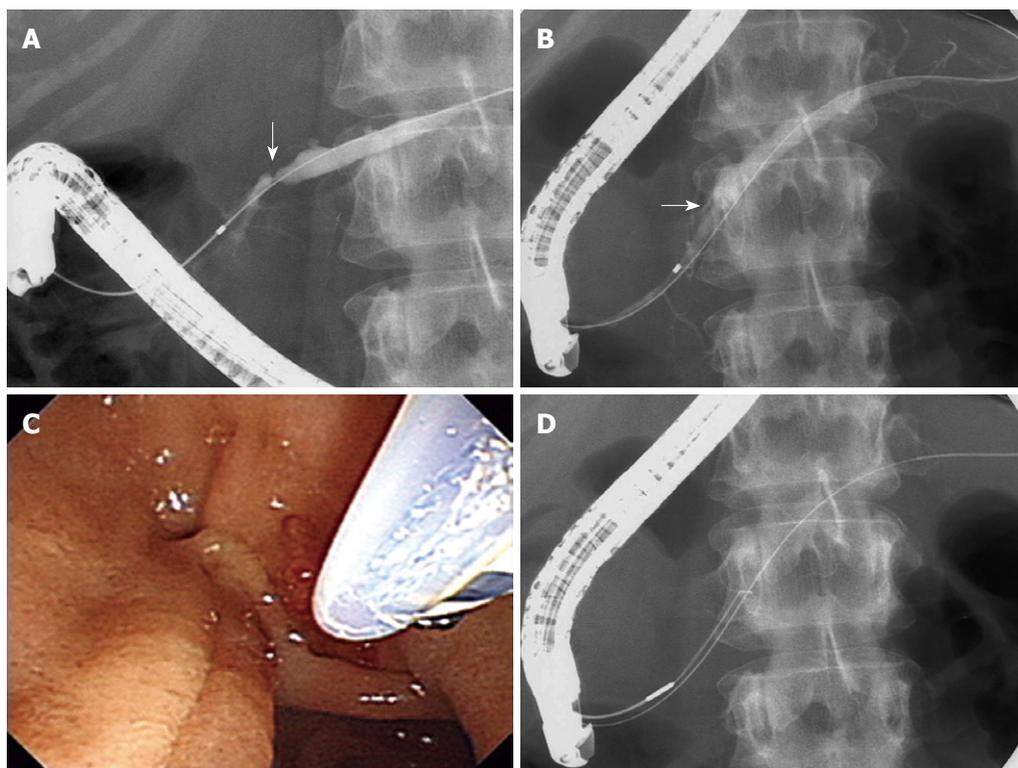

Figure 3 Pancreatic duct incision of a refractory pancreatic duct stricture. A: Pancreatography reveals a short pancreatic duct stricture (arrow) and upstream ductal dilation; B: Pancreatography after removal of a 10-Fr stent shows a stricture (arrow) still remaining; C: Pancreatic duct incision of the stricture using electrocautery snare; D: Wire-guided snare forceps advanced into the pancreatic duct through the major papilla.

3 years. Although pancreatography after removal of the 10-Fr stent still showed a PD stricture (Figure 3B), the stent was removed at the patient's request. However, 8 mo later, she developed severe epigastric pain due to recurrent pancreatitis. Since she refused regular stent exchange and surgical therapy, a PD incision was performed as described in the previous case. A 10-Fr stent was placed (Figure 3C and D). No complications occurred. The stent was removed one month later. She remains asymptomatic 18 mo later.

DISCUSSION

Placement of a pancreatic duct stent can often result in symptomatic improvement in patients with PD strictures caused by CP. However, long-term outcomes are not necessarily satisfactory. In patients with refractory PD strictures, regular, single or multiple stent replacements may be required for sustained symptom improvement^[4-6]. Such refractory strictures can be dilated using a Soehendra stent extractor^[7] or by self-expandable metal stent placement^[8]. Interestingly, Kawamoto *et al*^[9] reported the dissection of a difficult PD stricture using a needle-knife. Although the aim of their technique was recanalization of the pancreatic duct showing disconnection using a needle, our aim was persistent canalization without any stent.

Until now, endoscopic therapy using stents has been a well-established procedure. Nevertheless, several investigators have advocated that the technique of regular stent replacement is not recommended for CP with

circumscribed PD stenosis because outcomes of a surgical approach in these cases were superior to those of an endoscopic approach^[10-12].

In the present cases, the patients strongly refused surgical therapy. We therefore performed PD incision in anticipation that mechanical manipulation around the stricture might allow stricture resolution. We hypothesized that the snare could obtain a wider aperture compared to a sharp dissection using a needle knife. Although both cases were successful without complications we do not advocate that this method should be used routinely because of the potential for severe complications, e.g. bleeding, ductal perforation, or pancreatic parenchymal damage. In order to prevent these complications, we developed a wire-guided technique under fluoroscopic control. Furthermore, we advocate that the technique described here is rather experimental and should only be used in experienced hands due to the possibility of severe complications.

With regard to necessity and duration of a temporary stent placement after PD incision, this is a controversial issue because a relatively large PD incision can be expected. However, we used a stent to avoid acute obstructive pancreatitis due to edematous change for a period of 1 mo. We think this procedure may be useful in patients with circumscribed, straight PD strictures.

Limitations of this study include a small sample size, lack of a control group and no long-term outcomes.

In conclusion, although we do not think that this procedure can replace conventional endoscopic therapy

as the first-line treatment, this approach may have potential for selected patients with refractory circumscribed PD strictures due to CP.

Abstract

We report a unique case of intramucosal carcinoma in a tubulovillous adenoma arising from a single diverticulum. Endoscopic mucosal resection (EMR) was carried out successfully and completely with the assistance of laparoscopy. A 71-year-old man was admitted to our hospital because of melena and anemia. Emergent colonoscopy showed diverticulosis in the right-sided colon. However, endoscopy could not exactly detect the bleeding site. A flat elevated polyp was found within a single diverticulum located in the descending colon and diagnosed as an intramucosal carcinoma, as magnifying chromoendoscopy revealed a type IV pit pattern. As his diverticular bleeding repeated, a right-sided hemicolectomy was decided for treatment, the polyp within the diverticulum was also completely removed by EMR with the assistance of laparoscopy. Although a colonic perforation was detected immediately after EMR, the perforation was closed with endoclips intraluminally and also repaired laparoscopically from the serosal side. Histologically, the resected lesion was an intramucosal well-differentiated adenocarcinoma and the surgical margin was free of tumor.

INTRODUCTION

Colonic neoplasia can arise from the normal mucosa near or within a diverticulum. Adenoma or adenocarcinoma located within a diverticulum is, however, a very rare phenomenon and only sporadic cases have been reported to date^[1-8]. The reported cases are often cases of advanced cancers and could only be diagnosed postoperatively. Therefore, the association of adenoma or early cancer with a diverticulum is exceptionally rare^[3,4,6-8]. We herein describe a case of intramucosal carcinoma in a tubulovillous adenoma developed in a colonic diverticulum, which could be correctly diagnosed by magnifying chromoendoscopy and was subsequently treated by endoscopic mucosal resection (EMR) with the assistance of laparoscopy.

CASE REPORT

A 71-year-old man was admitted to our hospital because of melena and anemia. Emergent colonoscopy showed diverticulosis in the right-sided colon. However, endoscopy could not definitely detect the bleeding source. Additionally, colonoscopy showed a single diverticulum in the descending colon, and a flat elevated polyp, 15 mm in

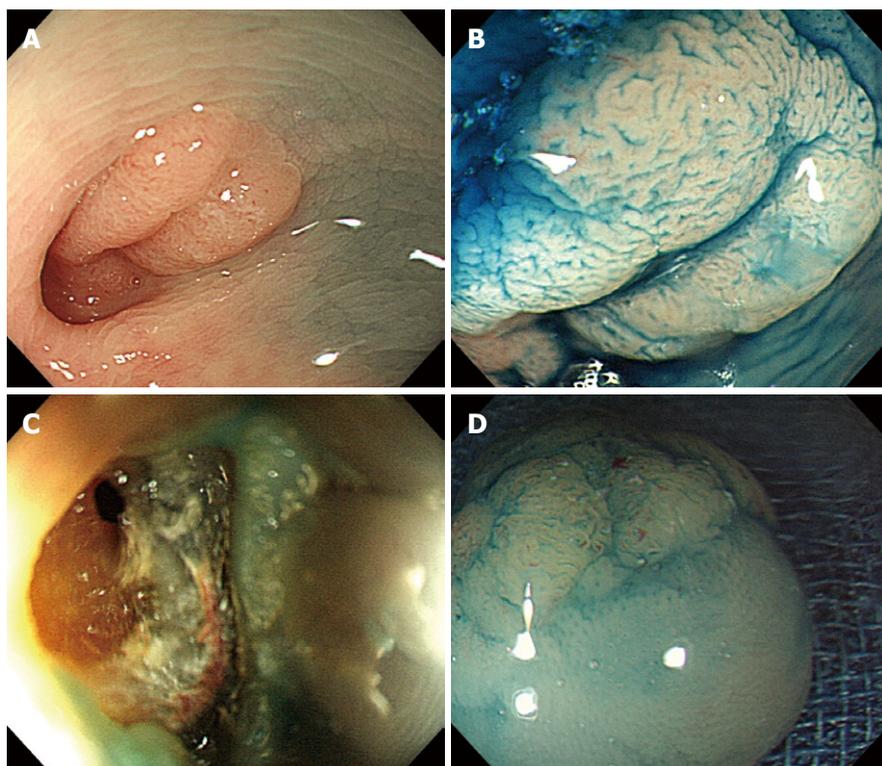

Figure 1 Colonoscopy and magnifying chromoendoscopy. A: Colonoscopy showing a single diverticulum in the descending colon and a flat elevated polyp (15 mm in diameter) within the diverticulum; B: Magnifying chromoendoscopy using 0.4% indigo-carmin dye spraying revealing a type IV pit pattern according to Kudo's classification; C: Endoscopy showing a pin-hole perforation immediately after endoscopic mucosal resection (EMR); D: Magnifying chromoendoscopy displaying negative neoplastic changes in the removed lesion.

diameter, within the diverticulum (Figure 1A). Magnifying chromoendoscopy using 0.4% indigo-carmin dye spraying revealed a type IV pit pattern according to Kudo's classification (non-invasive pattern according to Fujii's classification)^[9,10] (Figure 1B). Therefore, an endoscopic diagnosis of intramucosal carcinoma was established, and endoscopic resection was thus considered as the first line treatment. As his diverticular bleeding repeated, which could not be managed endoscopically, multiple blood transfusions were thus needed. Right hemicolectomy was decided for treatment. During laparoscopically assisted right hemicolectomy, EMR was also performed to remove the polyp within the diverticulum located in the descending colon. Glycerol was first injected into the submucosal layer to lift the polyp well (non-lifting sign negative), and subsequently EMR was successfully carried out. After EMR, a pin-hole perforation was detected endoscopically and laparoscopically (Figure 1C). Metal clips were used endoscopically to close the perforation which was also repaired laparoscopically. Magnifying chromoendoscopy of the removed lesion disclosed no neoplastic lesions at the surgical lateral margin (Figure 1D). The patient developed anal bleeding 6 d after surgery, and an urgent colonoscopy revealed bleeding at the anastomotic site of right hemicolectomy but not at the EMR site, and the bleeding was successfully stopped with metal clips. Histologically, the removed polyp was an intramucosal well-differentiated adenocarcinoma in a tubulovillous adenoma. No adenoma and adenocarcinoma were found

at the lateral and vertical margin of the removed lesion. No muscle layer was identified in the removed lesions on histology.

DISCUSSION

Cancer arising from diverticula may be diagnosed at the advanced stage despite its small size. As colonic diverticula lack of muscular coats, and thus cancer can more easily extend into the serosal surface than that arising from the normal mucosa apart from the diverticulum^[7]. We performed EMR to remove this lesion, as magnifying chromoendoscopy provided an endoscopic diagnosis of an intramucosal lesion. It is commonly accepted that colorectal cancers limited within the mucosal layer do not carry risks of lymph node metastasis and therefore are good candidates for endoscopic resection. Therefore, to avoid unnecessary surgery or endoscopic treatment, it is important to endoscopically evaluate the invasion depth of colorectal cancers before removal. The mucosal crypt patterns have been reported to be closely related to the histology and are helpful in endoscopic diagnosis by magnifying chromoendoscopy^[9,10].

Histologically, diverticula have a characteristically thin wall without muscular layer. Surgical treatment is, therefore, recommended even for mucosal cancer or adenomatous polyp near or within a diverticulum, as colonic perforation may easily occur after endoscopic resection for such lesions. As anticipated, our case developed

a colonic perforation immediately after EMR. Iatrogenic perforation is one of the most serious potential complications of colonoscopy^[11]. Treatment strategies for colonic perforation include non-operative management with or without endoscopic closure, laparoscopic repair, and open surgery. EMR was performed for this case in our department with the assistance of laparoscopy to treat the diverticular bleeding in the right-sided colon^[11,12]. Therefore, the perforation site of this case was first closed with endoclips intraluminally and thereafter repaired laparoscopically from the serosal side. In our opinion, this kind of pin-hole perforation can be managed only endoscopically with endoclips, and we would have tried EMR without laparoscopic assistance if there was no uncontrolled diverticular bleeding.

In conclusion, intramucosal cancer in a tubulovillous adenoma developed within a diverticulum can be correctly diagnosed by magnifying chromoendoscopy and successfully treated with minimally invasive surgery including EMR with the assistance of laparoscopy.

Abstract

Klippel-Trenaunay syndrome is a congenital vascular anomaly characterized by a triad of varicose veins, cutaneous capillary malformation, and hypertrophy of bone and (or) soft tissue. Gastrointestinal vascular malformations in Klippel-Trenaunay syndrome may present with gastrointestinal bleeding. The majority of patients with splenic hemangiomatosis and/or left inferior vena cava are asymptomatic. We herein report a case admitted to the gastroenterology clinic with life-threatening hematochezia and symptomatic iron deficiency anemia. Due to the asymptomatic mild intermittent hematochezia, splenic hemangiomas and left inferior vena cava, the patient did not seek any help for gastrointestinal bleeding until his admittance to our department for evaluation of massive gastrointestinal bleeding. He was referred to angiography because of his serious pathogenetic condition and inefficiency of medical therapy. The method showed that hemostasis was successfully achieved in the hemorrhage site by embolism of corresponding vessels. Further endoscopy revealed vascular malformations starting from the stomach to the descending colon. On the other hand, computed tomography revealed splenic hemangiomas and left inferior vena cava. To the

best of our knowledge, this is the first Klippel-Trenaunay syndrome case presenting with gastrointestinal bleeding, splenic hemangiomas and left inferior vena cava. The literature on the evaluation and management of this case is reviewed.

INTRODUCTION

Klippel-Trenaunay syndrome (KTS) is a rare congenital disorder of the vascular system and is characterized by the following triad of clinical signs. (1) Haemangiomas due to cutaneous capillary dysplasias; (2) Soft tissue and/or bone hypertrophy; and (3) Venous and lymphatic anomalies^[1]. At least two signs are present to establish the diagnosis^[2,3].

Although seemingly uncommon, vascular malformations involving the gastrointestinal (GI) tract have been reported and can be a source of significant morbidity and even mortality^[1]. Clinical manifestations range from occult to massive, life-threatening hemorrhage. KTS patients with clinically significant hemorrhage usually require resection of the involved bowel segment^[1]. Visceral

vascular malformations in KTS have been described involving organs such as the GI tract, liver, spleen, bladder, kidney, lung and heart^[4]. Computed tomography (CT) of the abdomen and pelvis provides a simple, noninvasive means of assessing visceral hemangiomas^[5].

The left inferior vena cava (IVC) in KTS has not been reported. The left inferior vena cava does not affect the blood circulation, so these patients have no symptoms. They are accidentally discovered by abdominal CT imaging.

We herein report the clinical presentation and management of a young male patient with the diagnosis of KTS.

CASE REPORT

A 19-year-old male patient was admitted to the Gastroenterology Clinic for management of life-threatening hematochezia and symptomatic iron deficiency anemia. When he was born, there was a few vascular malformations in his body and right leg. The lesion on body surface was enlarged along with his age. As the lesion limits the right leg, exeresis was performed. The pathological section revealed well-marked capillary and arteriolar proliferation in the epidermal layer. The patient had been frequently admitted to the emergency unit due to transfusion-dependent anemia caused by mild intermittent hematochezia since July 2003. But he did not seek any help for gastrointestinal bleeding. Afterwards, the mild intermittent hematochezia continued and the amount of gastrointestinal bleeding increased over time. He was admitted to our hospital for evaluation after a severe and debilitating attack of hematochezia.

Physical examination revealed that his skin was pale, and there were several vascular malformation lesions on the surface of his body (Figure 1A) and a giant scar at the lateral right knee joint, and the right leg was obviously thicker than the left (Figure 1B). Laboratory examination showed significant anemia with hemoglobin of 2.2 g/dL, hematocrit 8.9%, iron 2.8 $\mu\text{mol/L}$, and total iron binding capacity 98 $\mu\text{mol/L}$. The platelet count and coagulation parameters were normal.

We could not obtain hemostasis by medical treatment. During hospitalization, the patient had an attack of massive hematochezia with loss of consciousness. Due to the severe symptomatic anemia and increased amount of GI bleeding over time, interventional examination and therapy were considered. The digital subtraction angiography revealed the bleeding point was caused by vascular malformation at terminal ileum. Superselective vessel embolism was performed (Figure 2). The patient had never hemorrhaged since the treatment. Further endoscopic investigation was conducted (Figure 3). Gastroscopy revealed several vascular malformation lesions at gastric antrum and gastric corpus. Colonoscopy revealed that there were several vascular malformation lesions from terminal ileum to the descending colon. Several vascular malformation lesions

Figure 1 Cutaneous vascular malformations and abnormal right leg in the patient. A: Cutaneous vascular malformations of the gluteal region and body; B: The enlarged right leg.

were found distributed from jejunum to ileum on the capsule endoscopy. Abdominal CT imaging showed left IVC and multiple hemangiomas in the spleen (Figure 4). Based on the vascular malformations in GI, splenic hemangiomas, cutaneous vascular malformation and the enlarged right leg, the patient was diagnosed as having KTS.

DISCUSSION

Klippel-Trenaunay syndrome is a term used to describe the combination of a cutaneous capillary malformation, varicose veins, and hypertrophy of bone and/or soft tissue. Most cases of KTS are sporadic, the syndrome affects males and females equally, has no racial predilection, and manifests at birth or during childhood^[4].

Involvement of the GI tract may be more common in KTS than previously believed (occurring in perhaps as many as 20% of patients) and may be unrecognized in patients without symptoms^[6]. The most common bleeding sites in the GI system are the distal colon and rectum. Jejunal vascular malformation and esophageal varices as bleeding sources caused by prehepatic portal hypertension were reported in the literature^[1]. It is rare that the vascular malformation distributes in the whole GI. The spectrum of the GI bleeding may vary from asymptomatic occult bleeding to life-threatening massive bleeding. GI hemorrhage usually begins in the first decade of life and tends to be intermittent. Investigation of GI bleed-

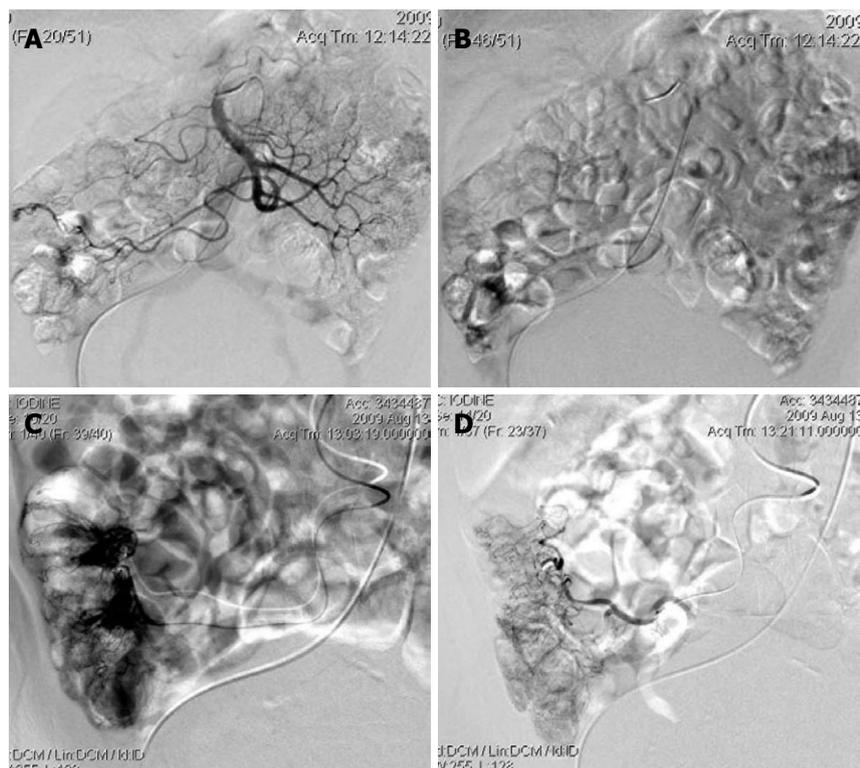

Figure 2 Angiograms demonstrate contrast opacification of the superior mesenteric artery and its branches. A: Some abnormal small veins that were filled earlier in the arterial phase; B: Manipulus contrast extravasation into the terminal ileum; C: Abnormal ectatic slow-emptying veins and extravasation of contrast material after superselective catheterization; D: No active bleeding after superselective vessel embolism with gelfoam.

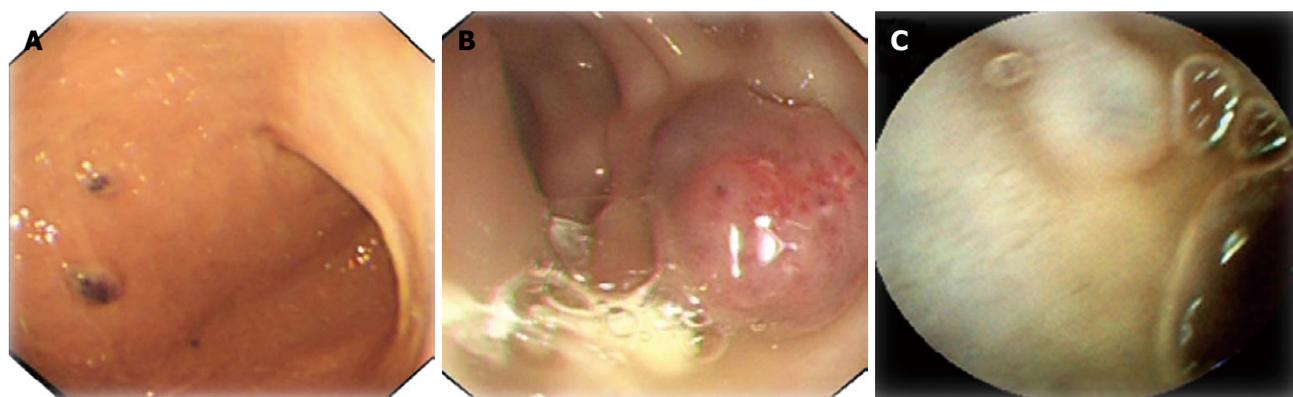

Figure 3 Lesions of gastrointestinal tract on endoscopy. A: Gastroscopy shows multiple polypoid mucosal nodules with abundant vasculature which had a purplish red chrysanthemum-like surface, which are centrally located at the greater curvature of the gastric antrum and gastric corpus; B: Colonoscopy shows several polypoid mass lesions with abundant vasculature, which are centrally located from the terminal ileum to the descending colon; C: Capsule endoscopy revealing several vascular malformation lesions distributing over the jejunum and ileum.

ing should begin with endoscopic examination in a patient with suspected KTS. Although endoscopy has the advantage of showing the localization and extension of vascular malformations, it might be misleading to accuse the vascular malformations observed during the endoscopy for bleeding due to possible metachromic localizations of vascular malformations in the different parts of the GI tract. With this point of view, endoscopic investigation of the entire GI tract should be made as the routine clinical practice for the exact localization and effective management of GI bleeding in patients with KTS. With the unawareness of this rare diagnosis, biopsies over the vascular malformations may be taken, which might be fatal in a patient with hematochezia^[7]. On the other hand, the patient could not tolerate the endoscopy during the

onset of serious hematochezia. So the interventional examination and therapy are ideal method at this time. First, advantages of angiography include the lack of requirement for bowel preparation. Secondly, angiography remains the gold standard for the diagnosis of vascular malformation. Following injection of contrast, vascular malformation can be recognized by ectatic slow-emptying veins, vascular tufts, or small veins that were filled earlier. Angiography is able to localize the bleeding source (when one is identified). Third, there is possibility of therapeutic intervention in some cases. Haemostasis can be achieved by intra-arterial infusion of vasopressin or arterial embolization *via* the angiographic catheter^[8].

Hemangioma is the most common benign primary tumor of the spleen. Splenic hemangiomas may occur

Figure 4 Contrast-enhanced abdominal computed tomography (CT) showing splenic hemangiomas (A) and left inferior vena cava (IVC) (B).

in a part of generalized angiomas as KTS. Complications of the splenic hemangiomas include rupture, hypersplenism, and malignant degeneration. The exact course for a given hemangioma is difficult to predict. Larger tumors (> 4 cm) are likely to be more prone to rupture than smaller ones, either spontaneously or from minor trauma, and may result in fatal hemorrhage. Spontaneous rupture has been reported as the most common complication, occurring in 25% of patients having large (> 4 cm) hemangiomas^[9]. Recent reviews in adult patients reported that asymptomatic patients with small splenic hemangioma (< 4 cm) have been managed conservatively with observation, and no rupture or other complications occurred^[10]. Kasabach-Merritt syndrome has been reported in patients with large hemangiomas^[11]. As our patient was asymptomatic with splenic hemangiomas < 4 cm, a conservative approach with observation was preferred and splenectomy was not performed.

A left IVC results from regression of the right supracardinal vein with persistence of the left supracardinal vein. The prevalence is 0.2%-0.5%^[12]. Typically, the left IVC joins the left renal vein, which crosses anteriorly to the aorta in the normal fashion, uniting with the right renal vein to form a normal right-sided prerenal IVC. The major clinical significance of this anomaly is the potential for misdiagnosis as left-sided para-aortic adenopathy^[13]. In addition, spontaneous rupture of an abdominal aortic aneurysm into a left IVC has been reported^[14]. The presence of vascular and renal anatomical anomalies may induce technical problems during abdominal aortic surgery^[15-17] and may give rise to serious intraoperative complications. Therefore, prior to aortic surgery, preoperative knowledge of the presence of such anomalies helps with operative planning and may reduce the associated risk of major venous hemorrhage^[15]. Abdominal CT is the most accurate investigation to discover such anomalies^[16].

The spectrum of clinical manifestations of KTS is wide and can include additional arterial and lymphatic system abnormalities beyond the classical manifestation^[18]. The potential of KTS to have widespread venous malformations in any part of the body implies that heterogeneous genetic mutations affecting mesodermal development may be present in patients with KTS^[19]. At present, molecular diagnosis for KTS is not available. In conclusion, KTS is a rare condition with protean manifestations. Hematochezia

should alert the physicians about the possibility of associated vascular malformations in the GI systems. Due to the progressive nature and wide extension of KTS lesions, endoscopic therapies have limited value in the management. Angiographic interventions should be used for visualizing the vascular anatomy and determining the disease extent. It is efficient to embolize the bleeding spots based on the examinations.

Abstract

The factors associated with an increase in gastric cardia adenocarcinoma are poorly understood. Environmental factors such as *Helicobacter pylori* (*H. pylori*) infection and diet have been hypothesized to play a role in the recently increased risk of this disease, but additional studies are needed. In conducting studies to establish the relationship between potential risk factors and gastric cardia adenocarcinoma, it is necessary to carefully consider the role of bias. In a recently published study, the reported associations between *H. pylori* as well as post-meal physical exertion and gastric cardia adenocarcinoma may have been greatly influenced by selection bias.

DOI: <http://dx.doi.org/10.3748/wjg.v16.i12.1553>

TO THE EDITOR

The positive association between *Helicobacter pylori* (*H. pylori*) infection and development of non-cardia gastric cancers is well established^[1,2]. Although various observational studies have been conducted to elucidate the roles of *H. pylori* and other environmental factors in the development of cancer in the gastric cardia^[3], these roles are still not well defined and therefore additional studies are needed.

A recent hospital based case-control study conducted by Chen *et al*^[4] attempted to address these roles, reporting a positive association between gastric cardia adenocarcinoma and *H. pylori* infection. Specifically, the study found that men with gastric cardia adenocarcinoma are almost three times more likely to have antibodies against *H. pylori* and also three times more likely to have conducted work or exercise after meals^[4]. While the authors did recognize that their conclusion may have been distorted by differential misclassification due to recall bias, the reported associations could also be explained by selection bias called exclusion bias.

Controls were cancer-free, inpatients from family medicine departments including inpatients reporting to the hospital for a general check-up^[4]. Furthermore, controls with "stomach-related" diseases were excluded from participating in the study^[4]. In order to prevent selection bias, controls should be selected so that they have a distribution of exposures similar to the population from which

cases arise^[5]. Rothman *et al*^[5] indicate that the exclusion of controls presenting with illness relating to and after the exposure “reduces the prevalence of the exposure in the controls ... hence biases the effect estimates upward”. Although the authors did not specify which stomach-related diseases were excluded, *H. pylori* infection has been identified as a major risk factor in the development of many stomach-related issues such as chronic gastritis, peptic ulcer disease and gastric adenocarcinoma^[6]. Furthermore, the development of precancerous lesions is preceded by a variety of stomach-related symptoms and factors including *H. pylori* infection possibly 20 years prior to the event^[1]. Hence, if control subjects with any of the aforementioned stomach-related diseases were excluded from the present study, fewer controls with antibodies against *H. pylori* would be identified compared to the study cases (men with gastric cardia adenocarcinoma). By excluding control subjects with stomach-related diseases, the authors inadvertently created an under representation of *H. pylori* in the control series compared to the population from which cases arose, which could explain the observed positive association between *H. pylori* infection and gastric cardia adenocarcinoma^[5].

Case-control studies have the potential to be internally valid and provide an efficient and cost effective means to estimate exposure-outcome associations, especially

for rare outcomes such as those in the present study. Of utmost importance in this and all studies, utilizing the case-control design, however, is the requirement to carefully select control subjects to avoid distorted estimates of effect for which post-study statistical analyses cannot ameliorate.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board

members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Article: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce Consensus and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Published by

Beijing Baishideng BioMed Scientific Co., Ltd.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Instructions to authors

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/1007-9327/Instructions-toAuthprs.asp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>; Writing requirements of abstract at: <http://www.wjgnet.com/1007-9327/links/Abstract.doc>.

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the

main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A...; B...; C...; D...; E...; F...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr-A*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

<http://www.wjgnet.com>

Telephone: +86-10-5908-0039

Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/1007-9327/news/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/1007-9327/news/12.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Ahmed MH. Ezetimibe as potential treatment for cholesterol gallstones: The need for clinical trials. *World J Gastroenterol* 2010; 16(13): 1555-1557 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i13/1555.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i13.1555>

Abstract

Obesity is associated with insulin resistance, non-alcoholic fatty liver disease (NAFLD) and gallstones. High fat diets (unsaturated fats) rich in cholesterol have been demonstrated to produce not only gallstones but also NAFLD and insulin resistance. Interestingly, a high incidence of gallstones is being reported in association with insulin resistance and NAFLD. Laparoscopic cholecystectomy is the best definitive therapy for symptomatic gallbladder disease. Ezetimibe is a drug that inhibits the absorption of both dietary and biliary cholesterol in the small intestine. Importantly, ezetimibe showed potential benefit not only in treating and preventing gallstones but also in insulin resistance and NAFLD. Further studies are required before the use of ezetimibe for the treatment of gallstones can be advocated.

INTRODUCTION

Gallstones are a common problem and is likely to have existed since the appearance of mankind on Earth. Interestingly, gallstones have been identified in autopsy studies of Egyptian mummies^[1]. Gallstones and associated complications cost approximately 6.5 billion dollars annually in the USA. The incidence of gallstones is more frequent in females than males and increase with age. The role of ethnicity and genetics is known in gallstone formation. Importantly, the distribution of gallstones in different populations appears to be related to high dietary intake of cholesterol and fats (Western diets). Furthermore, gallstones are primarily cholesterol or black pigment stones (bilirubin polymers) or brown pigment stones (calcium bilirubinate). The only established dietary risk is a high caloric intake. Other modifiable risk factors for gallstones are obesity, the metabolic syndrome, rapid weight loss, certain diseases (cirrhosis, Crohn's disease) and gallbladder stasis (from spinal cord injury or drugs such as somatostatin). Therefore, it is anticipated that diets containing fibre, vegetable protein, nuts, calcium, vitamin C, coffee, plus physical activity are all regarded as protective factors. In developed countries, cholesterol gallstones predominate; 15% are black pigment stones. It is thought that gallstones affect around 15% of white adults in developed countries. East Asians develop brown pigment stones in bile ducts, associated with biliary infection or parasites, or in intrahepatic ducts (hepatolithiasis). In view of the high prevalence of obesity and metabolic

syndrome, the burden of disease is epidemic in American Indians at around 60%-70%. The frequency of gallstones is reduced in Black Americans, Hispanics of mixed Indian origin, East Asians and sub-Saharan Africans^[2,3]. Most asymptomatic gallstone carriers require no therapy. Laparoscopic cholecystectomy is the best definitive therapy for symptomatic gallstone disease. Primary prevention is unproven but focuses on early identification and risk alteration to decrease the possibility of developing gallstones. Ursodeoxycholic acid has a limited role in stone dissolution but can prevent stone development in severe obesity during rapid weight reduction with diet therapy or after bariatric surgery^[4].

EZETIMIBE AND CHOLESTEROL GALLSTONES

Recently, it was shown both in animal models and humans that ezetimibe may prevent and treat cholesterol gallstones^[5]. Ezetimibe inhibits intestinal uptake of cholesterol with a half life of approximately of 22 h. The major metabolic pathway for ezetimibe consists of glucuronidation of the 4-hydroxyphenyl group by uridine 5'-diphosphate-glucuronosyltransferase isoenzymes to form ezetimibe-glucuronide in the intestine and liver. Approximately 78% of the dose is excreted in the faeces predominantly as ezetimibe, with the balance found in the urine mainly as ezetimibe-glucuronide^[6]. Niemann-Pick C1 like1 (NPC1L1), highly expressed in the jejunum of different species and only in human liver, is the main transporter of intestinal cholesterol. Mice deficient in NPC1L1 showed a significant > 70% reduction in cholesterol absorption, and a further reduction in cholesterol level with ezetimibe administration was not achievable. It was concluded that ezetimibe reduces intestinal absorption by inhibiting the action of NPC1L1. Ezetimibe significantly reduces low-density lipoprotein (LDL) cholesterol and is used as monotherapy or in combination with statins to treat hyperlipidaemia^[7].

Wang *et al*^[5] showed that ezetimibe treatment for 8 to 12 wk in male gallstone-susceptible C57L mice and in 7 patients (treated with 20 mg ezetimibe for 30 d) resulted in a decrease in intestinal cholesterol absorption and biliary cholesterol secretion. Ezetimibe also protected gallbladder motility function by desaturating bile. Furthermore, ezetimibe treatment promoted the dissolution of gallstones by forming an abundance of unsaturated micelles and reduced biliary cholesterol saturation. However, Tamel *et al*^[8] found that mice transgenic for *NPC1L1* gene, displayed an increase in biliary cholesterol concentration, suggesting that ezetimibe treatment may reduce biliary cholesterol secretion and increase the cholesterol saturation index. This is not in agreement with previous studies which showed the potential benefit of ezetimibe in treating gallstones, and may lead to speculation that it is actually intestinal cholesterol absorption which is largely responsible for the formation of cholesterol gallstones.

Furthermore, administration of ezetimibe in Golden Syrian hamsters fed a diet high in cholesterol and sun-

flower oil resulted in a significant reduction in absolute and relative cholesterol levels in bile^[9]. Ezetimibe treatment in C57BL female mice, prevented biliary crystals and normalized gallbladder wall fat and function^[10]. Importantly, gallstone-susceptible C57BL/6 inbred mice were fed control and lithogenic diets with or without simultaneous ezetimibe administration. Lithogenic diets increased biliary cholesterol content and secretion, and induced sludge or gallstone formation in 100% of the animals. Ezetimibe administration reduced intestinal cholesterol absorption by 90% in control animals and by 35% in mice receiving the lithogenic diets. Ezetimibe prevented the appearance of cholesterol crystals and gallstones. In addition, mice fed the lithogenic diets plus ezetimibe exhibited a 60% reduction in the biliary cholesterol saturation index. Of note, ezetimibe treatment caused a significant increase in bile flow (+50%, $P < 0.01$) as well as bile salt, phospholipid and glutathione secretion rates (+60%, +44% and +100%, respectively, $P < 0.01$), which was associated with a moderately increased expression of hepatic bile salt transporters^[11]. From the above discussion it is possible to suggest that ezetimibe acts by decreasing intestinal cholesterol absorption and biliary cholesterol secretion, preserving gallbladder motility function by de-saturating bile in mice, promoting the dissolution of gallstones by forming an abundance of unsaturated micelles and significantly reducing biliary cholesterol saturation and retarding cholesterol crystallization in the bile of patients with gallstones.

Another important precipitating factor for gallstones and a therapeutic target for ezetimibe is insulin resistance. Interestingly, Chang *et al*^[12] showed in 19 503 Korean men, that the prevalence of obesity, abdominal obesity, and metabolic syndromes in the subjects with gallstones were higher than in those without gallstones. The prevalence of elevated homeostatic model assessment (HOMA) (> 75 percentile) in subjects with gallstones was significantly higher than in those without gallstones, and this association remained even after the obesity stratification was applied. In multiple logistic regression analyses, only age and HOMA proved to be independent predictors of gallstones. Insulin resistance was positively associated with gallstones in non-diabetic Korean men, and this occurred regardless of obesity. Importantly, gallstones appear to be a marker for insulin resistance, even in non-diabetic, non-obese men. Furthermore, hepatic insulin resistance directly promotes the formation of cholesterol gallstones in mice^[13]. Nakeeb *et al*^[14] showed that in lean, non-diabetic volunteers without gallstones, gallbladder dysmotility is associated with an elevated fasting glucose as well as a high index of insulin resistance, and their conclusion was that insulin resistance alone may be responsible for gallbladder dysmotility which may result in acalculous cholecystitis or gallstone formation. Insulin resistance is also associated with non-alcoholic fatty liver disease (NAFLD)^[15]. Loria *et al*^[16] showed a higher prevalence of gallstones in association with NAFLD compared with a normal population. In liver biopsy screening for NAFLD, it was documented that 55% of subjects have gallstones^[17]. Recent studies showed the potential benefit of ezetimibe as treat-

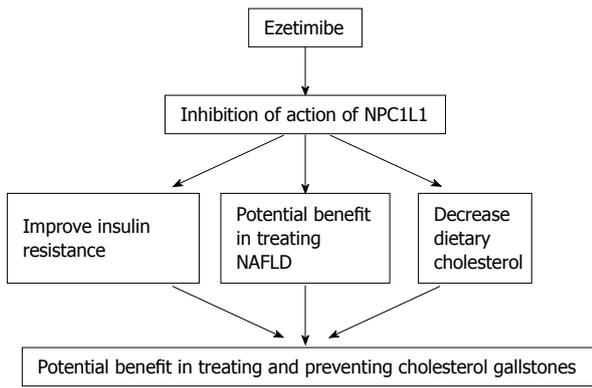

Figure 1 Mechanism of action of ezetimibe and ezetimibe may not only be of potential benefit in the treatment of cholesterol gallstones but also insulin resistance and NAFLD.

ment for NAFLD and associated hyperlipidaemia and insulin resistance. Interestingly, Zheng *et al*^[18] showed that ezetimibe treatment for 4 wk reduced alanine transaminase (ALT), hepatic triglyceride, hepatomegaly, cholesterol ester and free cholesterol in diet-induced obese mice fed a high fat/cholesterol diet for 7 mo with proof of NAFLD. Importantly, administration of ezetimibe in obese Zucker rats (a model of NAFLD and metabolic syndrome) resulted in a significant improvement in both cholesterol and triglyceride levels, hepatic steatosis and improved insulin resistance^[19]. This is in accordance with a recent study by Nomura *et al*^[20] who showed that ezetimibe improved hepatic insulin sensitivity.

CONCLUSION

In summary, Ezetimibe is a unique medication with potential for treating not only gallbladder stones but also insulin resistance and NAFLD (Figure 1). Taking all these factors into consideration, it is possible to suggest that a clinical trial designed to investigate the potential of ezetimibe for reducing biliary cholesterol saturation and insulin resistance in populations with a predisposition to cholelithiasis is now warranted.

Abstract

Magnetic resonance imaging (MRI) has now been used for about three decades to characterize the human liver in a non-invasive way, that is without the need of using ionizing radiation or removing tissue samples. During the past few years, technical progress has been considerable and novel applications of MRI have been implemented in the clinic. The beginning of a new decade offers an excellent opportunity for having five experts to present their view on the current status of MRI (and magnetic resonance spectroscopy) in the study of perfusion, fat and iron contents, diffusion and the metabolism of diffuse liver diseases. This topic highlight series thus provides an update of current knowledge in the field of liver MRI.

focus on five magnetic resonance imaging (MRI) methods offering opportunities for parametric exploration of the liver^[1]. The first contribution focuses on the microcirculatory status in liver parenchyma and liver lesions as studied by perfusion MRI, i.e. MRI with the use of (contrast) agents to improve the contrast between the features on images^[2]. Great progress has been made in turning perfusion weighted imaging into a quantitative method for detecting tumor, evaluating tumor viability after therapy and, for instance, the diagnosis of liver cirrhosis and its severity. Another important development is that nowadays, the sampling of liver tissue for the assessment of hepatic steatosis, related to alcoholic and non-alcoholic liver disease, metabolic syndrome, obesity and insuline resistance, can be replaced by the use of MRI or magnetic resonance spectroscopy (MRS) for determining liver fat content^[3]. The next review is a thorough assessment of the present status in another novel application of MRI presenting an alternative to biopsy: liver iron content determination^[4]. Accurate evaluation of iron overload is necessary to establish the diagnosis of hemochromatosis and guide chelation treatment in transfusion-dependent anemia. Diffusion weighted imaging (DWI), best used in combination with conventional unenhanced MRI and perfusion weighted MRI, is a promising tool used in predicting tumor responsiveness and following up oncological treatment since DWI might be capable of detecting recurrent disease earlier than conventional imaging^[5]. The final contribution features the use of MRS to study metabolism in diffuse liver diseases, diabetes and cancer^[6]. Although this method still is in the preclinical stage, it is anticipated that future developments such as clinical magnets with a higher field strength (3 T, 7 T) and improved delineation of multi-component signals, will lead to intensified research in metabolic syndrome, cardiovascular disease, hepato-biliary diseases, *etc.* We believe that this issue will be of interest not only to gastroenterologists, but also to those involved in metabolic studies, cell physiology and pathology.

Abstract

Hepatic steatosis as the most prevalent liver disorder can either be related to alcoholic liver disease (ALD) or non-alcoholic fatty liver disease (NAFLD). In both conditions, hepatocytes excessively accumulate fat-containing vacuoles within their cytoplasm, which is the key histological feature. In contrast to ALD, NAFLD is commonly associated with metabolic syndrome, obesity and insulin resistance. To determine increased liver fat content, liver biopsy is currently considered the gold standard. Besides the invasive technique, various other non-invasive techniques have been developed, such as ultrasound, computed tomography (CT), magnetic resonance spectroscopy (MRS) and magnetic resonance imaging (MRI) based methods. Among these techniques, ultrasound and CT provide only qualitative information about hepatic steatosis, whereas MRS- or MRI-based

methods are able to determine even small amounts of fat accurately. These non-invasive magnetic resonance techniques have already proven their great potential, especially in longitudinal and cross-sectional studies regarding various metabolic conditions and medical treatment regimens. In this review, the most common, non-invasive MRS/MRI techniques for assessment of intrahepatic lipid content are described with their inherent advantages and limitations.

INTRODUCTION

Hepatic steatosis is a common finding during liver examination and is found in a broad spectrum of diseases. It is related to an increased deposition of triglycerides within the cytoplasm of hepatocytes. Besides alcoholic liver disease (ALD), intrahepatic accumulation of lipids can also be associated with obesity, insulin resistance and metabolic syndrome, and is then termed non-alcoholic fatty liver disease (NAFLD). NAFLD is constantly gaining prevalence throughout the western world and is related to obesity as an increasing problem in recent decades^[1,2]. Nevertheless, NAFLD can also be found in non-obese subjects with a body mass index within the normal range. Those patients

often suffer from insulin resistance. Thus, intrahepatic fat fraction denotes an interesting metabolic parameter for longitudinal or cross-sectional studies regarding various metabolic conditions. Moreover, it is considered an independent risk factor for insulin resistance and atherosclerosis^[3-7]. The current gold standard for quantification of intrahepatic lipid content is based on invasive liver biopsies and subsequent histological analysis. However, due to its invasive character, it is not useful for longitudinal studies or metabolic studies on otherwise healthy subjects.

Magnetic resonance spectroscopy (MRS) and magnetic resonance imaging (MRI) provide non-invasive means to accurately quantify intrahepatic lipid content^[8-10]. In contrast to other modalities such as ultrasound and computed tomography (CT), MRI/MRS are capable of detecting even small amounts of intrahepatic lipid accumulation^[10]. Therefore, MRI/MRS are especially useful to measure changes in hepatic steatosis during various treatment regimens. During recent years, clinical and research investigations have been performed on this subject.

This review gives an overview of various magnetic-resonance-based methods that are capable of quantifying intrahepatic lipid content non-invasively. Different strategies of ¹H-MRS, as well as phase-sensitive and frequency-selective MRI methods are described.

¹H-MRS

In 1993, Longo *et al.*^[11,12] first published their results of ¹H-MRS of liver parenchyma and correlated the data with CT studies and biopsies. In these studies, they found an excellent agreement between the different investigated methods. Since then, several studies have been performed that have further verified these results by means of whole-body MR scanning^[13-15].

However, various strategies have been developed to obtain volume-selective ¹H-MR spectra from liver parenchyma *in vivo*. Spectra are usually recorded from volumes ranging from 1 to 27 cm³, which are small enough to be positioned well in the liver parenchyma. To record reliable spectra from pure liver parenchyma, voxels have to be carefully placed in order to avoid artificial signal contributions from surrounding adipose tissue or intrahepatic blood vessels.

Two main strategies are used for single-voxel spectroscopy (SVS): point resolved spectroscopy (PRESS) or stimulated-echo acquisition mode (STEAM)^[16,17]. The PRESS acquisition scheme (multi-echo single-shot technique) uses a 90°-180°-180° pulse sequence with long echo time (TE) and allows for better visualization of metabolites with long T₁ relaxation times. In contrast, the STEAM sequence applies a 90°-90°-90° pulse sequence and is less sensitive to J-coupling effects. The STEAM sequence provides shorter TE and lower signal yield compared to PRESS, which is usually not a limitation for fat quantification in the liver. However, both techniques can be applied for intrahepatic fat quantification in clinical examinations.

Since both techniques only provide spectra of a small sub-region of the liver parenchyma, so-called spectroscopic imaging techniques with 2D or even 3D matrices of spectra have been developed to obtain detailed information on lipid distribution^[18,19]. Compared to SVS, these techniques are rarely used clinically for routine investigation of liver parenchyma, due to their rather long acquisition and post-processing times^[20,21]. In most cases of NAFLD, hepatic lipid distribution has been shown to be relatively homogeneous, which allows one to quantify intrahepatic fat fraction by only one single representative voxel^[22-24]. However, it should be noted that significant differences in sub-regions of both liver lobes have also been reported^[13].

The above-mentioned ¹H-MRS techniques have been applied in studies investigating NAFLD in the general adult population^[25]. Moreover, an increasing number of longitudinal clinical studies have been performed evaluating intrahepatic fat fraction in the obese population or patients at risk for developing type 2 diabetes^[26-31]. Intrahepatic fat fraction has also been evaluated in morbidly obese patients undergoing bariatric surgery^[32-35]. Moreover, additional cross-sectional studies have revealed different intrahepatic fat fractions depending on genetic background or hormonal status of the examined subjects^[36-42].

All of these MRS fat quantification techniques have been shown to be safe and non-invasive alternatives to the current invasive gold standard (liver biopsy). They have been tested regarding their accuracy and have shown high intra-individual reproducibility in repeated measurements^[13,23,25]. However, one has to consider that MR spectroscopic fat quantification relies on determination of overall volume fraction of lipids in the liver parenchyma. In contrast, in histological examinations, the percentage of hepatocytes that show distinct fat droplets is used for quantification. Thus, the reported percentage values that characterize steatosis from MR examinations might differ from those in histological analysis. On the other hand, data from MRI and histology correlate with each other and both techniques allow, nevertheless, for reliable quantification of intrahepatic lipid content.

It should be also mentioned that spectroscopic examinations are especially recommended for assessment of small lipid fractions in the liver, because sensitivity to low signal intensities from fat is higher than for imaging-based strategies. Furthermore, water and fat signals can be well distinguished.

FAT-SENSITIVE IMAGING METHODS

¹H-MRS capabilities are still not available on all standard clinical scanners and require dedicated prerequisites including spectroscopic sequences and post-processing software. Therefore, ¹H-MRS still remains a research tool for clinical studies and is usually not used in daily routine liver examinations. There are, nevertheless, MRI sequences that allow for reliable and accurate quantification of intrahepatic lipid content.

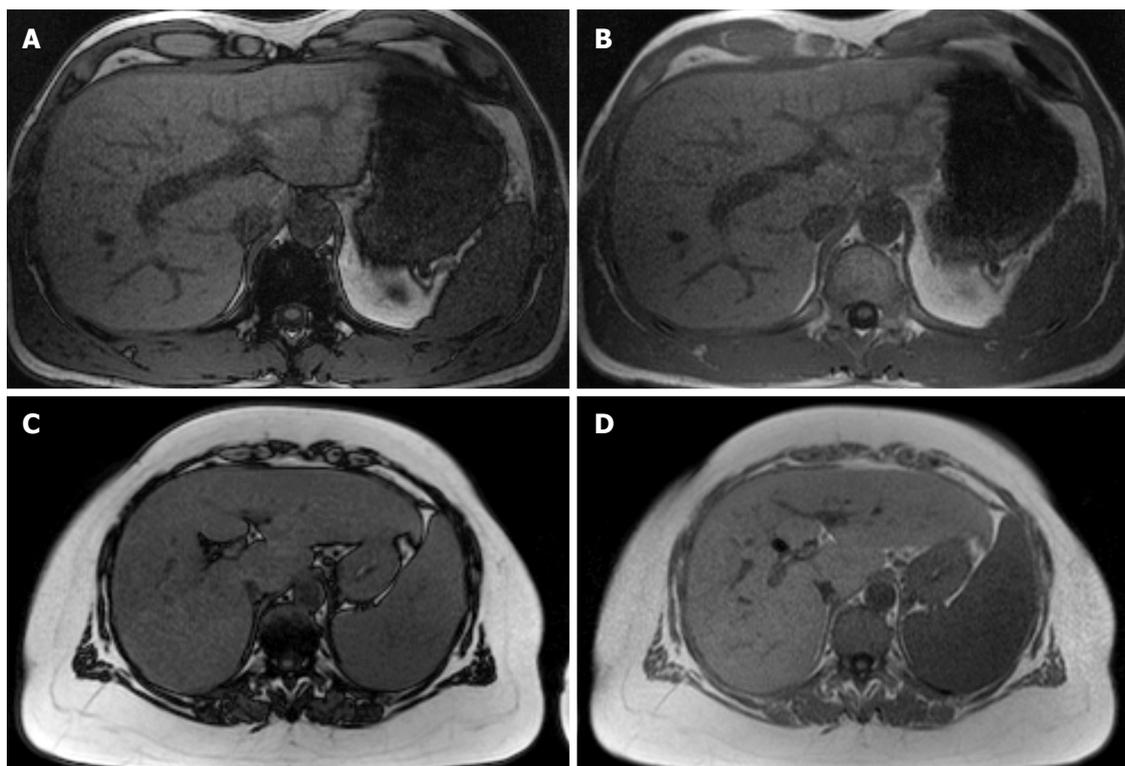

Figure 1 T1-weighted gradient echo images recorded with OP (parts A and C) and IP (B and D) conditions. A and B show a lean subject with almost equal signal intensity of the liver under OP (A) and IP (B) conditions, since no intrahepatic lipid storage is present. In contrast, C and D show an obese subject with lower signal intensity under OP conditions compared to IP conditions, which indicated relevant intrahepatic lipid storage.

Techniques based on differences in signal phase of water and fat

So-called in-phase/opposed-phase (IP/OP) techniques are available on most MR units and can be performed easily in routine examinations. Using this technique, T1-weighted images can be acquired extremely fast, with the use of multi-segment phased array coils and parallel imaging techniques. Moreover, T1-weighted gradient echo sequences can cover most of the liver parenchyma within a single breath-hold^[43-46]. The IP/OP technique is based upon the fact that, during TE, transverse magnetization vectors of fat and water develop a phase difference that results in decreased overall length of the magnetization vector under OP conditions. At a main magnetic field strength of 1.5 T, the frequency shift between fat and water is approximately 220 Hz, which results in OP conditions at a TE of about 2.4 ms and in-phase conditions at a TE of about 4.8 ms^[47-49]. The hepatic fat fraction can then be quantified by calculating the loss of signal intensity in OP images compared to IP images^[50-52], as shown in Figure 1. From congruent sets of IP and OP images, acquired within the same breath-hold, the fat fraction can be calculated pixel-wise and misregistration errors can be avoided. Thus, maps of intrahepatic fat fraction can be obtained to estimate liver fat content and show differences in regional fat distribution.

However, not only the phase difference between water and fat protons contribute to the observed signal loss in OP images, but also additional transverse and longitudinal relaxation effects may play a major role. Recent studies

have shown that especially transverse relaxation time can vary largely between different individuals, as well as intra-individually in the time-course of longitudinal studies^[46,53,54]. These changes in transverse relaxation time are mainly due to increased iron deposition in the liver parenchyma; either artificially acquired or, for example, hemochromatosis-associated^[55]. It has been shown that transverse relaxivity correlates well with serum ferritin levels^[53,56]. Thus, transverse relaxation time of liver parenchyma has to be measured additionally using a multi-echo gradient echo sequence. The data necessary for estimation of T2* can then be obtained within a single additional breath-hold. Integration of individual T2* values in the calculation of the fat fraction requires a somewhat more sophisticated approach^[57].

In contrast, longitudinal relaxation times are relatively stable throughout the population and individual calculation requires additional time-consuming sequences. Therefore, it seems legitimate for the general population to account for longitudinal relaxivity using constant values for longitudinal relaxation time of liver parenchyma.

Compared to the above-described gradient-echo-based IP/OP technique, Dixon *et al.*^[47] described in 1984 the use of a spin-echo technique with a small timing-offset of the 180° refocusing pulse, which is used to create a so-called OP image. The IP image is then acquired using a conventional spin-echo sequence. From these two images, fat- and water-selective images can be subsequently obtained. However, sensitivity to magnetic field inhomogeneity cannot be neglected and has prevented the wides-

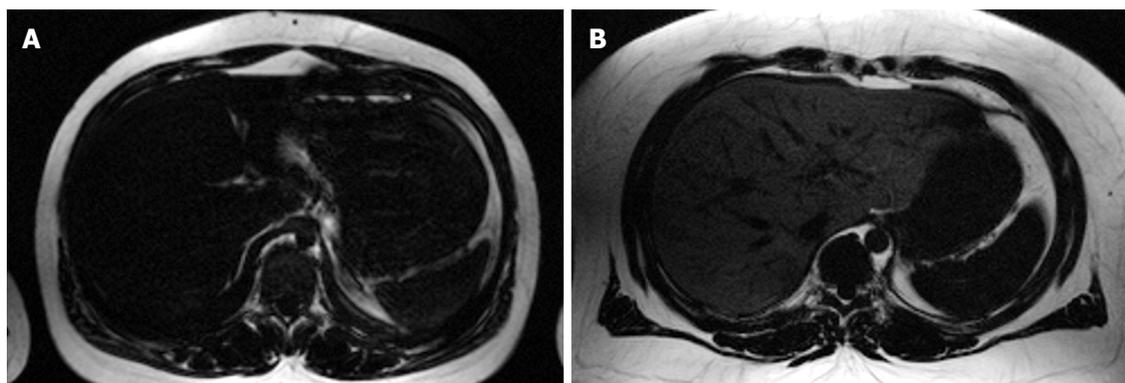

Figure 2 A and B show fat-selective spectral-spatial imaging of the body trunk. A lean subject with almost no intrahepatic lipid storage (A) and an obese subject with markedly increased lipid storage in the liver parenchyma is shown (B).

pread routine clinical usage of the Dixon technique. Since its introduction more than 20 years ago, several modifications have been reported that have aimed at overcoming its inherent limitations^[45,48,58,59]. Three-point Dixon methods have been developed that additionally acquire a third image with a phase shift of -180° or 360° . Then, using three different images and sophisticated phase-correction algorithms, true fat- and water-selective images are derived from the recorded data. This technique allows one to distinguish which constituent (water or fat) is predominant in each voxel^[60-66]. Acquiring all three images in a single breath-hold is often not possible, whereas recording in multiple breath-holds poses the problem of misregistration artefacts due to variable positions of the liver parenchyma.

Another approach was first described by Reeder *et al.*^[67-69] and is termed the IDEAL technique (iterative decomposition of water and fat with echo asymmetry and least squares estimation). Using optimized echo shifts and gradient echo imaging, it provides robust quantification of the intrahepatic fat fraction. This technique allows for fat quantification even in the presence of moderate inhomogeneities of the static magnetic field, which are often encountered in examinations of extremely obese patients on wide-bore MRI scanners. However, it is not free of limitations. Liu *et al.*^[70] have reported techniques for reduction of noise bias and longitudinal relaxation effects that affect quantification of the hepatic fat fraction in the IDEAL technique. These drawbacks can be partially overcome by small- or dual-flip angle approaches, magnitude discrimination and phase-constrained methods. Besides its capabilities in measuring parenchymal fat content, the IDEAL method has also been used for fat suppression in clinical studies of various body regions^[71-75].

Techniques based on frequency selective excitation

Previous studies have described a so-called spectral-spatial excitation technique to quantify fat content accurately in parenchymal organs and muscles^[57,76]. A combination of chemical shift selectivity and slice-selective excitation in gradient echo or spin echo imaging sequences provides a high sensitivity to detect even small amounts of fat^[23,49,77,78].

Furthermore, spatial information about parenchymal lipid distribution is also obtained. Slice-selectivity is implemented using six equidistant radio frequency pulses (time increment between pulses, 2.38 ms at 1.5 T) with nearly binomial amplitude ratios. These radio frequency pulses excite the methylene and methyl signal of fatty acids (0.8-2.0 ppm) selectively, as shown in Figure 2. Thus, signal contributions from water protons are below the noise level. To achieve this optimal spectral-spatial excitation, relatively homogeneous static magnetic fields are required, which makes adequate shimming procedures necessary. However, especially in wide-bore MR scanners that are designed to examine extremely obese patients, the inhomogeneity of the static magnetic field is often problematic. Even time-consuming shimming procedures might fail. For quantitative assessment of intrahepatic fat, adjacent subcutaneous or visceral fat is used as an internal reference because it contains almost 100% fat. The spectral-spatial excitation method is capable of detecting even small amounts of lipids (starting at 1%-2% volume fraction of fat in the liver), with additional spatial information about its distribution^[23]. However, some advantages and disadvantages of this technique should be noted. As a result of highly selective visualization of fat, the technique offers relatively low soft tissue contrast compared to conventional gradient echo sequences (Figure 3). Moreover, only a small number of representative slices can be acquired during a single breath-hold. Since only a reference region-of-interest in subcutaneous adipose tissue adjacent to liver parenchyma is needed for quantification of fat fraction, the calculation of intrahepatic lipid content can easily be done. Furthermore, there is no need for additional time-consuming sequences that are necessary to correct for transverse and longitudinal relaxation effects.

CONCLUSION

Several non-invasive methods have been developed for quantification of intrahepatic fat content using whole-body MRI scanners. Being aware of the inherent advantages and disadvantages of each technique, one has to choose carefully the appropriate method for specific examination

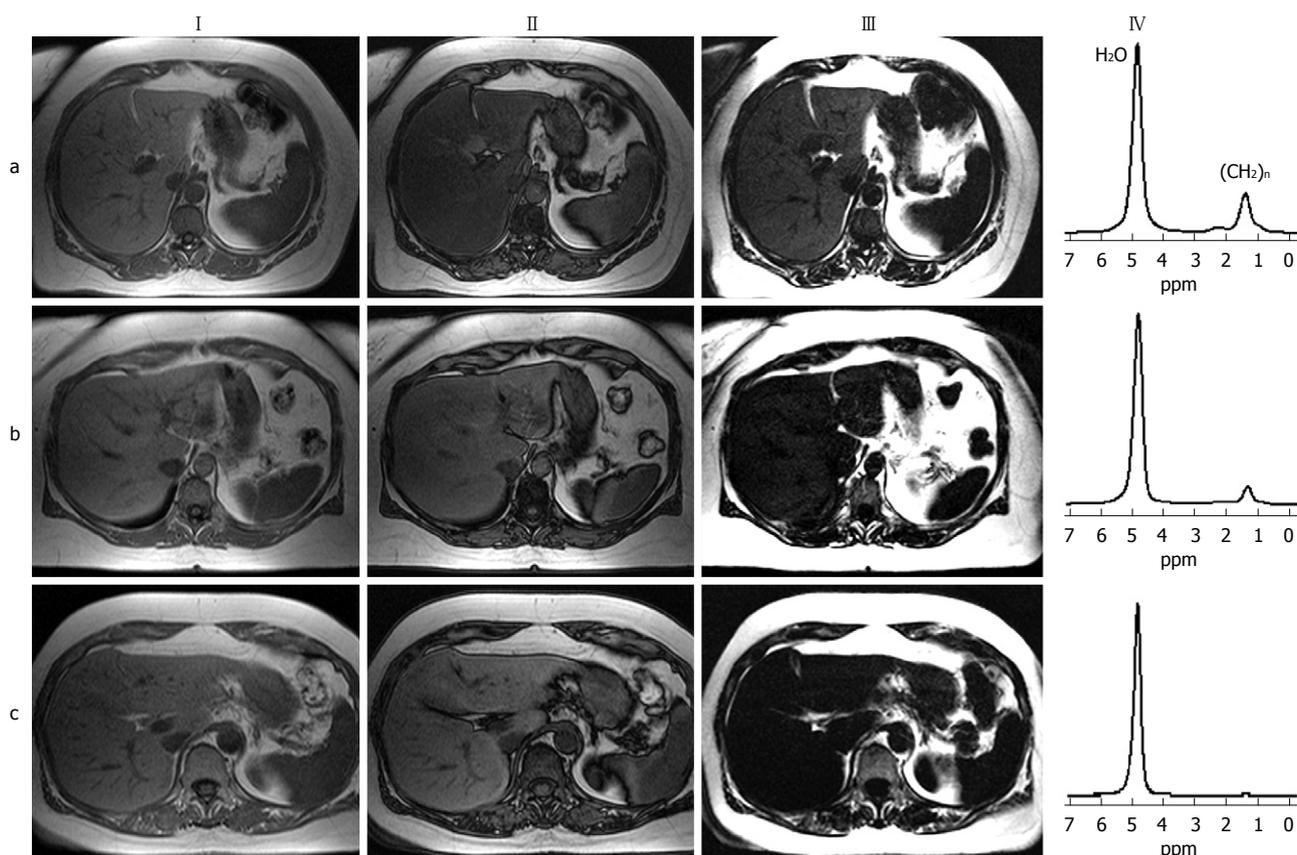

Figure 3 Three subjects with different intrahepatic lipid contents are compared. The subject in row (a) shows intrahepatic lipid content of about 20%; the subject in row (b) shows intrahepatic lipid content of about 10%; and the subject in row (c) shows intrahepatic lipid content in the normal range (about 1%). The figure shows IP (column I) and OP (column II) images of a T1-weighted gradient echo sequence. Column III shows the results of a fat-selective spectral-spatial imaging sequence, and column IV shows the results from single-volume ^1H -MRS using a STEAM sequence.

circumstances, as well as for hard- and software capabilities. Correctly applied, each technique (MRS/MRI) provides accurate data on intrahepatic fat fraction, correlating well with findings in liver biopsies, which is often considered as the current gold standard. The methods described above provide non-invasive quantification of the intrahepatic fat fraction, and give a reliable basis for longitudinal clinical and research studies. Thus, the influence of various medical treatments and diseases on intrahepatic lipid storage can be easily investigated in a non-invasive way.

Abstract

Diffusion weighted magnetic resonance imaging (DWI) is an imaging technique which provides tissue contrast by the measurement of diffusion properties of water molecules within tissues. Diffusion is expressed in an apparent diffusion coefficient (ADC), which reflects the diffusion properties unique to each type of tissue. DWI has been originally used in neuroradiology. More recently, DWI has increasingly been used in addition to conventional unenhanced and enhanced magnetic resonance imaging (MRI) in other parts of the body. The reason for this delay was a number of technical problems inherent to the technique, making DWI very sensitive to artifacts, which had to be overcome. With assessment of ADC values, DWI proved to be helpful in characterization of focal liver lesions. However, DWI should always be used in conjunction to conventional MRI since there is considerable overlap between ADC values of benign and malignant lesions. DWI is useful in the detection of hepatocellular carcinoma in the cirrhotic liver and detection of liver metastases in oncological patients. In addition, DWI is a promising tool in the prediction of tumor responsiveness to chemotherapy and the follow-up of oncological patients after treatment, as DWI may be capable of detecting recurrent disease earlier than conventional imaging.

INTRODUCTION

Magnetic resonance imaging (MRI) is an imaging technique which is used to visualize the internal structure and function of the body. MRI provides excellent tissue contrast, which is much greater than that of any other imaging modality^[1,2]. Tissue contrast is realized by a wide range of pulse sequences. For example, tissue contrast on T1- and T2-weighted images is based on the rate at which signals from protons in water molecules in a static magnetic field decay following excitation by a sequence of radiofrequency (RF) pulses. Diffusion weighted imaging (DWI) is another mechanism for developing image contrast and relies on changes in the diffusion properties of water molecules in tissues. DWI is a widely accepted technique in neuroradiology for detecting early ischemia in cerebrovascular accidents and characterization of brain tumors and intracranial infections^[1-3]. The use of DWI in other parts of the body is relatively new, but very promising for the detection and differentiation of benign and malignant lesions, imaging for dissemination (i.e. staging) in oncological patients before treatment and

for follow-up after treatment of liver tumors. Besides this, DWI is thought to be capable of predicting the response to therapy of malignant tumors (especially chemotherapy)^[4].

BASIC PRINCIPLES OF DWI

Diffusion

Diffusion is a physical property, which describes the microscopic random movement of (water) molecules driven by their internal thermal energy. This movement is known as Brownian motion. In biological tissues, water diffusion is movement of water molecules in intracellular, extracellular and intravascular spaces. Diffusion is affected by the biophysical properties of tissue cell organization (cell membranes, fibers and macromolecules), density, microstructure and microcirculation. Intracellular water diffusion is more hindered than that in the extracellular spaces which are lacking natural barriers. Pathological processes which change the volume ratio or physical nature of intra- and extracellular spaces affect the diffusion of water molecules. Restricted or impeded diffusion is seen in tissues with high cellularity, e.g. tumors, abscesses, fibrosis and cytotoxic edema. Relative free or unimpeded diffusion is encountered in tissues with low cellularity or tissues with disrupted cell membranes, for example in cysts and necrotic tissues^[3-5] (Figure 1A and B).

DWI

DWI relies on measuring diffusion of water molecules in the tissue by MRI. It uses a pulse sequence (T2-weighted spin echo sequence) and 2 strong motion probing gradients on either side of the 180° refocusing pulse, known as the Stejskal-Tanner sequence. The first gradient, prior to the 180° RF pulse is the dephasing (diffusion sensitizing) gradient. The second gradient, after the RF pulse, is the rephasing gradient. In tissues with restricted diffusion, the effect of the dephasing gradient is cancelled out by the rephasing gradient. This causes little impact on the overall T2 decay, reflected as a maintained T2 signal in the tissue. When diffusion is not impeded, water molecules can move a considerable distance between the dephasing and rephasing gradients. The mobile water molecules will not be fully rephased and a reduction in overall T2 signal intensity follows.

DWI is sensitive to very small scale motion of water molecules at a microscopic level. The sensitivity of a DWI sequence is characterized by its b-value, expressed in s/mm^2 . The b-value summarizes the influence of the gradients in DWI. The higher the b-value, the more sensitive the sequence is to diffusion effects. DWI is performed with at least two b-values. Diffusion is quantitatively reflected in a diffusion coefficient. The diffusion coefficient is related to the molecular mobility of water molecules and reflects tissue properties such as the size of the extracellular space, viscosity and cellularity. Diffusion coefficients in DWI are reflected in the *apparent diffusion coefficient* (ADC, expressed in mm^2/s), apparent because it is a mean value of diffusion contributed by

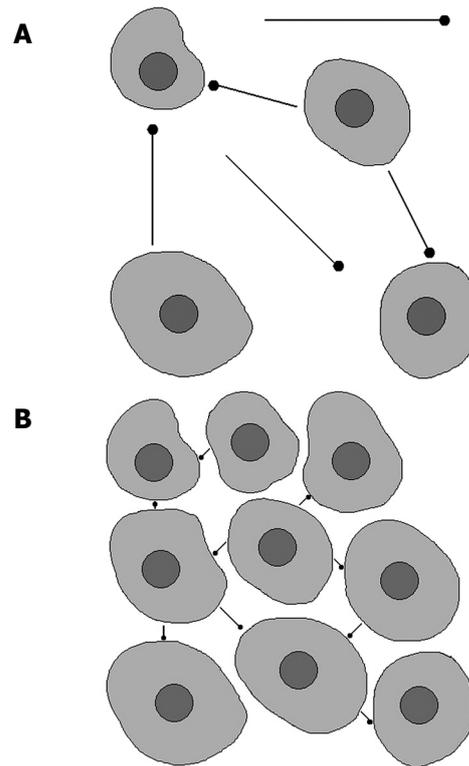

Figure 1 Brownian movements in hypocellular (A) and hypercellular (B) environment. A: Tissue with low cellularity permits movement of the water molecules; B: Tissue with high cellularity restricts the movement of water molecules.

movement of intracellular, extracellular and vascular water molecules within an image voxel (volumetric pixel) at different b-values. Analysis of ADC is an automated process, available as an application on most scanners or workstations. Calculation of ADC is made for each voxel of an image and can be displayed as a parametric (ADC) map. ADC measurements are then recorded for a given region by drawing regions of interest (ROIs) on the ADC map. Low ADC values mean restricted diffusion, thus in tissues which are highly cellular. High ADC values are seen in areas with relative free diffusion, thus in tissues with low cellularity^[1,3-5].

Problems encountered in DWI

DWI can be performed with different techniques, including spin-echo (SE), fast spin echo (FSE), gradient echo (GE) and echo-planar imaging (EPI). EPI is the gold standard DWI technique. When DWI is performed in the body, scanning can be carried out with free breathing, breath hold or respiratory triggered. There are some important limitations of DWI^[2,6].

Firstly, the signal-to-noise ratio (SNR, describes the relative contributions of the true signal and background noise to a detected signal) and spatial resolution are low due to hardware limitations and high bandwidth (a measure of frequency range, the range between the highest and lowest frequency allowed in the signal), inherent to the technique and EPI sequence. SNR will be decreased in incomplete spin echo formation, as is the case with

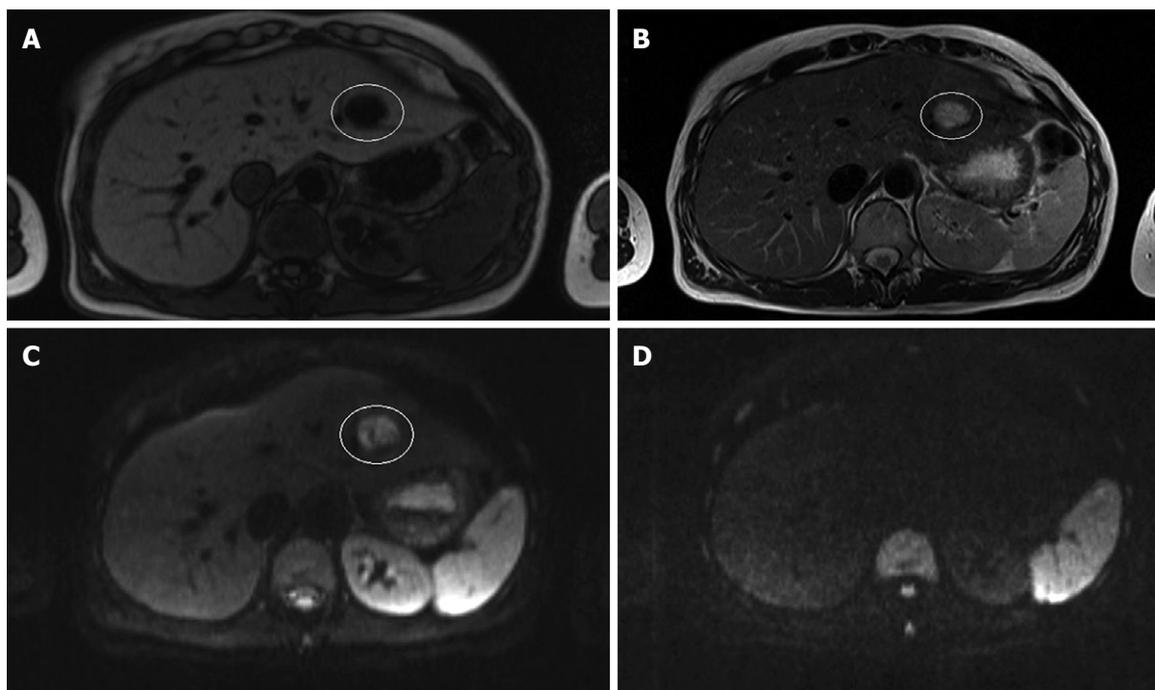

Figure 2 Magnetic resonance imaging (MRI) and diffusion weighted imaging (DWI) of a cyst. A: T1-weighted MRI; B: T2-weighted MRI; C: Diffusion weighted image (b-value 50 s/mm²); D: Diffusion weighted image (b-value 1000 s/mm²) in a 33-year old woman with multiple liver lesions. The cyst is hypo-intense on the T1-weighted image, hyper-intense on the T2-weighted image and the diffusion weighted image at a b-value 50 s/mm². Note that the cyst totally disappears on the diffusion weighted image at a b-value 1000 s/mm².

the most common DWI technique, the EPI sequence. SNR can be increased, but then spatial resolution is sacrificed^[2,3,6-8].

Secondly, DWI is susceptible to a number of artifacts. Ghosting images and blurring may arise from motion, caused by respiratory, cardiac and voluntary movements. Tissue contrast is maintained during free-breathing scanning, but breath hold and respiratory triggered techniques reduce image blurring. Breath hold scans have very short acquisition times of 20-30 s (i.e. the time the patient holds his or her breath) and are theoretically less likely to be degraded by motion-related artifacts. A disadvantage of breath-hold scanning is that the patient needs to hold his or her breath for a considerable time, which may be difficult when the physical condition does not allow him or her to do so. Respiratory triggering will make the acquisition time of the images longer (5 min), especially when the patient is breathing irregularly or slowly, but this is a minimal time penalty. Respiratory triggering provides substantially improved signal, spatial resolution and the ADC values are comparable to breath-hold DWI. In respiratory triggering, multiple b-values can be used to reduce errors in ADC calculation^[2,3,6,7,9-11].

Motion artifacts caused by the heart beating alter ADC in the left lobe of the liver, making measurements unreliable. Cardiac motion can be overcome by using electrocardiographic-triggering, but cardiac gating is not always reliable and increases acquisition times significantly^[2,3,6,7,12].

Susceptibility artifacts are due to magnetic field inhomogeneity (to be overcome by shimming techniques) or metal artifacts and are seen as bright spots, spatial

distortion or signal drop out. Susceptibility artifacts occur especially in fast imaging techniques like EPI^[2,6,7].

Artifacts caused by air-tissue interfaces or fat-water interfaces (chemical shift) appear as black or bright bands at the edge of an anatomical structure. Other artifacts are eddy currents, resulting from the rapid on and off switching of the gradients, leading to geometrical distortion and image shearing artifacts^[2,6,7].

Pathological diffusion

When evaluating diffusion on DWI images, the radiologist focuses on the measurement of extracellular diffusion. As mentioned earlier, the higher the cellularity in a tissue, the less far is extracellular water able to diffuse during the MR observation period without being blocked by cell membranes. Highly cellular tissues provide a short path of diffusion, resulting in low ADC values, as is seen in solid liver lesions and abscesses. Low cellularity means that there are fewer structural barriers, making the diffusion path longer. This results in high ADC values as is seen in cysts and necrotic lesions. In summary, ADC maps, derived from DWI provide a non-invasive measure of cellularity. This makes DWI a potential tool in diagnosis, treatment planning and monitoring, especially in oncology^[3-5]. Examples of different types of lesions and their diffusion weighted images are seen in Figures 2-5.

DWI IN THE LIVER

There are an increasing number of studies dealing with quantitative measurements of ADC in liver lesions, but

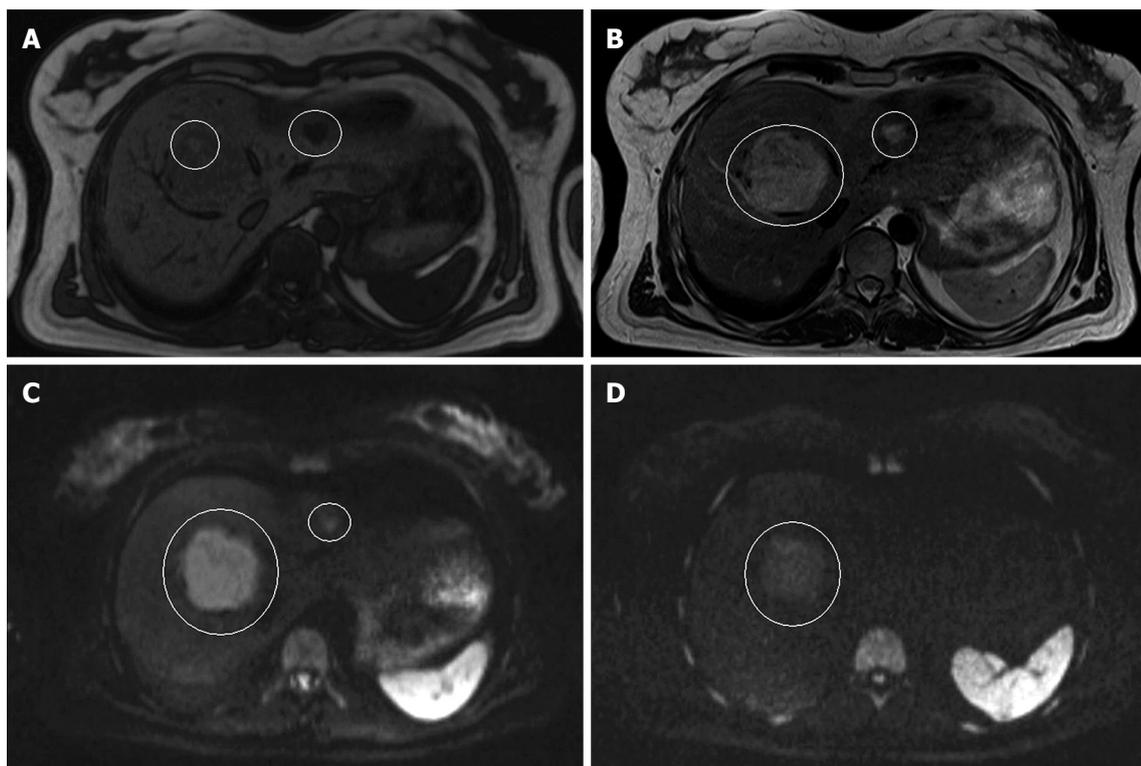

Figure 3 MRI and DWI of an adenoma and a hemangioma. A: T1-weighted MRI; B: T2-weighted MRI; C: Diffusion weighted image (b-value 50 s/mm²); D: Diffusion weighted image (b-value 1000 s/mm²) in a 41-year-old women with multiple liver lesions. The large lesion in segment 8 is an adenoma and the small one in segment 2-3 is a hemangioma. On the T1-weighted image, the adenoma is slightly hypo-intense to the normal liver parenchyma, and hyper-intense on the T2-weighted image. On the diffusion weighted images, it remains hyper-intense at both b-values. The hemangioma is also hypo-intense on the T1-weighted image and hyper-intense on the T2-weighted image. However, in contrast to the adenoma, it totally disappears at a b-value of 1000 mm/s².

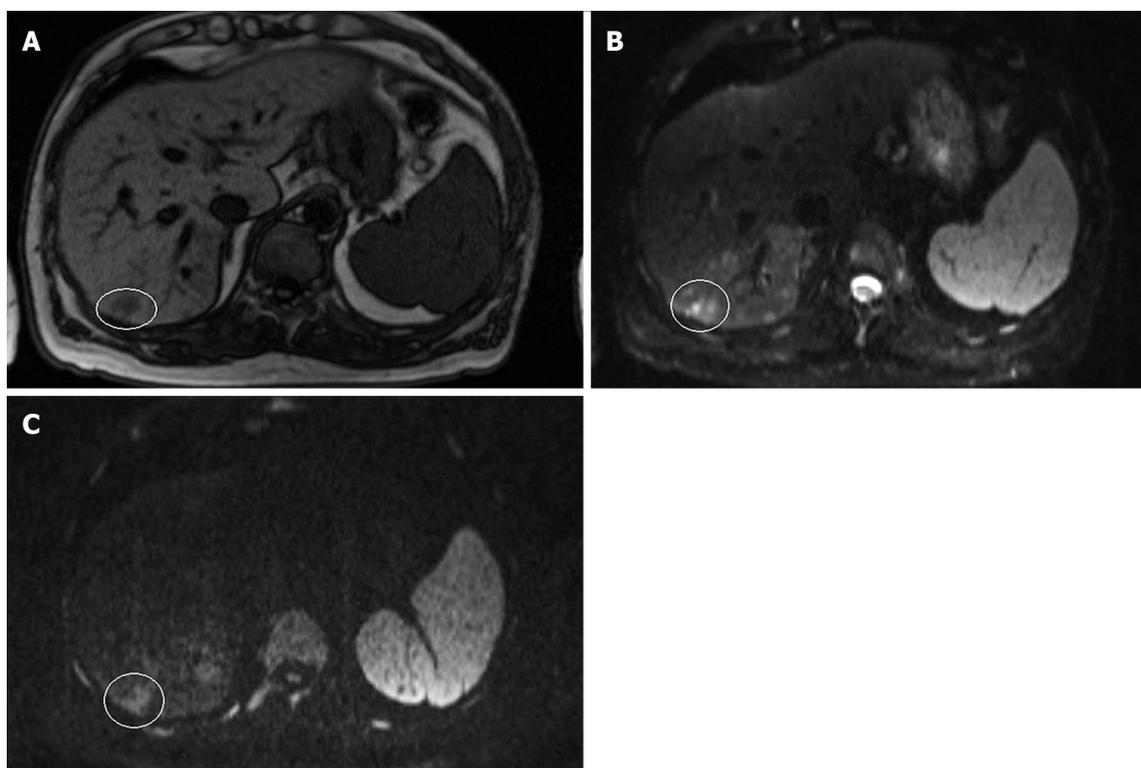

Figure 4 MRI and DWI of hepatocellular carcinoma. A: T1-weighted; B: DWI (b-value 50 s/mm²); C: Diffusion weighted image (b-value 1000 s/mm²) in a 67-year-old male with hemophilia, hepatitis C-based liver cirrhosis and HCC in segment 7. The HCC is hypo-intense on the T1-weighted image and hyper-intense on the diffusion weighted images at both b-values. Note that the lesion remains hyper-intense on the image with a b-value 1000 s/mm².

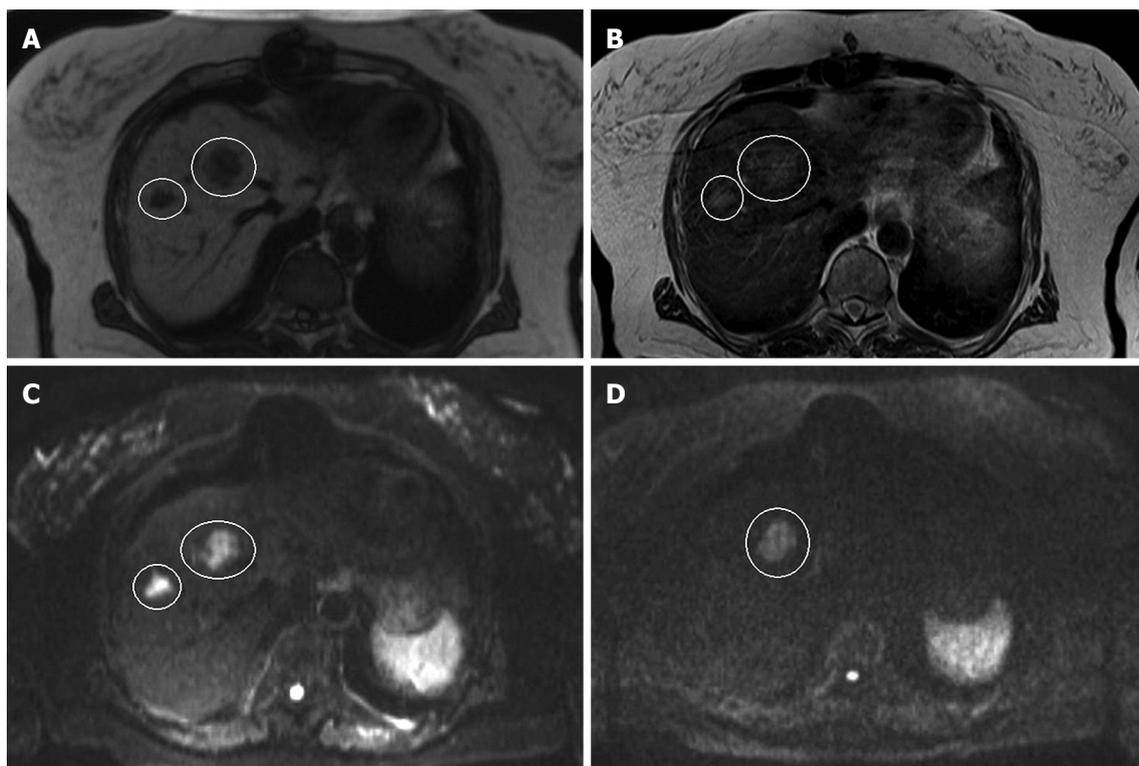

Figure 5 MRI and DWI of hepatic metastases. A: T1-weighted; B: T2-weighted; C: Diffusion weighted image (b-value 50 s/mm²); D: Diffusion weighted image (b-value 1000 s/mm²) in a 74-year-old woman with a history of rectal cancer, recently diagnosed with lung and liver metastases in segment 4 and 8, respectively. The lesions are hypo-intense to the liver parenchyma on the T1-weighted image and hyper-intense on the T2-weighted image. On the diffusion weighted image at a b-value 50 s/mm², both lesions appear hyper-intense, but at a b-value 1000 s/mm², only the lesion in segment 4 remains hyper-intense. The lesion in segment 8 has completely disappeared.

there are as many discrepancies in the reported ADC values (Table 1). This is often associated with the choice of b-values and other technical parameters. Low b-values lead to overestimation of the ADC due to the contribution of perfusion to the diffusion measurement. Large b-values underestimate ADC due to increasing contributions from low ADC components and SNR.

DWI as a tool for characterization of liver lesions

Several studies have suggested that the measurement of ADC values is useful in the characterization of focal liver lesions^[13-26]. Reduced ADC values have been reported for most malignant tumors. This finding is thought to be the result of cellular membranes impeding the mobility of water molecules. However, solid benign lesions, which are also highly cellular, exhibit decreased ADC values as well. Abscesses do so too because their viscous content with bacteria, inflammatory cells, mucoid proteins and cell debris result in restricted diffusion, thus low ADC values. On the other hand, necrotic and cystic malignancies show high ADC values resulting from larger diffusion distances as a consequence of lost membrane integrity. Benign lesions as simple cysts and hemangiomas show high ADC values because of their liquid content and large extracellular spaces. However, ADC values cannot discriminate between solid benign and malignant lesions, since there is considerable overlap. According to Feuerlein *et al*^[15], the pretest probability of malignancy is very important in the determination to which degree a large

ADC value is predictive for a malignancy, i.e. the history, demography and clinical picture of the individual patient. Even ADC values of lesions of the same kind show overlap and there is no cut-off value for ADC values in normal parenchyma, benign and malignant lesions. In the literature, ADC values vary between $0.94-2.85 \times 10^{-3} \text{ mm}^2/\text{s}$ for metastases and $0.69-2.28 \times 10^{-3} \text{ mm}^2/\text{s}$ for normal liver parenchyma. This is mainly because every study group uses their own scanning parameters. Differences in b-values are the main cause of non-equivocal results. Breath-hold, respiratory triggered and navigator echo techniques can also give different ADC values. There is need for an uniformly applicable scanning protocol to eliminate discrepancies in ADC values caused by different scanning parameters^[13].

DWI alone is not suitable for the characterization of liver lesions, because solid benign lesions also can show restricted diffusion, and cystic or necrotic malignant lesions have unimpeded diffusion. DWI can help direct the attention of the radiologist to findings that may otherwise be overlooked. Unenhanced and dynamic MRI contrast series alone are very capable in the discrimination of different types of liver lesions, but a combination of DWI and MRI increases the accuracy of the characterization of benign and malignant lesions^[15-17].

Detection of hepatocellular carcinoma

Multiphase multidetector contrast enhanced computed tomography (CT) has reached a high standard for the

¹These studies found significantly higher ADC values in benign liver lesions than in malignant liver lesions; ²This study evaluated the ADC values at different b-values. The lowest and highest ADC values are reported here. The lowest ADC value corresponds with the highest b-value, the highest ADC value with the lowest b-value; ³This study evaluated the ADC values of different types of benign and malignant lesions. The lowest and highest ADC values are reported here. ADC: Apparent diffusion coefficient; BH: Breath-hold; RT: Respiratory triggered; SD: Standard deviation; FNH: Focal nodular hyperplasia; HCC: Hepatocellular carcinoma.

evaluation of the cirrhotic liver and for the detection of hepatocellular carcinoma (HCC). On CT images, diagnosis of HCC is made based on neovascularization with increased arterial enhancement and rapid portal venous wash-out. In the last few years, (liver-specific) contrast enhanced multiphase dynamic MRI has increasingly been used for the detection of HCC. MRI proved to be superior to CT in the detection of HCC and for the characterization of nodules in patients with liver cirrhosis because of the high tissue contrast provided by MRI and the available liver-specific contrast agents. Contrast enhanced MRI is now regarded as the best non-invasive imaging modality. However, even with liver-specific contrast enhanced MRI, there is a diagnostic problem for small HCC lesions (< 10 mm) as well as in

the differentiation from other non-malignant nodules. Large HCC lesions are well-recognized on conventional MRI by their rapid enhancement in the arterial phase and their contrast agent wash-out in the portal-venous phase. Small HCC is less typical on conventional MRI, and differentiation of atypical nodules in the cirrhotic liver is challenging^[27-31].

Xu *et al*^[27,28] found that ADC values were not useful in cirrhotic livers, because cirrhotic parenchyma and solid benign lesions have low ADC values. They cannot be differentiated from lesions with malignant diffusion restriction because of the considerable overlap among their ADC values. Necrosis and vascularization within HCC also alter diffusion, often seen as a false increase in the ADC values.

Zech *et al*^[29] reported a higher sensitivity for DWI compared to conventional MRI in the detection of HCC in the cirrhotic liver (98% for DWI *vs* 83%-85% for MRI). Vandecaveye *et al*^[30] concluded that DWI provided higher sensitivity and positive predictive value for the detection of HCC < 20 mm compared to conventional contrast enhanced MRI (sensitivity and specificity 91.2% and 82.9% *vs* 67.6% and 61.6%, positive predictive value 81.6% and 59.0%, respectively). DWI did not show significantly better results than conventional MRI in detecting HCC > 20 mm. These findings can be explained by the better contrast-to-noise ratio and background suppression of normal liver parenchyma and vascular or bile structures in DWI, which make small lesions more visible, especially when they are in close vicinity to vessels or bile ducts. DWI provides a high negative predictive value on the presence or absence of HCC and reduces the rate of unnecessary invasive diagnostic procedures and follow-up.

Detection of liver metastases

Several studies have demonstrated the usefulness of DWI in the detection of liver metastases. They compared DWI to unenhanced and dynamic liver specific contrast enhanced MRI (Table 2).

Coenegrachts *et al*^[20] showed that lesion conspicuity of hemangiomas and metastases is significantly higher with respiratory triggered DWI at low b-values compared to conventional unenhanced MRI imaging. This is due to an excellent lesion to liver contrast and suppression of background signals from vessels.

Koh *et al*^[32] compared the diagnostic accuracy of DWI and mangafodipir trisodium (MnDPDP)-enhanced MRI alone and in combination in the detection of colorectal liver metastases. They found that a combination of MnDPDP MRI and DWI resulted in the highest diagnostic accuracy (0.94-0.96 *vs* 0.88-0.92 for MnDPDP alone and 0.83-0.90 for DWI alone) with an increased sensitivity, but no loss of specificity. DWI alone is not useful because the sequence is very susceptible to motion artifacts, which obscure lesions and make images difficult to interpret. This is especially the case in the left lobe of the liver. They also stated that experience is needed to interpret DWI correctly, mainly because of the large numbers of artifacts on the images^[33].

Parikh *et al*^[34] reported a significantly higher overall lesion detection rate for breath-hold or respiratory triggered DWI than for conventional T2-weighted MRI (88% *vs* 70%). Bruegel *et al*^[35] compared respiratory DWI-EPI with T2-TSE. They found a sensitivity and specificity for T2-TSE MRI of 45%-62% for unenhanced MRI and 88%-91% for DWI-EPI for lesions > 10 mm. When considering only small metastases < 10 mm, the differences between DWI and conventional MRI with and without contrast are even more pronounced: a sensitivity of 85% for DWI-EPI and 26%-44% for T2-TSE. Lesion detection on T2-TSE is hindered by low lesion to liver contrast and by the interfering bright signal from intrahepatic vessels. Lesion conspicuity with DWI is excellent and limitation

Table 2 Performance of DWI and conventional MRI in the detection of liver metastases *n* (%)

DWI RT (0, 500)	82	94			
SPIO MRI	66	90			

¹In this study, 2 observers reviewed the images. The given values in sensitivity, specificity and diagnostic accuracy refer to the separate results of both observers. PPV: Positive predictive value; NPV: Negative predictive value.

of the DWI sequence is predominantly referred to lesion characterization rather than to lesion detectability.

Nasu *et al*^[36] assessed the diagnostic accuracy of respiratory triggered DWI in combination with unenhanced MRI *vs* superparamagnetic iron oxide (SPIO)-enhanced imaging. On the basis of a receiver operator characteristic analysis (ROC), averaged over 3 observers, they found a sensitivity and specificity for SPIO-enhanced images of 66% and 90% and for DWI 82% and 94%, respectively.

Predicting response to therapy of primary and secondary liver malignancies by DWI

Tumor responses to chemotherapy and radiation therapy are conventionally assessed by measurement of percentage reduction in tumor size after chemotherapy. However, tumor size measurement on CT or MRI is insensitive to early treatment changes. Theoretically, DWI is sensitive to microenvironmental changes in tumors that occur after treatment. Studies on the predictive value of DWI in primary cancer demonstrated a strong negative correlation between mean pre-treatment ADC values and percentage size reduction of tumors after chemotherapy and chemoradiation. High pretreatment ADC values in tumors were associated with a poor response to chemotherapy^[37,38].

Koh *et al*^[37] showed that high pre-treatment ADC values in colorectal liver metastases were predictive of a poor response to oxaliplatin and 5-fluorouracil-based chemotherapy. They determined with ROC that a mean pretreatment ADC150-500 (ADC map with b-values 150 s/mm² and 500 s/mm²) of 1.69×10^{-3} mm²/s had 60% sensitivity and 100% specificity for identification of non-responding metastatic lesions. They found also a significant linear regression relation between mean ADC150-500 and percentage in tumor size reduction

after treatment. Responding tumors showed a significant increase in ADC values at the end of the treatment. Non-responding tumors and liver parenchyma did not show significant changes in ADC values. Cui *et al.*^[38] analyzed 87 liver metastases of colorectal and gastric origin in 23 patients. They also found significant lower ADC values in responding tumors than in non-responding ones. ADC increased in responding metastases, but not in non-responding ones. They found a weak correlation between tumor size reduction and pretreatment ADC values. The theoretical background for these findings is that higher ADC values are observed in necrotic tissue, and in tissue with loss of cell membrane integrity. When these changes are present before chemotherapy, it may indicate a more aggressive phenotype. Necrotic regions within a tumor are usually poorly perfused, resulting in less delivery of chemotherapeutic agents to these areas. Necrotic regions are also exposed to a more hypoxic and acidic environment, which diminishes the effect of chemotherapy. Necrosis in hepatic metastases is present in almost half of the cases. A possible explanation for non-responding tumors with lower ADC values may be the fact that necrosis is not always associated with high ADC values, especially in the case of coagulation necrosis without cell lysis or liquefaction. The increase in ADC values at the end of the treatment suggests a change from a more cellular pretreatment to a less cellular or necrotic phenotype.

Only one study assessed DWI in HCC treatment with sorafenib. Schraml *et al.*^[39] showed that ADC values with sorafenib, an angiogenesis inhibitor for treatment of HCC, actually showed a decrease instead of an increase. This may be a result of ischemia, induced by inhibition of angiogenesis. The extracellular volume is decreasing, leading to lower ADC values during treatment. They also often observed hemorrhage within the tumors (55%), which may contribute to a decrease in ADC. However, progression of HCC more than 3 mo after therapy was related to a decrease in ADC values. Only conventional MRI could differentiate between hemorrhage and tumor progression. Pre-treatment HCC had high ADC values, because of rich vascularization of the tumors. ADC changes early after chemotherapy seem to reflect the underlying mechanisms in tumor necrosis, most probably hemorrhagic, induced by the novel targeted agent sorafenib early after therapy and may indicate tumor reactivation in the later follow-up period.

DWI after locoregional treatment for liver tumors

Locoregional therapy for liver tumors is used in patients who are not eligible for surgery. The most commonly used local ablative therapies are radiofrequency ablation (RFA) and transcatheter arterial chemoembolization (TACE). The success of these procedures is determined by the rate of ablation site recurrences (ASR), i.e. tumor recurrence as result of incomplete ablation. Close and careful follow-up is needed in patients who underwent treatment by RFA and TACE to detect ASR at an early stage. Unfortunately, diagnostic management remains an issue in these patients,

because of difficulties in differentiating ASR from non-tumoral tissue changes after thermal therapy. Since DWI can provide information about molecular tissue characteristics, it may have an additional value in the evaluation and follow-up of local ablative therapies in patients with liver tumors.

There is one study which evaluated the time-related diffusion alterations after hepatic RFA with regard to potential diagnostic information for the detection of ASR. Schraml *et al.*^[40] reviewed 54 oncological patients treated by RFA for liver metastases from different origins. The ablation zone did not show significant alterations at different time points. Measurement of the ADC value of the entire ablation zone was not suitable for the detection of ASR, because locally changing ADC values were masked by the heterogeneous appearance of the entire ablation zone. Peripheral zones should be analyzed separately. An important technical limitation of ADC measurements after RFA is that the limited spatial resolution does not allow exact ROI positioning in the narrow peripheral rim. Viable tumors after RFA appeared as hyper-intense, and necrotic regions were recognized as hypointense areas on DWI. ASR showed significantly lower ADC values than the ablation zone and normal liver parenchyma ($1.02 \times 10^{-3} \text{ mm}^2/\text{s}$ vs $1.31 \times 10^{-3} \text{ mm}^2/\text{s}$). Suspected areas on DWI were more easily identified and analyzed in conjunction to conventional MR. Signal alterations in the periphery, especially ones with lower ADC values should raise suspicion on ASR. Edema, inflammation, fibrosis and necrosis are associated with higher ADC values. DWI together with conventional imaging is a promising tool in the evaluation of the post-RFA liver and may contribute to the detection of ASR.

The use of DWI after TACE in HCC has recently been investigated. Goshima *et al.*^[41] reported significant increases in ADC values after TACE, but they varied widely and did not contribute to the accurate diagnosis of tumor necrosis by any cut-off points. Yu *et al.*^[42] found that DWI added to conventional MRI could increase the sensitivity for determining ASR especially in the case of atypical lesions. However, they also noticed an increase in the number of false positive findings by adding DWI which affected the overall accuracy of MRI. This was caused by perilesional inflammation and arterial reperfusion of the perilesional atrophic area after TACE. ADC measurement was not helpful for distinguishing viable tumors from perilesional nontumorous changes, since there was great overlap between the ADC values of both entities.

CONCLUSION

DWI in the liver is a relative new and increasingly used imaging technique in addition to conventional unenhanced and contrast enhanced MRI. DWI proved to be helpful in the characterization of focal liver lesions, but should always be used in conjunction with traditional MRI since there is great overlap between ADC values of benign and malignant lesions. DWI is useful in the detection of

small HCC in the cirrhotic liver, with higher sensitivity, specificity and positive predictive value compared to conventional contrast enhanced imaging due to better lesion to liver contrast and background suppression of signals arising from vessels and bile ducts. This is also the case for the detection of metastases in the liver. However, it should be noted that DWI images are difficult to interpret since DWI is very sensitive to artifacts. It seems reasonable to use DWI in conjunction to conventional imaging. DWI is not yet commonly used in the follow-up after treatment of liver malignancies. Pre-treatment ADC values in tumors treated with chemotherapy seem to be useful in the prediction and evaluation of the treatment response of primary and secondary liver malignancies. DWI in the follow-up after RFA and TACE shows promising results in the detection of ablation site recurrences, especially in combination with conventional contrast enhanced imaging.

Abstract

This review provides an overview of the current state of the art of magnetic resonance spectroscopy (MRS) in *in vivo* investigations of diffuse liver disease. So far, MRS of the human liver *in vivo* has mainly been used as a research tool rather than a clinical tool. The liver is particularly suitable for static and dynamic metabolic studies due to its high metabolic activity. Furthermore, its relatively superficial position allows excellent MRS localization, while its large volume allows detection of signals with relatively low intensity. This review describes the application of MRS to study the metabolic consequences of different conditions including diffuse and chronic liver diseases, congenital diseases, diabetes, and the presence of a distant malignancy on hepatic metabolism. In addition, future prospects of MRS are discussed. It is anticipated that future technical developments such as clinical MRS magnets with higher field strength (3 T) and improved delineation of multi-component signals such as phosphomonoester and

phosphodiester using proton decoupling, especially if combined with price reductions for stable isotope tracers, will lead to intensified research into metabolic syndrome, cardiovascular disease, hepato-biliary diseases, as well as non-metastatic liver metabolism in patients with a distant malignant tumor.

Magnetic resonance spectroscopy to study hepatic metabolism in diffuse liver diseases, diabetes and cancer. *World J Gastroenterol* 2010; 16(13): 1577-1586 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i13/1577.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i13.1577>

INTRODUCTION

The liver is a particularly suitable and interesting organ for metabolic studies as it plays a central role in intermediary metabolism, has a high metabolic activity with rapid response to metabolic insults, and is profoundly altered in acute and chronic diseases. Magnetic resonance spectroscopy (MRS) has been established as a non-invasive technique to study cellular biochemistry and metabolism, both at high magnetic strengths *in vitro* and in the whole body *in vivo* at field strengths of up to 3 T.

MRS has a number of important advantages over conventional approaches when studying metabolism in diffuse liver disease in humans. The non-invasive character of the technique allows valid assessment of the metabolic profile of many hepatic metabolites *in vivo* which cannot

be accurately measured using invasive biopsy techniques, due to the instability of these compounds and the invasiveness of biopsies. In addition, the non-destructive character of MRS, combined with the large hepatic blood flow, allows repeated measurements over time in the same subject, facilitating long-term longitudinal (observational/intervention) studies as well as short-term dynamic metabolic intervention studies with real-time monitoring of biochemical or metabolic alterations after a meal or an oral or intravenous metabolic challenge by nutrients (sugars, amino acids, lipids), hormones *etc.* Moreover, the technique can be complemented by dynamic stable isotope tracer studies, allowing the simultaneous assessment of hepatic metabolite concentrations by MRS and turnover measurements in plasma. Of note, although challenge techniques are also used in clinical practice for diagnostic purposes, for instance, to diagnose inherited metabolic errors of metabolism, MRS of the human liver *in vivo* has so far mainly been used as a research tool rather than a clinical tool.

However, one limitation of MRS studies is that only compounds present at mmol/L concentrations can be detected, due to the low inherent sensitivity of the MR signal *in vivo*.

The liver is a particularly suitable and interesting organ for metabolic studies for a number of reasons: first, it plays a central role in intermediary metabolism, has a high metabolic activity with a rapid response to metabolic insults, and is profoundly altered in acute and chronic diseases. Second, its superficial location in the right upper abdomen, covered only by a thin layer of skin, adipose tissue and muscle, allows excellent MRS localization using a double-tuned surface coil, by different localization techniques such as chemical shift imaging (spectroscopic imaging, CSI/SI)^[1-3] and image-selected *in vivo* spectroscopy (ISIS)^[4,5]. Third, the relatively large volume of the liver allows the detection of signals with relatively low intensity in volumes of up to 1 L; of note, for the study of diffuse liver disease, the inherent low spatial resolution of MRS does not play a restrictive role.

Different nuclei such as ³¹P, ¹H, ¹³C and ¹⁹F have been applied in studies of diffuse liver disease. So far, ¹H MRS has mainly been applied to detect hepatic lipid levels, ³¹P MRS to investigate intracellular energy metabolism, phospholipid metabolism and gluconeogenesis, and ¹³C MRS to study liver lipid and glycogen metabolism. ¹H and ³¹P are naturally abundant isotopes, whereas ¹³C represents only 1% of total carbon (the majority being ¹²C). Therefore, in many ¹³C studies, investigators have infused ¹³C-labeled compounds to increase the MR signal in dynamic metabolic studies.

The present review provides an overview of the current state of the art of MRS in *in vivo* investigations of diffuse liver disease. First, we discuss publications regarding the application of MRS to study diffuse and chronic liver diseases including cirrhosis, fibrosis and alcoholic liver disease, followed by the application of MRS in congenital diseases and pediatrics. We then discuss the

application of MRS to study the metabolic involvement of the liver in diseases, such as diabetes or the presence of a malignant tumor elsewhere in the body. Finally, future prospects including potential clinical applications of MRS are discussed.

From the present review, we excluded T2 and MRS studies on liver iron and fat content as well as *in vitro* applications of MRS in hepato-biliary disease^[6,7], as well as MRS studies of focal liver diseases such as secondary liver tumors, lymphomas and adenomas, and transplantation. We also excluded ¹⁹F MRS studies of metabolites of fluorinated chemotherapeutic drugs such as 5-FU and capecitabine^[8].

MRS IN DIFFUSE AND CHRONIC LIVER DISEASE

Over the last two decades, the usefulness of ³¹P MRS for the diagnosis of liver disease has been investigated as a non-invasive alternative to liver biopsy, which is still the gold standard and carries significant morbidity^[9]. The *in vivo* spectra of the human liver reflect metabolic and biochemical alterations in disease. Several publications on liver functionality have addressed spectral changes related to the underlying liver disease. However, in order to be helpful as a diagnostic tool, MR spectra should provide both sensitive and specific information for different types of liver disease, such as hepatitis, steatosis, fibrosis or cirrhosis.

The ³¹P MRS spectrum provides information on phosphorylated compounds of hepatic metabolism: alpha-, beta- and gamma peaks of nucleotide triphosphates (NTP), inorganic phosphate (Pi), phosphomonoesters (PME) and phosphodiester (PDE). The NTP, PME and PDE peaks are multicomponent and individual resonances of their components cannot be distinguished by the majority of techniques currently used. PME reflects components from glucose metabolism (gluconeogenesis and glycolysis) and cell membrane precursors such as phosphoethanolamine (PE) and phosphocholine (PC)^[10]. The majority of the NTP resonance contains ATP components; below, we will use ATP and NTP as synonyms, following the nomenclature of the cited publications. The PDE peak contains information on cell membrane breakdown products, such as glycerophosphorylethanolamine (GPE) and glycerophosphorylcholine (GPC), and endoplasmic reticulum^[11].

The diagnostic value of ³¹P MRS for various types of diffuse liver disease has been investigated in several studies. Overall, diffuse liver disease was associated with increasing levels of PME and decreasing levels of PDE. These changes have been attributed to hepatocyte damage, increased phospholipid turnover in hepatocyte membranes, and/or altered glucose metabolism. In general, the magnitude of MRS changes increased significantly with increased disease severity and increased functional impairment.

In one of the earliest reports^[12], liver metabolite concentrations were studied in 24 patients with various types of diffuse liver disease as compared to healthy control subjects. The authors reported high PME and low PDE levels in patients with acute viral hepatitis, high PME levels in patients with alcoholic hepatitis, and decreased Pi and Pi/ATP ratios in primary biliary cirrhosis and in some patients with hepatitis^[12]. However, they noted that these changes were not present in all patients.

Cox *et al.*^[11] studied 49 patients with liver disease of varying etiology, including 25 patients with diffuse liver disease such as cirrhosis and non-hepatic malignancies. A non-specific elevation in PME/PDE was observed in the ³¹P MR spectra of 10 (40%) out of these 25 patients with mixed diffuse liver disease. Even though the spectral pattern did not distinguish between diseases of varying etiologies, there was a linear correlation between increasing PME/PDE and a reduction in plasma albumin concentrations ($P = 0.03$).

Subsequent MRS studies showed elevated PME/NTP levels compared to healthy controls in patient populations with primary biliary cirrhosis^[13] and compensated/decompensated cirrhosis of various etiology^[14]. Jalan *et al.*^[13] studied 23 patients with primary biliary cirrhosis of varying functional severity and healthy subjects using ³¹P MRS. PME/NTP, Pi/NTP, PME/PDE, and PME/Pi ratios were higher and PDE/NTP ratios significantly lower in patients compared with healthy volunteers. Significant correlations were seen between PME/Pi ratios and prognostic indicators such as the Christensen index, the Mayo R value, and the Pugh score.

Taylor-Robinson *et al.*^[14] compared 14 patients with compensated cirrhosis (Pugh's score ≤ 7) and 17 with decompensated cirrhosis (Pugh's score ≥ 8) of various etiology with healthy subjects. Worsening liver function was associated with increased PME/NTP and decreased PDE/NTP ratios. In freeze-clamped tissue, elevated PE and PC, and reduced GPE and GPC mirrored these *in vivo* changes, but no distinction was noted between compensated and decompensated cirrhosis. In contrast, electron microscopy showed that functional decompensation was associated with reduced endoplasmic reticulum (ER) in parenchymal liver disease, but elevated ER in biliary cirrhosis. In a more recent study in only 14 cirrhotic subjects^[15], reduced ATP and elevated PME/PDE levels were detected in patients with decompensated cirrhosis only.

The capability of ³¹P MRS to detect pathological processes was further investigated by comparing *in vivo* MRS results with histological samples. In 38 patients with various types of diffuse liver disease, van Wassenae-van Hall *et al.*^[5] showed that the degree of elevation of PME/Ptotal in individual patients was significantly correlated with necrosis, intralobular degeneration, and portal inflammation scorings in liver biopsies^[5], but not with fibrosis. However, ³¹P MRS was not able to classify patients into diagnostic categories, such as fibrosis *vs* cirrhosis, and no diagnostic value of MRS was found with respect to steatosis and cholangitis.

Dezortova *et al.*^[16] studied 80 patients with liver cirrhosis of different etiology and functional status, described by Child-Pugh score, and a control group of healthy subjects. Patients with both alcoholic and viral etiology had lower absolute PDE and ATP levels than healthy subjects. Patients with alcoholic etiology, but not viral etiology, also had lower Pi levels than controls. Patients with cholestatic disease had elevated PDE levels. Thus, these authors were able to distinguish alcoholic, viral and cholestatic etiologies of liver cirrhosis based on MR spectra.

Noren *et al.*^[17] studied patients with non-alcoholic fatty liver disease (NAFLD) and none to moderate inflammation ($n = 13$), patients with severe fibrosis or cirrhosis ($n = 16$), and healthy controls. All patients underwent liver biopsy and extensive biochemical evaluation. Absolute concentrations and the anabolic charge (AC), defined as $(PME)/[(PME)+(PDE)]$, were calculated. AC was increased and PDE reduced in the cirrhotic group relative to healthy subjects, whereas NAFLD patients showed values similar to controls. Using a PDE concentration of 10.5 mmol/L as a cut-off value to discriminate between mild, (F0-2) and advanced (F3-4) fibrosis, the sensitivity and specificity of PDE were 81% and 69%, respectively. AC, using a cut-off value of 0.27, showed a sensitivity of 93% and a specificity of 54%. The authors concluded that PDE is a potential marker of liver fibrosis, whereas AC is a potentially clinically useful parameter discriminating mild from advanced fibrosis.

Interestingly, few authors have performed dynamic ³¹P MRS studies with a metabolic challenge, in contrast with diabetes and cancer (see below). In healthy subjects, it is well known that fructose infusion induces a rapid rise in PME and marked reductions in ATP and Pi^[3,18,19]. An early Japanese study^[20] evaluated changes in the metabolic state of the liver after an intravenous fructose load (250 mg/kg) in six patients with liver cirrhosis and eight healthy volunteers. The cirrhotic livers did not show the usual increase in PME after the fructose load, suggesting that fructose metabolism in the cirrhotic livers had impediments before the fructose-1-phosphate stage. Furthermore, the spectra of the cirrhotic livers showed a significant drop in Pi, PDE and ATP peak after the fructose challenge. Dufour and colleagues^[21] studied nine patients with nonalcoholic cirrhosis. Fructose (250 mg/kg) was injected intravenously, and further spectra were collected sequentially every 6 min for 1 h. PME formation and utilization of Pi were markedly attenuated in cirrhotic patients; these measures correlated with the impairment of liver function as measured by galactose-elimination capacity^[21].

In summary, the general observation in cirrhosis and fibrosis is an increase in PME, often combined with reductions in PDE and ATP. Of note, the observed changes were correlated with classical markers such as Pugh score and plasma albumin. However, ³¹P MRS was not able to classify patients into diagnostic categories, such as fibrosis *vs* cirrhosis, and no diagnostic value of MRS was found with respect to steatosis and cholangitis.

An intravenous fructose load induced a rapid rise in PME and reductions in ATP and Pi.

VIRAL HEPATITIS AND HIV

A study of 26 patients with an acute viral hepatitis A infection showed increased PME/PDE ratios^[22]. After 6 wk of recovery, these abnormalities in liver metabolites were restored to normal levels, as reflected by decreasing PME and increasing PDE^[22].

Lim and colleagues^[9] used ³¹P MRS to assess disease severity in 48 patients with hepatitis C virus (HCV)-related liver disease. Worse liver function was correlated with an *in vivo* elevation in PME and decrease in PDE. PME/PDE ratios showed an increase from control (0.15), *via* mild disease (0.18) and moderate disease (0.25), to the cirrhosis group (0.38). An 80% sensitivity and specificity was achieved when using a PME/PDE ratio less than or equal to 0.2 to denote mild hepatitis and a corresponding ratio greater than or equal to 0.3 to denote cirrhosis^[9]. In a subsequent study^[23], the same authors applied ³¹P MRS to prospectively study 47 patients with biopsy-proven hepatitis C undergoing viral eradication treatment with interferon and ribavirin at 6-mo intervals over a total period of 6-18 mo. In 25 out of 32 patients with virological response to HCV treatment, this was accompanied by decreasing PME/PDE ratios over time, whereas in 15 patients without virological response, PME/PDE ratios increased^[23], suggesting that PME and PDE can be used to monitor treatment response to HCV.

Elevated levels of PME were also observed in a study of 75 chronic hepatitis B and C infected patients using ¹H-MRS^[24]. In addition, compared to healthy control subjects, glutamine/glutamate and glycogen/glucose resonances were increased, whereas lipids were decreased^[24]. As in studies using ³¹P MRS, increases in metabolite levels were correlated with disease severity^[24]. In a study in patients with hepatitis C virus infection (HCV, *n* = 14) and 20 HIV/HCV co-infected individuals^[25], a significant increase in glutamine/glutamate and PME, both measured relative to hepatic lipid levels, was observed in both groups when compared with healthy individuals. These changes in metabolite ratios were attributed to an increase in the particular metabolite contents and a decrease in lipid levels. HIV/HCV-infected patients treated with anti-retroviral therapy showed elevated PME and glutamine/glutamate levels and decreased total lipid levels compared to patients not undergoing anti-retroviral treatment^[25]. The authors concluded that ¹H-MRS could be used to detect even slight alterations in hepatic metabolite ratios in this type of patient.

Orlacchio *et al*^[26] also applied ¹H-MRS but used the water signal as a reference instead of the lipid signal. These authors studied 23 patients with biopsy-proven precirrhotic HCV-related liver disease, graded by the Ishak fibrosis (F) scoring system. Similar to the previous studies, increasing disease severity correlated with a significant increase in choline-containing compounds and glutamine/glutamate. In contrast, lipid levels in this study were found

to be increased in patients relative to healthy subjects^[26].

In summary, ³¹P MRS studies have demonstrated that PME/PDE ratios in viral hepatitis are increased, and normalization of PME/PDE over time correlates with treatment effectiveness. ¹H MRS studies showed increased glutamine/glutamate and glycogen/glucose resonances. The observation of either increased or decreased lipid resonances in different studies requires further investigation.

ALCOHOL ABUSE

Although the above data show that different ³¹P MRS studies have demonstrated elevated PME/NTP levels in patient populations with alcoholic liver disease compared to healthy subjects, there are few reports on the effects of alcohol abuse and alcohol abstinence *per se*. Menon *et al*^[27] studied 26 chronic alcohol abusers by ³¹P MRS 6-12 h after their last alcoholic drink and following abstinence from alcohol. Results showed that in patients with minimal liver injury, recent drinking was associated with a significant elevation in PDE/ATP and a non-significant rise in PME/ATP, and abstinence with normalization of both metabolite ratios. In contrast, in patients with alcoholic cirrhosis, recent drinking was associated with a significant elevation in mean PME/ATP and a non-significant increase in PDE/ATP, whereas abstinence was associated with no significant change in PME/ATP but with a reduction in PDE/ATP. The authors suggested that the changes in PDE/ATP most likely reflected the induction of hepatocyte ER.

In summary, recent alcohol consumption is associated with elevated PME and PDE. In patients with minimal liver injury, both metabolites are normalized during abstinence; in contrast, in patients with cirrhosis, only PDE is normalized during alcohol abstinence.

OTHER LIVER DISEASES

Several studies have been performed on acute poisoning, inherited diseases and pediatrics using ³¹P MRS. A study in 18 patients after acetaminophen overdose showed that liver metabolites including PME, PDE and ATP, were all dramatically decreased with increasing liver damage expressed as the international normalized ratio (INR) of prothrombin^[28]. Repeated MRS measurements in the same patients would be particularly valuable to see whether improvement in liver damage could also be confirmed by ³¹P MRS.

The presence of hemolysis, elevated liver enzymes and low platelets in pregnant women (HELLP syndrome) can be associated with disturbed hepatic metabolism. To investigate whether or not women with HELLP syndrome have detectable abnormalities of hepatic energetics, Magee *et al*^[29] studied seven patients with HELLP syndrome. One pregnancy was later terminated but the other women gave birth to healthy infants. One patient with the most clinically severe HELLP syndrome by laboratory criteria exhibited MR spectra which showed a relative increase in phosphomonoester and an absolute decrease in hepatic

ATP (to 62% of control)^[29]. Most patients with HELLP syndrome had normal liver metabolism as assessed by MRS, although these results show that clinically severe HELLP syndrome can be associated with disturbed hepatic metabolism consistent with that seen in hepatic ischemia and/or granulocytic infiltration of the liver.

In ten patients with severe hypothyroidism, prospective ³¹P MRS measurements before and after thyroid hormone treatment were performed. In contrast with striated muscle, which showed a marked normalization of phosphocreatine/Pi ratios within several weeks of thyroid treatment, no changes in hepatic metabolism during treatment were detected by ³¹P MRS^[30].

In a single patient with amyloid light chain (AL) amyloidosis, hepatic ¹H MR spectra were characterized by small line widths, a striking increase in trimethylammonium compounds, and the presence of a further resonance at 3.8 ppm^[31]. None of the healthy control subjects showed trimethylammonium levels of comparable intensity^[31].

Changes in liver metabolites in inherited liver diseases have been reported using ³¹P MRS. In a report by Dixon *et al.*^[32] on an infant with galactosemia, these authors showed increased levels of galactose-1-phosphate in the liver which decreased during diet therapy, paralleling the falling level of galactose-1-phosphate in red blood cells.

Elevated plasma uric acid concentrations (hyperuricemia), which are a characteristic feature in gout patients, may be caused by altered liver fructose metabolism. As hereditary fructose intolerance is known to be associated with hyperuricemia, this concept has been used in ³¹P MRS studies^[33-35]. The effect of a fructose challenge on liver metabolism was studied by ³¹P MRS in five patients with hereditary fructose intolerance (HFI) and eight heterozygotes for HFI^[33]. In patients with HFI, ingestion of small amounts of fructose was followed by an increase in sugar phosphates (PME) and a decrease in Pi in hepatic ³¹P MR spectra, combined with a rise in plasma uric acid. ³¹P MRS could be used to diagnose fructose intolerance in heterozygotes. Oral fructose (50 g) also led to sugar phosphate accumulation and Pi depletion in the liver, which was associated with a larger increase in plasma uric acid than in control subjects. The effect of fructose on liver Pi and plasma uric acid was most pronounced in heterozygotes with gout ($n = 3$). In a subsequent study in 18 additional subjects from different families with familial gout^[34], the authors demonstrated a positive association between response in ³¹P MR spectra (i.e. increase in PME, decrease in Pi) and response in serum uric acid after oral glucose, suggesting ³¹P MRS as a method for initial screening of this defect.

Limited MRS data are available in the pediatric population. Nevertheless, ³¹P MR spectra of infants have been compared with adult spectra in an attempt to investigate changes in hepatic metabolism with age^[36]. Spectra from three infants showed that PME/ATP levels were markedly higher than in adults, whereas PDE/ATP levels were decreased when compared with adults. Spectral hepatic concentrations of a single adolescent studied were

intermediary between the neonates and the adults. The authors hypothesized that this indicated an increased rate of membrane synthesis in the infant livers, and concluded that these differences should be taken into account when comparing studies using varying ages^[36].

In summary, a considerable amount of data on the use of MRS for the study of liver metabolism in disease is currently available, although most studies were performed in relatively small groups. Static measurements mainly reveal alterations in relative PME and/or PDE concentrations as compared to healthy controls. In contrast, dynamic applications of the MRS technique to obtain information during a challenge have remained limited to date. Challenge tests will be discussed in more detail in the following sections.

LIVER METABOLISM IN PATIENTS WITH DIABETES

Impairment of hypoglycemic counterregulation, which occurs even in intensively treated type diabetes, has traditionally been attributed to deficits in counterregulatory hormone secretion in type I diabetes, and to impaired hormone sensitivity of target organs in type II diabetes. In the normal fed state, the liver takes up glucose for energy production (*via* glycolysis and TCA cycle) and stores excess energy as glycogen, whereas in the fasted state, the liver releases glucose produced from glycogen and *via* gluconeogenesis; in fact, the liver is almost exclusively responsible for endogenous glucose production (EGP). After a glucose load, liver glycogen can be synthesized both directly from glucose (*via* glucose-6P, glucose-1P and UDP-glucose) and indirectly from 3 carbon units (*via* phosphoenolpyruvate-glucose-6P *etc.*). ¹³C MRS, either at natural abundance or combined with ¹³C tracer infusion, provides a tool to study glycogen content in the liver and thus, in dynamic studies, net glycogen synthesis and breakdown over time. Moreover, combined with turnover measurements using deuterated glucose tracer infusions and measurement of isotopic enrichment of UDP-glucose using acetaminophen (measured as acetaminophen glucuronide in plasma/urine) allows an estimation of relative contributions of the direct and indirect pathways of glycogen synthesis. Noninvasive sampling of hepatic glutamine pools by oral administration of phenylacetate allows simultaneous estimation of the contribution of pyruvate oxidation to the TCA cycle flux^[37].

Over the past decades, ¹³C MRS studies have significantly contributed to the notion that the liver plays a critical role in the derangements of plasma glucose regulation in both type I and type II diabetes. Most MRS studies to date have been performed in diabetes type I. To determine alterations in the direct and indirect pathways of glycogen synthesis in diabetes, Cline and coworkers^[37] studied subjects with poorly controlled diabetes type I using a 5 h hyperglycemic-hyperinsulinemic clamp (plasma glucose: 9 mmol/L, insulin: 400 pmol/L) and [1-¹³C]-glucose. Hepatic pools of UDP-glucose and glutamine

were noninvasively sampled by oral administration of acetaminophen and phenylacetate, respectively. Although total hepatic glycogen synthesis was similar in both groups, the flux through the indirect (gluconeogenic) pathway was found to be proportionately about twice as active in the diabetic subjects compared to the control subjects. Moreover, the relative contribution of pyruvate oxidation to the TCA cycle flux in diabetic subjects was decreased by circa 30%, indicating reduced glycolysis. The abnormalities were not immediately reversed by normalizing intraportal concentrations of glucose, insulin and glucagon, and might contribute to postprandial hyperglycemia.

Hwang *et al.*^[38] studied poorly controlled diabetes type I patients and weight-matched control subjects during a day in which three isocaloric mixed meals were ingested. Although fasting hepatic glycogen levels were identical in the two groups, the diabetic subjects synthesized less glycogen over the day than healthy subjects. Again, the flux through the gluconeogenic pathway relative to the direct pathway of glycogen synthesis was markedly reduced in diabetic subjects.

Bischof *et al.*^[39] studied poorly controlled diabetes type I patients (HbA1C: 8.8% and matched non-diabetic subjects (HbA1C: 5.5%) in an experiment over 24 h with 3 isocaloric mixed meals. Over 24 h, the mean plasma glucose concentration was 2.4-fold higher in diabetic subjects. Net liver glycogen synthesis and breakdown were calculated from linear regression of the glycogen concentration time curves from 19:30-22:30, and 22:30-8:00, respectively. Glycogen synthesis was reduced by 74% and glycogen breakdown by 47%, and both were partly but not completely normalized by intensified insulin treatment.

In a subsequent study in long-term well-controlled diabetes type I patients, Bischof *et al.*^[40], showed that tight glycemic control in diabetes type I patients normalized overall glycogen synthesis and breakdown as well as glucose production. However, the relative contribution of the indirect pathway of glycogen synthesis remained elevated in diabetic subjects, a finding which indicated augmented gluconeogenesis in type I diabetic patients, which would be consistent with experimental models showing increased PEP-carboxykinase and/or reduced glucokinase activity in the liver of diabetic animals.

Also, in 6 to 12-year-old children with diabetes type I^[41], the capacity to replenish hepatic glycogen after an overnight fast was at least as good as in age-matched healthy children.

Kishore *et al.*^[42] compared the hepatic response to hypoglycemia in well-controlled type I diabetes patients and healthy subjects. In the overnight fasted state, diabetes type I patients had decreased hepatic glycogen levels compared to controls. In insulin-induced hypoglycemia, the normal response of glycogenolysis observed in healthy subjects was virtually absent in diabetic subjects.

Type II diabetes patients were studied by Magnusson *et al.*^[43], who compared seven diabetic (mean duration 13 years) and five healthy subjects matched for age and body mass index (BMI) during 23 h of fasting after an initial liquid meal. Oral medication with sulfonylurea agents (n

= 5) was discontinued 3 d before the study and insulin treatment ($n = 2$) was discontinued the evening before the study. Blood glucose levels in the diabetic subjects were consistently higher throughout the experiment. Four hours after the meal, hepatic glycogen levels in diabetic subjects were < 50% of those in control subjects. During the subsequent fasting period, glycogen breakdown was reduced in diabetic subjects; instead, their rate of gluconeogenesis was markedly increased, resulting in a circa 20% overall increase in glucose output compared to healthy subjects.

Krassak and colleagues^[44] studied hepatic glycogen synthesis, glycogen breakdown and gluconeogenesis in patients with type II diabetes (mean duration 6 years) and age- and weight-matched healthy subjects before and after a mixed meal. Hepatic glycogen concentrations were lower in diabetic patients before and after dinner, and post-meal glycogen synthesis was reduced by circa 44%. Overnight, rates of glycogenolysis were also circa 50% lower in diabetic patients than controls. Endogenous glucose production was elevated in diabetic patients before dinner and remained so for 3 h after dinner; also, the nadir of glucose production was delayed in diabetic patients (240 min *vs* 60-90 min); thereafter, glucose production in patients and controls was similar. At 6-9 h after dinner, gluconeogenesis amounted to 67% of EGP in diabetic patients *vs* 43% in controls.

During a subsequent hyperglycemic-hyperinsulinemic clamp, glycogen synthesis was circa 46% lower in diabetic patients, with a similar contribution from the direct and indirect pathways. Glycogen breakdown was similar, resulting in circa 54% lower net glycogen synthesis. EGP was circa 30% elevated in diabetic patients both before and during the clamp. Hepatocellular lipid content was three times higher in type II diabetic patients and negatively correlated with rates of net glycogen synthesis and whole-body glucose uptake during the clamp test (which was circa 37% reduced in diabetic patients)^[44]. Petersen *et al.*^[45] demonstrated that an average weight loss of 8 kg in type II diabetic patients over a period of 7 wk led to normalization of plasma glucose concentrations as well as hepatic glycogenolysis, glucose production and gluconeogenesis, indicating marked restoration of hepatic insulin sensitivity. These changes were associated with a reduction in hepatic lipid content from 12% to 3%, whereas muscle lipid content and muscle insulin resistance remained unchanged^[45].

In summary, the presence of marked alterations in hepatic glucose and glycogen metabolism in type I and type II diabetes has been substantiated by ¹³C MRS in combination with isotope tracer studies. When compared with non-diabetic humans, both patients with type I and type II diabetes exhibit elevated endogenous glucose production by increased gluconeogenesis, combined with reduced glycogen synthesis and breakdown. In type I diabetes, this defect can be partly restored by combined long- and short-term optimized treatment with insulin. In contrast, in type II diabetes, increased gluconeogenesis appears to be the main cause of elevated glucose

production and fasting hyperglycemia, and it is normalized by weight reduction.

LIVER METABOLISM IN PATIENTS WITH A DISTANT MALIGNANT TUMOUR

The cancer-bearing state is generally associated with profound alterations in host metabolism. Many patients lose weight due to decreasing fat and muscle mass, a condition known as cancer cachexia, which not only leads to functional decline but is also an important predictor of poor prognosis. Although cancer cachexia is partly caused by decreased appetite, altered metabolism in host organs such as liver and muscle are now thought to play a major role in the pathogenesis of the condition. So far, most studies have concentrated on experimental animal models of cancer cachexia. To further explore the role of altered liver metabolism in the etiology of cancer cachexia in humans, Dagnelie *et al.*^[46] and Leij-Halfwerk *et al.*^[47-51] performed a series of studies in patients with advanced lung and breast cancer. Importantly, patients were only included if they were free of liver metastases, as confirmed by CT and/or ultrasound. In all studies, weight-stable and weight-losing cancer patients were compared with healthy subjects. Dietary energy intake was similar in all subjects, and all spectra were acquired in the overnight-fasted state. Since ATP peak areas differed between patients and controls, total phosphorous content of the liver (which was demonstrated to be stable) was used as a reference.

In one study, ATP peak areas were significantly reduced in both weight-stable (WS) and weight-losing (WL) cancer patients^[46]; in the second study, the reduction was only statistically significant in WL but not WS cancer patients^[47]. During a 90-min infusion of 2.8 mmol/kg per minute of the gluconeogenic amino acid alanine, liver ATP levels decreased in healthy subjects and patients to a similar extent for 60 min; however, from 60-90 min, ATP levels in WS cancer patients and healthy subjects recovered to baseline values despite continued infusion, but further decreased in WL patients, indicating impaired ATP recovery^[47]. Intravenous infusion of ATP at 75 µg/kg per minute over 24 h induced complete normalization of liver ATP levels both in WL and WS patients to levels similar to healthy subjects^[51].

As shown in Figure 1, baseline PME values in the liver were markedly increased in WL cancer patients relative to WS patients and healthy controls, due to increased glucose cycling and gluconeogenesis as indicated by both the observed downfield alteration of the PME chemical shift^[46] and the significant correlation of PME levels with glucose turnover and gluconeogenesis from alanine^[49]. Baseline alanine turnover as measured by tracer techniques was elevated in WL cancer patients, but not in WS patients^[48]. L-alanine infusion induced a steady 33% rise in PME in healthy subjects (Figure 1). In WS cancer patients, a markedly faster and higher (i.e. 69%) response of PME to alanine infusion was observed, whereas WL patients showed virtually no further rise in PME (7%) relative to their already elevated baseline PME levels (Figure 1)^[48].

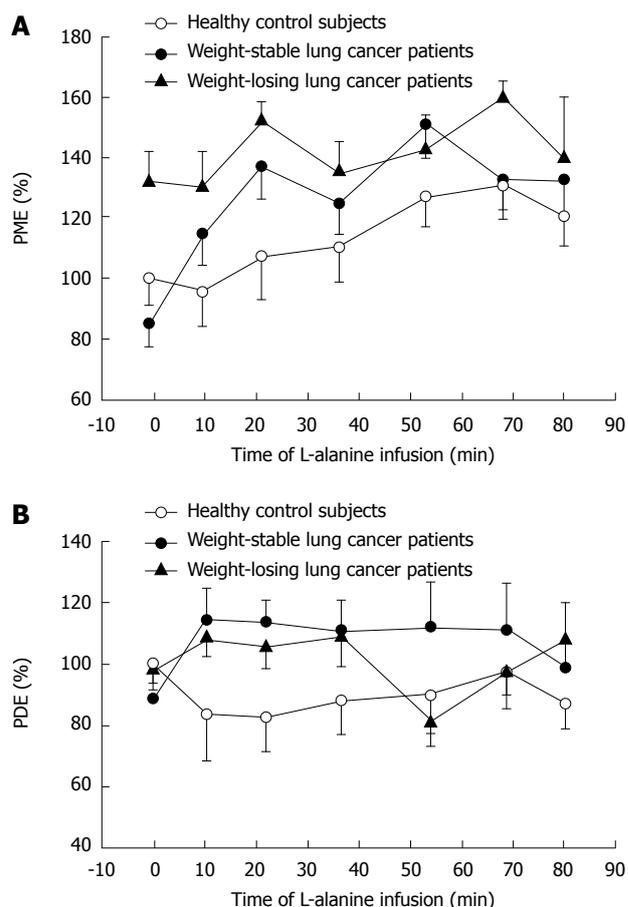

Figure 1 PME (A) and PDE (B) concentrations in the liver of healthy control subjects ($n = 9$) as well as weight-stable ($n = 10$) and weight-losing ($n = 7$) lung cancer patients during a primed-constant infusion of L-alanine (initial priming, 1.4-2.8 mmol/kg; infusion, 2.8 mmol/kg per hour). Curves represent means; bars, SE. Values are expressed as percentage of mean baseline value of healthy subjects (100%). Times during L-alanine infusion are mid-time points of ^31P MRS data collection referenced to the start of the L-alanine infusion (0 = baseline). From^[50], with permission.

In cancer patients, but not in healthy subjects, the rise in PME levels during alanine infusion was strongly inversely correlated with baseline PME ($r = -0.82$). Liver intracellular pH increased in the order: healthy < cancer-WS < cancer-WL^[46], suggesting that the host liver may have a similar intra-extracellular pH gradient as reported for cancerous tissue^[52-55].

In summary, using ^31P MRS, marked alterations in hepatic glucose metabolism were demonstrated in the non-metastatic liver of cancer patients, as shown by elevated hepatic concentrations of gluconeogenic intermediates in the overnight-fasted state, as well as during infusion of a gluconeogenic challenge. Of note, the rapid response of the PME peak to alanine infusion demonstrated rapid induction of the gluconeogenic pathway in WS cancer patients, corroborating the power of MRS as a tool to detect enzymatic alterations within the liver.

DISCUSSION

So far, MRS has primarily been used as a research tool.

MRS *in vivo* allows rapid assessment of the metabolic profile and function, including alterations in liver metabolism and physiology under different conditions. Dynamic studies have so far mainly been performed in diabetes and cancer. The limitation of these studies is the relatively high cost of the equipment and, even more, the cost of ^{13}C enriched compounds which are infused to increase hepatic ^{13}C content and to directly monitor the signal increase of ^{13}C in different metabolites above the 1% natural abundance of ^{13}C . As high-field machines become more available in the next decades, it is expected that the application of ^{13}C MRS studies in the liver may continue. However, the possibilities of ^{31}P MRS have by no means been exhausted, as is shown by the dynamic studies demonstrating altered host liver metabolism in patients with a malignant tumor elsewhere in the body. As the studies in cancer and diabetes demonstrate, metabolic challenges such as carbohydrates (like as glucose and fructose), amino acids (such as alanine) and lipids are likely to yield substantial new knowledge in the near future.

Comparing individual papers investigating disease states is difficult as there is no overall standard for representation of data or methods. Interpretation of part of the studies in diffuse liver disease is hampered by the notion that healthy controls were not always matched for age, weight/body mass index (BMI), gender, *etc.*; often, healthy subjects were younger than patients. As it has been shown that these factors may impact the quality of the spectra^[56] and concentrations of metabolites^[56], attempts should be made to minimize their bias. Many studies showed substantial between-subject variability within patient and control groups, e.g. with regard to PME.

Another important issue is the difference in magnetic field strengths and techniques used in different studies with regard to spatial resolution and differences in repetition times (TR), which lead to T1 weighting. T1 weighting in quantification of metabolites in liver MRS studies has so far been relatively neglected^[2]. Each data acquisition step in MRS comprises a brief excitation of nuclei of interest by irradiation with non-ionizing radiofrequency energy, followed by measurement of the signal derived from relaxing nuclei in the tissue of interest. TR is defined as the time between two subsequent radiofrequency pulses. The full information is only derived when the nuclei of interest are allowed sufficient time to fully relax. T1 weighting occurs when a new radiofrequency pulse is administered before full relaxation of the nuclei of interest. Although depending on the pulse angle, a rule of thumb is that the applied TR must be circa 5 times T1 or longer in order to obtain fully relaxed spectra. Sijens *et al.*^[2], using chemical shift imaging with 1 D phase encoding for localized measurement of ^{31}P metabolites to measure a large liver voxel, showed that, with a pulse angle of 70° at TR 1 s, concentrations of liver metabolites are only 54%-84% of those at full relaxation (TR 50 s). Importantly, T1 relaxation times may change in disease: Dagnelie *et al.*^[46] showed ATP concentrations in WL-cancer patients to be reduced relative to healthy subjects at TR 5 s and TR 20 s, but not at TR 1 s. In a later study, Leij-Halfwerk *et al.*^[51]

showed that ATP infusion induced an increase in hepatic ATP levels at TR 15 s; however, this was not observed at TR 1 s (Leij-Halfwerk *et al.*, 2002, unpublished data). Thus, accurate assessment of changes in metabolite concentrations in different conditions is only possible if TR is chosen to be sufficiently long to allow a large degree of relaxation. As the measured MR signal becomes larger as TR increases, signal to noise ratios will improve, allowing a smaller number of acquisitions per phase encoding step, thereby relatively reducing measurement time. Thus, using 4 phase encoding steps, Sijens *et al.*^[2] showed the following number of acquisitions and measurement time at TR 1, 5 and 20 s, respectively: 60 (4:08 min), 20 (7:20 min), and 8 acquisitions (13:20 min).

What are the prospects for the clinical application of MRS in diffuse liver disease? For use as a diagnostic tool, not only high sensitivity and specificity at an individual patient levels are essential, but also practicality of application including patient burden and costing. These requests are most likely to be fulfilled in inherited diseases, where marked metabolic alterations are typical, however, for the majority of diseases, other, less invasive tools will remain methods of first choice. However, MRS may be an excellent tool for assessing disease severity and for monitoring disease progress or recuperation, as shown e.g. in diabetes^[45] and patients with primary biliary cirrhosis^[13].

Finally, altered findings in MRS may predict disease progression, weight loss or survival, and thus assist in the estimation of patients' prognosis. For instance, preliminary analyses (Leij-Halfwerk & Dagnelie, unpublished observations) demonstrated that elevated baseline PME levels in WS cancer patients predicted subsequent weight loss and shorter survival.

CONCLUSION

MRS of diffuse liver disease has given important new insight in a number of diseases, including inherited diseases, hepatitis, steatosis and cirrhosis. Importantly, MRS has also allowed new insights in metabolic derangements in non-liver diseases such as diabetes and non-liver cancer. Based on the progress achieved so far by MRS studies in diabetes, it is anticipated that future technical developments such as clinical MRS magnets with higher field strength (3 T) and improved delineation of multi-component signals such as PME and PDE using proton decoupling, especially if combined with price reductions for stable isotope tracers, will lead to intensified research into metabolic syndrome, cardiovascular disease, hepatobiliary diseases, as well as non-metastatic liver metabolism in patients with a distant malignant tumor.

Of note, there are also potential drawbacks: thus, tightening regulations related to preparing and administering compounds by intravenous infusion or orally threaten to make metabolic research extremely costly (or perhaps even impossible) in the near future: a development which could have dramatic negative consequences for scientific and clinical progress in the field.

Emphasis should be placed on the development of standards of the techniques used in order to be able to compare data and to obtain valid estimates of absolute metabolite concentrations. In order to allow MRS to compete with standards of care, efforts should be made to validate results in larger patient cohorts and to minimize bias in distinguishing diseased states from healthy states.

Abstract

Accurate evaluation of iron overload is necessary to establish the diagnosis of hemochromatosis and guide chelation treatment in transfusion-dependent anemia. The liver is the primary site for iron storage in patients with hemochromatosis or transfusion-dependent anemia, therefore, liver iron concentration (LIC) accurately reflects total body iron stores. In the past 20 years, magnetic resonance imaging (MRI) has emerged as a promising method for measuring LIC in a variety of diseases. We review the potential role of MRI in LIC determination in the most important disorders that are characterized by iron overload, that is, thalassemia major, other hemoglobinopathies, acquired anemia, and hemochromatosis. Most studies have been performed in thalassemia major and MRI is currently a widely accepted method for guiding chelation treatment in these patients. However, the lack of correlation between liver and cardiac iron stores suggests that both organs should be evaluated with MRI, since cardiac disease is the leading cause of death in this population. It is also unclear which MRI method is the most accurate since there are no large studies that have directly compared the different available techniques. The role of MRI in

the era of genetic diagnosis of hemochromatosis is also debated, whereas data on the accuracy of the method in other hematological and liver diseases are rather limited. However, MRI is a fast, non-invasive and relatively accurate diagnostic tool for assessing LIC, and its use is expected to increase as the role of iron in the pathogenesis of liver disease becomes clearer.

INTRODUCTION

Iron homeostasis in humans depends exclusively on the modulation of iron absorption since iron excretion is passive (by shedding of intestinal and skin cells, and additionally, in women by menstruation), and cannot be actively upregulated^[1]. Therefore, patients with excessive iron absorption (hemochromatosis) or with transfusion-dependent congenital or acquired anemia are at increased risk for developing iron overload^[1]. Excessive iron is toxic because it generates free radicals and induces oxidative stress^[2]. Iron overload can result in the development of diabetes and other endocrinopathies, liver cirrhosis and hepatocellular carcinoma (HCC), cardiomyopathy and

premature death in patients with thalassemia major^[3-6] and hemochromatosis^[7-10]. In turn, the management of iron overload with chelation therapy in thalassemia major^[11-14] and with phlebotomy in hemochromatosis reduces the risk of diabetes, liver and cardiac disease and death^[7-9].

The accurate evaluation of iron overload is necessary to establish the diagnosis of hemochromatosis and guide chelation treatment in transfusion-dependent anemia^[3,15-17]. Serum ferritin levels are not an accurate measure of total body iron stores, particularly in patients with high iron burden, because concurrent conditions, particularly inflammation and liver disease, increase these levels independently of iron burden^[16,18,19]. Serum iron, transferrin, transferrin saturation and transferrin receptor levels are also imprecise markers of body iron stores^[18]. The liver is the primary site for iron storage in patients with hemochromatosis or transfusion-dependent anemia, therefore, liver iron concentration (LIC) accurately reflects total body iron stores^[1,19,20]. Liver biopsy with measurement of iron concentration by atomic absorption spectroscopy is considered the gold standard for LIC assessment^[16]. However, hepatic iron distribution appears to be uneven, particularly when cirrhosis is present, but also in the absence of cirrhosis^[21-25]. In addition, liver biopsy is an invasive procedure and complications requiring hospitalization are observed in approximately 0.5% of patients with thalassemia major who undergo liver biopsy, even in experienced centers^[26]. The risks of liver biopsy also preclude repeated biopsies, which are necessary in patients with thalassemia major in order to adjust chelation treatment and avoid iron overload and chelation-associated toxicity^[3,16,17,19].

It is apparent that there is a pressing need for non-invasive methods that can provide accurate LIC measurements. Superconducting quantum interference devices (SQUIDS) has been used for this purpose, but appear to underestimate LIC and are available in only a few centers^[16]. In the past 20 years, magnetic resonance imaging (MRI) has emerged as a promising method for measuring LIC in a variety of diseases. We review the potential role of MRI in LIC determination in the most important disorders characterized by iron overload, namely, thalassemia major, other hemoglobinopathies, acquired anemia, and hemochromatosis.

LITERATURE SEARCH

A literature search (using PubMed) was performed using the following key words: “thalassemia major”, “iron overload”, “MRI”, “liver”, “hemochromatosis”, “desferrioxamine”, “deferiprone”, “deferasirox”, “thalassemia intermedia”, “sickle cell disease”, “myelodysplastic syndromes”, “bone marrow transplantation”, “hepatitis C”, “alcoholic liver disease” and “non-alcoholic liver disease” up to 13 January 2010. The authors also manually reviewed the references of retrieved articles for any pertinent material.

MRI METHODS FOR ASSESSING LIC

The measurement of iron overload with MRI is based

on the shortening effect of the interaction of iron-containing molecules (particularly ferritin and hemosiderin) with hydrogen nuclei (mainly in water molecules) on T2 relaxation time^[19,27,28]. Hepatic iron deposition with MRI can be quantified by measuring the ratio of the signal intensity of the liver and of a reference tissue (mainly paraspinous muscle, which does not develop siderosis)^[27,28]. These signal intensity ratios (SIRs) can be derived from either spin-echo (SE) T2-weighted or from gradient recalled-echo (GRE) T2*-weighted sequences^[27,28]. Liver siderosis can also be determined by the direct measurement of relaxation time (relaxometry), either T2 [or 1/T2 (R2)] from SE sequences or T2* [or 1/T2* (R2*)] from GRE sequences; it is also possible to measure both R2 and R2* relaxation times (hybrid method)^[27,28]. SIR-measuring methods are faster than relaxometry but less sensitive, particularly in patients with severe iron overload^[27,28]. In addition, SIR-measuring methods appear to have smaller interscanner reproducibility than do relaxometry methods^[29,30]. Among relaxometry methods, R2 acquisition time is longer than R2* acquisition time^[30].

MRI IN THALASSEMIA MAJOR

LIC determination

Some early studies have assessed the accuracy of LIC quantification by liver/muscle SIR derived from either GRE or SE sequences^[21,31,32]. The correlation between LIC measured in liver biopsy and SIR was stronger when GRE sequences were used^[21,31,32]. However, both methods were inaccurate in patients with severe iron overload or liver fibrosis, who represent a sizable percentage of the thalassemia population^[21,31,33]. In contrast, the presence of viral hepatitis did not affect the correlation between MRI and liver-biopsy-based LIC measurements^[31]. More recent studies also have reported moderate correlations between SIR and LIC ($r = 0.65-0.89$)^[34-36].

Regarding relaxometry methods, two large studies ($n = 80$ and $n = 106$) have reported moderate correlations between liver T2 and T2* measured in 1.5 T scanners with LIC ($r = -0.82$ and $r = -0.81$, respectively)^[37,38]. The correlation coefficient between liver T2* and LIC was stronger in patients without hepatic fibrosis (-0.93 vs -0.68 in patients with liver fibrosis)^[38]. Two smaller studies ($n = 46$ and $n = 52$, respectively) reported relatively stronger correlations between LIC and liver R2 determined in a 1.5 T and 0.5 T imager, respectively ($r = 0.874$ and $r = 0.94$, respectively)^[39,40]. Interestingly, the presence of liver fibrosis reduced the accuracy of the method only in the 1.5 T scanner^[39,40]. Liver inflammation and chronic hepatitis C virus (HCV) infection also had no effect on the correlation between R2 and LIC in the 0.5 T unit^[39,40]. A recent study also has suggested that measuring liver R2* in higher field strength imagers (i.e. 3 T vs 1.5 T) yields less accurate measurements, particularly in patients with more severe iron overload^[41]. However, the latter studies evaluated patients with different characteristics and their results are not directly comparable^[39-41].

Several studies have shown that relaxometry methods are more accurate than SIR-measuring methods for LIC determination^[30,36,42,43]. In an early comparative study, liver R2 correlated more strongly with biopsy-determined LIC than liver/paraspinal muscle SIR measured in SE sequences ($r = 0.97$ and 0.71 , respectively)^[42]. Moreover, the presence of liver fibrosis or inflammation did not affect the correlation between liver R2 and LIC^[42]. Liver/subcutaneous fat SIR did not correlate significantly with LIC^[42]. In another early small study ($n = 10$), liver R2 relaxation time measured with a 0.5 T MRI unit was better correlated with LIC than was R2* relaxation time^[43]. In a large study in patients with thalassemia major ($n = 57$), sickle cell disease (SCD) ($n = 34$), thalassemia intermedia ($n = 6$) and other causes of iron overload (aplastic anemia, hemochromatosis and heme-metabolism defects; $n = 5$), liver R2 and R2* measured with a 1.5 T scanner showed a strong correlation with LIC ($r = 0.98$ and 0.97 , respectively; Figure 1)^[30]. R2 showed less variability between imaging slices and better reproducibility between examinations compared with R2*^[30]. Combined measurement of R2 and R2* did not improve diagnostic accuracy^[30]. We also recently showed in 94 patients with thalassemia major a strong correlation between liver R2, R2* and GRE-derived liver/muscle SIR in a 1.5 T unit^[36]. Liver R2 was more accurate than the other methods in patients with more severe iron overload^[36]. According to current guidelines for the management of patients with thalassemia major, MRI is a feasible alternative to liver biopsy for determining LIC^[16]. The use of R2 sequences and local individual calibration is recommended^[16].

LIC and iron overload in other organs in thalassemia major

Myocardial iron-overload-induced heart failure is the cause of death in approximately 60% of patients with thalassemia major^[4]. Measurement of cardiac T2* is the currently recommended method for assessing cardiac iron overload^[16]. However, several large cross-sectional studies (total, $n = 429$) have not identified a significant correlation between cardiac and liver T2*^[38,44-47]. Only one large study ($n = 180$) has reported a weak, albeit significant, correlation between liver T2* and cardiac T2* ($r = 0.18$, $P < 0.05$)^[48]. In smaller studies ($n = 46$ and 38 , respectively), liver R2 and R2* did not correlate significantly with cardiac R2 and R2*^[39,49,50]. We also found no correlation between myocardial R2* and liver R2, and R2* and GRE-derived liver/muscle SIR in 94 patients^[36]. Only a few studies have reported a significant correlation between liver T2 and heart T2^[37], or between liver R2* and cardiac R2*^[51]; however, the correlation was weak ($r = 0.34$ and 0.23 , respectively)^[37,51]. Cardiac iron overload has also been reported in patients with minimal iron deposition in the liver^[50-52]. Finally, in a recent large study in 652 patients with thalassemia major, liver T2* was very weakly correlated with cardiac T2* ($R^2 = 0.003$, $P = 0.04$)^[53]. More importantly, liver T2* was not associated with the development of heart failure or arrhythmia, whereas cardiac T2* predicted heart failure and arrhythmia^[53].

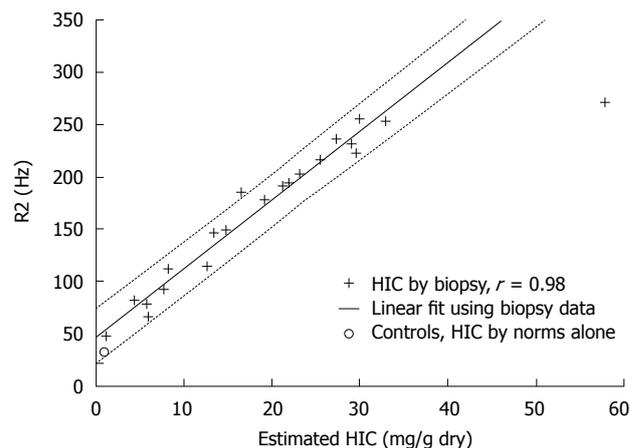

Figure 1 Plot of transverse relaxivity R2 (1/T2) vs biopsy-measured LIC in 20 patients (22 biopsies). R value was 0.98, and dotted lines indicate 95% prediction intervals for the regression. Average R2 value for 13 healthy controls is shown by "o", plotted using an LIC value estimated from normative data (no biopsy) (reproduced with permission from^[30]).

The lack of correlation between liver and cardiac iron load might be explained by different mechanisms of iron uptake in the two organs^[28]. In addition, small studies have suggested that iron deposition and chelation-induced clearance of iron from the heart lag behind liver iron changes^[50,54]. Moreover, patients receiving treatment with different chelators might experience iron clearance from the liver and heart at different rates^[46,55-58]. It appears that desferrioxamine is more or similarly effective than deferiprone in removing iron from the liver, but less effective than the latter in removing iron from the heart^[46,55-58]. Deferasirox, another oral chelator, appears to be similarly effective to desferrioxamine in reducing liver iron (assessed with liver biopsy or SQUID) when appropriately dosed^[59,60]. In uncontrolled studies, deferasirox also has reduced cardiac iron deposition (assessed with cardiac T2*)^[61,62]. These findings suggest that myocardial iron overload should also be monitored closely in patients with thalassemia major^[16]. According to recent guidelines for the management of these patients, myocardial iron deposition should be monitored with T2* MRI every year in patients with a poor chelation history, or in those with LIC, who show a non-optimal response to chelation therapy^[16].

Endocrine disorders, particularly hypogonadism and diabetes, are frequently observed in patients with thalassemia major^[63,64]. However, liver iron load does not appear to predict the extent of iron deposition in the pancreas or the pituitary gland, as assessed by SIR^[65-67], T2^[68], R2^[49] or T2*^[69]. However, in the largest study that has assessed the relationship between hepatic and pancreas/pituitary gland iron stores ($n = 180$), liver T2* correlated weakly, albeit significantly, with pancreas and pituitary gland T2* ($r = 0.35$ and 0.17 , respectively)^[48]. Liver T2* also correlated significantly with pituitary gland T2 and pituitary gland/muscle SIR ($r = 0.21$ and 0.63 , respectively)^[48]. However, liver T2* was not associated with the presence of endocrine disorders (diabetes, hypothyroidism, hypo-

gonadism and hypoparathyroidism)^[48]. No differences in liver iron overload between diabetic and non-diabetic patients were reported in other studies using T2*^[69,70] or SIR obtained from SE or GRE sequences^[34]. There was also no correlation between liver T2* and insulin resistance or pancreatic β -cell reserve^[69]. Only one small study ($n = 31$) has reported more severe liver iron overload (assessed with liver/paraspinous muscle SIR in GRE sequences) in diabetic patients^[66]. Regarding hypogonadotropic hypogonadism, one study of 36 patients has reported no difference in liver/subcutaneous fat SIR between patients with hypogonadotropic hypogonadism and those without pituitary gland dysfunction^[67], whereas another larger study ($n = 50$) has identified low liver T2* as a predictor of the presence of hypogonadism (but not of diabetes)^[70]. The apparent lack of association between the iron burden in liver, pancreas and pituitary gland might be partly due to different mechanisms of iron accumulation in these organs^[49,65-69]. In addition, pancreatic T2 and R2 are also reduced by the development of fatty degeneration, which might also confound the relationship between liver and pancreatic relaxation times in MRI^[49,66,68].

Liver MRI in patients with thalassemia major who have undergone bone marrow transplantation

Allogeneic bone marrow transplantation (BMT) from an HLA-identical donor is a potentially curative treatment for thalassemia major, particularly when pre-transplantation chelation treatment is adequate and there is no portal fibrosis or hepatomegaly^[71-74]. In these patients, liver iron overload progressively decreases without phlebotomy but may persist for 4-6 years after BMT in older patients^[75,76]. In patients who have undergone BMT for thalassemia major, higher LIC independently predicts progression of liver fibrosis^[77]. In these patients, phlebotomy reduces liver iron overload and improves liver and myocardial function^[78-80]. Liver MRI has also been used in these patients to assess iron overload^[81]. Measurement of liver T2 and T2* with a 1.5 T imager revealed iron overload in four out of eight patients, even though a mean time of 11.3 years had elapsed since BMT, and seven patients had received iron chelation treatment with phlebotomy, desferrioxamine or their combination for a mean 39 mo^[81]. In contrast, heart T2 and T2* were normal in all patients^[81].

LIC DETERMINATION WITH MRI IN OTHER HEMOGLOBINOPATHIES

Thalassemia intermedia is a diverse group of hemoglobinopathies that are characterized by less severe transfusion dependency and iron overload than in thalassemia major^[82,83]. Liver iron overload assessed with measurement of the T2* relaxation time is less pronounced in patients with thalassemia intermedia than in those with thalassemia major^[84]. Even though patients with thalassemia intermedia have liver iron overload compared with healthy controls, cardiac T2* does not differ between the former and the latter^[84]. In a study of 26 patients with thalassemia

intermedia, liver T2 strongly correlated with LIC ($r = -0.82$, $P = 0.0003$) but not with heart T2 ($r = -0.17$, $P = 0.41$)^[37]. Iron overload can develop in patients with thalassemia intermedia who have not been regularly transfused^[82,83]. In patients with thalassemia intermedia who received < 10 red blood cell (RBC) units, liver R2 revealed iron overload in two-thirds of the patients, whereas cardiac T2* was normal in all patients^[85]. In a very recent study in 49 patients with thalassemia intermedia, liver T2* revealed the presence of hepatic iron overload in 77.5% of patients, even though 44.9% had never been transfused and only 8.2% were being regularly transfused^[86]. In contrast, no patient had cardiac iron overload and liver T2* did not correlate with cardiac T2*^[86].

Beta thalassemia/hemoglobin E, a frequent hemoglobinopathy in Asia, manifests as thalassemia intermedia in half of the patients and as thalassemia major in the other half^[87,88]. Iron overload can develop even in patients who do not require regular transfusions and is due to increased intestinal absorption of iron^[87,88]. In a pivotal study in patients with beta thalassemia/hemoglobin E ($n = 41$), thalassemia major ($n = 9$) or hereditary hemochromatosis ($n = 23$), liver R2 strongly correlated with LIC measured in biopsy ($r = 0.98$, $P < 0.0001$)^[89]. However, R2 variability increased with increasing LIC^[89].

Hemoglobin H (Hb H) disease is another frequent hemoglobinopathy in Asia, which results from the deletion of three of the four α -globin genes (deletional Hb H disease) or from deletion of two α -globin genes and a non-deletional mutation of a third α -globin gene (non-deletional Hb H disease). In all cases, there is an excess of β -globin chains that form β_4 tetramers (Hb H)^[88,90,91]. The clinical phenotype of Hb H disease is variable and often resembles thalassemia intermedia^[88,90,91]. Regular transfusions are infrequently required but iron overload can develop even in never-transfused patients^[88,91]. Increased intestinal iron absorption due to hemolysis and ineffective erythropoiesis appears to explain the development of iron overload in these patients^[91]. Non-deletional Hb H disease has more severe presentation and more frequently leads to iron overload than does deletional Hb H disease^[91,92]. In an early study in 36 non-transfusion-dependent patients with Hb H disease, liver/paraspinous muscle SIR obtained from GRE sequences was more sensitive in detecting iron overload than SIR determined from SE sequences^[93]. Liver iron overload was observed in 33/36 patients, whereas iron overload in the heart and pancreas were present in only one and six patients, respectively^[93]. In a large study in 114 Chinese patients with Hb H disease, liver/paraspinous muscle SIR measured from GRE sequences revealed liver iron overload in 85% of the patients^[92]. Iron overload was present even though only one patient was transfusion-dependent and only eight had received more than five transfusions (median number of transfusions: 5.5; range: 5-20)^[92]. Patients with deletional Hb H disease had more severe iron overload than those with non-deletional Hb H disease^[92]. In a smaller recent study in 37 patients with Hb H

disease or thalassemia intermedia and serum ferritin levels > 1000 pmol/L, liver T2* was abnormal in most patients (84%)^[94]. Log-liver T2* correlated with serum ferritin levels but not with heart, pancreas or pituitary siderosis, as assessed by MRI, or with abnormalities in pancreatic function or the growth hormone axis^[94].

Chronic RBC transfusion therapy is increasingly being used in patients with SCD, particularly for the primary or secondary prevention of stroke^[95]. However, iron overload frequently develops in patients with SCD who are receiving chronic RBC transfusion therapy^[96]. The development of iron overload in these patients increases the risk for hospitalization^[97] and death^[98], whereas chelation treatment reduces mortality^[97]. In a recent study in patients with SCD, thalassemia major or bone marrow failure, liver R2* was strongly correlated with LIC assessed with liver biopsy ($r = 0.96-0.98$, $P < 0.001$), regardless of the presence of fibrosis^[99]. In another study in 35 patients with SCD, liver T2 was moderately correlated with LIC ($r = -0.80$, $P = 0.00001$) but not with heart T2 ($r = 0.10$, $P = 0.56$)^[37].

LIC DETERMINATION WITH MRI IN OTHER HEMATOLOGICAL DISORDERS

Iron overload frequently develops in patients with myelodysplastic syndromes (MDSs), which can result in abnormal liver function, diabetes and heart failure and increase the risk of death^[100-104]. In these patients, treatment with desferrioxamine improves liver, pancreas and pituitary gland function^[100,102,105]. Several small studies ($n = 10$ or 11) have assessed liver iron deposition by measuring liver T2* and have revealed liver iron overload in almost all patients^[106-109]. Log liver T2* correlates with RBC units transfused^[106,107]. In contrast, myocardial siderosis was present in only 10%-15% of patients and cardiac T2* did not correlate with liver T2*^[106,108,109]. Only one study has assessed pancreas and pituitary gland siderosis with MRI in patients with MDS, and has reported no association between liver T2* and pancreas or pituitary gland siderosis, but a correlation between log liver T2* and indices of insulin resistance and reduced beta cell reserve^[106]. According to recent guidelines, iron overload should be monitored in patients with MDS, using serum ferritin and transferrin levels, whereas liver MRI is considered useful but not essential^[92].

Iron overload is frequently observed in patients who have undergone allogeneic BMT for hematological diseases other than thalassemia major, and results primarily from RBC transfusions^[110-112]. Iron overload in these patients appears to be associated with increased risk for infections, veno-occlusive disease, hepatic dysfunction^[110,113,114] and death^[111,114-118]. Phlebotomy improves liver function in this population^[118]. It is recommended that patients who have undergone BMT and have iron overload should be treated with phlebotomy and/or chelation therapy^[112]. Liver MRI is a useful tool for quantifying body iron stores in this population^[110]. In an early study in 13 children who had

undergone autologous BMT, mostly for non-hematological disorders (neuroblastoma in 8 patients), liver iron overload assessed with liver/paraspinal muscle SIR measured in SE sequences was present in 10 patients (77%)^[119]. Liver iron overload is correlated with RBC units transfused^[119]. Three small studies ($n = 32$, 19 and 20) have revealed liver iron overload in the majority of patients (97%, 95% and 85%, respectively) who had undergone allogeneic BMT for leukemia, MDS, multiple myeloma, lymphoma, aplastic anemia or myelofibrosis, who had serum ferritin levels greater than the upper limit of the normal range, > 1000 ng/mL or > 1600 pmol/L, respectively^[120-122]. Liver iron deposition was assessed by liver/paraspinal muscle SIR measured from GRE sequences^[122], R2^[121] or T2*^[120]. Liver siderosis correlated with RBC units transfused^[122]. Patients with more advanced liver siderosis more frequently exhibited elevated transaminases, which normalized in most of them after phlebotomy^[122]. However, liver iron deposition did not correlate with heart, pancreas or pituitary siderosis as assessed by MRI, or with abnormalities in pancreatic function or the growth hormone axis^[120]. In addition, the duration of post-BMT follow-up, type of graft or conditioning, and the presence of chronic graft-versus-host-disease had no effect on the presence of liver iron overload^[121].

Two small case-series ($n = 11$ and 3 , respectively) have evaluated iron overload with MRI in patients with acute leukemia or solid tumors who received multiple RBC transfusions due to chemotherapy-induced anemia^[123,124]. Liver/muscle SIR identified liver iron overload in all patients, whereas cardiac T2* was marginally reduced and pancreas/skeletal muscle SIR was normal in all patients^[123,124].

LIC DETERMINATION WITH MRI IN NON-HEMATOLOGICAL DISEASES

Hemochromatosis is an autosomal recessive disease with variable penetrance. In most patients, it results from a mutation of the *HFE* gene, which leads to iron overload by increasing intestinal iron absorption and by enhancing iron release from macrophages after phagocytosis of erythrocytes^[7,8,15]. In an early study in 20 patients with hemochromatosis and 18 with hematological diseases (mainly MDS), liver/muscle SIR obtained from SE sequences correlated strongly with LIC ($r^2 = 0.98$)^[125]. However, in subsequent studies in patients with suspected hemochromatosis, SIR obtained from GRE sequences has provided a more accurate determination of LIC than from SE sequences^[126,127]. In a more recent and larger study in 174 patients with suspected hemochromatosis or with chronic HCV infection, Gandon *et al.*^[128] have shown that liver/muscle SIR obtained from GRE sequences identifies liver iron overload with high sensitivity and specificity. The severity of hepatic siderosis and the presence of cirrhosis does not affect the accuracy of MRI measurements. The diagnostic accuracy of the technique proposed by Gandon *et al.*^[128] has been replicated in other studies in patients

with suspected hemochromatosis, chronic HCV infection, or persistent elevation of transaminase levels^[129,130]. However, it should be mentioned that this method does not appear to be accurate in assessing LIC in patients with thalassemia major or MDS, who have higher LIC than patients with hemochromatosis^[35]. Two smaller studies ($n = 11$ and 23 , respectively) have reported a strong correlation between liver R2 and biopsy-determined LIC in hemochromatosis^[89,131]. Some experts consider liver MRI to be the method of choice for documenting iron overload in patients with suspected hemochromatosis^[15]. Nevertheless, others argue that MRI has limited sensitivity to detect mild iron overload in patients with suspected hemochromatosis^[7].

Besides hemochromatosis, mild to moderate iron overload is also present in some patients with other liver diseases, including chronic hepatitis B or C, alcoholic liver disease and non-alcoholic fatty liver disease^[1,132-136]. In chronic hepatitis B or C and alcoholic liver disease, low levels of hepcidin, a protein that regulates iron absorption, may play a role in the development of iron overload^[1,132-134,136]. Increased iron uptake from hepatocytes due to upregulation of transferrin receptors might also contribute^[136]. In non-alcoholic fatty liver disease, insulin-induced redistribution of intracellular transferrin receptors to the hepatocyte membrane, and downregulation of the iron exporter protein due to the pro-inflammatory state present in these patients, may contribute to the development of liver iron overload^[132]. MRI is a sensitive method for evaluating liver iron deposition in patients with chronic HCV infection^[128-130]. However, liver biopsy is required in most of these patients to assess the presence of inflammation, fibrosis and cirrhosis.

Increased LIC is frequently observed in patients with non-biliary cirrhosis (not due to hemochromatosis) and can occasionally be severe; in contrast, liver siderosis is rare in biliary cirrhosis^[1,23,134]. Liver/paraspinous muscle SIR obtained from SE or GRE sequences has revealed liver iron overload in 40% of cirrhosis patients^[137]. However, in studies in patients with cirrhosis of various etiologies in whom liver biopsy had been performed, there was only a moderate correlation between liver/muscle SIR in GRE sequences and histological grading of liver siderosis ($r = 0.515$, $P < 0.001$)^[138]. Moreover, others did not find a difference in liver iron load (assessed with SIR obtained from GRE sequences) between patients with viral hepatitis and cirrhosis^[139]. In addition, liver siderosis in either SE or GRE sequences did not increase with the progression of viral hepatitis-induced cirrhosis^[140]. Despite these discrepant findings, MRI might be particularly useful when cirrhosis is present because of the risk of bleeding in these patients during liver biopsy and because of the uneven iron distribution in the cirrhotic liver^[21-25].

Finally, MRI might be useful for the evaluation of iron stores in porphyria cutanea tarda, a familial or sporadic disease that is characterized by decreased activity of hepatic uroporphyrinogen decarboxylase (UROD), which is frequently associated with iron overload^[141]. In these patients, iron inhibits UROD activity, and phlebotomy is

the treatment of choice^[136,141]. A recent study in 20 patients with porphyria cutanea tarda measured liver/paraspinous muscle SIR from GRE sequences and identified liver iron overload in 11 (55%)^[142].

CONCLUSION

MRI is a potentially useful non-invasive method for evaluating liver iron stores in a wide spectrum of hematological and liver diseases. Most studies have been performed in thalassemia major and MRI is currently a widely accepted method for guiding chelation treatment in these patients. However, the lack of correlation between liver and cardiac iron stores suggests that both organs should be evaluated with MRI, since cardiac disease is the leading cause of death in this population. It is also unclear which MRI method is the most accurate because there are no large studies that have directly compared the different techniques. Another issue is the reproducibility of the various methods in different centers. Liver/muscle SIR obtained from GRE sequences^[128-130] and liver and heart T2* have been shown to be reproducible in different scanners^[143-145] but more data are needed. The role of MRI in the era of genetic diagnosis of hemochromatosis is also debated, whereas data on the accuracy of the method in other hematological and liver diseases are rather limited. However, MRI is a fast non-invasive and relatively accurate diagnostic tool for assessing liver iron content, and its use is expected to increase as the role of iron in the pathogenesis of liver disease becomes clearer.

Abstract

Perfusion magnetic resonance imaging (MRI) studies quantify the microcirculatory status of liver parenchyma and liver lesions, and can be used for the detection of liver metastases, assessing the effectiveness of anti-angiogenic therapy, evaluating tumor viability after anti-cancer therapy or ablation, and diagnosis of liver cirrhosis and its severity. In this review, we discuss the basic concepts of perfusion MRI using tracer kinetic modeling, the common kinetic models applied for analyses, the MR scanning techniques, methods of data processing, and evidence that supports its use from published clinical and research studies. Technical standardization and further studies will help to establish and validate perfusion MRI as a clinical imaging modality.

INTRODUCTION

Perfusion magnetic resonance imaging (MRI) refers to imaging of tissue blood flow (i.e. tissue microcirculation), which is beyond the resolution of the MR scanner to directly visualize. In the liver, perfusion MRI can be applied to measure microcirculation in the liver parenchyma or in tumors. Whilst there are techniques available for direct measurement of blood flow in macroscopic vessels, such as the portal vein and hepatic artery, such as Doppler ultrasound (US), contrast-enhanced US, xenon computed tomography (CT) or phased contrast MR angiography; these are beyond the scope of the current review. Instead, our discussions are primarily focused on dynamic contrast-enhanced (DCE) MRI techniques with tracer kinetic modeling, which allows for the quantitative characterization of parenchymal and tumor microcirculatory alterations in the liver. Selected DCE liver perfusion studies using other imaging modalities are used to illustrate the value of perfusion imaging.

In the liver, conventional characterization of focal liver lesions is reliant on observing the rate and pattern of contrast enhancement assessed visually on DCE scans. The rate and pattern of contrast enhancement reflects the time evolution of the contrast agent within the liver tissue, which occurs as a result of the microcirculatory

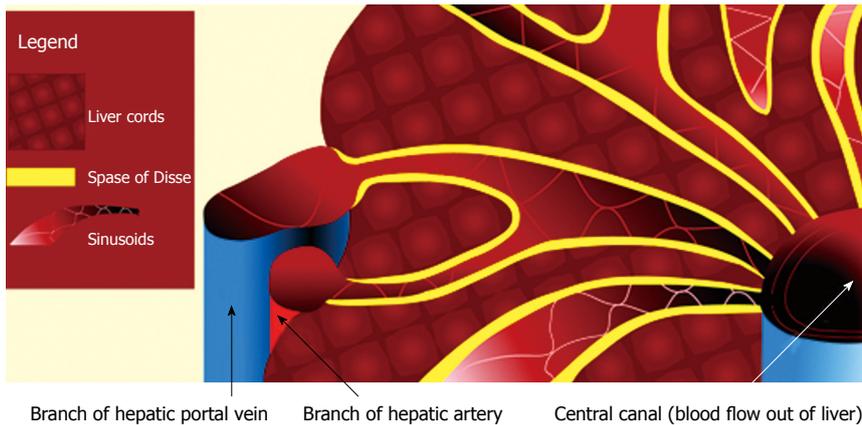

Figure 1 Schematic diagram illustrating the vascular architecture of the liver. Note the dual blood supply into the liver derived from the portal vein and hepatic artery. The vascular inflow is channeled into the hepatic sinusoids, which normally communicate freely with the Space of Disse (yellow). The Space of Disse is an interstitial space that lies between the sinusoids and the liver cords. From the hepatic sinusoids, blood is drained out of the liver via branches of the hepatic vein.

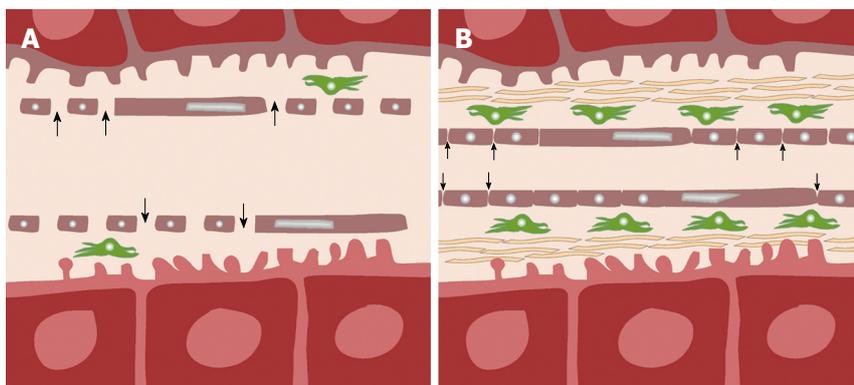

Figure 2 Schematic diagram showing pathophysiological differences between normal (A) and cirrhotic (B) liver. In normal liver (A), normal fenestrae along the hepatic sinusoids allow free passage of blood (arrows) into the Space of Disse, in which, stellate cells (green) are found. In liver cirrhosis (B), there is an increase in the number of stellate cells, associated with deposition of collagenous fibers in the Space of Disse, and loss of fenestrae as the sinusoids become more capillary-like. As a result, transfer of low-molecular-weight compounds (e.g. contrast medium) from the sinusoids into the Space of Disse becomes more impeded (small arrows).

pathophysiological changes. Perfusion MRI could extend the currently used qualitative assessment applied for the differential diagnosis of focal liver lesions, by applying quantitative metrics to describe their vascular behavior.

In the treatment of liver tumors, current therapy for hepatocellular carcinoma (HCC) includes novel anti-angiogenic agents such as sorafenib. As these drugs may have significant clinical effects without causing tumor shrinkage, the microcirculatory characteristics, such as blood flow and tumor capillary permeability, have the potential to be response biomarkers, which allow these drug effects to be confidently assessed. Furthermore, it may also be possible to explore whether the quantitative microcirculatory parameters correlate with drug exposure and whether they can predict response. Quantitative vascular measurements could also be applied to assess the efficacy of local tumor ablation such as by trans-arterial chemo-embolization (TACE), radiofrequency ablation (RFA) or yttrium-90 microsphere embolization.

The early detection of liver metastases remains challenging, but changes in the relative hepatic arterial *vs* portal venous blood supply allow earlier detection of microscopic liver metastases^[1]. Likewise, changes in the relative contribution of hepatic arterial and portal blood flow are also observed in patients with liver cirrhosis^[2-8].

Central to the assessment of liver perfusion are model-based or model-free methods that analyze the contrast concentration-time curve in focal liver lesions or liver parenchyma, derived from the DCE-MRI images. Although similar concentration-time curves may be obtained using

CT and nuclear medicine studies, radiation burden is a practical concern, which becomes even more significant on repeated measurements. The ability of MRI to acquire such information without radiation burden and in a potentially more favorable scan plane (e.g. oblique coronal), to demonstrate the vascular input into the liver, are important advantages.

NORMAL AND ABNORMAL LIVER CIRCULATION

The liver is a highly vascular organ that consists of a series of porous vascular channels (sinusoids with fenestrae) that are predominantly supplied by the portal vein (75%) and supplemented by the hepatic artery (25%)^[9]. The two arterial inputs mix in the sinusoids at different time intervals to supply the liver cords. There is a small space (Space of Disse) that separates the sinusoids from the tightly ordered hepatic cords, which comprise two rows of closely apposed hepatocytes. The Space of Disse may be considered as an interstitial space within the liver. However, due to the large size of the fenestrae of the sinusoids, there is usually free exchange of low-molecular-weight compounds (e.g. gadolinium contrast medium) between the vascular space (sinusoids) and the interstitial space (Space of Disse) (Figures 1 and 2)^[10].

In cirrhosis, due to sinusoidal capillarization, there is loss of normal fenestrae, due to deposition of basement membrane and new formation of capillary tight junctions along the sinusoids. There is also deposition of fibers by

activated Ito cells (hepatic stellate or antigen presenting cells), which results in enlargement of the Space of Disse. Consequently, transfer of low-molecular-weight gadolinium contrast medium from the vascular sinusoids into the interstitial space becomes increasingly impeded (Figure 2)^[11].

In liver metastases and HCC, tumor blood supply is initially derived from proliferation of the sinusoidal cells that become capillarized with loss of fenestrae and formation of basement membrane. This also results in a significant barrier to the free passage of low-molecular-weight contrast medium between the sinusoidal space and interstitial space of the tumor. As the tumor continues to grow, there is recruitment of new vessels directly supplied by the hepatic artery (neoarteriogenesis). This is a prominent feature of HCC but can also be seen in the peritumoral area of liver metastases^[12-15]. Such arterialization of the vascular supply is typical of malignant liver tumors.

MRI TECHNIQUE FOR MEASURING HEPATIC PERFUSION

For perfusion MRI of the liver, injection of a low-molecular-weight gadolinium-chelate contrast is necessary, and this is administered through a wide bore (20G or larger) intravenous cannula sited within a large antecubital vein. Contrast medium is injected using a programmable pump injector, which ensures uniform and rapid contrast delivery as a tight bolus. The amount of contrast medium administered is based on body weight. For example, using Gd-DTPA (Magnevist®, Bayer-Schering, Germany), 0.1-0.2 mmol of contrast medium/kg body weight is typically administered. Once the contrast medium is injected, imaging of the liver commences using an MRI sequence that is capable of rapid and repeated measurements, to enable the passage of contrast medium through the liver to be tracked accurately. Liver perfusion imaging is typically performed using T1-weighted MRI sequences. On T1-weighted imaging, liver or tumor perfusion is observed as increasing enhancement as contrast medium passes through the liver or tumor.

With regard to technical details, a T1-weighted 3D spoiled gradient echo technique with variable flip angles is useful. Parallel imaging could be applied to reduce scan time and improve temporal resolution. Compared with 2D imaging sequences, the 3D technique eliminates inaccuracies due to the radiofrequency excitation pulse profile, and also has the advantage of better signal-to-noise ratio. However, the peripheral image sections may still have to be excluded from analysis because they may have unfavorable slice profiles or be degraded by wrap artifacts that result from phase under-sampling. T1 mapping or calibration, a necessary step for quantitative analysis, can be performed using the variable flip angle method described by Wang *et al.*^[16]. As the gadolinium contrast concentration is inversely proportional to change in the reciprocal of T1, a gadolinium contrast concentration-time curve of the liver or tumor can be generated, which is then used to derive quantitative vascular perfusion

Table 1 Illustrative example of a perfusion MRI sequence performed on a 1.5 T MR platform

MRI platform	Avanto (Siemens, Erlangen, Germany)
Type of pulse sequence	3D FLASH
TR	2.72 ms
TE	1 ms
Partition thickness	8 mm
Slices per slab	10
Matrix	256 × 159
Phase encode direction	Anterior to posterior
Number of averages	1
Sensitivity encoding factor	2
Flip angle before contrast	2° and 14°
Flip angle after contrast	14°
Bandwidth	490 Hz
RF spoiling	Yes
Temporal resolution	1.98 s per slab of 10 slices.
Precontrast scans	10 measurements of each flip angle averaged for calculation of native T1
Gadolinium injection	0.2 mmol/kg at 3 mL/s followed by 20 mL flush
Patient respiration	Quiet breathing
Post contrast scans	A total of 180 consecutive measurements. Inject contrast only when the 20th measurement has been completed
Scan sections to use for processing	Center 6 image sections only

MRI: Magnetic resonance imaging; FLASH: Fast low-angle shot; TR: repetition time; TE: Echo time.

indices. Table 1 provides an example of a liver perfusion MRI protocol implemented on a commercial scanner. It is important to note that such an imaging sequence may vary from one imaging platform to another, and it is important to engage the help of an experienced clinical scientist to ensure that the performance of the sequence is optimized. Although some workers have advocated simpler methods of estimating gadolinium concentration by measuring differences in signal intensities before and after contrast arrival in the liver, we would like to caution that the success of this simplified approach might be dependent on the imaging sequence, as well as the range of signal intensity and tracer concentration encountered.

In order to track liver perfusion reliably, MRI of the liver should employ a high temporal resolution technique (i.e. repeated imaging of the same area in the liver about every 4 s), in a scan plane that shows the lesion or area of interest. Ideally, the aorta and the portal vein should be included in the same image sections. Hence, an oblique imaging plane (e.g. oblique coronal) afforded by the MRI technique would be particularly helpful to ensure all these structures are included. The signal intensity changes within these structures, together with the T1 calibration maps, are used to derive the gadolinium contrast concentration-time curves in the liver and tumors. Once the gadolinium contrast concentration-time curve in an area of interest is known, knowledge of the contemporaneous contrast enhancement within the aorta and portal vein allows analytic methods to be applied to extract quantitative or semi-quantitative parameters that describe the vascular

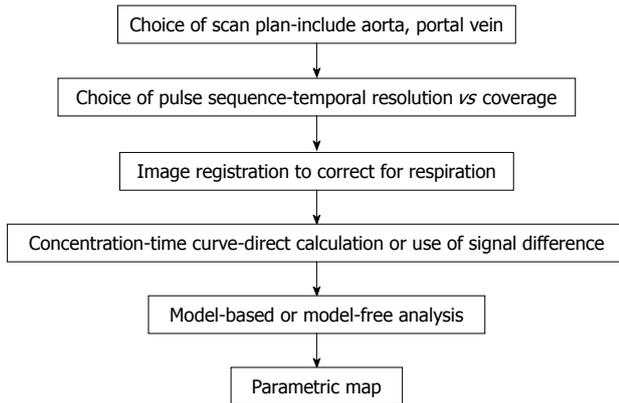

Figure 3 Chart shows workflow involved from data acquisition to obtaining vascular information by perfusion MRI of the liver.

properties. The MR images may also be qualitatively assessed by visual survey for areas of increased enhancement relative to the normal liver parenchyma. However, such comparisons can be subjective. The various approaches to extracting quantitative and/or semi-quantitative liver perfusion data are discussed in the next section.

One of the challenges to acquiring high quality liver perfusion MRI is respiratory motion, which can substantially degrade image quality. It is currently a subject of debate whether to acquire images during breath-hold or quiet respiration. Imaging in quiet respiration is widely performed, which allows rapid uninterrupted image acquisition for high temporal resolution data. However, the images often need to be aligned using image registration techniques, which can be complex, prior to quantitative analysis. Furthermore, respiration can result in through-plane motion and non-linear tissue deformation that cannot be easily overcome. For these reasons, imaging in sequential breath-hold has been advocated as a method to minimize the effects of respiratory motion. Images are acquired during suspended respiration (usually expiration), followed by a short period of normal breathing, after which respiration is again suspended for image acquisition. Imaging during expiration can be monitored by navigator control. Breath-hold imaging minimizes the need for complex image registration, but the main potential disadvantage is decreased temporal sampling because images cannot be acquired continuously. One method which can be used to improve temporal sampling of breath-hold studies is to acquire two datasets (instead of one) during each breath-hold^[17]. Single breath-hold studies have also been reported. In single breath-hold studies, patients are required to breath-hold for 40–60 s during which the first passage of gadolinium contrast is observed^[18].

EXTRACTING LIVER PERFUSION INFORMATION FROM MRI DATA

Once the MRI data have been acquired, they have to be analyzed in a meaningful way to extract information

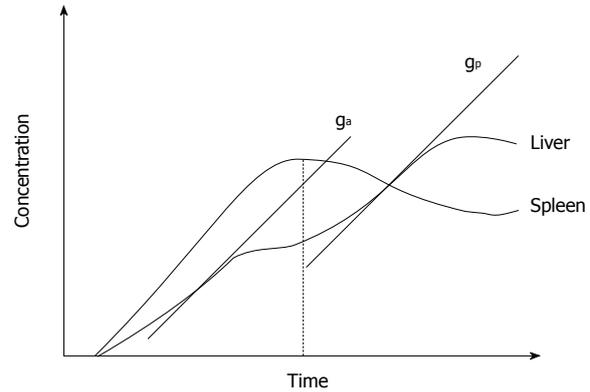

Figure 4 Schematic plot of gadolinium concentration-time curve in liver tissue obtained from a perfusion MRI study. The diagram illustrates how the maximum gradient for arterial perfusion (G_a) and portal perfusion (G_p) are derived (based on Miles *et al.*^[2]). Note that the peak splenic enhancement is used to define the transition between arterial and portal phase of liver parenchyma enhancement. The maximum slope after the peak splenic enhancement is used to define portal perfusion.

that describes tissue vascularity. Dynamic MRI data can be processed using a model-free or a model-based approach, with the former being simpler to implement.

Using model-free approaches, semi-quantitative descriptions of liver perfusion can be derived by observing the rate of liver tissue signal change in the arterial and portovenous phases of contrast enhancement. One semi-quantitative description of liver vascularity is the hepatic perfusion index (HPI), which describes the relative contribution of arterial *vs* portovenous flow to the total liver perfusion. The HPI has been investigated using different imaging techniques, and appears to provide biologically meaningful information despite its relative simplicity.

However, the quantitative model-based approach is appealing because it may provide more sophisticated descriptions of tissue vascular properties, by underpinning the data analysis on mathematical assumptions that reflect alterations in the underlying pathophysiology. Both model-free and model-based approaches are being widely investigated; each has provided unique information that has shown to improve liver disease assessment.

A simplified schema which shows the workflow for performing DCE-MRI is shown in Figure 3.

Model-free approaches for vascular quantification

These methods are based on simply observing the MR signal changes that result from the passage of contrast agent through the liver parenchyma or liver tumor, but may not directly relate these to the contemporaneous change in the aorta or portal vein. Disease characterization is based on the fact that the perfused liver or tumor shows enhancement with the arrival of contrast agent and therefore perfusion can be estimated by the rate of tissue enhancement. Hence, most model-free approaches use parameters derived from the initial slope of the tissue signal intensity-time or contrast concentration-time curve (Figure 4).

HPI

One semi-quantitative index that can be calculated using the model-free approach is the HPI. The HPI was first proposed by Miles *et al.*²¹. HPI refers to the proportion of hepatic perfusion that is derived from the hepatic artery, and it can be calculated using the following formula: arterial perfusion/arterial perfusion + portal venous perfusion). Miles *et al.*²¹ have used the time to peak in the splenic enhancement curve to distinguish between the arterial and portal venous phases of the liver. Liver arterial perfusion is then estimated by the maximum slope in the liver enhancement curve before the splenic peak, divided by the peak aortic enhancement (Figure 4). Correspondingly, liver portal venous perfusion is estimated by dividing the maximum slope in the liver enhancement curve after the splenic peak by the peak aortic enhancement (Figure 4).

Blomley *et al.*³¹ have further refined calculation of portal venous perfusion by removing the contribution of the hepatic artery from the liver contrast concentration-time curve by subtracting from it a scaled splenic contrast concentration-time curve. This is because the spleen is predominantly supplied by the aorta and not by the portal vein. Using the arterially subtracted liver contrast concentration-time curve, the portal venous perfusion is estimated by dividing the maximum slope of the arterially subtracted liver curve by the peak portal enhancement. This more direct method of estimating portal vascular contribution has also been advocated by Tsushima *et al.*¹⁹. However, liver arterial perfusion can be estimated in a similar way as proposed by Miles *et al.*²¹.

The key advantage of using model-free approaches is that they are relatively easy to derive and do not require complex computation.

Understanding tracer kinetic modeling for perfusion MRI

Applying tracer kinetic modeling enables quantitative vascular information to be extracted from temporally sampled MRI data, when the passage of contrast medium through the liver parenchyma or tumor is observed over time. Generally, an assumption is made that the imaged voxel contains a supplying impermeable artery that leads to a permeable capillary that leaks tracer (gadolinium contrast) into the interstitial space (Figure 5). The tracer is cleared from the voxel *via* an impermeable vein. However, the vessels and the interstitial space are beyond the resolution of the MRI scanner to directly image. What is measured by the MRI scanner is the average concentration of the tracer at any one time (reflected by the measured signal intensity) within the image voxel, which changes as contrast medium courses through.

Tracer kinetic modeling uses mathematical curve fitting to describe the tissue contrast concentration-time curves. If the contrast concentration-time curve of the vascular supply is known (arterial input function), subsequent mathematical operations by convolution or deconvolution allow quantitative vascular parameters to be derived that best fit the tumor or tissue contrast

concentration-time curves. Such an approach could be applied to tumor and non-tumor tissues, although the mathematical and pathophysiological assumptions may be different for each. Using one particular kinetic model (e.g. distributed parameter model), quantitative parameters such as hepatic arterial flow, portal venous flow, fraction of total flow contributed by hepatic artery, capillary permeability-surface area product (PS), percentage of intravascular space (v_1), percentage of interstitial space (v_2), and mean transit time (MTT) are derived. However, depending on the mathematical model applied and physiological assumptions made, variants of such quantitative parameters are obtained. Hence, when applying tracer kinetic modeling to clinical studies, it is important to state the choice of kinetic model employed at the outset. Currently, there is no consensus as to which kinetic model is best suited to evaluate the liver, and development of an international consensus in this area would be welcomed.

It has been observed that a hypervascular tumor (usually a tumor with a larger vascular space relative to the interstitial space) shows a pattern of rapid arterial enhancement followed by washout, whereas a hypovascular tumor (usually a tumor with a larger interstitial space relative to the vascular space) shows progressive enhancement. These observations could also be explained by considering tracer kinetic modeling.

A hypervascular tumor is predominantly supplied directly by hepatic arterial neovessels. As the intravascular space is relatively larger than the interstitial space, the average concentration imaged by the voxel predominantly reflects changes in the intravascular space. In such lesions, there is rapid and strong enhancement in the arterial phase. However, in the equilibrium phase, the contrast redistributes to the interstitium and the rest of the body. This reduces the concentration of tracer in the tumor vascular space and is visualized as contrast wash-out within the voxel.

A hypovascular tumor may be supplied by the hepatic artery and the portal vein. As the interstitial space is relatively larger than the intravascular space, the averaged contrast medium concentration within the image voxel predominantly reflects changes in the interstitial space. Hence, there is faint enhancement in the arterial phase as contrast agent diffuses into the relatively large interstitial space. With continued blood flow in the portal venous phase, more contrast medium diffuses outwards and the concentration in the interstitium increases. In the equilibrium phase, although the tracer concentration in the vascular space has reduced due to redistribution to the rest of the body, it is still higher than the concentration in the tumor interstitium. Hence, there may even be a net efflux of contrast medium into the interstitium in the equilibrium phase, and such a tumor may demonstrate a pattern of progressive enhancement.

Clearly, the above explanations could be simplistic, as other measurement factors determine the degree of tumor enhancement. Nevertheless, these descriptions

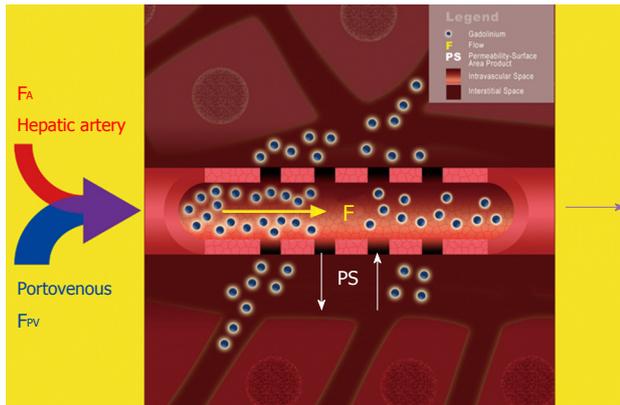

Figure 5 Schematic diagram illustrating a dual-input dual-compartment tracer kinetic model. Dual blood supply carrying gadolinium contrast molecules (blue spheres) from the hepatic artery (F_A) and portal vein (F_{PV}) enters the hepatic sinusoids (intravascular space). From here, the contrast molecules can leak outwards into the Space of Disse (interstitial space). Using a dual-input, dual compartment tracer kinetic model allows the estimation of intravascular properties (e.g. blood flow, F), as well as characteristics of the interstitial space (e.g. PS).

can help us to appreciate how the pathophysiological differences in different disease processes could account for their imaging behavior.

Model-based vascular quantification

Several kinetic models are currently in use for the assessment of liver perfusion. A detailed mathematical analysis of these is beyond the scope of this review. Kinetic models applied to the liver vary according to the physiological assumptions made, and can broadly differ in the following ways.

Single-input vs dual-input: Single-input models assume that the vascular input is derived from the hepatic artery only, whereas dual-input models assume that the vascular input is derived from both the hepatic artery and the portal vein. Dual-input models are more physiological, although in tumors, where the blood supply is highly arterialized, assumption of a single vascular input may suffice to approximate the vascular behavior.

Single-compartment vs dual-compartment: Single compartment models assume that the contrast is confined to only one compartment (i.e. vascular space), whereas dual compartment models assume that there is dynamic distribution of contrast between two compartments (i.e. the vascular space and the interstitial space). Single-compartment models are computationally simpler and could be applied as an approximation for the normal liver, because the Space of Disse communicates freely with the sinusoids. Dual-compartment models are computationally more demanding but may give a better reflection of the microcirculation of the diseased liver, resulting from tumor or cirrhosis^[4,20] (Figure 6).

Conventional compartment (CC) model vs distributed parameter (DP) model: In several kinetic models,

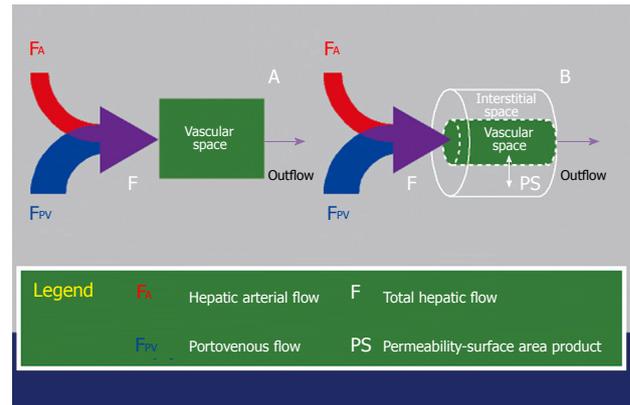

Figure 6 Schematic diagram illustrating the key difference between a single-compartment model (A) and a dual-compartment tracer kinetic model (B). Using a single-compartment model, only the vascular compartment is considered and kinetic properties related to this (e.g. blood flow, F) can be estimated. The behavior of the normal liver can be approximated by a single-compartment model. Using a dual-compartment model, kinetic properties that describe the interstitial space (e.g. PS) can be quantified in addition. In disease states (e.g. liver cirrhosis and tumors), the vascular behavior of these tissues are better described using a dual-compartment model.

the assumption is made that there is instantaneous mixing or equilibrium of the contrast medium along the entire course of a vessel. We term these as CC models. One example of a CC model is Toft's model^[21]. Another approach takes into account a concentration gradient within the vascular space. This approach is called the DP model. CC models are simpler to implement and computationally easier to solve but make more assumptions about the microcirculation. By comparison, DP models are more complex, which attempts to make fewer assumptions about the microcirculation, but are computationally more intensive and require higher temporal resolution data to derive meaningful results.

Derived microcirculatory parameters: Generally, dual compartment models are necessary to extract parameters that describe the interstitial space, e.g. v_2 , PS and extraction fraction (EF) using the DP model; or extracellular extravascular volume using the Toft's model. Such parameters cannot be derived using a single-compartment model. Single compartment models allow for estimates of blood flow, volume of distribution and mean transit time.

Clearly, the choice of the kinetic model depends on many factors including local expertise, available software to perform the perfusion analysis, understanding of the disease pathophysiology, MRI measurement technique applied, and the quality (spatial and temporal resolution) of the MRI data. At the time of writing, only a few commercial softwares are available to undertake such analyses, and many research groups are therefore reliant on self-scripted software for data evaluation. Not surprisingly, this has led to disparate efforts in developing analysis tools, which are often institution-specific and non-standardized. The lack of standardization in the methodologies applied

Table 2 Examples of the types of tracer kinetic models that have been applied for perfusion MRI of the liver

Study	Diseases	Comment
Single-input, single compartment, CC model		
Scharf <i>et al.</i> ^[48]	Preclinical study in pigs	Experimental model of normal liver in pigs. Only arterial input from hepatic artery taken into account. Such a model may lack physiological realism, especially when there is substantial vascular input contribution from the portal vein
Single-input, dual-compartment, DP model		
Sahani <i>et al.</i> ^[30]	HCC	Single input assumed because majority of vascular input to HCC is derived from hepatic artery. Dual-compartment model used to probe interstitial space and PS, which can be substantial in tumors. DP model implemented as standard on General Electric (GE) perfusion software 2.0 used for analysis
Dual-input, single-compartment, CC model		
Materne <i>et al.</i> ^[45-47]	Normal and cirrhotic livers	Assumption of single compartment based on understanding that the fenestra in the sinusoids of liver are extremely porous and allows free exchange of low-molecular-weight contrast tracers between the vascular and the sinusoidal interstitial space. To simplify calculations, assumption was made that there was instantaneous mixing of contrast medium from the dual input ^[6,7,27,45-47,49] within the single compartment. In this way, quantitative parameters such as arterial perfusion, portal venous perfusion, MTT and volume of distribution (Ve) could be derived. Cuenod <i>et al.</i> ^[27,49] applied a deconvolution technique to fit these parameters, and variants of such a model were also used by Funabasam <i>et al.</i> ^[50] and Miyazaki <i>et al.</i> ^[51]
Cuenod <i>et al.</i> ^[27,49]	Metastatic disease	
Dual-input, dual-compartment, DP model		
Koh <i>et al.</i> ^[4,20]	Metastases, HCC and cirrhosis	The DP model applies a concentration gradient within the vascular space. Parameters derived include, arterial flow, portal venous flow, fractional arterial flow, permeability, fractional intravascular space, fractional interstitial space, MTT, contrast arrival time. A dual-input dual-compartment approximation of the DP model is used commercially (CT Perfusion 3.0; General Electric, Milwaukee, USA) and was also adopted by Chen <i>et al.</i> ^[42,52,53] in perfusion studies of the liver

CC: Conventional compartment; HCC: Hepatocellular carcinoma; DP: Distributed parameter; MTT: Mean transit time; CT: Computed tomography.

for data analysis is an acknowledged issue by researchers in the field, and there is fortunately increasing international efforts towards the harmonization and standardization of imaging acquisition and data analysis. Such developments are paramount for the wider clinical adoption of the technique and institution-vendor partnerships are being developed to address such challenges.

Some of the kinetic modeling approaches that have been applied in the published literature are summarized in Table 2.

CLINICAL APPLICATIONS OF PERFUSION MRI IN THE LIVER

Liver metastases

Model-free approach: Several studies have demonstrated the potential of perfusion imaging to detect changes in the liver of patients at risk of liver metastases. Totman *et al.*^[22] have shown that there is a difference in the portal perfusion index (PPI) between patients with and without cancer. Leggett *et al.*^[11] have observed that the HPI is elevated in patients with overt metastases compared with those without metastases. In another study, Tsushima *et al.*^[23] have found that the normal looking liver in a patient with liver metastases shows a reduction in the PPI, which suggests that there is potential for using liver perfusion studies to detect microscopic metastases. These cross-sectional imaging observations have been corroborated by nuclear scintigraphy studies^[24,25]. Despite the reported relationship between high HPI and low PPI with increased likelihood of liver micrometastases in patients with cancer, few studies have had longitudinal follow-up to validate the subsequent development of macroscopic liver metastases. For example, in the study by Leggett

et al.^[11], follow-up data were only available in eight patients, of which three who subsequently developed macroscopic liver metastases showed decreased portal perfusion. Although there is great potential to use liver perfusion studies to detect or predict microscopic liver metastases, more work involving longitudinal studies is required to establish its clinical role (Figure 7).

Meijerink *et al.*^[26] have found functional liver perfusion maps to be helpful supplements to the routine radiological diagnosis of liver metastases. Compared with routine four-phase CT, total-liver-volume CT perfusion studies with calculation of the HPI increased the sensitivity of metastases detection to 89.2% from 78.4% and specificity to 82.6% from 78.3%. Four out of a total of 37 metastases were detected with the help of perfusion maps. Perfusion CT maps increase the conspicuity of metastatic disease because of the increased perfusion at the tumor rims, which makes liver metastases appear larger, thus facilitating the detection of smaller lesions.

Model-based approach: There have been few studies using a model-based approach for evaluating liver metastases. Cuenod *et al.*^[27] have applied a dual-input single-compartment model in rats and have observed that the presence of micrometastases in an apparently macroscopically normal liver resulted in a 34% decrease in portal blood flow and a 25% increase in the MTT for blood to pass through the liver. The changes were similar for macrometastases but more marked.

Koh *et al.*^[20] have employed a dual-input dual-compartment DP model in three patients with liver metastases for a technical validation study. Using the particular model, they found that the normal liver had near zero interstitial space volume and PS (which may be explained by the

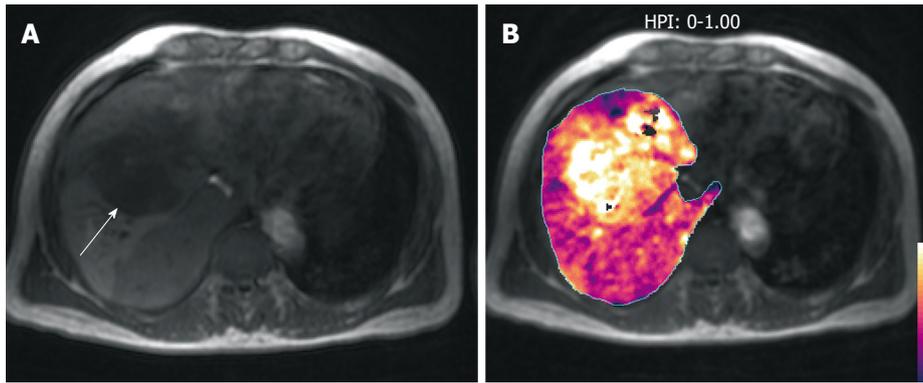

Figure 7 A middle-aged man with colorectal liver metastases to the liver. A: T1-weighted axial MR image demonstrates a hypointense liver metastasis in the right liver lobe (arrow); B: HPI map (calculated by the method described by Miles *et al*^[2]) overlaid on the T1-weighted image shows increased HPI within the metastasis, typical of malignant disease.

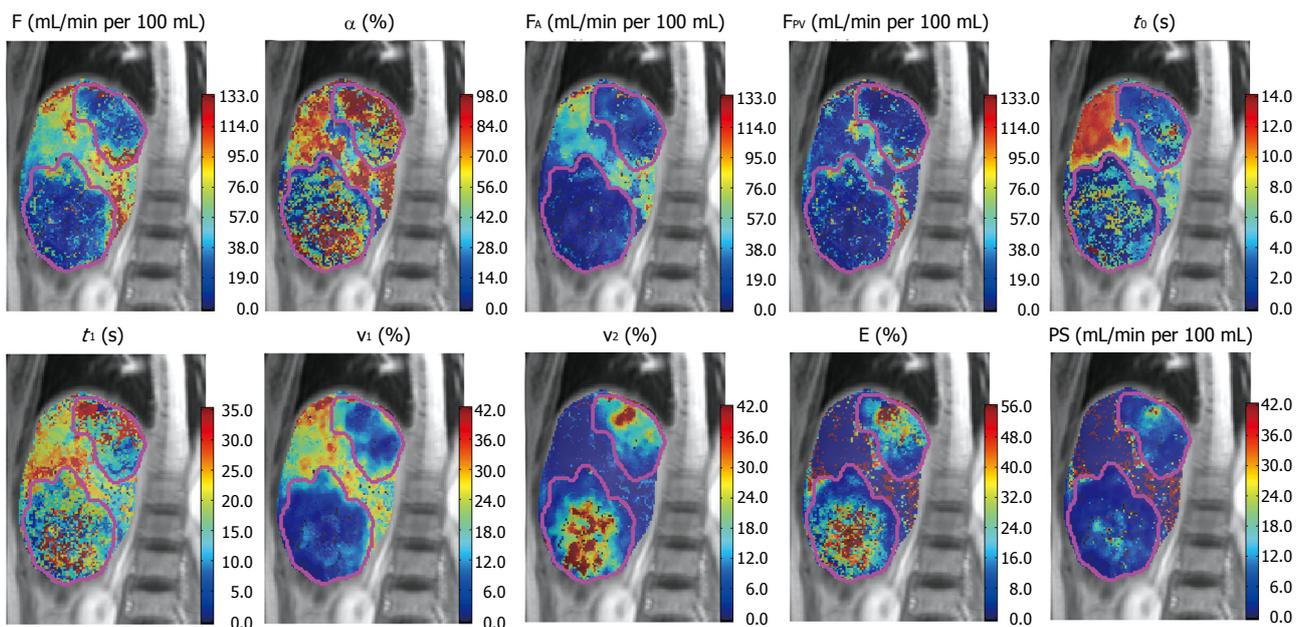

Figure 8 Parametric maps of a patient with colorectal metastases derived from a dual-input, dual-compartment, DP tracer kinetic model. F (blood flow), α (arterial fraction, or % hepatic arterial flow from total hepatic blood flow), F_A (hepatic arterial blood flow), F_{PV} (hepatic portal venous blood flow), t_0 (contrast arrival time), t_1 (MTT), v_1 (fractional intravascular volume), v_2 (fractional interstitial volume), E (extraction fraction), PS (permeability-surface area product). Note that in the two liver metastases demonstrated (outlined in pink), the lesions were characterized by lower total blood flow, but higher arterial fraction and fractional interstitial volume.

large fenestrae allowing free contrast medium exchange between the Space of Disse and the liver sinusoids), and that liver metastases have a non-zero and finite interstitial space volume and PS. Using this quantitative technique, there is an increase in the arterial fraction (arterial flow/sum of arterial and portal flow) to the metastases, although the portal flow remains significant (Figure 8). These observations of the difference in kinetic modeling behavior between the normal liver and liver metastases are supported by histopathological observations reported by Liu and Matsui^[12]. Thus, the dual-input dual-compartment DP model appears to have the potential to characterize microcirculatory pathophysiology but larger studies are required to confirm the initial findings.

HCC

Model-free approach: Abdullah *et al*^[28] have studied the differences between colorectal metastases and HCC and have found no significant difference in HPI between the two malignant entities. However, there is an increase in

arterial flow, portal flow, and total blood flow in HCC compared to colorectal metastases. The distribution volume is also observed to be higher in HCC.

Model-based approach: Fournier *et al*^[29] have applied the dual-input single-compartment model in a rat HCC model and have found that HCC is characterized by higher arterial flow and lower portal flow.

Sahani *et al*^[30] have employed a single-input dual-compartment DP model in patients with HCC and have found that blood flow, blood volume and PS are higher in well-differentiated HCC compared with moderately or poorly differentiated HCC, which suggests that such vascular quantification could yield information on tumor grade.

Koh *et al*^[4] have used the dual-input dual-compartment DP model in four patients with HCC and have measured the fractional interstitial space and associated extravasation parameters (PS and extraction ratio). HCC is characterized by increased arterial flow, increased total blood flow,

as well as early contrast agent arrival time. The early arrival of contrast agent is postulated to be related to arteriogenesis and direct tumor supply by branches of the hepatic artery. Tumor vascularity (fractional intravascular volume) was higher for two out of four patients. Portal venous flow decreased but remained significant. The derived microcirculatory parameters were supported by histopathological findings of arteriogenesis in HCC^[15,31]. Together with other imaging modalities such as diffusion-weighted MRI, MR perfusion imaging has the potential to contribute significantly to the multi-parameteric functional assessment of the liver to improve the diagnosis and characterization of HCC^[52].

Assessment of treatment response

Anti-angiogenic agents have emerged as a class of anti-tumor agents that target tumor vasculature. The rationale of anti-angiogenic therapy is based on the observation that tumors require new blood vessels for growth and survival. Based on the diffusion distances of oxygen and nutrients, tumor cells cannot survive if they are further than 2 mm from a blood vessel. Thus, effective anti-angiogenic therapy acts by depriving a growing tumor of its nutrients, and can thus curb the growth of the primary tumor as well as its metastasis.

However, current methods of assessing efficacy of chemotherapy, such as the Response Evaluation Criteria in Solid Tumors (RECIST), are based on observing a decrease in tumor size^[35]. Effective anti-angiogenic therapy often manifests as lack of tumor growth rather than decrease in tumor size because the therapy is not cytotoxic. Hence, there is a need for a reliable response biomarker to assess the efficacy of such therapy.

The challenge for a reliable response biomarker holds true for HCC that is treated by local tumor ablation. Ablated tumor differs from viable tumor in its blood supply. Previous international consensus conferences have recommended that the RECIST criteria be modified for HCC to assess only the viable tumor^[34-36]. Viable tumor is defined as tumor that shows enhancement in the arterial phase. Thus, MR perfusion imaging also has the potential to provide valuable functional information that can be used to distinguish viable tumor from necrosis in HCC^[57].

Model-free approach: Wang *et al.*^[38] have analyzed the arterial uptake slope in MR liver perfusion studies of patients with HCC treated with thalidomide. They have found that there was a greater decrease in the peak enhancement, maximum enhancement, and slope of enhancement in patients without disease progression compared to those who progressed on treatment. Miyazaki *et al.*^[39] have applied HPI to assess the efficacy of anti-angiogenic therapy in patients with liver metastases and have found a median 15% decrease in HPI at 28 d after anti-angiogenic treatment in patients who responded to treatment. In another study, Meijerink *et al.*^[40] have evaluated liver HPI and have found that HPI decreased in liver tumor treated with combination anti-angiogenic therapy with AZD2171 and gefitinib. However, most of these

studies involved relatively small numbers of patients, and more studies are therefore required to establish whether MR liver perfusion indices can serve as a reliable response biomarker for anti-angiogenic drug therapy.

Meijerink *et al.*^[41] also have evaluated HPI for assessing local recurrence in liver metastases treated with RFA. The authors have found that an increase in HPI parallels disease recurrence detection by ¹⁸F-fluorodeoxyglucose positron emission tomography.

Model-based approach: There are few published studies that have applied a model-based approach for the evaluation of treatment response in hepatic malignancy. Chen *et al.*^[42] have studied the effects of transarterial chemo-embolization using a dual-input dual-compartment DP model and have found that the hepatic arterial fraction, hepatic arterial perfusion, and hepatic blood volume are significantly reduced by effective embolization. These indices could also help to indicate the presence of viable tumor. The potential of using model-based approaches for assessing the effects of anti-angiogenic or antivascular treatment is currently being investigated (Figure 9).

Cirrhosis

Model-free approach: Increase in hepatic arterial perfusion and decrease in portal venous perfusion have been reported in perfusion scintigraphy studies in patients with liver cirrhosis^[43]. Miles *et al.*^[2] and Blomley *et al.*^[3] also have found an increase in HPI and decreased PPI respectively in cirrhotic liver.

Model-based approach: Guan *et al.*^[44] have applied a dual-input dual-compartment DP model in rats treated with diethylnitrosamine. As diethylnitrosamine induces a continuum of hepatitis, hepatic fibrosis and eventually cirrhosis, a gradual increase in hepatic arterial flow and MTT are observed across these groups, accompanied by a corresponding gradual decrease in blood volume and blood flow.

Koh *et al.*^[4] have utilized a dual-input dual-compartment DP model and have found that cirrhotic livers return a measurable fractional interstitial space, whereas normal liver shows a near-zero fractional interstitial space. In another study, Hashimoto *et al.*^[5] have applied a dual-input dual-compartment DP model and have found that the hepatic arterial fraction increases with the extent of fibrosis and cirrhosis.

The use of a single-compartment kinetic model has also been found to be useful for the assessment of liver cirrhosis.

Annet *et al.*^[6] have investigated a dual-input single-compartment CC model and have found that the microcirculatory parameters derived from such a technique correlate with the severity of cirrhosis and portal pressure. The measured portal pressure, a reflection of the degree of portal hypertension, is correlated with the calculated portal fraction, portal perfusion and MTT. Furthermore, the severity of cirrhosis as assessed by Child-Pugh class has been found to correlate with portal fraction, portal

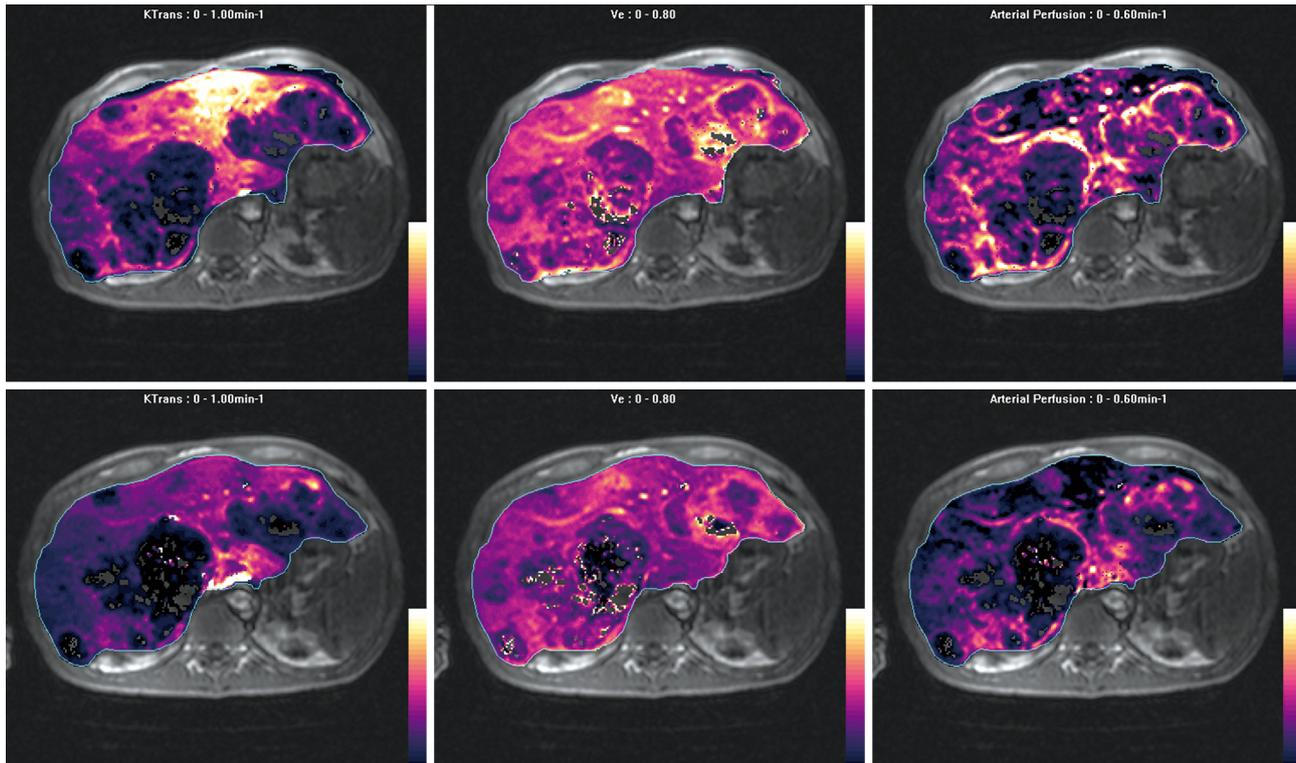

Figure 9 Parametric maps of efflux constant (Ktrans), extravascular extracellular space (Ve) and arterial perfusion fraction before (top row) and after (bottom row) anti-angiogenic therapy obtained using a dual-input, single-compartment, conventional compartment model (after Materne *et al*^[46]). Note multiple metastases in the liver, which are largely hypovascular but show increased arterial perfusion at the edge of the lesions. The metastases also show moderate Ve. After treatment with anti-angiogenic drug, arterial perfusion is reduced at the tumor rims, also with a decrease in tumor Ve. The Ktrans in the left lobe of the liver is also decreased, which may reflect drug effects on microscopic disease.

perfusion, arterial perfusion and MTT. Cirrhotic livers have shown an increase in arterial perfusion, decrease in portal perfusion, decrease in total blood flow, and an increase in MTT.

These findings can be corroborated with other published studies. In an earlier study by Van Beers *et al*^[71], a cutoff threshold of 22.6 s for the MTT in the liver enabled the diagnosis of liver cirrhosis to be made with a sensitivity and specificity of 81%. In another study, Hagiwara *et al*^[81] have used a dual-input single-compartment CC model and have found that there was an increase in the arterial blood flow, arterial fraction, distribution volume, and MTT in patients with advanced hepatic fibrosis. Receiver operating curve analysis has shown that the MTT, distribution volume and arterial flow are good predictive parameters with an area under the receiver operating characteristic curves that ranges from 0.791 to 0.824, and reported sensitivity of 76.9%-84.6% and specificity of 71.4%-78.5%. Thus, MR liver perfusion appears to be a promising method for the non-invasive diagnosis of liver cirrhosis and for assessing the severity of the condition.

CONCLUSION

MR liver perfusion imaging provides functional information about the microcirculation of liver parenchyma and focal liver lesions and appears to be a promising technique for evaluating liver metastases and HCC;

for assessing the efficacy of anti-angiogenic or local tumor ablation therapy; and for diagnosing cirrhosis and assessing its severity. However, standardization of imaging acquisition and analysis techniques need to be actively addressed for the technique to be widely adopted.

ACKNOWLEDGMENTS

The authors would like to acknowledge Mr. Septian Hartono (National Cancer Centre, Singapore) and Dr. Keiko Miyazaki (Institute of Cancer Research, UK) for their valuable assistance in the preparation of the manuscript.

Abstract

Colorectal anastomotic leak remains one of the most feared post-operative complications, particularly after anterior resection of the rectum with, the shift from abdomino-peritoneal resections to total mesorectal excision and primary anastomosis. The literature fails to demonstrate superiority of stapled over hand-sewn techniques in colorectal anastomosis, regardless of the level of anastomosis, although a high stricture rate was noted in the former technique. Thus, improvements in safety aspects of anastomosis and alternatives to hand-sewn and stapled techniques are being sought. Here, we review alternative anastomotic techniques used to fashion bowel anastomosis. Compression anastomosis using compression anastomotic clips, endoluminal compression anastomotic rings, AKA-2, biofragmental anastomotic rings, or Magnamosis all involve the concept of creating a sutureless end-to-end anastomosis by compressing two bowel ends together, leading to a simultaneous necrosis and healing process that joins the two lumens. Staple line reinforcement is a new approach that reduce the drawbacks of staplers used in colorectal practice, i.e. leakage, bleeding, misfiring, and inadequate tissue approximation. Various non-absorbable, semi or fully absorbable materials are now available. Two other techniques can provide alternative anastomotic support to the suture line: a colorectal

drain and a polyester stent, which can be utilized in ultra-low rectal excision and can negate the formation of a defunctioning stoma. Doxycycline coated sutures have been used to overcome the post-operative weakness in anastomosis secondary to rapid matrix degradation mediated by matrix metalloproteinase. Another novel technique, the electric welding system, showed promising results in construction of a safe, neat, smooth sutureless bowel anastomosis. Various anastomotic techniques have been shown to be comparable to the standard techniques of suturing and stapling. However, most of these alternatives need to be accepted and optimized for future use.

INTRODUCTION

Since the first reports of laparoscopic colectomy in the 1990's, this technique has matured into a well-developed mode of therapy. It has introduced the colorectal surgical world to the advantages, and the unique perspectives and concerns of minimal access surgery. Colorectal anastomotic leakage remains one of the most feared post-operative complications, particularly after anterior resection of the rectum, with the shift from abdomino-peritoneal resections to total mesorectal excision and primary

anastomosis. It is also associated with a higher local recurrence rate and lower long-term survival. Moreover, long-term functional outcome might be adversely affected by anastomotic leakage^[1-4]. The importance of surgical technique is underscored by the wide variations of anastomotic leakage rates among surgeons. The frequency of anastomotic leakage ranges from 1% to 24%^[5-7]. The rate of leakage is generally considered to be higher for elective rectal anastomosis (12% to 19%) than for colonic anastomosis (11%)^[8-10].

PHYSIOLOGY OF GASTROINTESTINAL HEALING

Better appreciation of the principles of intestinal healing will lead to a better adoption of techniques to overcome the risk factors inherent to the laparoscopic approach and hence anastomotic dehiscence. The environment for wound healing is substantially different in an anastomosis, due to the presence of shear stress (secondary to intraluminal bulk transit and peristalsis), as well as the presence of aerobic and anaerobic bacteria.

The process of intestinal anastomotic healing can be arbitrarily divided into an acute inflammatory (lag) phase, a proliferative phase, and, finally, a remodeling or maturation phase. Collagen is the single most important molecule for determining intestinal wall strength, which makes its metabolism of particular interest for understanding anastomotic healing. After surgery, degradation of mature collagen begins in the first 24 h and predominates for the first four days. This is caused by the upregulation of matrix metalloproteinases (MMPs), which are an important class of enzymes involved in collagen metabolism. *In vivo* use of MMP inhibitors has been found to increase the strength of intestinal anastomoses by up to 48% at postoperative day three, which suggests that these enzymes are important in determining the risk of leakage. By postoperative day seven, collagen synthesis takes over, especially proximal to the anastomosis. After five to six weeks, there is no significant increase in the amount of collagen in a healing wound or anastomosis, though turnover and, thus synthesis, are extensive. The strength of the scar continues to increase progressively with time. The orientation and the cross-linking between collagen fibers maintain the tensile strength of the tissues^[11,12].

Bursting pressure is used as a quantitative measure to grade the strength of an anastomosis *in vivo*. This pressure has been found to increase rapidly in the early postoperative period, reaching 60% of the strength of the surrounding bowel by three to four days and 100% by 1 wk^[11]. In 1887, Halsted^[13] discovered that the submucosa provides the GI tract with the majority of its tensile strength. The bulk of collagen is contained within this layer, along with blood vessels, lymphatics, and nerve fibers. Type I collagen predominates (68%), followed by type III collagen (20%), and type V collagen (12%). The serosa is a thin layer of connective tissue that covers the muscularis propria. When creating an anastomosis, direct

apposition of this layer minimizes the risk of leakage^[14,15]. During the first postoperative days, anastomotic strength is limited, and hence the risk of wound failure is greatest, as collagen breakdown increases. Early anastomotic strength is therefore dependent on the suture- or staple-holding capacity of existing collagen, until a large amount of new collagen can be synthesized by both fibroblasts and smooth muscle cells. Postoperatively, anastomosis will be weak for one or two days until this occurs^[16-19].

FASHIONING ANASTOMOSES

Over the past two decades, numerous different materials have been used to join one bowel end to another, including catgut, stainless steel, and newer monofilamentous and absorbable sutures. In the past 30 years, stapling devices have been embraced enthusiastically by the surgical community^[11]. However, the choice of either technique in fashioning anastomoses is a matter of controversy among various schools^[18].

Apart from inert substances, most foreign materials will evoke an inflammatory reaction in the human body and surgical sutures are no exception. It is now known that silk has the ability to evoke an inflammatory reaction that can persist for weeks after implantation. Substances such as polypropylene (Prolene), catgut, and polyglycolic acid (Dexon) evoke a milder response. There is little difference between absorbable and nonabsorbable sutures with respect to the strength of the anastomosis^[11].

STAPLING

Surgical stapling devices were first introduced by Hülth, Humer (Budapest) in 1908; but their use has grown since the introduction of new and reliable disposable instruments in the past 30 years^[11]. However despite comparable results in terms of mortality, anastomotic dehiscence, and wound infection, the rate of stricture at the anastomotic site is considerably higher with staples than with sutures: 8% *vs* 2%, respectively, for colorectal anastomosis^[20].

Lim *et al*^[21] confirmed the presence of foreign body reaction in stapled human GI anastomoses. The source of the foreign materials eliciting this reaction was the stapler cartridges.

The literature fails to demonstrate superiority of stapled over hand-sewn techniques in colorectal anastomosis, regardless of the level of anastomosis, although a high stricture rate was noted with the former technique.

The use of staplers for intraperitoneal anastomosis has been questioned^[20]; Matos systematically reviewed (Cochrane Database) nine studies involving 1233 patients (622 stapled and 611 hand-sewn) and found that overall leaks were 13% *vs* 13.4%, clinical 6.3% *vs* 7.1%, radiological 7.8% *vs* 7.2%. There was insufficient evidence to demonstrate superiority of either technique^[20]. The decision over which technique to use must be judged on the basis of previous experience, clinical circumstances, and available resources. Another systematic review showed that both techniques (stapler *vs* Hand-sewn) are effective,

and the choice may be based on personal preference^[22]. Other prospective and randomized trials have shown different results. No significance intergroup difference was found in regard to time for anastomosis construction or occurrence of complications in colorectal anastomosis^[23]. In addition, the routine use of stapling instruments for infraperitoneal colorectal anastomosis could not be recommended because of a higher incidence of mishaps and strictures, even though the operation took less time to perform and anastomotic leakage occurred less often^[24].

Therefore, there is an ongoing search for an ideal method of anastomosis that would not only lower the incidence of dangerous complications, but also avoid the need for a defunctioning colostomy or ileostomy. Based on the aforementioned data, there is still controversy between surgeons.

It is therefore necessary to review all relevant studies and trials to resolve this issue. Multi-center, well-designed, randomized controlled trials are required to build a link between new technology and practice. As technology advances, the use of newer techniques should allow improvements in the quality of patient care.

COMPRESSION ANASTOMOSIS

Connecting sections of the intestine after the surgical removal of a diseased portion has been the subject of research and invention since the 19th century. The goal has been to find a method to eliminate the leakage associated with anastomosis. The principle of compression anastomosis consists of two opposing rings trapping the cut ends of the transected bowel with subsequent ischemia and eventual sloughing of the trapped bowel, thus releasing the rings into the fecal stream^[25]. Despite its technical safety, it was not accepted^[26].

The idea of compression anastomosis was first reported in 1826 by Denan, who conceived a sutureless bowel anastomosis that encompassed the inverting technique proposed by Lembert. The idea was to compress two bowel walls together and cause a simultaneous necrosis and healing process leading to the joining of the two lumens. In 1892, Murphy introduced a mechanical device known as “Murphy’s button” that was used for years^[27].

It comprises a pair of metal rings that hold circular segments of intestine together under continuous pressure; the rings are expelled several days after surgery. However, its clinical success was limited and the results were mediocre. Moreover, it was a metallic foreign body that remained in the lumen of the bowel for several days until it was spontaneously discharged from the body with the necrotic tissues^[28].

In the 1980s a device comprising two magnetic rings was used for intestinal anastomosis, but this concept was not further pursued^[29].

In 1984, Kanshin *et al*^[30] developed the AKA-2 device (Seidel Medipool, Munich, Germany) for colorectal surgery. In 1985, Hardy *et al*^[31] introduced the Valtrac biofragmentable anastomotic ring (BAR) (Davis and

Geck/Cyanamid, Danbury, CT). Numerous publications, including prospective randomized controlled trials (RCTs), reported that the BAR was safe and efficacious in both emergency and elective surgery^[31-39]. Both devices adopted the concept of compression anastomosis, and incorporated some of the basic features of Murphy’s button. However, in contrast to the BAR, the AKA-2 ring is not absorbable and it is usually disconnected from the anastomosis after four to six days. In addition, it was made exclusively for transanal application^[40].

Years later a novel device for performing compression anastomosis using the shape memory alloy (SMA) of nickel-titanium was introduced. The device is available both as a clip (Compression Anastomosis Clip or CAC, NiTi Medical Technologies, Netanya, Israel), and as a ring (Compression Anastomosis Ring or CAR, NiTi Medical Technologies). After approximately one week, the entire device, together with the necrosed tissue, detaches and is naturally expelled from the body^[41-44]. A summary of the four main types of compression devices is presented in Table 1.

CLASSIFICATION OF DIFFERENT COMPRESSION DEVICES

Valtrac™ BAR

Valtrac™ BAR is composed of two segments containing absorbable polyglycolic acid (87.5%) and barium sulfate (12.5%). It comes in a size range (25, 28, 31, and 34 mm). The two components interdigitate on a central frame; a 6-mm gap is seen between the scalloped edges of the BAR in the open position, and a 1.5-mm, 2-mm, or 2.5-mm gap is made in the fully closed position to accommodate different thicknesses of bowel wall. This also limits the amount of tissue necrosis^[45].

Each ring is securely placed into the cut bowel ends with the aid of a purse-string suture, and the device snapped shut. Between two and three weeks after the operation, the BAR rings fragment and are passed into the stool. This results in the production of a sutureless, inverted, serosa-to-serosa intestinal anastomosis^[46]. The BAR has been used for construction of various types of anastomosis, including procedures involving the upper and lower GI tract. Prior to the development of the transanal applicator, early studies often excluded patients with low rectal anastomosis^[47].

In a randomized control trial comparing BAR with stapling devices in extra-peritoneal mid-rectal anastomosis, surgeons did not consider the use of BAR to be more difficult than a stapled anastomosis. The time required to create a BAR anastomosis was slightly shorter than the time needed for a stapled anastomosis, although this was not statistically significant. The overall operating time, intraoperative blood loss, and postoperative complication rates were similar with both anastomotic techniques^[48]. Correspondingly, there were no statistical differences in the complication rates between the BAR and a sutured anastomosis in elective and emergency procedures^[48].

Table 1 Characteristics of the four main compression devices

	BAR	AKA-2	CAC	EndoCAR ²⁷
Absorbable	Yes	No	No	No
Application	Laparoscopy, laparoscopy, transanal	Transanal	Laparotomy, laparoscopy, hand-assisted lap	Laparotomy, laparoscopy, hand-assisted lap
Internal Lumen	11-20	25, 28, 31	8	One ring size (27 mm) replaces a number of competitive sizes (25-34 mm)
Average time to expulsion (d)	14-21	4-6	7	7-10
Type of surgery				
Elective/emergency	Yes/yes	Yes/yes	Yes/no	Yes/no
Foreign body reaction	No	Possible to metal pins	No	No
Tissue healing	Extensive fibrosis/may cause stricture	Extensive fibrosis/may cause stricture	Primary intention/no strictures reported	Primary intention/no strictures reported (recovery of multi-layer lumen structure)
Anastomotic index	Lumen capacity depends upon standardized ring size		Full lumen capacity within 8-12 wk	
Efficacy	Safe and secure and can be applied to achieve multiple anastomosis (in case requiring rapidity and security)			
Learning curve ¹	Technically difficult than the other three devices		Technically simple after education	
Cost ²	About \$600	NA	About \$3	NA (however higher than conventional staples)
Tissue thickness accommodation	Selecting ring size to be compatible with diameter and thickness of bowel wall	Same as BAR	Only one size, shape memory alloy that accommodates varies tissue thickness. Unique thermo-mechanical properties and super elasticity	
Type of anastomosis	End-to-end, end-to-side, side-to-side		Side-to-side	End-to-end
Site of anastomosis	Suitable for intestinal, colonic and rectal anastomosis	Distal colon and rectal only	Intestinal, colonic and rectal anastomosis	

¹Galizia *et al*^[47] described a learning curve of nine patients for BAR anastomosis. A meta-analysis of over 500 cases in North America, Europe and Israel, 75% of surgeons rated the CAR²⁷ device to be very easy or easy to use^[83]; ²Cost-effectiveness depend upon a number of factors namely learning curve and post operative morbidity. However, as multiple staplers are used for construction of most colonic/rectal anastomosis, there might be a cost advantage for compression devices. BAR: Biofragmentable anastomotic ring; CAC: Compression anastomotic clip.

An initial study with large animal models (300 dogs and 31 pigs) presented a randomized analysis of 28 pigs, comparing sutured, stapled and BAR anastomosis. They found the “Burst” pressure at day 0 was highest with the BAR and equal at days seven and 16 in all three types of anastomosis. The authors stated that the BAR anastomoses were performed more easily and quickly than the other two anastomoses. Microscopic examination also revealed the least amount of tissue necrosis for the BAR anastomosis^[46].

In 1987, Hardy *et al*^[49] published results of the first 27 patients who had colorectal anastomoses using the BAR device. They reported no difficulties and all patients tolerated a regular diet before fragmentation of the rings.

In the 1990s, the device gained popularity and a number of prospective studies confirmed that the results with the device were satisfactory, although there were reports of intraoperative problems, such as failure of the purse-string suture, incorrect estimation of the diameter of the colon lumen, subsequent mucosal tears, and failure of the device to lock. Many of these might simply have been because of the operator’s learning curve^[33,50-53].

Based on the previously mentioned studies, possible limitations of the device include: (1) Failure of purse string sutures; (2) Incorrect estimation of colon lumen diameter; (3) Subsequent mucosal tears; (4) Failure of the device to lock (the bowel might be contused by closing maneuver from outside the gut); (5) Excessive snapping

pressure could shatter the friable device; (6) fragmentation delay; (7) possibility of postoperative tenesmus and frequent stool passage before excretion of fragments; (8) bulky and uncomfortable device to deploy; and (9) potential risk of relative obstruction due to smaller inner diameter of the ring.

AKA-2

In 1984, Kanshin *et al*^[30] developed the AKA-2 device (Seidel, Medipool) to address the transanal approach for compression anastomosis. The AKA-2 is composed of two rings: a base ring, which includes metal pins and metal springs, attached on a plastic ring (the “distal ring”), and a proximal plastic ring (the “proximal ring”). The rings are applied with a transanal applicator. The AKA-2 works on a similar principle to that of endoanal stapling devices, though the bowel edges are pressed together with intraluminal rings and held in place by metal pins. Circular blades cut the central cuff of bowel, and the metal pins ensure constant compression on the inverted bowel edges. The two plastic rings and the compressed resection margins separate from the anastomosis after four to six days and are expelled with the feces^[46]. The technique had an advantage in that it created a good lumen size for stool passage.

There is only one report in English of the use of this device^[40]; the majority of the literature being in Russian or German. A prospective audit presented the results of

442 patients undergoing colorectal surgery for benign and cancerous disease. There was a 5.4% overall complication rate, with 11 patients (2.5%) developing clinical features of an anastomotic leak, which is relatively low compared to other series using various anastomotic techniques^[48,49,54,55]. Fourteen of the 442 patients died (3.2%), of which three cases were related to anastomotic leak (0.7%). Among 442 patients who underwent AKA-2 anastomosis only two patients developed a stricture^[40].

The authors maintain that the advantage of this device is that it produces a good size lumen for the passage of feces. The plastic ring sizes are 25, 28, and 31 mm, respectively. In addition, necrosis of inverted resection margins is the only biological factor leading to the rejection of the plastic rings, which is an advantage in cases with delayed healing. However, early device exclusion raised the possibility of higher leak rate, as it is concurrent with the maximal breaking strength of anastomosis^[46].

Compression anastomotic clip

Nitinol^[60] (Nickel Titanium Naval Ordnance Laboratory), an alloy of nickel and titanium, is a temperature-dependent, shape-memory alloy (SMA) that has been used in the formation of compression anastomoses^[56]. The metal is shaped under high temperatures, and when it is ice cooled (to less than 0°C), it loses its rigidity and becomes flexible. At or above room temperature, it resumes its preset configuration. It has been used mostly for vascular prostheses, orthodontic braces, and for internal fixation of bone fractures for its inherent advantage of controlled compression with a constant force^[46].

The Nitinol CAC device (Niti Medical Technologies) has been approved by the food and drug administration (FDA) for use in GI surgery^[41]. The device consists of a double-ring that, in the open and flexible state (at 0°C), has a diameter of 30 mm and an opening angle of 30 degrees. At body temperature, the rings return to their closed configuration and hold bowel tissue under a constant compressive force, regardless of the thickness of intervening tissue. This leads to ischemia of the entrapped bowel wall and the formation of a compression anastomosis. The internal diameter of the rings is 8 mm, and is pierced by a 5-mm blade built into the applicator to restore bowel continuity in the early period. The device is elastic, pliable, and easy to manipulate^[46].

Initial reports on both animal and human studies using the CAC device to create a side-to-side anastomosis in upper and lower GI tracts revealed no signs of anastomotic stricture or leakage, with formation of a uniform, completely re-epithelialized anastomotic line^[41]. There were no reported postoperative complications, and colonoscopic examination at six months demonstrated a satisfactory anastomosis^[43].

The safety of this device has been documented in numerous animal studies^[41,57], and the safety of the alloy has been demonstrated by its extensive uses in other medical procedures. The CAC was considered to be

safe, simple, and effective in colon surgery in a study that evaluated the thermo-mechanical properties of the device^[58].

In line with this conclusion, a randomized control trial studied the clinical effects of using the CAC device in small intestinal anastomosis proximal to the ileocecal valve. CAC anastomosis was performed in 33 out of 66 patients, with the other 33 patients being used as a control group for whom a stapled anastomosis was constructed. The main indication was gastric cancer in both groups. Anastomosis was fashioned to reconstruct a Roux-en-Y loop, entero-entrostomy, Billroth II gastro-jejunostomy, and gastro-jejunostomy. The authors found no post-operative complications whatsoever in terms of leakage, obstruction, bleeding, or stenosis after six months of follow-up^[59].

Clinical trials for SMA of nickel-titanium in intestinal anastomosis are scarce, and all of the clinical reports are of CAC from a single center that included only elective cases performed both by laparotomy and laparoscopically^[42-44]. None of the patients who underwent surgery with CAC had a protective stoma. None of the patients reported so far in published clinical studies experienced a clinical leak and initial experience with a laparoscopic technique had similar results, thus precluding the learning curve among surgeons.

The consensus among the published studies was that microscopic examination of the CAC anastomosis showed minimal inflammation and no foreign body reaction, with very little scar tissue at the anastomotic line.

The specific advantages of the CAC include a one sized clip with a wide external diameter, preprogrammed round shape negating the need to forcefully close the rings and therefore diminish the risk of shattering the device. It exerts constant compression of the bowel ends, regardless of the intervening tissue thickness; coils exert a constant stress plateau at about 400 Mpa. The result is a smooth homogenous anastomosis formed by the gradual controlled necrosis of the tissue, limited by the coil perimeter while the external edges become sealed^[46]. A drawback of this device is the need for suture closure of the insertion incisions made in the bowel wall.

Endoluminal compression anastomotic ring, EndoCAR²⁷

The endoluminal compression anastomotic ring, EndoCAR²⁷ (spectrum of the shape memory alloy of nickel-titanium), utilizes two separate synthetic rings that are mounted on an instrument very similar to a circular stapler. An anvil containing one ring is fixed to the proximal bowel end, and the instrument with the other ring is inserted trans-anally for a rectal anastomosis. When engaged, the rings are locked together by Nitinol springs that exert the desired constant controlled pressure force (7.7 Newtons or 1.65 Pounds), and a circular knife resects the access tissue. As in the side-to-side device, a simultaneous necrosis-healing process takes place, and at the completion of this process (seven to ten days), the

device is detached and expelled naturally. Furthermore, the longitudinally orientated metal prongs further fixate both bowel ends and prevent tissue slippage from axial movements. An advantage of this contemporary device is that there is no anastomotic-scarred lip inside lumen and a safe applicator removal without fishtailing^[60].

Two separate studies looked at bursting strength in a porcine model. Kopelman *et al*^[57] measured a mean bursting strength of 247.7 mmHg (range 100-300 mmHg) in nine animals at time zero (immediately after the excision of the fashioned anastomosis). Furthermore Stewart *et al*^[61] revealed a significantly higher bursting pressure after compression anastomosis in comparison with a conventional double stapling technique (103, 75.3 mmHg *vs* 3, 23 mmHg, respectively). Four of the nine compression anastomoses failed at the anastomotic line whereas nine of nine stapled anastomoses failed at the staple line (Fishers' exact test, $P < 0.01$). Bursting pressures measured at two weeks after the anastomosis revealed equal pressures (266, 32.2 mmHg and 230, 87.5 mmHg, respectively). Compression therefore seems to be capable of overcoming anastomotic weakness during the 'classical' lag-phase and to result in equal strength after detachment of the ring^[62].

Kopelman *et al*^[57] looked at the anastomotic index (ratio of the mean bowel diameter 5 cm proximal and distal to the anastomosis and on antero-lateral and posterior view), which was 0.81 (0.60-0.92) at two months.

An early clinical trial was performed in Israel using the EndoCAR²⁷ device to construct a left-side anastomosis. Four patients were enrolled. No device related complications were noted in these patients and no anastomotic leak reported (unpublished data). Based upon that experience, a pilot study was started in May 2007 in Uppsala (Sweden) and in Leuven (Belgium) to obtain clinical data in a consecutive group of 40 patients^[62]. The recruited patients had either malignant or benign (diverticular) disease requiring resection with a high colorectal anastomosis (between 10 and 15 cm from the anal verge). Preliminary results from that pilot study showed that of the first ten patients, nine underwent high

anterior resection, and left colectomy was performed on one patient. No leak age occurred in this first group of patients. No other data is available yet.

These promising results demonstrate that this device could be a revolutionary invention in colorectal practice; however, there are still doubts regarding its efficacy in low/ultralow rectal anastomoses. The location of the ring above the pelvic floor could induce persistent anal sensation (urge) and it is still unknown whether a spontaneous evacuation will occur in diverted patients.

Magnamosis

Controlled magnetic approaches have shown promise in biliary and vascular anastomoses (although the latter involves permanent implantation). A specially designed self-orienting device has been put into a trial to test the hypothesis of creating a magnetically mediated intestinal anastomosis using a temporary device that is expelled some time after creating the desired compression-necrosis effect (Department of Surgery, University of California, San Francisco)^[63].

Two topologies were evaluated; namely the uniform and the gradient compression device. The study was conducted on 16 pigs with the creation of a side-to-side anastomosis. Half of these were created with the uniform device and the rest with the gradient. They also created hand-sewn and stapled side-to-side anastomosis for comparison. Devices were designed with surface fields of approximately 3000 Gauss (G). Preliminary experimentation had revealed that combinations of 3000/6000 G and 6000/6000 G uniformly caused necrosis and perforation within 48 h independent of device geometry. The results were promising, with the creation of successful patent anastomosis using the magnetic devices and no leaks reported^[63].

The mechanical integrity of the magnetic anastomoses was not statistically significantly different from stapled or hand-sewn; however, there was a trend toward greater strength with the gradient type device and earlier patency. No evidence of stenosis was reported^[63].

Table 2 presents the past clinical experience with

Table 3 List of reinforcement materials^[64]

	Material	Stapler type	Company
Non-absorbable	ePTFE	Linear	W.L. Gore, Elkton, MD, USA
Semi-absorbable	Bovine pericardium (peristrips dry)	Circular linear	Synovis Life Technologies, Inc.
	Porcine small bowel (surgisis)	Linear	Cook Biotech Inc.
Absorbable	Polyglycolic acid:trimethylene carbonate (seamguard bioabsorbable)	Linear circular	W.L. Gore & Associates, Inc.

	Knitted calcium alginate (foreseal)	Linear	Laboratoires Brothier, Nanterre, France

compression anastomosis devices and their related complications.

BUTTRESSING OF INTESTINAL ANASTOMOSIS

Many staple devices are commercially available, however all the different types and models have inherent drawbacks that contribute to post-operative complications. Complications such as enteric leakage, bleeding, inadequate tissue approximation, and misfiring (technical failures) have been reported. However, complications related to colorectal anastomosis are the most devastating in terms of morbidity and mortality^[64].

A new approach to reduce this is to use staple line reinforcement materials. Gastrointestinal reinforcement is well known, but its application in colorectal surgery is relatively new^[65]. The application of buttressing materials is thought to moderate the tension of the stapler line because it acts as a neutralization plate. It reinforces the stapler line by sealing the gaps between staples and narrowing the spaces, thus reducing tearing of tissues, bleeding, and leakage^[64]. Reinforcement materials can be applied exogenously to the staple line or incorporated into it. The material is composed of two regions, one that secures it to the stapler prior to activation, and is later discarded, and the other forms the seal. It has an adhesive surface and is readily packed in a sterile manner^[65].

Reinforcement material can be non-absorbable, semi- or fully-absorbable. Studies have shown diminished incidence of leakage and stapler line failure in gastrointestinal and pulmonary surgery. Although all types of materials seem equally adequate in reducing staple line complications, the material itself can cause problems^[65]. Therefore, the choice of material must be considered from a safety point of view, although there seems to be advantages of absorbable material over the other two types.

The effects of the materials in colorectal anastomosis have been tested in a small clinical pilot study by Franklin *et al.*^[66,67] using bio-absorbable seamguard (BSG) with a linear stapler. Published data revealed no bleeding, or apparent bleeding, at the staple line.

Several reports support the theoretical benefits of reinforcement materials in increasing the burst pressure^[68-71]. It

was also hypothesized that buttressing of stapler line can have a positive effect on tumor recurrence^[66]. Although published studies showed a decrease in complications with these materials, no previous studies have shown significant results for reducing bleeding or leak rates at the stapler line. Thus, further research and investigations are required. Table 3 refers to the list of materials used as staple line adjuncts.

Non-absorbable materials

ePTFE: ePTFE is a very easy and quickly employed material composed of non-absorbable expanded polytetrafluoroethylene. It is constructed like a sleeve that can be slid over both arms of the stapling device negating the need for additional fixing to the stapler before firing. After firing, the material is released from the arms by pulling a ripcord. The potential benefits of this material include a low host response and biocompatibility. There are no reports of strip erosion or migration with this material, which evokes a minimal tissue inflammatory reaction. It provides thick tissue coverage for an extended period of time with no extra handling time required for its preparation and use. Its application suits open and laparoscopic procedures^[72,73].

Semiabsorbable material

Bovine pericardium: This material is composed of bovine pericardium (peristrips dry). It is temporarily attached to the stapler with gel (which is applied to inner surface of both stapler arms), after which the stapler is positioned and locked over the strips. It can be applied on linear, as well as circular, staplers. The material is then incorporated by the host tissue after firing the stapler. Apart from increasing the burst pressure, this material demands relatively more handling time than other materials. However, it has the potential of to reduce the time required to stop staple line bleeding. Possible limitations include a high risk of animal source contamination, resulting in an inflammatory reaction to the xenomaterial (non-biocompatible). This makes it prone to erosion and migration^[64]. Recently, its combination with Veritas technology results in remodeling of the material into indistinguishable host tissue.

Porcine small intestinal submucosa: This is a completely resorbable, acellular xenograft composed of

porcine small animal submucosa. It is suitable for anastomotic and non-anastomotic staplers. A potential advantage is that it provides a bioscaffold for tissue growth, inducing submucosal regeneration and also achieving an increase in burst pressure^[74,75]. However, its efficacy in human staple-line reinforcement is undocumented.

Absorbable material

Polyglycolic acid:trimethylene carbonate: This is a synthetic fiber web that is composed of polyglycolic acid: trimethylene carbonate Maxon polymer. It is formed like a sleeve to be fitted over the stapler arms and released by pulling the suture that holds the sleeve in place. It can also be affixed as discs onto circular-type staplers. The material is strongly biocompatible, simple and easy to apply on the stapler and is non antigenic. It maintains its strength for four to six weeks and is fully resorbed after six months (hydrolytic and enzymatic reactions lead to the breakdown of the material)^[76,77]. Overall, it minimizes staple-line bleeding, leakage, and operative time^[78-80].

Cellulose: Cellulose (XylosT M Surgical Reinforcing Material. Xcell SDMC surgical film) was originally developed as a wound dressing. This dry sterile material is composed of a microbially-derived cellulose matrix having multilayered, three-dimensional structures. The cellulose is produced by *Acetobacter xylinum* bacteria and is processed into a resorbable form. Research is in progress to evaluate and construct it as a possible staple line reinforcing material in GI surgery^[81].

Knitted calcium alginate: This material is composed of polysaccharidic polyglycuronates biopolymers (highly purified fractions from calcium alginates), originating from seaweeds. The device consists of preformed coated knitted bio-absorbable sheets held into the form of sleeves (one cartridge device, one anvil device) sized to fit snugly onto the forks of the surgical stapler. When applied to wet surfaces, the material becomes highly conformable and acquires bio-adhesive and sealant properties. It contains no additives or preservatives, and therefore no presoaking or rinsing is required as a preparatory step. The device is easy to handle and simple to apply, eliciting minimal foreign body response^[82]. However, clinical trials are scarce.

OTHER FORMS OF ANASTOMOTIC SUPPORT

C-seal (polyganics)

The colorectal drain (C-seal) is applied with a circular stapler. It is a single use tubular device, closed at one end and composed of biodegradable synthetic material. It is a thin walled tube with an approximate diameter of 3 cm and an approximate length of 20 cm. This drain works as a shield covering the newly formed anastomosis, preventing contact between the bowel contents and the

anastomosis. Degradation process starts gradually, and the material is expelled from the bowel after approximately 10-15 d. Its theoretical benefits lie in the ability to protect a low rectal anastomosis, preventing leakage. It can also be used as a staple line adjunct. It is microbiologically safe and is completely expelled after two weeks, negating the use of a protective defunctioning stoma in low rectal excision^[83].

Polyester stent

Most recently, covered intraluminal stents have been successfully introduced to manage anastomotic leaks after esophagectomy and gastric bypass operations.

A randomized control trial in a large animal model addressed this issue in stapled colorectal anastomosis. The study found that placement of a covered polyester stent across a colorectal anastomosis prevents leak-related complications and supports healing of an anastomotic leak^[84].

It consists of a polyflex self-expandable covered plastic stent (25 mm proximal flare and 12 cm long) and a delivery system. The outer layer is composed of braided polyester and the inner layer is silicone (no gaps in this layer). It is applied through a standard flexible colonoscope using a guide wire and a delivery system, and is deployed under fluoroscopic control after reconstruction of the end-to-end anastomosis. The components of the material allow it to adapt elastically to the lumen wall, exerting a well-balanced radial force. The silicone membrane provides a reliable leak occlusion, preventing ingrowth of granulation tissue; hence allowing stent repositioning or removal. Similarly to C-Seal, it negates the need for a diverting stoma in low rectal excision. However, the main disadvantage for the future of these types of stents is migration^[84].

NOVEL TECHNIQUES

Doxycycline coated sutures

Experimental studies revealed that the strength of an intestinal anastomosis diminishes postoperatively reaching a nadir on the third postoperative day. This is mediated by the increased activity of MMP, causing local matrix degradation in the tissue surrounding the sutures. This activity is higher still in concurrent bacterial peritonitis, with subsequently greater deterioration of anastomotic strength. Several experimental studies showed that MMP inhibitors administered systemically alleviate postoperative weakening of intestinal anastomoses. Other studies have shown the beneficial effects of treatment with systemic MMP inhibitors, e.g. doxycycline, most notably on the critical third postoperative day^[85-87].

Potent MMP inhibitors administered systemically can cause joint stiffness, swelling^[88], and other toxic reactions^[89]. Additionally, there are concerns about detrimental effects of broad-spectrum hydroxamate MMP inhibitors on secondary healing of cutaneous wounds^[90], although these types of MMP inhibitors can increase tensile strength of primary skin wounds^[91]. The less

potent MMP inhibitor doxycycline does not appear to delay wound closure^[92]. Due to adverse systemic effects, local delivery of an MMP inhibitor in humans would be advantageous over systemic administration^[93].

This hypothesis was studied by Pasternak *et al*^[93] in 2008. They implemented a novel method for coating sutures with a cross-linked fibrinogen film and then bound the MMP inhibitor (doxycycline) into this film. The sutures were then used in a standard rat model for evaluating mechanical properties of colonic anastomosis three days after surgery. The breaking strength of the anastomosis was higher with the doxycycline-coated sutures than with the controls. This might inspire further studies involving pharmacological manipulation of intestinal healing by local drug delivery^[93].

Electric “Welding” of soft tissues

Experience of the application of electric surgery for cutting tissues and hemostasis is about one hundred years long. It has been established that under certain conditions, it is possible to join incisions in different organs and soft tissues by a method based on heating the joint zone by a high-frequency current. Electric welding to join incisions of live tissues and organs during surgery was applied for the first time by the team of researchers of the E.O. Paton Electric Welding Institute of NASU in cooperation with the scientists and specialists of the experimental department of the Institute of Surgery and Transplantology (IS&T) of AMSU with participation of International Association (Welding) and financial support of CSMG Company, USA^[94].

They developed a novel welding system that includes a power unit comprising a power source (High frequency coagulator) with an adaptive automatic control system and special software, bipolar welding tools (forceps, clamps and laparoscopes) connected to a power source, and special assembly devices. The control system is based on feedbacks. The tissue layers being joined are brought into contact over their surface layers by means of the welding tool. The surgeon clamps the tissue to be welded by the electrodes of the tool and switches on the welding current source. Upon completion of the process (i.e. thermal denaturation of albumin molecules), control program power is turned off. Clamped tissue is then released and process repeated until complete wound closure^[94].

The device has been tested in multiple experimental trials and on more than 2000 patients in the clinics and hospitals of Kiev, Ukraine. The author maintains that the advantage of the device is in the formation of an attractive, neat, smooth thin welded anastomosis. In addition, it is a fumeless and odorless technology, causing no burns to surrounding tissues. The report demonstrates a reduction of blood loss and no organ deformation or stenosis. It also shortens the average operative time (20-40 min)^[94].

CONCLUSION

Although alternatives to the conventional methods have

been sought, many have been abandoned by the surgical community.

Compression anastomosis, although existing for decades, has not gained worldwide popularity. This concept seems to be difficult for surgeons to accept, as it includes relying on a device to create an anastomosis and letting it be spontaneously discharged from the body. Re-institution of this concept using new technology, such as Nitinol, could be a potential replacement for the current available techniques. Controlled magnetic anastomosis is no exception to this. It is a promising novel technique for creation of a side-to-side anastomosis but requires to be optimized for future use.

The theoretical benefits of colorectal seals and the polyester stents as adjuncts to creating an end-to-end anastomosis could alleviate the need for a defunctioning stoma for lower rectal tumor resections. This is another concept that needs to be accepted and subjected to further research to optimize its use. In line with this, staple line reinforcement is an effective technique for reducing perioperative complications in stapled resection and anastomoses, with absorbable materials having a considerable advantage over semi or non-absorbable material(s). However, there has been little experience with absorbable staple line reinforcement materials.

A contemporary and sophisticated technique, such as electric tissue welding shows a promising future in modern surgical techniques. It is a revolutionary technique that still needs acceptance and research, utilizing greater patient samples in colorectal surgical practice.

Finally, overcoming the postoperative anastomotic weakness due to over activity of matrix metalloproteinases, and hence the risk of dehiscence, using doxycycline coated sutures should also be explored.

In summary, these various techniques fulfill the requirements of creating a safe anastomosis (overcoming the lag-phase, increasing the bursting pressure, and decreasing the rate of leakage, bleeding and stricture). They revealed great differences in avoiding dramatic complications that can occur with the conventional methods; an outcome that every colorectal surgeon would advocate. Surgeons need to widen their scope of practice, and further trials and research are required to overcome “dogmas” in traditional colorectal practice. Keeping abreast of technological advances is considered vital in every surgeons training and daily practice; failure to do so could lead to reduced quality of patient care.

Abstract

AIM: To investigate the potential therapeutic effect of exopolysaccharide (EPS)-producing *Streptococcus thermophilus* (*S. thermophilus*) CRL 1190 fermented milk on chronic gastritis in Balb/c mice.

METHODS: Balb/c mice were fed with the fermented milk for 7 d after inducing gastritis with acetyl-salicylic acid (ASA, 400 mg/kg body weight per day for 10 d). Omeprazole was included in this study as a positive therapeutic control. The gastric inflammatory activity was evaluated from gastric histology and inflammation score, number of interleukin-10 (IL-10), interferon- γ (INF γ) and tumor necrosis factor- α (TNF- α) cytokine-producing cells in the gastric mucosa, and thickness of the mucus layer.

RESULTS: Animals receiving treatment with the EPS-

producing *S. thermophilus* CRL 1190 fermented milk showed a conserved gastric mucosa structure similar to that of healthy animals. Inflammation scores of the fermented milk-treated mice were lower than those of mice in the gastritis group (0.2 ± 0.03 vs 2.0 ± 0.6 , $P < 0.05$). A marked decrease in INF γ^+ (15 ± 1.0 vs 28 ± 1.2 , $P < 0.05$) and TNF- α^+ (16 ± 3.0 vs 33 ± 3.0 , $P < 0.05$) cells and an increase in IL-10 $^+$ (28 ± 1.5 vs 14 ± 1.3 , $P < 0.05$) cells compared to the gastritis group, was observed. Also, an increase in the thickness of the mucus gel layer (2.2 ± 0.6 vs 1.0 ± 0.3 ; 5.1 ± 0.8 vs 1.5 ± 0.4 in the corpus and antrum mucosa, respectively, $P < 0.05$) compared with the gastritis group was noted. A milk suspension of the purified EPS from *S. thermophilus* CRL1190 was also effective as therapy for gastritis.

CONCLUSION: This study suggests that fermented milk with *S. thermophilus* CRL 1190 and/or its EPS could be used in novel functional foods as an alternative natural therapy for chronic gastritis induced by ASA.

INTRODUCTION

Gastritis is a common disorder where discontinuity of the gastric mucosa is observed. It is caused by several factors,

such as alcohol, stress, infection with *Helicobacter pylori* (*H. pylori*)^[1-3], resulting in an imbalance between offensive acid-pepsin secretion and defensive mucosal factors like mucin secretion and cell shedding^[4]. Non-steroidal anti-inflammatory drugs (NSAIDs) such as acetyl-salicylic acid (ASA) are used worldwide as anti-inflammatory and analgesic agents in the treatment of chronic diseases such as rheumatoid arthritis and osteoarthritis^[5] as well as for the prevention of cardiovascular diseases. However, gastrointestinal injury is a serious adverse effect of NSAIDs producing a broad range of toxic effects mainly in the stomach^[6], the toxicity of ASA being attributed to direct damage of mucosal cells^[7]. Furthermore, ASA affects various mucosal defense lines such as bicarbonate secretion, mucus synthesis, decrease of mucosal blood flow^[8,9] with amplification of the inflammatory process by expression of pro-inflammatory cytokines^[10].

Among the most conventional drugs employed for the treatment of gastritis are proton-pump inhibitors such as omeprazole (OM)^[11]; however, most of these drugs also produce undesirable side effects and drug interactions^[12].

Probiotics are “live microorganisms which when consumed in adequate numbers confer a health benefit on the host^[13]”. Probiotic foods containing lactic acid bacteria (LAB) have been used in the treatment of various gastrointestinal disorders, such as gastric ulcers and inflammation related to *H. pylori* infection, gastrointestinal infections or antibiotic-associated diarrhea^[14-16], providing beneficial effects to the host by modulating immune functions, e.g. systemic cytokine production^[17]. The mucosal immune system is functionally divided into sites where foreign antigens are taken up and meet immune cells to initiate the immune response through a network of signals among different cell populations. This cell network is highly integrated by cytokine production, and finely regulated by the selective expression of cytokine receptors. The T-helper (Th) cell subsets and cytokine patterns determine the nature of the immune response^[18].

Some LAB strains secrete exocellular carbohydrate polymers named exopolysaccharides (EPS). A large diversity of EPS from LAB strains exists regarding their chemical characteristics, yield, technological and functional properties^[19-21]. EPS play an important role in the dairy industry mainly in yogurt production and certain kinds of cheeses such as reduced-fat cheddar and mozzarella^[22], improving the textural, melting and sensory characteristics of the products. The health-promoting effects ascribed to probiotic strains or foods arise not only from the bacteria themselves but also from the metabolites produced during fermentation.

EPS from LAB have been claimed to participate in various regulatory processes such as immunomodulatory, cholesterol-lowering and anti-ulcer activities^[23,24]. In previous work^[25], we demonstrated that Balb/c mice fed a fermented milk with the EPS-producing *S. thermophilus* CRL 1190 was efficient in gastritis prevention through the modulation of the immune response and maintenance of the mucus layer. The present study addressed the potential

therapeutic application of fermented milk prepared using the EPS-producing *S. thermophilus* CRL 1190 strain for the treatment of ASA-associated chronic gastritis.

MATERIALS AND METHODS

Strain, culture conditions and preparation of the fermented milk

S. thermophilus CRL 1190 {EPS⁺ and producing also capsular EPS, CPS⁺; [Centro de Referencia para Lactobacilos (CERELA) culture collection, Tucumán, Argentina]} was used in this study. This strain was previously selected for the physicochemical properties of its polysaccharide^[20], for displaying no secondary effects such as bacterial translocation (liver and spleen), and for its effectiveness in preventing gastritis induced by ASA^[25]. The strain was cultured (10 mL/L inoculum) in LAP1g broth (peptone, 15 g/L; tryptone, 10 g/L; yeast extract, 10 g/L; glucose, 10 g/L; and tween 80, 1 mL/L) and sub-cultured at least twice in reconstituted skim milk (RSM, 100 g/L) just prior to experimental use. The strain was maintained at -20°C in RSM containing 100 mL/L glycerol, 10 g/L glucose, and 5 g/L yeast extract.

Fermented milk was prepared in sterile RSM (sterilized at 115°C for 20 min and cooled down to 37°C) using a 10 mL/L inoculum of an active culture of the EPS⁺ strain *S. thermophilus* CRL 1190 (named FM 1190), incubated at 37°C for 16 h and maintained at 4°C prior to experimental use. Non-fermented milk was used as a control.

Animals

Six week-old Balb/c male mice (25-30 g) were obtained from a closed colony kept at the animal facilities of CERELA and maintained in a room with a 12-h light/dark cycle at 20 ± 2°C. Animals were individually housed in cages (20 cm × 30 cm × 15 cm) with litter tray (20 cm × 30 cm × 6 cm) and allowed to have free access to conventional balanced diet and water *ad libitum*. All mice received no food for 24 h before the assays but had free access to water. Animal protocols were approved by the Ethical Committee for animal care of CERELA.

Experimental protocol

Chronic gastritis was induced following the protocol previously standardized in our laboratory^[25]. Oral administration of ASA (BAYER[®]) supplied in the drinking water given at an approximate daily dose of 400 mg/kg per day for 10 d induced chronic gastritis in Balb/c mice (gastritis group, G). The administered dose was twice the analgesic dose for mice and was applied to induce gastritis in a short experimental time period. Healthy mice (H) received drinking water without ASA during the same experimental period (negative control group).

To evaluate the therapeutic effect of FM 1190 on the chronic gastritis model, animals were randomly divided into 6 groups ($n = 5$ each): (1) H group: received drinking water without ASA for 10 d; (2) G group: received ASA for 10 d as described above; (3) FM 1190 group: received

FM with the EPS-producing strain CRL 1190 for 7 d after gastritis induction. FM 1190 was administered *ad libitum* at an approximate dose of 10^8 cfu/mL; daily fermented milk consumption was monitored and intake was set at 5 mL/d; (4) Omeprazole (OM) group: received OM (used as positive control in ASA-induced gastric lesions) at a daily dose of 30 mg/kg per day^[26] for 7 d after gastritis induction; (5) Milk group (M): received non-fermented milk for 7 d after gastritis induction; and (6) Water group (W): received water for 7 d after gastritis induction (used as negative control).

To determine whether the EPS produced by *S. thermophilus* CRL 1190 (EPS 1190) had an anti-gastritis effect, the polymer was isolated from 16-h milk cultures grown at 37°C by using a deproteinization/precipitation technique with 200 g/L (final concentration) trichloroacetic acid, and ethanol (ratio 1:3)^[20], was further purified as described previously^[19], and freeze-dried and stored at 4°C until use. The EPS 1190 was resuspended in RSM (M-EPS 1190) or in water (W-EPS 1190) and administered to mice intragastrically at a dose of 4 mg/kg per day for 7 d after gastritis induction. The administered EPS amount was calculated based on the EPS quantity received by the animals when they were fed with FM 1190.

After the experimental period (day 11 for groups 1 and 2, and day 18 for the remaining groups), mice were sacrificed by cervical dislocation and weighed. Stomachs were aseptically removed, weighed and rinsed several times with saline solution and used for the assays described below.

Histopathological evaluation of gastric samples

Stomachs were fixed in 10% paraformaldehyde in 0.1 mol/L phosphate-buffered saline (PBS) pH 7.0 and embedded in paraffin following the Sainte-Marie technique^[27]. Three serial paraffin sections (4 µm) of each sample were cut from each specimen and stained with hematoxylin-eosin followed by light microscopy examination (Leica DM LS2, Wetzlar, Germany). The pathologic characteristics and degree of inflammation of the gastric mucosa were assessed according to the updated Sydney system^[28] by microscopic observation without knowledge of the experimental groups and expressed as follows: normal appearance of scattered mononuclear cells in the lamina propria (same degree as healthy control mice): none = score 0; mild infiltration of mononuclear cells in the lamina propria and the submucosa, and no erosion in the epithelium: mild = score 1; moderate infiltration of mononuclear cells in the lamina propria and the submucosa, and no erosion in the epithelium: moderate = score 2; and severe infiltration of mononuclear cells in the lamina propria and the submucosa, and erosion in some parts of the epithelium: severe = score 3.

Determination of the number of IL-10, INF-γ, and TNF-α-producing cells in gastric mucosa by indirect immunofluorescence assay

Histological slices of the antral and corpus regions of the stomach, processed as described earlier, were depar-

affinized and rehydrated in a graded series of ethanol. After incubation at room temperature for 30 min in 10 g/L blocking solution of bovine serum albumin (Sigma Chemical Co.), histological slices were incubated at 37°C for 60 min with rabbit anti-mouse IL-10 or INF-γ (Peprotech Inc., NJ, USA) or TNF-α (eBioscience, San Diego, CA, USA) polyclonal antibodies. Then, sections were washed twice with saline solution and treated with a 1/10 dilution of a goat anti-rabbit antibody conjugated with fluorescein isothiocyanate (FITC) (Jackson Immuno Research Inc., PA, USA) at 37°C for 45 min; washed again with saline solution and examined with a fluorescent light microscope (Leica DM LS2). Results were expressed as the number of IL-10, INF-γ and TNF-α-producing cells (fluorescent cells) per 10 fields (magnification × 1000)^[29]. Data were obtained by counting 30 fields from 3 histological slices for each animal group.

Mucus layer determined by periodic acid-Schiff staining

The mucus layer was identified by periodic acid-Schiff (PAS) staining^[30]. Briefly, after deparaffinization and rehydration, tissue sections were oxidized in 10 mL/L periodic acid for 5 min. Then they were rinsed in distilled water and stained with Schiff's reagent for 10 min. After a second washing with distilled water, tissue sections were counterstained with hematoxylin and rinsed in running tap water. Finally, they were dehydrated, cleared and mounted. Sections were viewed under a microscope (Leica M LS2) and the thickness of the mucus-secreting layer in the corpus and antrum mucosa was assessed with an image analyzer (× 1000) and the ratio of the mucus gel layer thickness to that of the lamina propria mucosa was calculated as a percentage.

Statistical analysis

Experimental data were expressed as mean ± SD and statistically evaluated by analysis of variance (ANOVA) with the SPSS software. Multiple group data were analyzed using one-way ANOVA and the Tukey multiple comparison test. Differences were considered statistically significant at $P < 0.05$.

RESULTS

Body weight and stomach weight

No significant changes in body weight or stomach weight were found during the entire experimental period in animals of any group other than those of the FM 1190 and M-EPS 1190 groups, which showed an increase (between 30%-40% with respect to H and G, respectively) in the stomach weight at the end of the experimental period (data not shown). No correlation between stomach weight and induced gastritis was found.

Histopathological evaluation of gastric samples

Mice subjected to oral administration of ASA at doses of 400 mg/kg per day for 10 d (gastritis group, G) showed moderate infiltration with scattered lymphocytes and

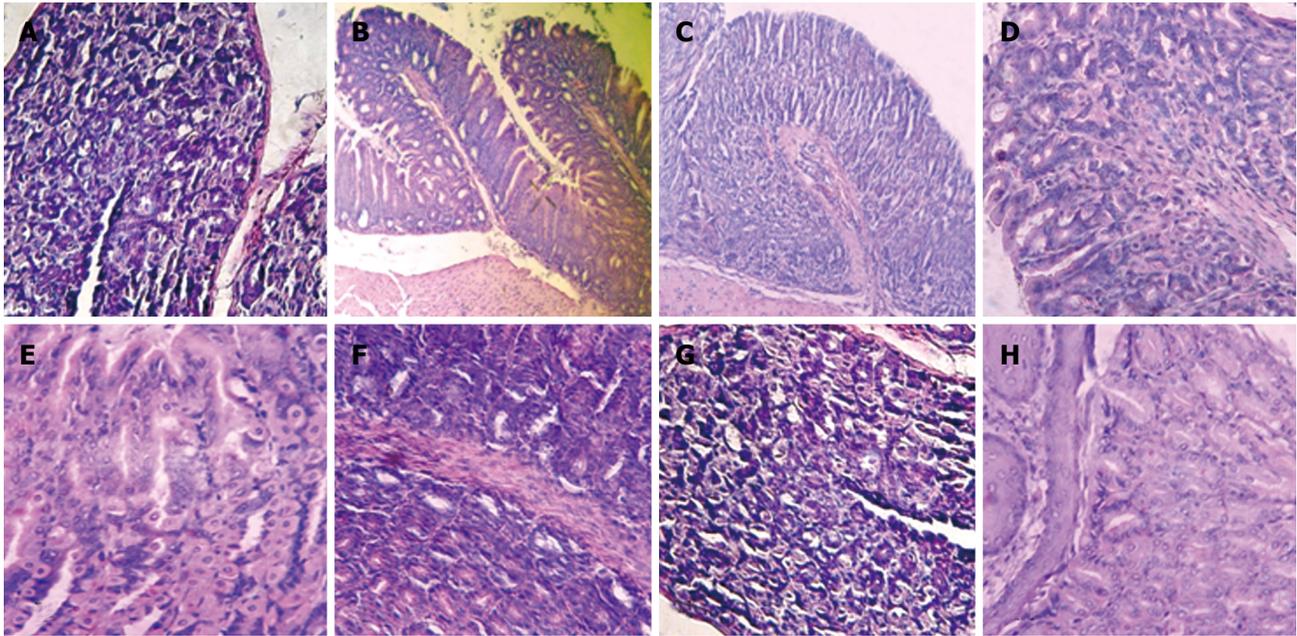

Figure 1 Histological micrographs of mice stomachs. A: H (Healthy) group; B: G (Gastritis) group; C: FM 1190 group (fermented milk with *Streptococcus thermophilus* CRL 1190); D: OM (omeprazole) group; E: M (Milk) group; F: W (Water) group; G: M-EPS 1190 group (EPS produced by *S. thermophilus* CRL 1190 resuspended in milk) showed conserved histological structures; and H: W-EPS 1190 group (EPS produced by *Strep. thermophilus* CRL 1190 resuspended in water) displayed chronic inflammatory infiltrations in the mucosa surface (Hematoxylin & eosin, light microscope, $\times 100$).

macrophages in the surface of the mucosa and folds of mucosa, in the direction of the submucosa, without formation of lymphoid follicles, and predominance in the gastric corpus region (Figure 1B). The induced lesions were classified as superficial chronic gastritis with inflammation score = 2 (Figure 2). No significant increase in polymorphonuclear infiltration in the normal gastric mucosa was observed. Healthy animals (group H) showed an absence of gastritis (Figure 1A). Interestingly, the stomachs from animals treated with FM 1190 and M-EPS 1190 displayed no leukocyte infiltration in the gastric mucosa immediately after treatment (day 18) (Figure 1C and G). Similar stomach structures of mice therapeutically treated with OM (Figure 1D) were observed, showing lower inflammatory scores than the gastritis group (0.2 ± 0.02 vs 2.2 ± 0.4 , $P < 0.05$, Figure 2). In contrast, the animals treated with milk, water and W-EPS 1190 showed high inflammation scores (1.8 ± 0.5 , 2.0 ± 0.5 , 1.7 ± 0.4 , respectively, $P < 0.05$), compared to those of the gastritis group.

Determination of the number of regulatory and pro-inflammatory cytokine-producing cells in the gastric mucosa

The stomachs from group G mice showed a significant decrease in the regulatory cytokine-producing cells ($IL-10^+$: 14 ± 1.3 vs 22 ± 1.7 , $P < 0.05$) and an increase in the pro-inflammatory cytokine-producing cells ($INF\gamma^+$: 28 ± 1.2 vs 14 ± 1.0 and $TNF-\alpha^+$: 33 ± 3.0 vs 15 ± 2.0 , $P < 0.05$) with respect to healthy animals (Figure 3A-C).

The therapeutic administration of FM 1190 to mice regulated the gastric inflammatory process, significantly

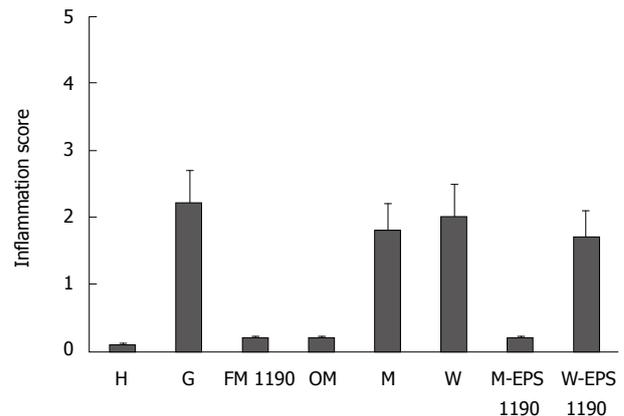

Figure 2 Inflammation score of stomachs in different groups (mean \pm SD).

decreasing the number of pro-inflammatory cytokine-producing cells ($INF\gamma^+$: 15 ± 1.0 vs 28 ± 1.2 , $P < 0.05$ and $TNF-\alpha^+$: 16 ± 3.0 vs 33 ± 3.0 , $P < 0.05$) and increasing the regulatory cytokine-producing cells ($IL-10^+$: 28 ± 1.5 vs 14 ± 1.3 , $P < 0.05$), as compared to the G group. Furthermore, the number of cytokine-producing cells were similar to those of OM and H groups showing $IL-10^+$ values slightly higher than these 2 groups (28 ± 1.5 vs 20 ± 2.9 ; 28 ± 1.5 vs 22 ± 1.7 , respectively, $P < 0.05$). In contrast, a significant decrease in the number of $IL-10^+$ cells and an increase in the number of both pro-inflammatory cytokine-producing cells ($INF\gamma^+$ - and $TNF-\alpha^+$) similar to those of the G group (Figure 3) were found in the M and W groups, used as controls.

M-EPS 1190 but not W-EPS 1190 was able to modulate the induced gastritis in a similar way to FM

1190, showing a decrease in the number of pro-inflammatory cytokine-producing cells (INF γ^+ : 15 ± 2.0 vs 28 ± 1.2 , $P < 0.05$ and TNF- α^+ : 20 ± 2.6 vs 33 ± 3.0 , $P < 0.05$) and an increase in the regulatory cytokine-producing cells (IL-10 $^+$: 21 ± 2.1 vs 14 ± 1.3 , $P < 0.05$), as compared to the G group (Figure 3).

A correlation between the histopathological structure and the number of regulatory and pro-inflammatory cytokine producing-cells was observed for all groups.

Mucus layer determined by PAS staining

The thickness ratio in the corpus and antrum mucosa, and representative photomicrographs of PAS-stained corpus mucosa from control (H), gastritis (G) and different therapeutic groups (FM 1190, OM, M and W) are shown in Figure 4A and B. The animals treated with ASA (G group) displayed a disruption in the protective mucus layer and exhibited a significant decrease of 80%-85% in the thickness of the mucus gel layer in both the corpus and antrum gastric regions as compared to healthy animals (corpus: 1.07 ± 0.3 vs 5.4 ± 1.0 ; antrum: 1.47 ± 0.4 vs 10.0 ± 1.3 , $P < 0.05$).

In general, the different treatments for gastritis revealed a marked depletion (approximately 80%) in the mucus layer with concomitant reduction in the volume of PAS-positive intramucosal mucus in either the corpus or antrum mucosa of animals of most groups compared to the H group. A different behavior was observed in animals of group FM 1190, which showed a decrease of 49%-59% in the mucus layer of the antrum and corpus mucosa, compared with healthy animals (2.2 ± 0.6 vs 5.4 ± 1.0 ; 5.1 ± 0.8 vs 10.0 ± 1.3 , respectively, $P < 0.05$). However, an increase in the thickness of the mucus gel layer as compared to animals displaying gastritis (G group) was observed (2.2 ± 0.6 vs 1.0 ± 0.3 ; 5.1 ± 0.8 vs 1.5 ± 0.4 , in corpus and antrum mucosa respectively, $P < 0.05$). The volume of intramucosal mucus was maintained compared to the G group, suggesting that FM 1190 was able to protect the stomach mucosal barrier.

Mice treated with M-EPS 1190 showed an increase in the thickness of the mucus gel layer compared to animals with gastritis (2.1 ± 0.5 vs 1.0 ± 0.3 ; 5.0 ± 0.75 vs 1.5 ± 0.4 , in corpus and antrum mucosa, respectively, $P < 0.05$) and was similar to the FM 1190 group.

DISCUSSION

It has been demonstrated previously that ASA administration to mice caused chronic inflammation of the gastric mucosa^[25]. Mononuclear cell infiltration, an increase in the number of pro-inflammatory cytokine-producing cells, a decrease in the regulatory cytokine-producing cells, and depletion of both the mucus gel layer and volume of intramucosal mucus were observed. The use of probiotics has been proposed to ameliorate different gastrointestinal tract disorders including inflammatory bowel diseases, diarrhea, pancreatitis, irritable bowel syndrome and colorectal cancer^[31,32]; however, little attention has been paid to gastric disease. Uchida and Kurakazu^[33] reported

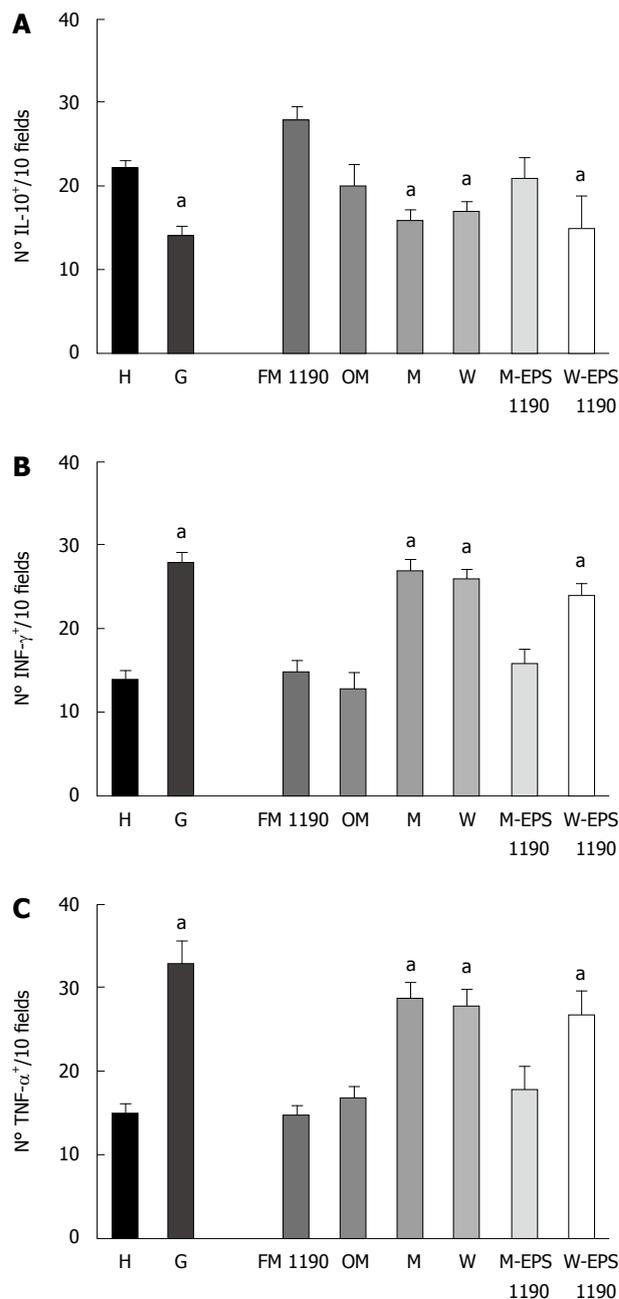

Figure 3 Number of (A) IL-10-, (B) INF- γ - and (C) TNF- α -producing cells on histological slices of stomachs of mice of different groups. Results are presented as means of 3 determinations and are expressed as the number of IL-10-, INF- γ - and TNF- α -producing cells per 10 fields (magnification $\times 100$). ^a $P < 0.05$ compared to the controls.

that yogurt LG21 significantly inhibited the formation of acute gastric lesions caused by HCl in rats; the beneficial effect being dose-dependent. Recently, Liu *et al.*^[34] reported that continuously feeding LAB-fermented soy-skim milk to rats for 28 d inhibited acute gastric lesions induced by ethanol and pylorus ligation in a dose-dependent manner, and improved prostaglandin E2 and superoxide dismutase activities. In addition, some authors have demonstrated the anti-ulcer properties of LAB-fermented milks on *H. pylori*-induced gastric lesions^[14,35]. Based on the multiple functional effects of probiotics on the gastrointestinal

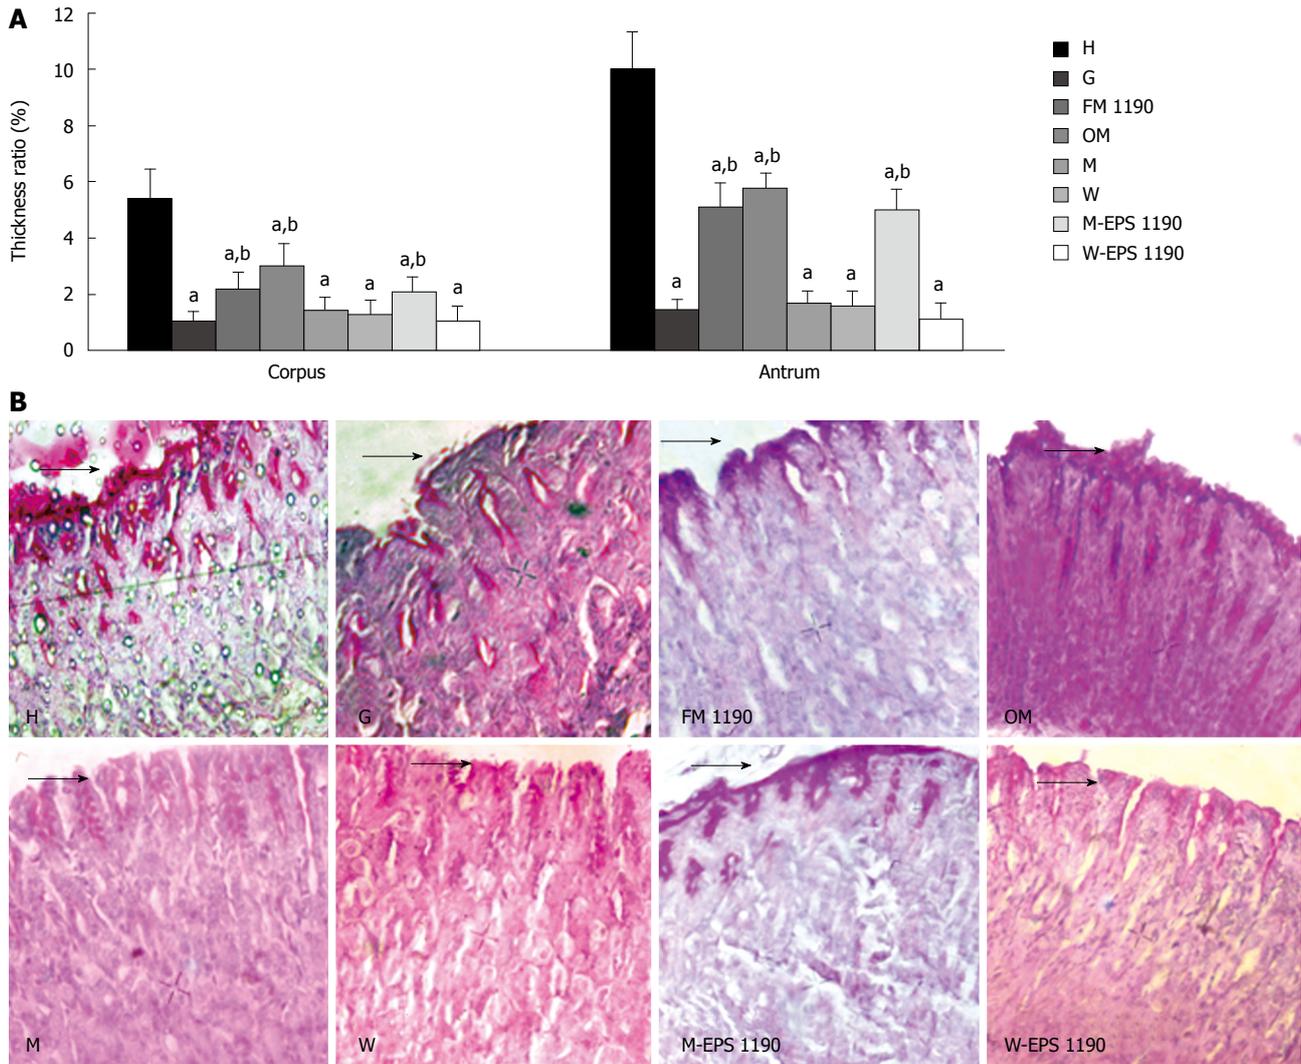

Figure 4 Periodic acid-Schiff (PAS)-positive mucus on the mice gastric mucosa. A: Thickness ratio of the mucus gel layer to the lamina propria mucosa in corpus and antrum mucosa. tract, we have previously studied the capability of 2 EPS-producing LAB strains to protect the gastric mucosa from challenges produced by ASA; only the strain *S. thermophilus* CRL 1190 successfully prevented gastric damage by modulation of inflammation with significant preservation of the mucus gel layer^[25]. *S. thermophilus* CRL 1190 produces a slime heteropolysaccharide of high molecular mass (MM) composed of D-glucose and D-galactose (molar ratio 1.0:1.5) as well as CPS in milk cultures^[20]. In this work, we evaluated the therapeutic effect of milk fermented with *S. thermophilus* CRL 1190 on ASA-induced chronic gastritis. The therapeutic administration of FM 1190 showed a marked ($P < 0.05$) immunomodulatory effect when comparing the pro-inflammatory cytokine-producing cells (TNF- α ⁺ and INF- γ ⁺) of healthy animals, as a result of inhibition of IL-10 on Th1^[36]. Similar immunological modulation of the preventive effect of *S. thermophilus* CRL 1190 on chronic gastritis was observed in our previous work. Bibiloni *et al.*^[37] demonstrated that the Th1 cell response could be modulated by probiotic bacteria

in pathological processes such as inflammatory bowel disease or colon cancer^[38]. Th1 cytokines such as INF- γ and TNF- α , released by lymphocytes and macrophages that infiltrate the gastric mucosa are associated with immune activation and tissue injury. TNF- α has been shown to be a crucial mediator of NSAID-induced gastric mucosal damage^[39]. In contrast, IL-10 (Th2 type cytokine) suppresses the differentiation and effector functions of Th1 cells and the production of pro-inflammatory cytokines by dendritic cells and macrophages, thus maintaining immune homeostasis^[40]. The proton pump inhibitor drugs used clinically, such as omeprazole, exert an anti-inflammatory action beyond strong acid suppression^[41]. It has been reported that omeprazole regulates the cytokine profile in *H. pylori*-infected patients with duodenal ulcer disease by suppressing cytokine synthesis of the Th1 cells^[42]. In our study, this drug was used as a positive control in the treatment of ASA-induced gastritis, and it displayed similar therapeutic effectiveness to FM 1190, though the fermented milk displayed slightly higher

numbers of regulatory cytokine-producing cells (IL-10⁺) than did omeprazole. On the other hand, this drug has diverse adverse effects such as diarrhea, abdominal pain, cutaneous reactions, decreased bone density and microscopic colitis^[43,44] as well as drug interactions^[45]. Thus, the use of FM 1190 as a therapeutic agent constitutes a safe and nutritional alternative for gastritis treatment.

Myeloperoxidase activity as a neutrophil infiltration marker in gastric tissue was assayed but it could not be used as an inflammatory parameter in the chronic gastritis model as the values obtained were similar to that of the healthy groups (data not shown).

Milk alone, water, omeprazole or the prepared fermented milk did not cause any damage *per se* on the gastric mucosa of healthy animals.

To determine if the therapeutic effect obtained after administration of FM 1190 resulted from the presence of its EPS, the produced biopolymer was isolated, purified and resuspended in milk or water, and assayed for its potential therapeutic effect. As previously observed^[25], only the EPS dissolved in milk (M-EPS 1190) displayed a similar behavior to the fermented milk with respect to the cytokine profile and the histological structures, suggesting that EPS-milk protein interactions play a major role in the immune response modulation and consequently, in the therapeutic effect observed. Whey proteins have been reported to possess biological functions including immunomodulatory activities^[46] in addition to their nutritional value. Rosaneli *et al.*^[47] reported the protective effect of bovine milk whey protein concentrate on the ulcerative lesions caused by administration of indomethacin. Moreover, the gastro-protective effect of α -lactalbumin, one of the major whey proteins, against gastric injury induced by ethanol was demonstrated by enhancing the gastric defense mechanisms such as mucin synthesis and secretion in mucus-producing cells^[48-50].

The mucus gel layer is an important defense barrier, covering gastric epithelial cells and holding bicarbonate ions to neutralize hydrogen ions that diffuse back into the gastric mucosa. However, this layer is frequently disrupted by acid, pepsin, alcohol, and other injurious agents in the gastric lumen resulting in damage to gastric epithelial cells^[51]. The mucus gel layer thickness in the mouse gastric mucosa as well as the volume of intramucosal PAS-positive mucus were evaluated, as a continuous supply of mucus from the intramucosa is important to preserve the surface gel layer. Therapeutic administration of FM 1190 and M-EPS 1190 increased the thickness of the mucus gel layer in both corpus and antrum mucosa without reducing intramucosal mucus. Thus, the activation of mucin synthesis by FM 1190 and M-EPS 1190 led to the increase in the mucus gel layer and a stable mucus supply from the intramucosa. The stimulation of mucus metabolism contributes to the gastroprotective action. *L. rhamnosus* GG, a probiotic EPS-producing strain widely used in dairy products, is able to increase the mucus layer thickness in the gastric glandular mucosa^[29]. Also, it has been observed that the

fungal polysaccharide from *Ganoderma lucidum* reinstated the gastric mucus levels^[52].

Nagaoka *et al.*^[53] reported anti-ulcer effects of EPS produced by bifidobacteria, *Lactobacilli* and *Streptococci* strains, which were attributed to the high rhamnose content (> 60%) of the polysaccharides. Conversely, the fermented milk with the EPS-producing strain *S. thermophilus* CRL 804, which produced an EPS with rhamnose and galactose in its monomer composition^[20], did not show any anti-gastritis effect in contrast to the EPS 1190 that contained galactose and glucose and displayed a gastroprotective effect. Sengül *et al.*^[54] showed that a high MM EPS produced by the probiotic strain *L. delbrueckii* subsp. *bulgaricus* B3 significantly ameliorated experimental colitis in rats. Gao *et al.*^[52,55] found that treatment of acetic acid-induced ulcers in rats with high MM polysaccharide from *Ganoderma lucidum* suppressed or restored the decreased gastric mucus levels, increased gastric prostaglandin concentrations and partly suppressed the TNF- α gene. In addition, a high MM pectin polysaccharide from Chinese herbs has shown to be a potent anti-ulcer compound in experimental HCl-ethanol induced ulcers^[56]. Moreover, a high MM-homopolysaccharide from marine microalga *Gyrodinium impudicum* strain KG03 presented immunostimulatory effects, enhancing the tumoricidal activities of macrophages and natural killer cells *in vivo*^[57]. In this case, the beneficial effect was attributed to the sulfate groups present in the polymer, which also contained galactose and uronic acids. In our work, the anti-gastritis effect observed for FM 1190 may be ascribed to the large polymer size of EPS 1190, independently of its monomer composition. In addition, it was recently demonstrated^[58] that EPS 1190 was partially degraded when the polymer was submitted to the harsh conditions of an *in vitro* gastric system, indicating that this polymer may still exert its beneficial properties *in vivo*.

The present findings indicate that the milk fermented with *S. thermophilus* CRL 1190 and/or its EPS was effective in the therapeutic treatment of chronic gastritis by modulating the immune response of the mice and by increasing the thickness of the gastric mucus gel layer. Thus, the application of this fermented milk and/or its EPS constitutes a potential natural alternative for the prevention and treatment of ASA-associated gastric damage.

COMMENTS

Background

Gastritis is a common disorder where there is discontinuity in the gastric mucosa. It is caused by several factors including the intensive consumption of anti-inflammatory drugs such as acetyl-salicylic acid (ASA), commonly used in the treatment of chronic diseases and prevention of cardiovascular pathologies. The conventional drugs employed as therapies against gastritis often produce undesirable side effects. The administration of specific probiotics provides a new therapy against gastric disease.

Research frontiers

Gastritis affects 80% of the worldwide population according to data of the Worldwide Health Organization. The use of probiotics has been proposed to ameliorate different gastrointestinal tract disorders such as inflammatory bowel disease, diarrhea, irritable bowel syndrome, etc.; however, little attention has been

paid to gastric disease. Thus, the authors decided to investigate the therapeutic effect of milk fermented with exopolysaccharide (EPS)-producing *S. thermophilus* CRL 1190 and its polymer on chronic gastritis induced by aspirin in mice.

Innovations and breakthroughs

This research demonstrates for the first time the therapeutic effect of the fermented milk with the polymer-producing strain *S. thermophilus* CRL 1190 and/or its EPS on chronic gastritis induced by ASA in mice. Both the fermented milk and the EPS were able to modulate the immune response in mice and increased the thickness of the gastric mucus gel layer. Furthermore, the therapeutic effectiveness observed was similar to omeprazole[®], a commercial drug commonly employed in the treatment of gastritis.

Applications

The fermented milk with the EPS-producing strain *S. thermophilus* CRL 1190 and/or its EPS constitutes a potential natural alternative for the prevention and treatment of ASA-associated gastric damage.

Terminology

EPS are carbohydrate polymers naturally produced by certain bacteria, alga, yeasts and fungi. These polymers are extensively used in several industries mainly due to their thickening, texturizing, and gelifying properties.

Peer review

The research is a well carried out study.

Abstract

AIM: To evaluate the role of thymidine phosphorylase (TP) in cholangiocarcinoma using small interfering RNA (siRNA).

METHODS: A human cholangiocarcinoma-derived cell line KKU-M139, which has a naturally high level of endogenous TP, had TP expression transiently knocked down using siRNA. Cell growth, migration, *in vitro* angiogenesis, apoptosis, and cytotoxicity were assayed in TP knockdown and wild-type cell lines.

RESULTS: TP mRNA and protein expression were decreased by $87.1\% \pm 0.49\%$ and $72.5\% \pm 3.2\%$, respectively, compared with control cells. Inhibition of TP significantly decreased migration of KKU-M139, and suppressed migration and tube formation of human umbilical vein endothelial cells. siRNA also reduced the ability of TP to resist hypoxia-induced apoptosis, while suppression of TP reduced the sensitivity of KKU-M139 to 5-fluorouracil.

CONCLUSION: Inhibition of TP may be beneficial in decreasing angiogenesis-dependent growth and migration of cholangiocarcinoma but may diminish the response to 5-fluorouracil chemotherapy.

INTRODUCTION

Cholangiocarcinoma is a common hepatobiliary malignancy among the Northeastern Thai population and it is an important public health problem because the incidence and fatality rates are high^[1,2]. Liver fluke (*Opisthorchis viverrini*) infection is a risk factor for cholangiocarcinoma, which accounts for about 89% of all liver cancer cases in Khon Kaen province, where the liver fluke is highly endemic and the incidence of cholangiocarcinoma is the highest in the world (97.4 per 100000 males and 39 per 100000 females)^[1]. A number of different genes have been implicated in carcinogenesis of cholangiocarcinoma, e.g. *p53*^[3], *MDM2*^[3], *bMLH1* and *bMSH2*^[4,5], and *TFE1*^[6]. We previously demonstrated the high prevalence of thymidine phosphorylase (TP) gene amplification (53.8%; 35 of 65 cases) in cholangiocarcinoma tumor tissues, suggesting that TP may play an important role in carcinogenesis of liver fluke-related cholangiocarcinoma^[7].

TP (EC 2.4.2.4) is located in chromosomal region 22q13.33 and encodes a protein that catalyzes the reversible phosphorolysis of thymidine, deoxyuridine, and their analogs to their respective bases and 2-deoxyribose-1-phosphate, which is then dephosphorylated to 2-deoxy-D-ribose^[8]. TP has been proposed to function in DNA synthesis, cell growth, chemotaxis stimulation in endothelial cells *in vitro*, and to enhance angiogenesis *in vivo*^[9,10]. TP is abnormally expressed in certain cancers of the gastrointestinal tract e.g. pancreatic cancers^[11], colon carcinomas^[12], gallbladder adenocarcinomas^[13], and intrahepatic cholangiocarcinoma^[14]. Interestingly, TP expression was found to be elevated from 10- to 260-fold in nearly all biopsies examined from carcinomas of the stomach, colon, ovary, and bladder when compared to non-neoplastic regions of these organs^[15,16]. Nevertheless, how TP expression is up-regulated in human tumors remains unclear.

During the past few years the utility of RNA interference (RNAi) and post-transcriptional gene silencing has significantly advanced the study of the effects of loss of individual gene functions. Therefore, we investigated the functions and roles of TP in carcinogenesis of liver fluke-related cholangiocarcinoma using small interfering RNA (siRNA) to suppress TP expression. Understanding the functions of TP involved in cholangiocarcinoma will help us elucidate the molecular mechanisms of chol-

angiocarcinogenesis and thus could potentially provide important strategies for prevention, early diagnosis, and early treatment to reduce the cancer incidence and increase cholangiocarcinoma patient survival.

MATERIALS AND METHODS

Cell lines and culture condition

The KKKU-M139 cell line was established from the primary tumor of a 53-year-old Thai woman with squamous cell type cholangiocarcinoma. It was selected for this work after prior screening of TP expression in 5 cholangiocarcinoma-derived cell lines (data not shown). KKKU-M139 was maintained in RPMI-1640 medium containing 100 IU/mL penicillin, 100 µg/mL streptomycin, and 100 mL/L heat-inactivated fetal bovine serum (FBS) as a complete medium. The human umbilical vein endothelial cells (HUVECs) isolation procedure followed the protocol of Jaffe *et al.*^[17]. HUVECs were maintained in M199 medium containing 100 U/mL penicillin, 100 µg/mL streptomycin, 50 mL/L pooled human serum, and 300 mL/L heat-inactivated FBS. Culturing was carried out at 37°C in a humidified 50 mL/L CO₂ incubator. Confluent HUVEC monolayers (passages 2-4) were used in the assays.

Transient knockdown of TP using siRNA

siRNA sequences against human TP were designed and synthesized by Stealth RNAi (Invitrogen, Carlsbad, CA, USA). The siRNA sequences were 5'-AUAGACUCCA GCUUAUCCAAGGUGC-3' (sense) and 5'-GCACCU UGGUAUAGCUGGAGUCUAU-3' (antisense). A non-related control siRNA that lacked identity with known gene targets was used as a control for non sequence-specific effects. TP siRNA or control siRNA (20 pmol) was transiently transfected into 1 × 10⁵ KKKU-M139 using OligofectAMINE (Invitrogen) according to the manufacturer's instructions. Briefly, siRNA:OligofectAMINE complexes were mixed gently in Opti-MEM I reduced-serum medium and incubated for 20 min at room temperature. Then 200 µL of the complex mixture was added to cells growing in a 35-mm Petri dish containing 800 µL Opti-MEM I and mixed gently. After 24 h incubation at 37°C in a 50 mL/L CO₂ incubator, the complexes were replaced by complete medium. Cells were incubated further for 24 h and gene function assays performed within 72 h post-transfection. The intensity of TP expression, either mRNA or protein, was analyzed using ImageJ software version 1.32j (NIH, Bethesda, MD, USA). To determine the knockdown efficiency, the density of TP expression was normalized with its corresponding β-actin for mRNA or α-tubulin for protein. The normalized intensity was compared between TP siRNA-transfected cells (TP-deficient cells) and control siRNA-transfected cells (control cells).

Reverse transcription and semi-quantitative polymerase chain reaction

Total RNA from the KKKU-M139 cell line was reverse transcribed using Omniscript reverse transcriptase (QIA-

gen, Hilden, Germany). The forward and reverse primer sequences of TP were 5'-GGCATGGATCTGGAG-GAGAC-3' and 5'-CTCTGACCCACGATACAGCA-3', respectively. The forward and reverse primer sequences for β -actin as control were 5'-ACTGGGACGACATG-GAGAAA-3' and 5'-ATAGCACAGCCTGGATAGCA-3', respectively. Polymerase chain reaction (PCR) amplification was carried out in a final volume of 20 μ L containing first-strand cDNA, 10 pmol of each primer, 5 U Taq polymerase in 1 \times Taq buffer (67 mmol/L Tris-HCl, 16.6 mmol/L ammonium sulfate, and 10 mL/L Tween 20), 2.5 mmol/L MgCl₂, and 0.2 mmol/L dNTPs. The amplification was initiated by incubation at 94°C for 5 min followed by 40 cycles of denaturation at 94°C for 30 s, annealing at 59°C (for TP) or 60°C (for β -actin) for 30 s, and extension at 72°C for 30 s, with a final 10-min extension at 72°C. PCR products were separated on a 20 g/L agarose gel containing 100 ng/mL ethidium bromide. Gels were visualized and photographed on a UV Transilluminator.

Western blot analysis

Total protein was separated on 10% SDS-PAGE then transferred onto a nitrocellulose membrane and blocked with TBST buffer (20 mmol/L Tris-HCl, 150 mmol/L NaCl, 0.5 mL/L Tween 20) plus 50 g/L skim milk. The membrane was probed with anti-TP (Taiho Pharmaceutical Co., Ltd. Japan) or anti- α -tubulin (Zymed Laboratories Inc., San Francisco, CA, USA) as a control at a dilution of 1:1000 in TBST followed by a dilution of 1:2000 of a horseradish peroxidase-conjugated secondary antibody. Immunopositive bands were detected with freshly prepared ECL chemiluminescent solution (Amersham Biosciences, Buckinghamshire, England) and visualized by exposure to X-ray film.

Cell growth assay

To evaluate the cellular growth rates, 1×10^4 wild-type, TP-deficient, or control cells were seeded in 6-well cell culture plates and grown in complete medium at 37°C in a 50 mL/L CO₂ incubator. The cells were counted in triplicate every day for up to 6 d following a trypan blue dye exclusion assay. The population doubling time was calculated from the exponential growth phase.

Migration assays

The migration of HUVECs stimulated by TP-expressing KKU-M139 cells was evaluated by a 2-chamber assay using a 96-well modified Chemotaxicell chamber (Kurabo, Japan) with an 8- μ m pore size membrane. In brief, 100 μ L total protein of wild-type, TP-deficient or control cells (PBS alone as a negative control) was added to the lower chamber. HUVECs (1×10^5 resuspended in 60 μ L PBS) were placed in the upper chamber then incubated at 37°C in a 50 mL/L CO₂ incubator for 4 h. The number of cells that moved through the pores toward the attractant—that is, TP protein produced by KKU-M139 cells—and settled on the bottom chamber was counted using trypan blue staining. The assays were performed in triplicate. The

migration assay for KKU-M139 cells was carried out using the same protocol, but the lower chamber contained 100 μ L of a complete medium as a chemoattractant. RPMI-1640 medium containing 10 mL/L FBS served as a negative control. Wild-type, TP-deficient or control cells (1×10^5 in suspension in 60 μ L fresh RPMI-1640) were placed in the upper chamber.

In vitro angiogenesis assay

The HUVEC tube-like structure was determined using the Endothelial Tube Formation Assay (Cell Biolabs Inc., San Diego, CA, USA) according to the manufacturer's protocol. In brief, HUVECs were harvested and resuspended in M199 culture medium containing 100 mL/L FBS and angiogenesis mediators, i.e. serum of endometriosis patients as a positive control, total protein from KKU-M139 cells before and after treatment with TP-siRNA. Cell suspension (150 μ L, 1.5×10^4 cells) was layered on the 50 μ L of solidified extracellular matrix (ECM) gel in each 96-well plate, and the plate was incubated at 37°C for 18 h to allow the HUVECs to reorganize into a 3-dimensional tubular structure. The tube-like structures were stained with Calcein AM fluorescent dye, and examined and captured under a fluorescence microscope (Olympus CKX41, Tokyo, Japan). The tube length was quantified using ImageJ (NIH, Bethesda, MD, USA) and represented as total tube length (μ m) for 3 photographic fields per experimental condition. Each treatment was performed in duplicate, and the set of experiments was repeated twice independently.

TUNEL apoptosis assay

The DeadEnd™ Colorimetric TUNEL System (Promega, Madison, WI, USA) was used to detect apoptosis in cultured cell lines. In brief, cells grown in a 35-mm petri-dish were exposed to hypoxic conditions for 48 h. Cells were allowed to undergo apoptosis at 37°C in a humidified 50 mL/L CO₂ incubator for 12 h. Treated cells were fixed with 40 g/L buffered formaldehyde, permeabilized by 2 mL/L Triton X-100, and equilibrated with Equilibration buffer (Promega). The cells were incubated with recombinant terminal deoxynucleotidyl transferase (rTdT) reaction mix, containing biotinylated nucleotides, inside a humidified chamber at 37°C for 1 h to allow end-labeling of the fragmented DNA of apoptotic cells to occur. The reactions were terminated by addition of 2 \times SSC buffer, and endogenous peroxidases were blocked with 3 mL/L H₂O₂. To detect the incorporated biotinylated nucleotides, streptavidin-horseradish peroxidase solution (Promega) in PBS was used. A total of 100 μ L diaminobenzidine chromogen was added to each plate and developed until a light brown background occurred. Cells stained brown was counted per total number of cells in the 100 \times power field of inverted microscope. The assays were performed in duplicate, and the experiment was repeated at least 3 times.

MTS cytotoxicity assay

To determine the concentration of 5-fluorouracil that

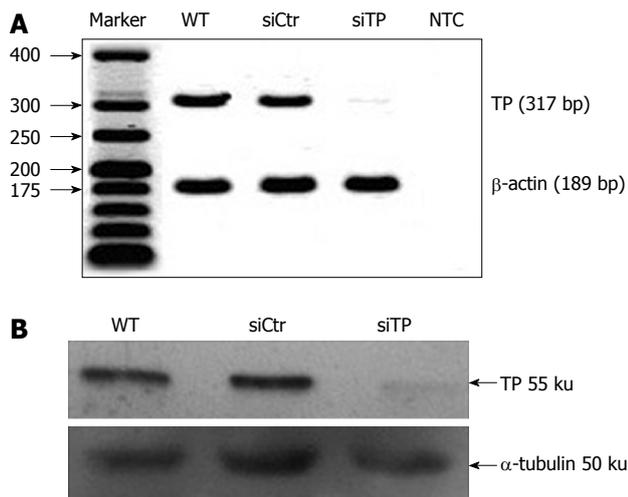

Figure 1 Small interfering RNA (siRNA) significantly reduced thymidine phosphorylase (TP) mRNA analyzed by semi-quantitative polymerase chain reaction (A) and protein (B) analyzed by Western blot of TP-deficient (siTP) cells compared with wild-type (WT) and control (siCtr) cells. For negative control (NTC), no cDNA was present in the reaction.

inhibited cell proliferation by 50% (IC₅₀), the MTS assay (Promega) was used according to the manufacturer's instructions. Briefly, at one day post-transfection, 100 μL of cell suspension (1 × 10⁵ cells/mL) was added to each well of a 96-well flat-bottom culture plate then incubated at 37°C in a humidified 50 mL/L CO₂ incubator. After 24 h incubation, 100 μL medium containing various concentrations of 5-fluorouracil or fresh medium for untreated controls was added to each well for 48 h. The culture medium containing dead cells was then removed, and 100 μL of medium containing 20 μL MTS solution (317 μg/mL) was added to each well for 2 h to allow living cells to catalyze the MTS to a colored formazan product which was measured at 490 nm using a microplate reader (Tecan Austria GmbH, Salzburg, Austria). The assays were performed in duplicate, and the experiment was repeated twice.

Statistical analysis

Values are presented as mean ± SD. The statistical significance of the data was analyzed by one-way ANOVA using SPSS statistical software version 10.0 for Windows (SPSS Inc, Chicago, IL, USA). *P* < 0.05 was considered statistically significant.

RESULTS

TP is not a pivotal factor for tumor cell proliferation in cholangiocarcinoma

After TP-siRNA transfection, expression of TP mRNA (Figure 1A) and protein (Figure 1B) was suppressed by 87.1% ± 0.49% and 72.5% ± 3.2%, respectively, compared with control cells. To evaluate TP function on the proliferation of KKU-M139, the cell growth assay was performed. The population doubling time calculated from exponential growth phase (day 1-day 4) of wild-

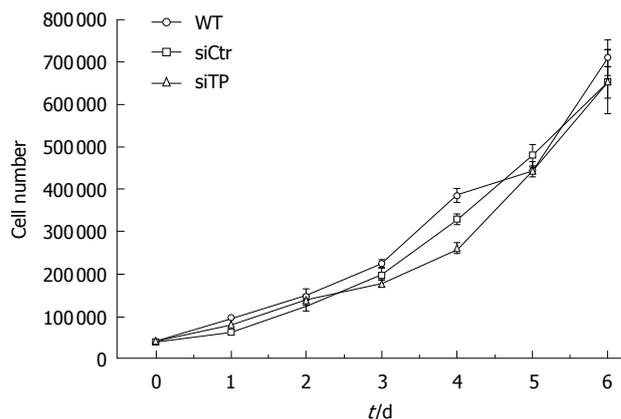

Figure 2 Kinetic growth curves of KKU-M139 WT, control (siCtr), and TP-deficient (siTP) cells. The doubling time of TP-deficient cells was not significantly different from that of WT or control cells.

type, TP-deficient, and control cells was 25.7 ± 4.7, 29.7 ± 2.4, and 29.6 ± 6 h (*n* = 4), respectively (Figure 2). Doubling time of TP-deficient cells was not significantly different from that of wild-type or control cells.

TP-siRNA decreases TP-induced migration of HUVECs and KKU-M139

Angiogenesis, which is crucial for the development and progression of various cancers, requires migration and proliferation of endothelial cells in order to form the vasculature. Therefore, we tested the ability of TP to activate migration of endothelial cells using a 2-chamber assay. Migration of HUVECs toward total protein of TP-deficient cells was similar to that of PBS (Figure 3A). Use of total protein of TP-expressing KKU-M139 cells as a chemoattractant induced the migration of HUVECs by more than 2-fold relative to PBS (*P* < 0.05). Migration of cancer cells is important for invasion and metastasis. We investigated the migration of wild-type, TP-deficient, and control cells directed to 100 mL/L FBS as a chemoattractant. Migration towards 100 mL/L FBS of TP-deficient cells was significantly reduced by 2.4-fold compared with wild-type (*P* < 0.001) and 1.8-fold compared with control cells (*P* < 0.01) (Figure 3B).

TP-siRNA attenuates TP-induced tube formation of HUVECs

To assess the effect of TP on the formation of blood vessels, we analyzed the ability of TP produced from KKU-M139 to induce HUVECs to form tube structures using an ECM gel angiogenesis assay. Tube-like structures were formed by HUVECs activated by serum of endometriosis patients as a positive control (Figure 4A) but not by the PBS as a negative control (Figure 4B). HUVECs exhibited significant tube formation when total protein from wild-type KKU-M139 cells (Figure 4E and F), which endogenously express TP, was added (*P* < 0.001 *vs* PBS). Pre-treatment of KKU-M139 cells with TP-siRNA (Figure 4D) to suppress TP expression reduced tube formation of HUVECs compared with control cells (Figure 4C) (*P*

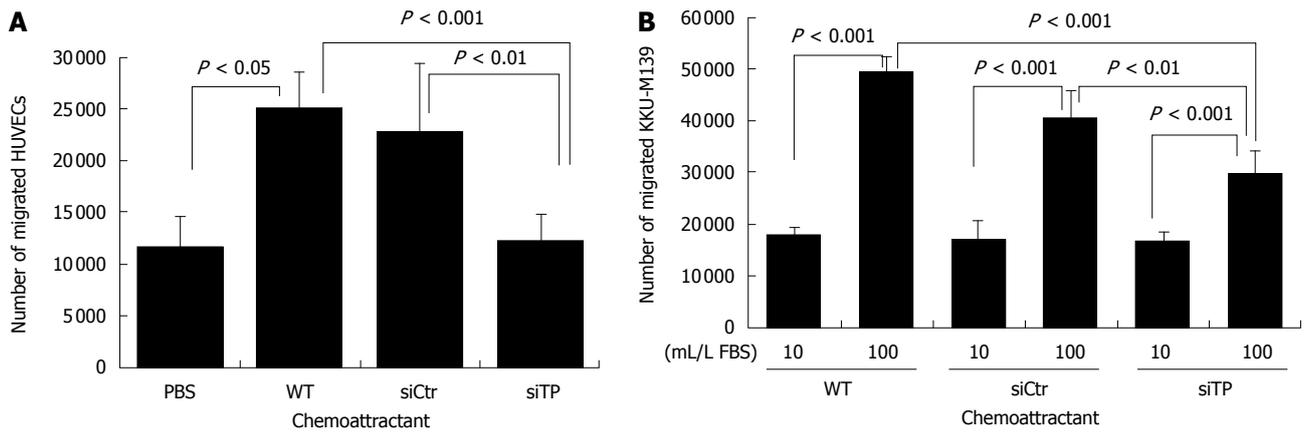

Figure 3 Knockdown of TP reduces migration of HUVECs and KKU-M139. **A:** Migration of HUVECs toward protein produced from TP-deficient cells (siTP) was similar to that of PBS, and 2-fold less than that of wild-type (WT); **B:** TP-deficient KKU-M139 cells are less migratory in response to FBS compared with wild-type, and control.

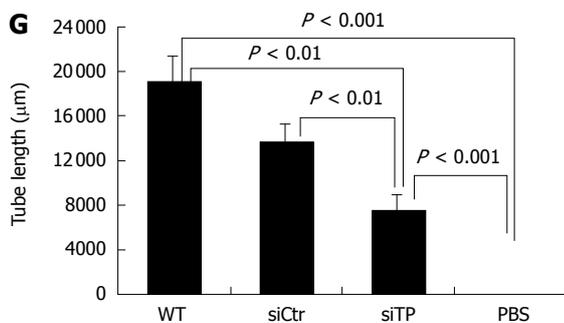

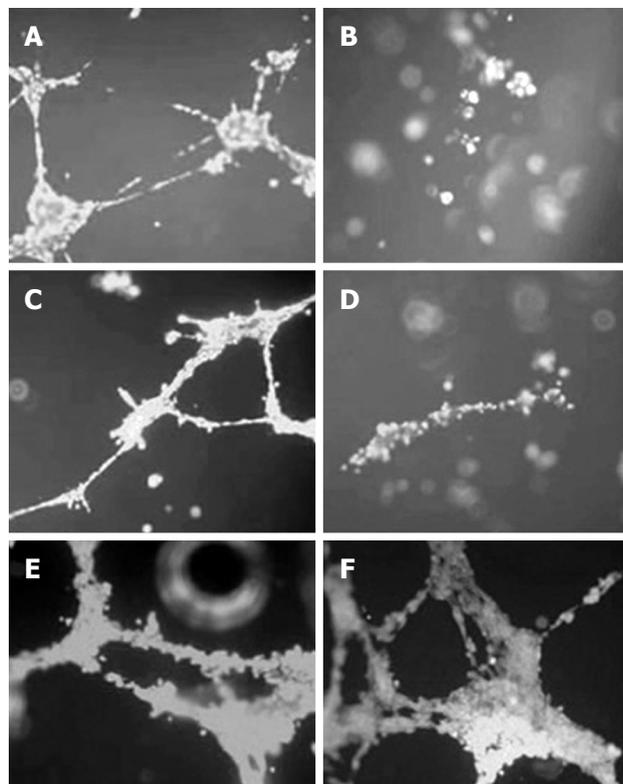

Figure 4 Knockdown of TP decreases the formation of tube-like structures in an ECM gel angiogenesis assay. Serum of endometriosis patients was used as a positive control (A), and PBS as a negative control (B). Total protein of control (siCtr) (C), TP-deficient (siTP) (D), or WT cells (E and F) were assayed. The tube length was quantified (G).

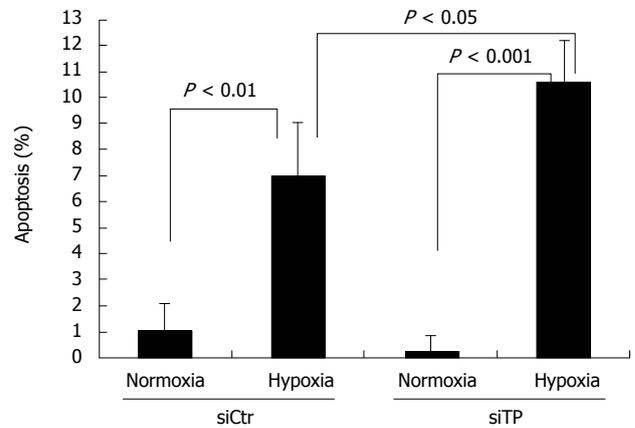

Figure 5 Knockdown of TP leads to increased cell death under hypoxic conditions. TP-deficient (siTP) or control (siCtr) cells were exposed to normoxic or hypoxic conditions for 48 h. Apoptosis was measured with the TUNEL assay.

< 0.01) or wild-type cells ($P < 0.01$) as shown in Figure 4G.

Reduced TP expression decreases resistance to hypoxia-induced apoptosis of KKU-M139

TP was reported to confer resistance to apoptosis induced by hypoxia. Under hypoxic conditions, the TP-deficient cells exhibited significantly more cell death than did the control cells ($P < 0.05$). Thus, TP seems to confer resistance to hypoxia-induced apoptosis in control cells. For both control and TP-deficient cells, the percent apoptosis under normoxic conditions was less than that under hypoxic conditions ($P < 0.01$ and $P < 0.001$, respectively). Anti-apoptotic activity of KKU-M139 under 48 h hypoxic conditions was suppressed by TP knockdown (Figure 5).

TP-siRNA decreases the sensitivity of KKU-M139 cells to 5-fluorouracil

5-fluorouracil is a commonly used chemotherapeutic drug for cholangiocarcinoma, and TP is needed for 5-fluorouracil activation. To determine to what extent TP contributes to the cytotoxic effect of 5-fluorouracil, cells were

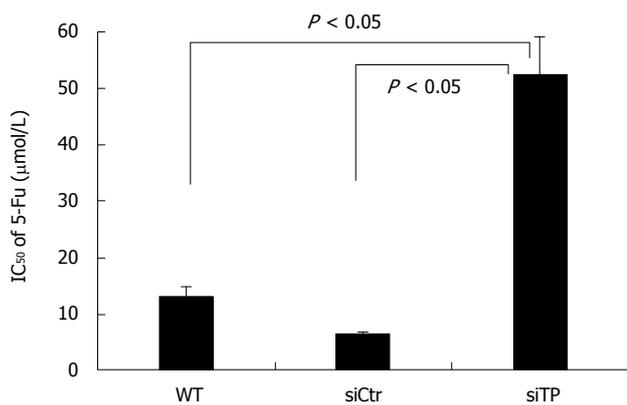

Figure 6 Effects of TP-siRNA on 5-fluorouracil (5-Fu) cytotoxicity of KKKU-M139. KKKU-M139 WT, control (siCtr), and TP-deficient (siTP) cells were incubated with various concentrations of 5-fluorouracil for 48 h. Sensitivity of the cells to 5-fluorouracil was then determined with a MTS cytotoxicity assay.

exposed to a range of concentrations of 5-fluorouracil in the presence or absence of siRNA against TP. The IC₅₀ of control and wild-type cells were 6.4 ± 0.36 and 13 ± 1.70 µmol/L 5-fluorouracil, respectively. As expected, TP-deficient cells required 52.3 ± 6.8 µmol/L 5-fluorouracil, an 8.2-fold increase over that in control cells (*P* < 0.05), to inhibit cell proliferation by 50% (Figure 6).

DISCUSSION

We previously reported that 35 of 65 (53.8%) liver fluke-related cholangiocarcinoma cases exhibited TP amplification, suggesting that TP may contribute to the pathogenesis of cholangiocarcinoma^[7]. Here, we report that TP confers resistance to apoptosis, induces migration of a cholangiocarcinoma-derived cell line, and mediates migration and tube formation of HUVECs. However, TP is essential for activation of 5-fluorouracil, a commonly used anti-cancer drug for treatment of cholangiocarcinoma. In fact, TP amplification and overexpression have been reported for various solid tumors that exhibited invasion, metastasis, angiogenesis, and poor prognosis, including cholangiocarcinoma^[15-16,18,19]. In this study, transfection with TP-siRNA suppressed TP mRNA expression by approximately 87% and protein expression by 72% (Figure 1), indicating effective gene silencing. The population doubling time of TP-deficient cells was not significantly different from that of wild-type or control cells (Figure 2), suggesting that TP is not a pivotal factor for tumor cell proliferation in cholangiocarcinoma.

Increased TP expression has been shown to increase invasiveness of KB epidermoid carcinoma cells compared with control cells^[20]. Migration is an important characteristic of metastatic cancer cells. TP-expressing KKKU-M139 also exhibited greater migration than TP knockdown cells (Figure 3B). Nakajima *et al.*^[21] determined the molecular basis for induction of invasive activity by TP. They suggested that TP and 2-deoxy-D-ribose induces the expression, secretion, and activity of matrix metalloproteinase-9 (MMP-9) that subsequently confers

invasiveness on cancer cells, but the exact mechanism by which TP and one of its degradation products, 2-deoxy-D-ribose, enhance MMP-9-mediated invasive activity is not known. The expression level of TP was reported to significantly correlate with that of the invasion-related genes MMP-1, MMP-7, and MMP-9^[22]. Taken together, these data indicate that TP enhances the invasion of tumor cells through the induction of invasion-related genes in cholangiocarcinoma.

The study by Hotchkiss *et al.*^[23] demonstrated that TP-expressing cells mediated HUVEC migration via the intracellular metabolism of thymidine by TP and the subsequent extracellular release of 2-deoxy-D-ribose, which formed a chemotactic gradient. Later, they proved that both TP and 2-deoxy-D-ribose stimulated HUVEC migration by increasing cell surface expression of the integrins α_vβ₁ and α_vβ₃ to form focal adhesions. Integrins bind to the ECM and directly activate focal adhesion kinase signaling pathways, mediating cell attachment and migration^[24]. KKKU-M139, which endogenously expresses TP, also strongly induced HUVEC migration, an early step in angiogenesis. Our study showed that TP-expressing KKKU-M139 could stimulate the migration and formation of tube-like structures of HUVECs to a much greater degree than TP-silenced KKKU-M139 (Figure 3A and 4). In addition, 2-deoxy-D-ribose can mediate an oxidative stress mechanism and upregulate other angiogenic factors^[25]. Attracted endothelial cells proliferate upon stimulation by growth factors released from cancer cells and subsequently form new blood vessels. Suppression of TP-mediated migration and angiogenesis of HUVECs by TP-siRNA thus can be explained by the fact that TP and its product, 2-deoxy-D-ribose, could not exert their effect on cell migration and tube formation. Chemically synthesized TP inhibitor (TPI) has been demonstrated to suppress tumor growth by increasing the proportion of apoptotic cells and probably by inhibiting angiogenesis; TPI completely suppressed angiogenesis by TP-cDNA transfected KB cells^[26]. 2-deoxy-L-ribose, the stereoisomer of 2-deoxy-D-ribose, is also a TPI, as shown by the ability of 2-deoxy-L-ribose to inhibit 2-deoxy-D-ribose-mediated angiogenesis and metastasis of tumor cells expressing TP^[20,27]. Our study also demonstrated that TP-siRNA was able to act as TP suppressor or inhibitor.

Resistance to apoptosis is a key process in tumor formation. 2-deoxy-D-ribose was found to be involved in a hypoxia-induced apoptotic pathway. 2-deoxy-D-ribose inhibited hypoxia-induced phosphorylation of p38 mitogen-activated protein kinase but not c-jun NH₂-terminal kinase/stress-activated protein kinase in human leukemia HL-60 cells^[28]. In addition, 2-deoxy-D-ribose and thymine partially prevented hypoxia-induced apoptosis^[29]. 2-deoxy-D-ribose may be an important energy source under hypoxic conditions^[30]. The ability of TP-siRNA to increase the proportion of apoptotic KKKU-M139 cells (Figure 5) was most likely attributable to an inhibition of TP pathways, however, further studies are needed to de-

termine the exact role of TP in these tumor phenotypes.

The enzymatic activity of TP is also indispensable for the activation of prodrug 5'-deoxy-5-fluorouridine (5'-DFUR) to active 5-fluorouracil and fluorodeoxyuridine in tumors. The sensitivity of TP cDNA-transfected MCF-7 breast cancer cells to 5'-DFUR was increased approximately 20-fold compared to the parent cells or cells with control vector alone, and sensitivity to 5-fluorouracil was also somewhat increased^[31]. The sensitivity of a TP-transfected SMMC-7721 hepatocellular carcinoma cell line to 5'-DFUR was also significantly enhanced; however, endothelial cell migration was also promoted at the same time^[32]. We demonstrated that TP-siRNA was able to suppress TP expression *in vitro* and that this treatment impaired the therapeutic efficacy of 5-fluorouracil in KKU-M139 (Figure 6), indicating that TP enzyme activity is needed for 5-fluorouracil activation.

In conclusion, we found that TP plays a dual role in development and therapy of cholangiocarcinoma. TP confers apoptotic resistance and migration of a cholangiocarcinoma-derived cell line, and also induces migration and tube formation of HUVECs. On the other hand, TP is essential for the therapeutic efficacy of 5-fluorouracil chemotherapy. It may be useful to examine the expression level of TP in tumors of early stage cholangiocarcinoma patients to select those likely to respond well to 5-fluorouracil. However, most cholangiocarcinoma patients are diagnosed at a late stage, and there are several chemotherapeutic drugs of choice in addition to 5-fluorouracil for cholangiocarcinoma. Inhibition of TP activity may be helpful in decreasing tumor aggressiveness i.e. migration, angiogenesis and anti-apoptosis, and improving the poor prognosis of cancer patients who show high TP expression.

ACKNOWLEDGMENTS

The authors thank the Liver Fluke and Cholangiocarcinoma Research Center, Faculty of Medicine, Khon Kaen University, for contributing the cholangiocarcinoma cell lines in this study. We thank the Taiho Pharmaceutical Co., Ltd. (Japan) for the gift of mouse antibody against human TP.

COMMENTS

Background

Liver fluke-related cholangiocarcinoma is the most common hepatobiliary malignancy found in Northeast Thailand. Amplification of thymidine phosphorylase (TP) copy number was found in most cholangiocarcinoma patients suggesting that it has a significant role in tumor progression.

Research frontiers

TP catalyzes the reversible phosphorolysis of thymidine, deoxyuridine, and their analogs to their respective bases and 2-deoxyribose-1-phosphate which is then dephosphorylated to 2-deoxy-D-ribose. TP is abnormally expressed in certain cancers of the gastrointestinal tract including cholangiocarcinoma. However, how TP expression is upregulated in human tumors remains unclear. In this study, the authors investigated the roles of TP in liver fluke-related cholangiocarcinoma using RNA interference to suppress TP expression.

Innovations and breakthroughs

Suppression of TP not only reduces angiogenesis, resistance to apoptosis, and

tumor migration but also diminishes chemosensitivity to 5-fluorouracil in cholangiocarcinoma.

Applications

Because of its significance in tumor aggressiveness and 5-fluorouracil sensitivity, TP expression may be used as a prognostic and predictive marker as well as targeted therapy in cholangiocarcinoma.

Peer review

The TP gene is aberrantly expressed in different human malignancies including cholangiocarcinoma. In the current manuscript submitted by Thanasai *et al.*, the authors made several interesting observations. This article reports the effects of TP expression on tumor migration and 5-fluorouracil sensitivity in cholangiocarcinoma cells, as well as tumor cell-induced angiogenesis of endothelial cells *in vitro*.

Abstract

AIM: To investigate the correlation between hepatic osteodystrophy and osteoporosis in patients with liver cirrhosis.

METHODS: Bone mineral density of the patients ($n = 55$) and that of the control group ($n = 30$) were measured by dual-energy X-ray absorptiometry. All the women in the study were premenopausal. Deoxypyridinoline, pyridinoline and urinary Ca^{2+} were measured as bone destruction markers, while alkaline phosphatase (ALP), osteocalcin and insulin-like growth factor-1 (IGF-1) were measured as bone formation markers. Furthermore, interleukin-1 (IL-1), IL-6, tumor necrosis factor α (TNF- α), vitamin D3, direct bilirubin, albumin, cortisol and parathyroid hormone (PTH) levels were measured. The independent Student t test and χ^2 test were employed in comparing both groups, and the Pearson correlation test was used to determine associations.

RESULTS: Comparing cirrhosis and control groups, lumbar total T-score ($-1.6 \pm 1.2 \text{ g/cm}^2$ vs $-0.25 \pm 1.3 \text{ g/cm}^2$, $P < 0.001$), lumbar total Z-score ($-1.2 \pm 1.23 \text{ g/cm}^2$ vs $-0.6 \pm 1.3 \text{ g/cm}^2$, $P < 0.001$), total femur T-score ($-0.05 \pm 1 \text{ g/cm}^2$ vs $-0.6 \pm 0.9 \text{ g/cm}^2$, $P = 0.003$) and total femur Z-score ($-0.08 \pm 1.5 \text{ g/cm}^2$ vs $0.7 \pm 0.9 \text{ g/cm}^2$, $P =$

0.003) showed significantly lower values in the cirrhosis group. Blood ALP level ($109.2 \pm 57 \text{ U/L}$ vs $62.6 \pm 32.5 \text{ U/L}$, $P < 0.001$), IL-6 level ($27.9 \pm 51.6 \text{ pg/mL}$ vs $3.3 \pm 3.1 \text{ pg/mL}$, $P = 0.01$), TNF- α level ($42.6 \pm 33.2 \text{ pg/mL}$ vs $25.3 \pm 12.3 \text{ pg/mL}$, $P = 0.007$) and direct bilirubin level ($0.9 \pm 0.7 \text{ mg/dL}$ vs $0.3 \pm 0.2 \text{ mg/dL}$, $P < 0.001$) were significantly higher in the cirrhosis group. IGF-1 level ($47.7 \pm 26.2 \text{ ng/mL}$ vs $143.4 \pm 53.2 \text{ ng/mL}$, $P < 0.001$), osteocalcin level ($1.05 \pm 2.5 \text{ ng/mL}$ vs $7.0 \pm 13 \text{ ng/mL}$, $P = 0.002$) and 24 h urinary Ca^{2+} ($169.6 \pm 227.2 \text{ mg/dL}$ vs $287 \pm 168.6 \text{ mg/dL}$, $P = 0.003$) were significantly lower in the cirrhosis group. Urinary deoxypyridinoline/creatinine ($9.4 \pm 9.9 \text{ pmol}/\mu\text{mol}$ vs $8.1 \pm 5.3 \text{ pmol}/\mu\text{mol}$, $P = 0.51$), urinary pyridinoline/creatinine ($51.3 \pm 66.6 \text{ pmol}/\mu\text{mol}$ vs $29 \pm 25.8 \text{ pmol}/\mu\text{mol}$, $P = 0.08$), blood IL-1 level ($3.4 \pm 8.8 \text{ pg/mL}$ vs $1.6 \pm 3.5 \text{ pg/mL}$, $P = 0.29$), vitamin D3 level ($18.6 \pm 13.3 \mu\text{g/L}$ vs $18.4 \pm 8.9 \mu\text{g/L}$, $P = 0.95$), cortisol level ($11.1 \pm 4.8 \mu\text{g/dL}$ vs $12.6 \pm 4.3 \mu\text{g/dL}$, $P = 0.15$) and PTH level ($42.7 \pm 38 \mu\text{g/dL}$ vs $34.8 \pm 10.9 \mu\text{g/dL}$, $P = 0.27$) were not significantly different.

CONCLUSION: Hepatic osteodystrophy is an important complication encountered in patients with liver cirrhosis and all patients should be monitored for hepatic osteodystrophy.

INTRODUCTION

Liver cirrhosis develops when the liver parenchyma takes a nodular form as a result of fibrosis arising from delayed wound-healing in chronic liver damage. Osteoporosis, characterized by a reduced bone mass and an increase in bone fragility due to distortion of bone tissue microstructure, is a multifactorial disease and the most common bone disease. Dual energy X-ray absorptiometry is a method of measuring bone mineral density which has become the standard in many centers and is a highly accurate X-ray method.

It is known that liver diseases may lead to bone disease^[1]. Although chronic liver disease is associated with a broad spectrum of bone diseases, the most common type of hepatic osteodystrophy is osteoporosis. If an increase in bone resorption exceeds bone formation, or decreased bone formation is present together with normal bone destruction, then in advanced cases, bone mass will decrease and the risk of fracture will increase^[2]. Increased cytokine levels in chronic liver disease and liver cirrhosis contribute to the development of hepatic osteodystrophy. Levels of interleukin-1 (IL-1), IL-6 and tumor necrosis factor α (TNF- α) are higher in patients with alcoholic hepatitis and liver cirrhosis than gender- and age-matched controls^[3]. It is thought that a reduction in growth factors, such as insulin, or an excess of growth inhibitors such, as bilirubin, in patients with cirrhosis causes osteoblastic function disorder^[4]. Low bone formation and a high resorption rate in chronic liver disease patients results in osteoporosis. It has been shown that serum osteocalcin decreases depending on reduction of osteoblast function. A decrease in serum osteocalcin levels and an increase in deoxypyridinoline (DPD) level can be explained by lower bone turnover^[4-7].

Osteopenia is more frequent than osteomalacia in the primary biliary cirrhosis (PBC)-associated metabolic bone diseases in patients in North America^[8]. Osteoclastic activity may be increased in premenopausal PBC women. In these people there is a disorder in the formation of new bone. Calcium and vitamin D metabolism is often normal in anicteric PBC patients^[8]. Osteoporosis is a common complication of cholestatic liver disease. In primary sclerosing cholangitis (PSC), the cause of osteoporosis is multifactorial. The pathophysiological mechanism of osteoporosis has not been identified clearly yet^[9,10].

The aim of this study was to establish the osteoporosis risk in liver cirrhosis, and to investigate the role of IL-1, IL-6, TNF- α , osteocalcin, insulin-like growth factor-1 (IGF-1), alkaline phosphatase (ALP), parathyroid hormone (PTH), cortisol and 25(OH)D3 in bone metabolism, and to investigate urinary DPD, pyridinoline and Ca²⁺ levels, which are biochemical markers of bone cycling.

MATERIALS AND METHODS

Our study comprised a cohort of 85 patients, 55 men and 30 premenopausal women (older than 18 years) with liver cirrhosis, and a control group (15 men and 15 women).

The etiology was 37 hepatitis B, 10 cryptogenic, 2 PBC, 2 cardiac, 2 hepatitis C and 2 Wilson diseases in the patients with liver cirrhosis. The diagnosis of liver cirrhosis was done by biochemical and serological tests, abdominal ultrasonography, upper gastrointestinal endoscopy. Liver biopsy could not be performed because of ascites. Twenty-four patients had Child-Pugh stage C (score 11.2), 17 patients had Child-Pugh stage B (score 7.9), 14 patients had Child-Pugh stage A (score 5.6) cirrhosis. Previous diseases, fracture anamnesis, smoking, using of alcohol or coffee were investigated in all cases included in the study. There was no history of diabetes mellitus, hypertension, goitre, early menopause, surgical menopause, hyperparathyroidism or Cushing's syndrome in any of the study subjects, and none took any drug associated with increased risk of osteoporosis (anticoagulant, oral contraceptive, steroid, thiazide, diuretics, *etc.*).

Height, weight and body mass indexes (BMI) of all cases were calculated. Blood samples were analyzed in the laboratory department. Urea, creatinine, aspartate aminotransferase (AST), alanine aminotransferase (ALT), ALP, gamma glutamyl transpeptidase, Ca²⁺, P⁺, bilirubin and albumin levels were measured on an Abbott Aeroset device. Plasma cortisol, thyroid stimulating hormone, free T4, parathyroid hormone (PTH) and alpha-fetoprotein (AFP) levels were determined on a Modulator E 170 autoanalyser by electrochemiluminescence method. IGF-1 was measured on an Immulite 2000 autoanalyser, cytokines (IL-1, IL-6 and TNF- α) on an Immulite 1000 autoanalyser and vitamin D3 on an Agilent 1100 autoanalyser by HPLC.

Hydrochloric acid was added to 24 h urine for determination of pyridinoline and DPD, markers of bone destruction, by HPLC. Calcium was also determined in 24 h urine. Clearance of creatinine was calculated as (24 h urine volume \times urine creatinine)/(plasma creatinine \times 1440). Bone mineral density measurements were conducted in the triangle of L1-L4 vertebrae and femoral neck, trochanteric major, intertrochanteric region. The results were calculated as g/cm². T and Z scores for all subjects were analyzed.

Statistical analysis

Statistical assessment was carried out by SPSS 13.0. The independent Student *t* test and χ^2 test were used for comparing the groups. The Pearson correlation test was used to determine associations.

RESULTS

Seventeen female and 38 male patients with liver cirrhosis and 15 female and 15 male controls were included in the study. There were no significant differences in BMI and gender between the patients and the controls. The mean age of the patients was significantly higher than in the control group (mean, 44.8 years *vs* 34.8 years, Table 1). All the women included in the study were premenopausal, and none took alcohol or coffee. There was no fracture anamnesis. T- and Z-scores were significantly lower in

the cirrhosis group than in controls when bone mineral densities were compared (Table 1). IL-6 and TNF- α were significantly higher in the liver cirrhosis group, but there was no significant difference in IL-1 (Table 1). ALP levels were significantly higher in the cirrhosis group, but IGF-1 and osteocalcin were significantly lower compared to the control group (Table 1). There were no significant differences in DPD/creatinine and pyridinoline/creatinine levels, nor in blood cortisol, PTH and vitamin D levels (Table 1). There were no significant differences in sedimentation rate, AFP and C-reactive protein levels. Prothrombin time and direct bilirubin were significantly higher and albumin level significantly lower in the cirrhosis group (Table 1).

DISCUSSION

Hepatic osteodystrophy is an important health problem encountered in patients with liver cirrhosis^[1,2]. The reported prevalence of osteoporosis among patients with liver cirrhosis ranges from 20% to 50% depending on patient selection and diagnostic criteria, and the prevalence of fracture ranges from 5% to 20%^[9]. In the present study, osteoporosis was found in 37% of patients in accordance with the literature. The fact that all the female patients were premenopausal allowed reliable examination of the effect of liver cirrhosis on osteoporosis. Diamond *et al*^[5] found in their 2 separate studies that the prevalence of osteoporosis was 30%-48% in patients with chronic liver disease of different etiologies.

Hepatic osteodystrophy is defined as bone disease associated with chronic liver disease^[5,6,11,12]. The mechanism of hepatic osteodystrophy encountered in liver cirrhosis patients has not been clearly determined. Osteoporosis has been reported in patients with cholestatic liver, chronic viral hepatitis, alcoholic liver, hemochromatosis and benign and malignant tumors of the liver^[13]. In our study, the prevalence of osteoporosis was determined as 37% from the T-scores in lumbar vertebrae. Lumbar total BMD T-score and Z-score in patients with cirrhosis were significantly lower than those of the control group ($P = 0.003$).

IL-1, IL-6 and TNF- α cytokines are the cytokines most associated with postmenopausal osteoporosis^[14]. These cytokines can affect bone metabolism through either increasing osteoclast formation or increasing osteoclast activity. In addition, the cytokines can block osteoblast function directly and increase formation of other cytokines^[9]. IL-1, IL-6 and TNF- α levels were higher in patients with alcoholic hepatitis or liver cirrhosis compared to gender- and age-matched controls^[13]. The incidence and severity of osteoporosis is increased in patients with chronic hepatitis or intestinal diseases. Inadequate nutrition, use of steroids, and cytokines have roles in this outcome. Pfeilschifter *et al*^[15] concluded that these cytokines were strong resorptive agents. In the present study, IL-1, IL-6 and TNF- α levels were higher than those of the control group. It is thought that increased IL-6 and TNF- α levels were effective in promoting hepatic osteodystrophy in our patients with liver cirrhosis.

Table 1 Clinical features and laboratory test results of the liver cirrhosis and control groups

	Cirrhosis (n = 55)	Control (n = 30)	P-value
Lumbar total T-score (g/cm ²)	-1.6 ± 1.2	-0.25 ± 1.3	< 0.001
Lumbar total Z-score (g/cm ²)	-1.2 ± 1.2	-0.6 ± 1.3	< 0.001
Total femur T-score (g/cm ²)	-0.05 ± 1	0.6 ± 0.9	0.003
Total femur Z-score (g/cm ²)	-0.08 ± 1.5	0.7 ± 0.9	0.003
Age (yr)	44.8 ± 12.9	34.8 ± 8.2	< 0.001
BMI (kg/m ²)	25.5 ± 4.3	25.5 ± 3.7	0.970
IL-1 pg/mL	3.4 ± 8.8	1.6 ± 3.5	0.290
IL-6 pg/mL	27.9 ± 51.6	3.3 ± 3.1	0.010
TNF- α pg/mL	42.6 ± 33.2	25.3 ± 12.3	0.007
AFP (ng/mL)	2.6 ± 16.9	2.6 ± 1.1	0.100
Direct bilirubin (mg/dL)	0.3 ± 0.2	0.9 ± 0.7	< 0.001
CRP (mg/L)	5.8 ± 5.9	5.4 ± 11.3	0.800
Osteocalcin (ng/mL)	1.05 ± 2.5	7.0 ± 13	0.002
IGF-1 (ng/mL)	47.7 ± 26.2	143.4 ± 53.2	< 0.001
ALP (IU/L)	109.2 ± 57	62.6 ± 32.5	< 0.001
24 h urinary Ca ²⁺ (mg/dL)	169.6 ± 227.2	287 ± 168.6	0.003
Deoxypyridinoline/creatinine (pmol/ μ mol)	9.4 ± 9.9	8.1 ± 5.3	0.510
pyridinoline/creatinine (pmol/ μ mol)	51.3 ± 66.6	29 ± 25.8	0.080
Cortisol level μ g/dL	11.1 ± 4.8	12.6 ± 4.3	0.150
PTH level μ g/dL	42.7 ± 38	34.8 ± 10.9	0.270
Vit D3 level μ g/L	18.6 ± 13.3	18.4 ± 8.9	0.950
Albumin (g/dL)	2.5 ± 0.5	4 ± 0.4	0.001
Prothrombin time (s)	17.1 ± 5.2	11.7 ± 1.7	< 0.001
Sedimentation rate (h)	18.8 ± 10.6	11.6 ± 9.6	0.030

BMI: Body mass index; IL: Interleukin; TNF: Tumor necrosis factor; AFP: α -fetoprotein; CRP: C-reactive protein; ALP: Alkaline phosphatase; IGF: Insulin-like growth factor.

Menon *et al*^[16] have shown that there is a positive correlation between serum bilirubin level and bone destruction ratio. In the present study, increased serum bilirubin levels in patients with osteoporosis concur with studies in the literature. Gillberg *et al*^[17] have established that idiopathic osteoporosis exists together with a reduced IGF-1 level. It was thought that reducing growth factors, such as insulin, or increasing bilirubin in cirrhosis patients induces an osteoblastic function disorder^[4]. In our study, we found significantly lower IGF-1 levels in the liver cirrhosis group ($P < 0.001$), and direct bilirubin levels were significantly higher ($P < 0.001$).

In recent studies it has been reported that there is no abnormality in Ca²⁺, phosphorus and vitamin D metabolism in patients with PBS, which was unexpected^[18]. However in some studies vitamin D was lower. In our study, in accordance with the literature, vitamin D levels were not higher than the healthy group suggesting that vitamin D metabolism was normal in the liver cirrhosis group.

In another study conducted by Karan *et al*^[19], 24 patients with liver cirrhosis developing after hepatitis were compared with 22 healthy controls, and osteocalcin levels were non-significantly lower in the patient group. In the study of Capra *et al*^[20], comprising 20 people with cirrhosis and 22 healthy controls, osteocalcin levels in the cirrhosis group were lower than in the control group,

whereas plasma calcitonin levels in the cirrhosis group were higher than in the control group^[20].

In most studies, ALP levels in chronic liver patients were elevated, including the study of Karan *et al*^[19]. It is necessary to measure enzyme function of osteoblasts (bone ALP) for diagnosis of osteoporosis. If liver-gallbladder disorders can be excluded, serum total ALP levels only can be used as an index of bone formation. In contrast, bone specific isoenzyme of ALP (BAP) is inside the osteoblast membrane and if osteoblast activation exists it is excreted into the circulation. Thus, measurement of BAP is more accurate and is affected less by non-bone pathologies.

Low bone formation and a high resorption ratio in chronic liver patients results in osteoporosis. It has been shown that serum osteocalcin decreases with reduction in osteoblast function. A reduction in serum osteocalcin and an increase in urine DPD can be explained by lower bone turnover^[4-7]. Monegal *et al*^[21] have established that serum osteocalcin in patients with PBC is low. They emphasized that this was associated with a reduction in bone formation. Guañabens *et al*^[22] have found that the volume of bone decreases because of a reduction in bone formation in PBC.

Osteoclastic activity may be increased in premenopausal women with PBC. In these patients there is a disorder in formation of new bone. Calcium and vitamin D metabolism in anicteric patients with PBC is often normal^[9]. Osteoporosis is a common complication of cholestatic liver disease. The causes of osteoporosis in PSC are multifactorial. The pathophysiological mechanism of osteoporosis has not been identified clearly yet^[10].

In the present study, we investigated osteocalcin and ALP as measures of bone formation. Osteocalcin levels were lower than those of the control group ($P = 0.002$), whereas ALP levels were higher ($P < 0.001$). Lower osteocalcin levels exhibit lower osteoblastic activity. A higher ALP level, which is a bone formation marker, can be associated with cholestasis, while lower serum osteocalcin levels may be associated with a reduction in bone formation. Urine 24 h calcium levels in the liver cirrhosis patients were significantly reduced, and could be associated with inadequate nutrition in these patients, or might indicate that osteoclastic activity did not increase, or even decrease, to reduce bone formation.

PTH stimulates both bone resorption and bone formation, but it is known that if it remains at a high level, osteoclasts are stimulated, whereas osteoblasts are inhibited. Some authors have been reported that hepatocellular dysfunction increases serum PTH levels, while some authors reported no change or even a reduction^[23]. In addition to the studies reporting that serum PTH levels in liver cirrhosis patients are higher than that of controls, there exists some studies indicating that the PTH level is lower^[23]. In the present study, although there was an increase in PTH levels in the liver cirrhosis group, it was not statistically significant.

Urinary DPD/creatinine and pyridinoline/creatinine level were non-significantly increased in the cirrhosis

patients. This finding suggests there may be more bone resorption than normal. Both insulin and IGF-1 have an influence on osteoblast function and contribute to bone formation. IGF-1 levels in the cirrhosis group were significantly lower in the study. This implied that IGF-1 reduction is an important factor in progression to hepatic osteodystrophy. There is an increase in the urinary hydroxyproline/creatinine ratio especially in advanced stages of liver cirrhosis^[20]. The urinary deoxypyridine/creatinine ratio and serum bone ALP levels increase in osteoporosis developing from hepatitis C virus-associated liver cirrhosis^[4]. Increased activity of the osteoprotegerin system can be associated with increased TNF- α and IL-6 levels^[24,25].

In conclusion, metabolic bone diseases are important complications of chronic liver diseases. The bone mineral density of patients with liver cirrhosis is reduced. A decreased osteocalcin level in patients with liver cirrhosis means reduced bone formation, which, in turn, may contribute to development of osteoporosis. Increased TNF- α and IL-6 levels in patients with cirrhosis may contribute to the development of hepatic osteodystrophy. Decreased IGF-1 levels in patients with liver cirrhosis may contribute to the development of osteoporosis. Early scanning for osteoporosis in patients with liver cirrhosis will reduce the risk of morbidity and mortality. As advanced hepatic osteodystrophy is difficult to treat and adversely affects both the quality of life and the long-term prognosis of patients with chronic liver disease, special care is required in order to prevent the development of clinical bone disease in individuals with advanced hepatic disease.

COMMENTS

Background

Liver cirrhosis develops when the liver parenchyma takes a nodular form as a result of fibrosis arising from delayed wound-healing in chronic liver damage. Osteoporosis, characterized by a reduced bone mass and an increase in bone fragility due to distortion of bone tissue microstructure, is a multifactorial disease and the most common bone disease. In North America, osteopenia is more frequent than osteomalacia in patients with metabolic bone diseases associated with primary biliary cirrhosis. In primary sclerosing cholangitis, the causes of osteoporosis are multifactorial. The pathophysiological mechanism of osteoporosis has not been identified clearly yet.

Research frontiers

Metabolic bone diseases are important complications of chronic liver diseases. Increased cytokine levels in chronic liver disease and in cirrhosis contributes to the development of hepatic osteodystrophy. This study compared bone mineral density and cytokines in patients with liver cirrhosis and controls.

Innovations and breakthroughs

Cytokines have a role in hepatic osteodystrophy. Screening and treatment of symptoms are very useful for patients with liver cirrhosis.

Applications

Early diagnosis of osteoporosis by scanning in patients with liver cirrhosis will reduce the risk of morbidity and mortality. Therefore life quality will be better in patients with liver cirrhosis.

Peer review

The manuscript investigated the correlation between hepatic osteodystrophy and osteoporosis by comparing 55 patients with liver cirrhosis and 30 healthy controls and there are several comments and suggestions. This is an interesting study as the pathogenesis of hepatic osteodystrophy has not been studied extensively.

Abstract

AIM: To explore the expression of leukemia related protein 16 (LRP16) in colorectal carcinoma, and analyze its correlation with clinicopathologic features and prognosis.

METHODS: Immunohistochemistry for LRP16 was performed in 201 cases of colorectal carcinoma and 60 cases of distal normal mucosa. Medical records were reviewed and clinicopathological analysis was performed.

RESULTS: LRP16 expression was detected in 117 of 201 cases of the colorectal carcinoma and in 21 cases of 60 distal normal mucosa. The expression of LRP16 in carcinoma was significantly higher than that in normal mucosa ($\chi^2 = 9.999$, $P = 0.002$). LRP16 protein expression was found in 43.3% (52/120) of carcinoma at stage I and II, and 80.2% (65/81) of carcinoma at stage III and IV ($\chi^2 = 27.088$, $P = 0.001$). Correlation

between LRP16 expression and clinicopathological factors was significant in differentiation ($P = 0.010$), tumor size ($P = 0.001$), infiltrative depth ($P = 0.000$) and distant metastasis ($P = 0.027$). The difference of median survival time between cancer patients with LRP16 expression (38.0 mo) and those without was statistically significant (105.0 mo, Log rank = 41.455, $P = 0.001$). The multivariate survival analysis revealed that LRP16 expression was correlated significantly (Cox's regression: $P = 0.001$, relative risk = 2.082) with shortened survival in the patients with colorectal cancer.

CONCLUSION: The expression of LRP16 is related to the degree of differentiation, invasiveness, metastasis and prognosis of colorectal carcinoma.

INTRODUCTION

Leukemia related protein 16 (LRP16), which was originally recognized and isolated from human lymphocytes in 1999, was identified as an estrogen-responsive gene. It

localizes on chromosome 11q12.1 and encodes nuclear factor^[1-5]. It expresses in testicle, ovaries, mucosa of colon, prostate, small intestine, spleen, thymus^[2,3] and gastric carcinoma^[6]. LRP16 is also an estrogen receptor α (ER α) coactivator. Its expression level is strongly dependent on the estrogen activities. It is involved in estrogen signaling pathway and can strengthen the ER α responsive gene activation.

Colorectal carcinoma is a major cause of cancer-related morbidity and mortality. In the Western countries, it is the second leading cause of death from cancer^[7]. The incidence of colorectal cancer has increased in China recently, therefore, some new molecular markers are necessary to raise the efficiency of tumor diagnosis and to predict prognosis of the patients or even for therapeutic application. It has been reported that ER is identified in colorectal cancer^[8-10]. However, no immunohistochemical and clinicopathological studies of LRP16 have been performed in colorectal carcinoma. Here, we investigated the expression of LRP16 in colorectal cancer specimens and normal mucosa by an immunohistochemistry (IHC)-based technique and analyzed the relationship between LRP16 expression and the clinicopathological features of Chinese patients with colorectal cancer.

MATERIALS AND METHODS

Patients and specimens

A series of 201 consecutive colorectal carcinoma patients who were treated surgically in Chinese People's Liberation Army General Hospital (Beijing, China) between August 1999 and September 2003 and 60 cases with distal normal mucosa were recruited in this study. There were 127 men and 74 women with ages ranging from 20 to 81 years (median, 62 years; mean, 57.8 years). The carcinomas were located in the cecum ($n = 9$), ascending colon ($n = 29$), transverse colon ($n = 14$), descending colon ($n = 9$), sigmoid colon ($n = 48$) and rectum ($n = 92$). Of these patients, 24 were grade I, 110 grade II and 67 grade III, according to histological grading; and 48 were stage I, 72 were stage II, 70 were stage III and 11 were stage IV, according to clinical TNM stage revised by International Union Against Cancer in 2003. All the patients were followed up for survival. During the follow-up period from the date of surgery until April 30, 2009, 126 patients died and 75 were alive (median survival time, 51 mo, range, 0.10-115 mo).

Histological examination

The resected specimens were fixed in 10% formalin. The gross appearance and the size of tumor were recorded. Patients' medical records and histopathology of each specimen were reviewed. The tissues (cancer and normal) were cut into 5-mm slices, embedded in paraffin for histological and immunohistochemical examinations. Each paraffin block was cut at 4 μ mol/L in thickness, and sections were mounted onto adhesive-coated slides. Slides were deparaffinized in xylene twice for 10 min and

rehydrated through descending concentration of ethanol. Antigen retrieval was performed in 0.01 mol/L citrate buffer (pH 6.0) by microwave oven for 2 min and 30 s at 100°C. Endogenous peroxidase activity was blocked with 0.3% hydrogen peroxidase for 15 min. After washing with phosphate-buffered saline (PBS), the sections with primary polyclonal rabbit antibody to human LRP16 (recognized and isolated in 1999 by Department of Molecular Biology of our hospital) that was diluted 1:1000 in blocking solution were incubated at 4°C overnight, in a humidified chamber. After washing three times with PBS, the sections incubated for 30 min with biotinylated secondary antibody (polyperoxidase-anti-mouse/rabbit IgG, Zymed) then washed again with PBS. 3,3'-Diaminobenzidine was used as the chromogen. Sections were then counterstained with hematoxylin for 1 min, raised in water, dehydrated in ascending concentrations of ethanol followed by clearance with xylene, and cover slipped permanently for light microscopy. Normal ovary tissue was used as a positive control, whereas the primary antibody was replaced by PBS as a negative control.

Evaluation of score

Immunohistochemically stained slides were reviewed by two investigators independently who were blinded to all clinical data. Slides were analyzed under light microscopy using manual methods. Staining was graded for intensity of staining (0, negative; 1, weak; 2, moderate; 3, strong) and percentage of cells stained (0, < 5%; 1, 6%-25%; 2, 26%-50%; 3, > 50%). The final score was determined by the combined staining score (extent + intensity). Score 0 was defined as negative expression (-), scores 1-3 as weak staining pattern (+), and 4-6 as strong expression (++)

Statistical analysis

Statistical analysis was performed using SPSS 13.0 software (SPSS Inc., Chicago, Illinois). The χ^2 test was used to examine the various clinicopathological characteristics and LRP16 expression. Cumulative survival curves were drawn by the Kaplan-Meier method. The difference between the curves was analyzed by the Log-rank test. Multivariate survival analysis was based on Cox proportional hazard model. $P < 0.05$ was considered statistically significant.

RESULTS

Pattern of LRP16 expression in colorectal carcinoma and normal mucosa

LRP16 staining was performed in 201 colorectal cancer patients and 60 cases of normal tissues by IHC. The result showed that in cancer tissues, LRP16 staining was negative (-) in 41.8% (84/201) cases, weak positive (+) in 21.4% (43/201) cases and strong positive (++) in 36.8% (74/201) cases; whereas in normal mucosae, LRP16 was negative in 65% (39/60) cases, weak positive in 13.3% (8/60) and strong positive in 21.7% (13/60) cases. As a whole, LRP16 expression was detected in 58.2%

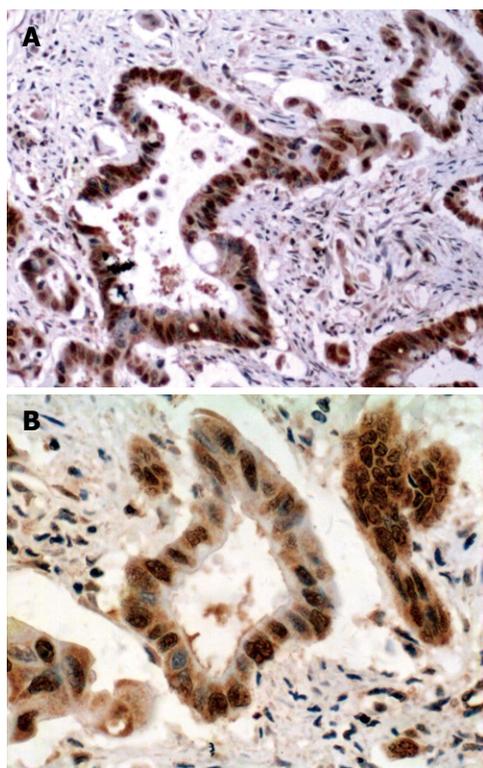

Figure 1 Positive leukemia related protein 16 (LRP16) expression in colorectal adenocarcinoma. The final score was 6, including 3 scores (strong) related to intensity of staining and 3 scores (> 50%) related to extent of staining. Thus it was defined as strong staining pattern (++). A: Immunohistochemistry (IHC), × 100; B: IHC, × 400.

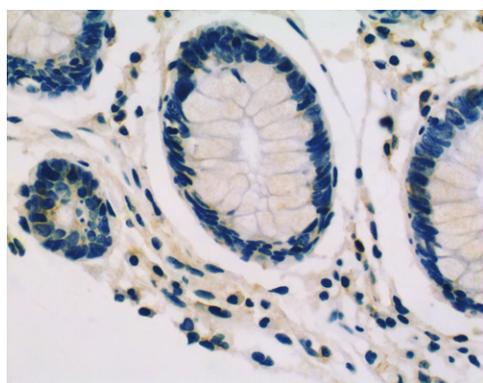

Figure 2 Negative LRP16 expression in normal colorectal mucosa (IHC, × 400). The final score was 0, including 0 score (negative) related to intensity of staining, and 0 scores (< 5%) related to extent of staining. Thus it was defined as negative expression (-).

(117/201) colorectal carcinoma, and in 35% (21/60) distal normal mucosa (Figures 1 and 2). The expression of LRP16 protein was found in cell nucleus or both cell nucleus and cytoplasm. The difference of LRP16 expression between colorectal cancer and normal mucosa was statistically significant ($\chi^2 = 9.998, P = 0.002$).

Correlation of LRP16 expression and clinicopathological features in colorectal cancer

Upon clinicopathological analysis, more LRP16 expres-

^a $P < 0.05$, statistically significant. LRP16: Leukemia related protein 16.

sion was present in bigger tumors ($P = 0.001$). When comparing the LRP16 status with clinicopathological variables, we found significant positive correlations between LRP16 expression and degree of differentiation ($P = 0.010$), depth of invasion ($P = 0.001$), lymph node metastasis ($P = 0.001$) and distant metastasis ($P = 0.027$). The level of LRP16 in cases of low TNM stage (I + II) was lower than that of high stage (III + IV) ($\chi^2 = 27.088, P = 0.001$) (Table 1).

Relationship between LRP16 expression and overall survival of colorectal cancer patients

All 201 patients were followed up for survival to assess LRP16 expression as a prognostic factor. Kaplan-Meier survival curves and Log-rank test demonstrated that LRP16 positive cases showed a significantly shortened median survival time (38.0 mo) in comparison with other patients (105.0 mo) (Log rank = 41.455, $P = 0.001$) (Figure 3).

Table 2 Cox regression analysis of prognostic factors in colorectal carcinoma

Prognostic variables	B	SE	Wald value	P value	RR
Gender	0.261	0.197	1.756	0.185	1.298
Age (yr)	0.191	0.124	2.366	0.124	1.211
Tumor location	0.071	0.060	1.338	0.239	1.074
Histologic differentiation	0.747	0.162	21.128	0.001	2.110
Tumor size	0.123	0.188	0.433	0.510	1.131

TNM stage	0.717	0.236	9.236	0.002	2.049
LRP16 expression	0.741	0.225	10.868	0.001	2.099

B: Partial regression coefficient; RR: Relative risk. $P < 0.05$, statistically significant.

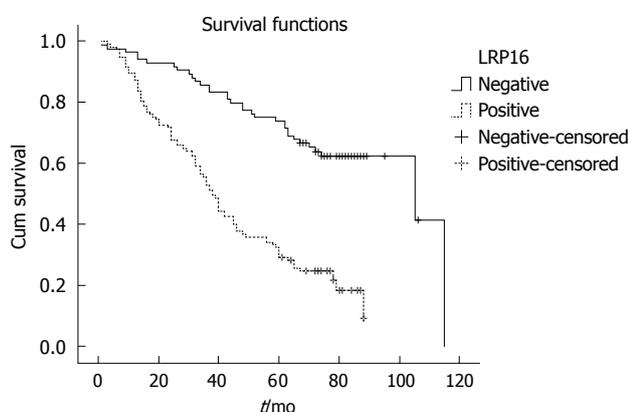

Figure 3 Cumulative survival according to LRP16 expression in colorectal cancer patients. The Kaplan-Meier plot of colorectal carcinoma patients ($n = 201$) demonstrates a significantly lower survival with LRP16 positive expression, $P = 0.001$.

The overall 5-year survival rate of the LRP16 negative patients (71.4%) was higher than that of the LRP16 positive group (29.1%). LRP16 expression appeared as a significant independent prognostic factor ($P = 0.001$) with a relative risk of 2.082 (confidence interval, 1.3-3.2) in the multivariate survival analysis of the patients. Other independent prognostic factors in multivariate survival analysis included tumor shape, degree of differentiation, depth of invasion and distant metastasis (Table 2).

DISCUSSION

LRP16 was originally recognized and isolated from human lymphocytes in 1999^[1]. It was identified as an estrogen responsive gene^[1-5]. The expression of LRP16 was found in different tissues in varying degrees, including ovary, testicle, prostate, small intestine, spleen, thymus and stomach^[2-3,6]. Furthermore, LRP16 is overexpressed in tumors, compared with their matched normal tissues^[2]. Some studies have indicated that LRP16 may play an important role in the carcinogenesis and progression of hormone-dependent breast cancer^[5,11]. Overexpression

of LRP16 significantly stimulated MCF-7 cell proliferation by promoting G1/S transition^[4]. The suppression of the endogenous LRP16 in ER α -positive MCF-7 cells not only inhibits cell growth but also significantly attenuates the cellular estrogen-responsive proliferation ability and sensitizes tumor cells to radiation^[11-13]. However, some authors thought that expression of LRP16 in ER α -negative cells had no effect on proliferation^[11]. The expression of *LRP16* gene was dependent on the estrogen activities^[14,15], LRP16 was also involved in estrogen signaling and could strengthen the ER α -responsive gene activation, therefore, it is also considered as an ER α coactivator^[11]. Previous studies have demonstrated that ER α /PR status, tumor size and auxiliary lymph node metastasis were closely correlated with LRP16 overexpression^[16]. ER includes two subtypes, ER α and ER β . They have been identified in colorectal cancer tissue and normal mucosa^[8-10]. It was also reported that the ER expression level of carcinoma was higher than that of non-cancerous colon tissues^[10]. Activation of ER signaling pathway plays an important role in multi-tissue development^[17-20]. Therefore, we propose that LRP16, a coactivator of ER α , may display an important function in the carcinogenesis and progression of colorectal cancer as in breast cancer.

Although the detailed molecular mechanism involved in this process is unclear, our study have potentially clinical benefits. LRP16 expression that could be detected by IHC may be a useful molecular marker to predict the prognosis in colorectal carcinoma patients. Moreover, LRP16 and ER α could inter-regulate each other, as LRP16 is an ER α coactivator. This study raises the possibility that anti-estrogen therapy could be used in the patients with high LRP16 expression. This information may help us individualize patient care (e.g. progression and prognosis of patients after operation). In this study, LRP16 expression was commonly up-regulated in colorectal carcinoma and was associated with shortened survival time of the patients in univariate and multivariate analyses. However, further investigations and clinicopathological correlation are necessary.

ACKNOWLEDGMENTS

We thank all colleagues from the Department of Molecular Biology, Chinese People's Liberation Army General Hospital, for their help and supports in this study.

COMMENTS

Background

Colorectal cancer is a major cause of cancer-related morbidity and mortality. In the Western world it is the second leading cause of death from cancer. The evidence of colorectal cancer has increased recently in China. Although this disease is curable by surgical interventions together with chemotherapy and radiation in its early stages, the patients are often asymptomatic before the metastasis occurred. Therefore, effective screening and preventive strategies for colorectal cancer are necessary to enhance our capability to predict the clinical outcome of the disease.

Research frontiers

Leukemia related protein 16 (LRP16) gene plays an important role in the

carcinogenesis and progression of hormone-dependent breast cancer. *LRP16* expression was also reported to be associated with invasion, metastasis and prognosis of gastric carcinoma. But no comprehensive description of LRP16 protein expression in colorectal cancer has been reported. In this study, the authors investigated the expression patterns of LRP16 protein in human colorectal cancers and compared the clinical and pathological variables including survival time of the patients.

Innovations and breakthroughs

To date, only limited data on LRP16 protein expression in solid tumors are available. This study is believed to be the first trial for verifying the relationship between LRP16 expression and clinicopathological factors of colorectal carcinoma.

Applications

The authors presented some evidences to show a significant association between high LRP16 expression in colorectal cancer and early disease progression or the disease related death, and they believe that the LRP16 expression status detected by immunohistochemistry (IHC) may be a molecular marker to predict the prognosis of colorectal carcinoma patients.

Peer review

In this paper the authors have analyzed by IHC the expression of LRP16 protein in 201 cases of colorectal carcinoma and 60 cases of distal normal mucosae and they have correlated the expression of this marker with the degree of differentiation, invasiveness, metastasis and prognosis of colorectal carcinoma. The study is well performed and the results are quite interesting, and are potentially helpful for clinical application, the quality of the research and presentation, including photomicrographs and figures, is high, the discussion is clear and well written.

Abstract

AIM: To investigate the role of perioperative chemoradiotherapy (CRT) in the treatment of locally advanced thoracic esophageal squamous cell carcinoma (ESCC).

METHODS: Using preoperative computed tomography (CT)-based staging criteria, 238 patients with ESCC (stage II-III) were enrolled in this prospective study between January 1997 and June 2004. With informed consent, patients were randomized into 3 groups: preoperative CRT (80 cases), postoperative CRT (78 cases) and surgery alone (S) (80 cases). The 1-, 3-, 5- and 10-year survival were followed up. Progression-free survival (PFS) was chosen as the primary endpoint by treatment arm measured from study entry until documented progression of disease or death from any cause. The secondary endpoint was overall survival (OS) determined as the time (in months) between the date of therapy and the date of death. Other objectives were surgical and adjuvant therapy complications.

RESULTS: With median follow-up of 45 mo for all the enrolled patients, significant differences in the 1-, 3-, 5-, 10-year OS (91.3%, 63.5%, 43.5%, 24.5% vs 91%, 62.8%, 42.3%, 24.4% vs 87.5%, 51.3%, 33.8%, 12.5%, $P = 0.0176$) and PFS (89.3%, 61.3%, 37.5%, 18.1% vs 89.1%, 61.1%, 37.2%, 17.8% vs 84.5%, 49.3%, 25.9%, 6.2%, $P = 0.0151$) were detected among the 3 arms. There were no significant differences in OS and PFS between the preoperative CRT and postoperative CRT arm ($P > 0.05$). For the patients who had radical resection, significant differences in median PFS (48 mo vs 61 mo vs 39.5 mo, $P = 0.0331$) and median OS (56.5 mo vs 72 mo vs 41.5 mo, $P = 0.0153$) were detected among the 3 arms, but there were no significant differences in OS and PFS between the preoperative CRT and postoperative CRT arm ($P > 0.05$). The local recurrence rates in the preoperative CRT, postoperative CRT group and S group were 11.3%, 14.1% and 35%, respectively ($P < 0.05$). No significant differences were detected among the 3 groups when comparing complications but tended to be in favor of the postoperative CRT and S groups ($P > 0.05$). Toxicities of CRT in the preoperative or postoperative CRT arms were mostly moderate, and could be quickly alleviated by adequate therapy.

CONCLUSION: Rational application of preoperative or postoperative CRT can provide a benefit in PFS and OS in patients with locally advanced ESCC.

INTRODUCTION

Esophageal squamous cell carcinoma (ESCC) is one of the common malignancies and the seventh leading cause of cancer-related deaths in the world^[1]. The 5-year survival rate is only 15%-20% in patients with locally advanced esophageal cancer^[2]. Treatment failure mainly results from recurrence or metastasis. A standardized comprehensive treatment is still under development. Radiotherapy can control local-regional esophageal cancer and chemotherapy has both local and systemic antineoplastic activity. With increasing enthusiasm for multidisciplinary treatment modalities to improve outcome, a commonly employed treatment approach for esophageal cancer is chemoradiotherapy (CRT) in addition to surgical resection^[3]. Preoperative CRT had been applied to patients with esophageal carcinoma in an effort to reduce the relapse rate and improve survival. Many studies have demonstrated the effectiveness of neoadjuvant CRT^[4-9]. In contrast to data available on preoperative CRT, although a number of trials compared adjuvant chemotherapy or radiotherapy with surgery alone, there are almost no randomized trials comparing adjuvant CRT with surgery alone. The only exception is a trial that compared surgery alone with surgery and adjuvant CRT for patients with resectable cancers of the stomach and gastroesophageal junction^[10]. Although the results suggest that resection followed by concurrent CRT should be considered for patients with adenocarcinoma of the stomach and the gastroesophageal junction, the question remains whether postoperative CRT can improve overall survival in patients with ESCC.

To our knowledge, as yet no study is available to determine the best sequencing of CRT and surgery. To resolve this deficiency, the present prospective study was conducted in our center from January 1997 to June 2004.

MATERIALS AND METHODS

Patients

Two hundred and seventy one patients with ESCC were diagnosed by endoscopic biopsy and histopathology between January 1997 and June 2004 in our center. According to the preoperative computed tomography (CT) staging criteria, 238 patients with stage II-III thoracic ESCC were enrolled in this prospective study. The CT staging criteria were as follows: Stage I, the tumor was limited to the esophageal lumen or the thickness of the esophageal wall varied between 3 and 5 mm; Stage II, the thickness exceeded 5 mm but there was no invasion of the mediastinum or distant metastasis; Stage III, the tumor invaded the adjacent mediastinal structure; and

Stage IV, there was distant metastasis. All patients gave informed consent prior to their inclusion in the study. The form had been reviewed by the appropriate ethics committee and had been developed and was administered in accordance with the ethical standards laid down in an appropriate version of the 1964 Declaration of Helsinki. The enrolled patients were randomized into 3 groups: preoperative CRT, postoperative CRT, and surgery alone (S). The randomization method was based on random numerals produced by computer. Characteristics of the preoperative patients are shown in Table 1.

Treatment

The surgical procedure used in this study was either a radical resection, which involved an esophagectomy through a left or right thoracotomy with 2-field lymphadenectomy, or palliative resection or esophageal bypass. All the patients who underwent palliative resection or esophageal bypass had taken traditional Chinese medicine themselves.

For patients in the preoperative arm, surgical resection was to be performed 4-6 wk after induction of CRT. The patients treated with postoperative CRT underwent surgery and received CRT 4-6 wk later. For patients treated with preoperative CRT, radiation was delivered in a total dose of 40 Gy (20 fractions at 2 Gy per fraction) in anteroposterior fields including esophageal tumors and enlarged lymph nodes, with a 4-5 cm proximal and distal margin and a 1-2 cm radial margin. For 30 out of 78 patients treated with postoperative CRT, radiation was delivered in daily fractions of 2 Gy to a total dose of 40 Gy over 4 wk by using the same double field technique as the preoperative CRT group, and the anteroposterior fields of the following 48 patients were extended from the sixth cervical vertebrae to the first lumbar vertebrae, including the origin of esophagus and lymph drainage that encompassed the supraclavicular regions and left gastric lymph nodes. Then a 10 Gy boost was delivered through parallel opposed lateral or oblique portals for limitation of spinal

cord radiation dose. Radiotherapy was carried out by linear accelerators with 6 MV photons; treatment ports were designed to include enlarged regional nodes based on CT evaluation and endoscopic ultrasound.

For chemotherapy, 2 cycles were administered on days 1-3 and days 22-24 of radiotherapy. A paclitaxel (PTX) + cisplatin (DDP) regimen was used, including PTX (135 mg/m² per day) administered as a short-term infusion on day 1 of each cycle, while DDP (20 mg/m² per day) was delivered as a continuous infusion over 24 h on days 1-3 of each cycle. The patients received the antiemetics granisetron and metoclopramide before and after the cisplatin infusion. The dose of chemotherapy in the second cycle was adjusted according to hematological toxicities.

Efficacy assessment

Any perioperative complications were observed and recorded. During treatment, the patients were monitored weekly with a physical examination and blood chemistry evaluation. Clinical evaluation was carried out by endoscopy, endoscopic ultrasonography, and CT scans. All results of the examination were collected and evaluated by the oncology experts. The 1-, 3-, 5- and 10-year survival were followed up.

Follow-up

Clinical follow-up after completion of treatment was based on periodic visits (every 3 mo during the first 2 years, every 6 mo after 2 years). The follow-up time for survivors ranged from 5 to 124 mo (median 45 mo).

Statistical analysis

STATA 10.0 for Windows (StataCorp, College Station, Texas 77845, USA) was used for statistical analysis. The differences in age group, sex, tumor location, and tumor staging, complications, and cause of death among groups were compared by the χ^2 test or Fisher's Exact test. The survival among groups were described by Kaplan-Meier curves and analyzed by the log-rank test. *P* values less than 0.05 were considered statistically significant. Progression free survival (PFS) was chosen as the primary endpoint by treatment arm measured from study entry until documented progression of disease or death from any cause. The secondary endpoint was overall survival (OS) determined as the time (in months) between the date of therapy and the date of death. Other factors determined were surgical and adjuvant therapy complications.

RESULTS

By June 30 2009, 228 out of all cases were followed up by means of telephone or outpatient service, and 10 cases were lost. There were 3.8% treatment-related deaths in preoperative CRT but no treatment-related deaths in the postoperative CRT and S group, and 51.3% of patients died from the local tumor recurrence and distant metastasis.

Median PFS was 46.5 mo (95% CI: 37.4-66.3) in the preoperative CRT group, 45 mo (95% CI: 35.8-67) in the postoperative CRT group, and 32.5 mo (95% CI:

25.4-42.3) in the S group. The 1-year PFS in preoperative CRT, postoperative CRT and S groups was 89.3%, 89.1% and 84.5%, respectively, with no significant differences ($\chi^2 = 0.64$, *P* = 0.4123). However, the 3-, 5- and 10-year PFS of the preoperative CRT (61.3%, 37.5%, 18.1%, respectively) and postoperative CRT groups (61.1%, 37.2%, 17.8%, respectively) were significantly different ($\chi^2 = 4.16$, *P* = 0.0319; $\chi^2 = 4.14$, *P* = 0.0321; $\chi^2 = 5.38$, *P* = 0.0203; respectively) from those of the S group (49.3%, 25.9%, 6.2%, respectively). There was no significant difference in PFS between the neoadjuvant and adjuvant therapy groups ($\chi^2 = 0.14$, *P* = 0.7060) (Figure 1A). Median OS was 53 mo (95% CI: 43-64.3) in the preoperative CRT group, 48 mo (95% CI: 38.5-72.5) in the postoperative CRT group, and 36 mo (95% CI: 29.7-47.3) in the S group. The 1-year OS in the preoperative CRT, postoperative CRT and S groups was 91.3%, 91% and 87.5%, respectively, which were not significantly different ($\chi^2 = 0.72$, *P* = 0.3970). However, the 3-, 5- and 10-year survival rates of the preoperative CRT (63.5%, 43.5%, 24.5%, respectively) and postoperative CRT groups (62.8%, 42.3%, 24.4%, respectively) were significantly different ($\chi^2 = 3.98$, *P* = 0.0453; $\chi^2 = 4.76$, *P* = 0.0402; $\chi^2 = 4.27$, *P* = 0.0389; respectively) from those of the S group (51.3%, 33.8%, 12.5%, respectively). There was no significant difference in OS between the neoadjuvant and adjuvant therapy groups ($\chi^2 = 0.46$, *P* = 0.4978) (Figure 1B).

For the patients who experienced radical resection, median PFS of the preoperative CRT group, postoperative CRT group and S group was 48 mo (95% CI: 40-67.0), 61 mo (95% CI: 44.0-75.4), and 39.5 mo (95% CI: 30-60), respectively. A significant difference in PFS was detected among the 3 arms ($\chi^2 = 6.82$, *P* = 0.0331), however, there was no significant difference in PFS between neoadjuvant and adjuvant therapy groups ($\chi^2 = 0.22$, *P* = 0.6416) (Figure 1C). There was a significant difference in OS among the 3 arms ($\chi^2 = 8.36$, *P* = 0.0153). The median OS of the preoperative CRT group, postoperative CRT group and S group was 56.5 mo (95% CI: 44-72), 72 mo (95% CI: 49.6-88.4), and 41.5 mo (95% CI: 31.6-57.7), respectively. However, there was no significant difference in OS between neoadjuvant and adjuvant therapy groups ($\chi^2 = 0.16$, *P* = 0.6873) (Figure 1D).

The local recurrence rates of the preoperative CRT group, postoperative CRT group and S group were 11.3%, 14.1% and 35% respectively, and showed a statistically significant difference (*P* = 0.011). There was no significant difference among the 3 groups when comparing perioperative complications but there was a tendency in favor of the postoperative CRT and S groups (*P* = 0.179).

For the 158 patients receiving CRT, incidence of grade 3 or greater leucopenia, thrombocytopenia, anemia and vomiting were 11.4% (18/158), 6.3% (10/158), 1.3% (2/158) and 6.3% (10/158), respectively. Postoperative pathologic staging and perioperative complications, and the causes of death are presented in Table 2.

DISCUSSION

Patients with resectable ESCC should receive multimod-

al treatment to prolong OS^[11,12]. There is still controversy about how to improve prognosis and how to reduce local recurrence and distant metastasis. Both chemotherapy and radiotherapy may be active against different

tumor cell populations, the chemotherapy may be effective against micrometastases while radiation counteracts spatial metastases. In the Western world, preoperative chemotherapy and CRT can increase OS by 4.4% and

6.4%, respectively, however, treatment-related mortality increases by 1.7% with neoadjuvant chemotherapy and by 3.4% with CRT, compared with surgery alone^[13]. There were a few nonrandomized trials on postoperative CRT in treating esophageal carcinoma^[14-19], however, the results had discrepancies. Regretfully, the most optimal sequence of CRT in relation to surgical resection is unclear. Thus our study is a unique randomized controlled study to evaluate the outcome of preoperative CRT in patients with local advanced thoracic ESCC, and it includes a long-term follow-up.

The present study showed a benefit in PFS and OS with neoadjuvant or adjuvant therapy. Meanwhile, our study indicated that preoperative CRT reduced the rate of local recurrence, and the survival benefit resulted from improved local cancer control brought about by the adjuvant arm. Although there was no significant difference found in 1-year PFS and OS, both preoperative CRT and postoperative CRT showed a significant advantage in longtime PFS and OS. A meta-analysis had suggested that preoperative CRT may improve survival and locoregional control but was associated with higher toxicity and increased mortality^[3]. Our results also confirm this point. Rice and coworkers found that 31 patients treated with postoperative adjuvant CRT had improved survival, in a retrospective review^[20]. Together with our present study, it further confirms that postoperative CRT may be an alternative option especially for locally advanced thoracic ESCC. Moreover, the results indicated that postoperative CRT may have almost the same long-term of efficacy as preoperative CRT, although the latter showed a nonsignificant trend of higher survival compared to the former.

To throw further light on the benefit in PFS and OS with neoadjuvant or adjuvant therapy for ESCC, we subsequently analyzed the data in patients who had undergone radical resection. The results also showed the same advantages as the above when including the palliative resection and esophageal bypass patients. The results also showed no significant difference in survival rates when comparing the preoperative CRT and postoperative CRT arms. It further clarifies that adjuvant CRT can provide almost the same long-term of efficacy as neoadjuvant CRT.

In addition, there was no suggestion that treatment-related mortality was increased by the use of postoperative CRT, which was accomplished with manageable toxicity. Most patients had less than grade 2 hematological toxicities. However, our results showed an increase in postoperative deaths and a trend for relatively higher perioperative complications in the neoadjuvant CRT arm. The involved reasons could be as follows: surgeons may undertake a challenging esophagectomy resulting in surgical difficulty and postoperative complications when performed after neoadjuvant CRT. For example, radiation might contribute to the failure of an anastomotic leak and postoperative acute lung injury. The results also showed that preoperative CRT can facilitate complete resection by downstaging tumors when compared to postoperative CRT and surgery alone. Thus, whether

or not the survival benefit of neoadjuvant CRT can be negated by an increase in postoperative deaths should of concern. In addition, loss to follow-up was low (4.2%), with only 3 patients receiving preoperative CRT and 3 patients receiving postoperative CRT and 4 patients receiving surgery alone, thus our study is robust.

In conclusion, long-term survival is maximized by the use of CRT followed by surgery for locally advanced esophageal cancer. However, patients are more likely to develop toxicity. As therapies improve, it is likely that the toxicity may be reduced and neoadjuvant CRT may provide a more marked benefit in esophageal cancer. Meanwhile, postoperative CRT can also be safely administered and considered as the multimodal treatment of choice for locally advanced ESCC. In appropriately selected patients, either pre- or postoperative CRT is a viable strategy. Further comparison of pre- and postoperative CRT in treating esophageal cancer is required for verification through multicenter and large sample randomized clinical trials.

COMMENTS

Background

Esophagectomy is a standard treatment for resectable esophageal carcinoma but relatively few patients are cured. Combined neoadjuvant chemoradiotherapy (CRT) or adjuvant CRT with surgery may improve survival but there is concern about treatment morbidity and the best sequencing of CRT and surgery.

Research frontiers

This study investigated the overall survival and progression-free survival data (up to 10-year survival).

Innovations and breakthroughs

Some studies have demonstrated the effectiveness of neoadjuvant CRT and there are almost no randomized trials comparing adjuvant CRT with surgery alone. As yet no study is available to determine the best sequencing of CRT and surgery. The most optimal sequence of CRT in relation to surgical resection is unclear. This study was a unique randomized controlled study to evaluate the outcome of preoperative and postoperative CRT in patients with local advanced thoracic esophageal squamous cell carcinoma, and it includes a long-term follow-up.

Peer review

The authors present the results of a randomized prospective study which examined the efficacy and safety of 3 treatment regimens in esophageal squamous cell carcinoma stage II and III. The study is of interest to readers of the journal. The discussion is satisfactory and is limited to the topic. Tables depicted essential data and are well constructed.

Abstract

AIM: To evaluate the diagnostic value of double-balloon enteroscopy (DBE) for obscure gastrointestinal bleeding (OGIB).

METHODS: The data about 75 OGIB patients who underwent DBE in January 2007-June 2009 in our hospital were retrospectively analyzed.

RESULTS: DBE was successfully performed in all 75 patients without complication. Of the 75 patients, 44 (58.7%) had positive DBE findings, 22 had negative DBE findings but had potential bleeding at surgery and capsule endoscopy, *etc.* These 66 patients were finally

diagnosed as OGIB which was most commonly caused by small bowel tumor (28.0%), angiodysplasia (18.7%) and Crohn's disease (10.7%). Lesions occurred more frequently in proximal small bowel than in distal small bowel (49.3% vs 33.3%, $P = 0.047$).

CONCLUSION: DBE is a safe, effective and accurate procedure for the diagnosis of OGIB.

INTRODUCTION

Obscure gastrointestinal bleeding (OGIB) is defined as recurrent or persistent gastrointestinal bleeding when gastric and colonic endoscopy is negative^[1]. OGIB accounts for approximately 5% of all gastrointestinal bleeding events^[2]. Most OGIB events are attributable to small bowel diseases.

The detection and management of small bowel bleeding are a challenge in the past due to the length and ana-

tomical position of small bowel. The diagnostic rate of conventional diagnostic strategies including small intestine radiography, abdominal computed tomography (CT), angiography, and red blood cell scan for small intestine disease is low^[3]. Introduction of capsule endoscopy (CE) has significantly revolutionized the study of small bowel as it is a reliable method to evaluate the entire small bowel^[4]. However, application of CE in diagnosis of OGIB is limited by the handling controllability, biopsy, endoscopic treatment, retention of capsule in stenosis intestine^[5].

Etiological diagnosis of OGIB has been markedly improved with the development of double-balloon enteroscopy (DBE) since 2001^[6]. DBE can be performed either through the mouth or through anus, and is thus able to explore a large part of the small bowel. DBE has the advantages including image clarity, handling controllability, biopsy, and endoscopic treatment over CE^[7]. It has been demonstrated that DBE is a safe and useful procedure for the diagnosis of small intestinal disease, especially for OGIB^[8]. In China, very few data are available on the diagnostic value of DBE for OGIB.

In this study, the data about 75 OGIB patients admitted to our hospital from January 2007 to June 2009 were retrospectively analyzed and the diagnostic value of DBE for OGIB was evaluated.

MATERIALS AND METHODS

Patients

DBE was performed in 75 OGIB patients (37 males, 38 females, at a mean age 51.5 ± 16.6 years, range 16-86 years) admitted to our hospital in January 2007-June 2009. Melena, hematemesis, hemaecia, and fecal occult bleeding were detected in the patients enrolled in this study. The duration of symptoms ranged 1 d-over 10 years. The main characteristics of patients are shown in Table 1. All the patients were suspected of small bowel diseases. However, standard gastric and colonic endoscopy for them was negative. Other routine methods such as CT and small intestine radiography showed no exact diagnosis of etiology.

DBE system

OGIB was detected in patients using a Fujinon enteroscope (EN450-P5/20, Fujinon Inc, Saitama, Japan) consisting of a mainframe, an enteroscope, an overtube and an air pump. Two soft latex balloons that can be inflated and deflated are attached to the tip of enteroscope and overtube. The balloons are connected to a pump through an air channel in the endoscope that can automatically modulate the air according to the different balloon pressures. By utilizing the overtube in combination with serial inflation and deflation of the balloons, endoscope can be inserted into the small bowel.

Preoperative preparation

The patients were fasted overnight and 2 boxes of polyethylene glycol electrolyte mixed with 3000 mL water

Table 1 Characteristics of OGIB patients *n* (%)

Characteristics	<i>n</i> = 75
Age (yr)	51.5 ± 16.6 (16-86)
Sex (male/female)	37/38
Causes of OGIB	
Melena	45 (60.0)
Hematemesis and melena	7 (15.6)
Hemaecia	17 (22.7)
Occult bleeding	6 (8.0)
Duration of symptoms (mo)	
< 1	29 (38.7)

> 12	22 (29.3)

OGIB: Obscure gastrointestinal bleeding.

were taken 4-5 h prior to DBE through anus or mouth. At the same time, 5-10 mg of midazolam and 10 mg of scopolamine butylbromide were also injected intramuscularly 10 min before DBE. The patients were anaesthetized with 10 mL of oral 2% lidocaine hydrochloride before DBE through mouth. Oxygen was inhaled with electrocardiography monitored when necessary.

Procedure

DBE through mouth or anus was performed according to the suspected site of lesions. When the site was uncertain, DBE was performed through mouth.

DBE was not performed when the cause of bleeding could be explained, the operation time was too long to be tolerated, and more than half of the small intestine examined was negative.

Statistical analysis

Statistical analysis was performed using SPSS 11.5. Data were expressed as mean ± SD. Difference was detected by χ^2 test. $P < 0.05$ was considered statistically significant.

RESULTS

General information

DBE was performed 84 times in 75 patients, including 57 times through mouth and 27 through anus. Two patients completed DBE of the entire small bowel through mouth at one time.

All the procedures were successful without anesthesia. No hemorrhage, perforation, acute pancreatitis or other serious complications occurred. Nausea, vomiting, abdominal distension, and abdominal pain occurred in some patients during the procedure. However, these symptoms were transient and tolerable. In general, DBE through anus was more tolerable than through mouth.

DBE findings

Of the 75 patients, 44 (58.7%) had positive DBE, 22 had negative DBE with potential bleeding sites observed at surgery and CE, *etc.* The distribution of OGIB patients

Table 2 DBE findings in OGIB patients

Lesion	Diagnosed by DBE	Diagnosed by other methods	Location			Difference in proximal and distal small bowel
			Stomach and duodenum	Jejunum	Ileum	
Tumor	17	4	3	14	4	66.7% vs 19.0% ($P = 0.002$)
Gastrointestinal stromal tumor	7	1 ²	1	6 ²	1	
Non-hodgkin lymphoma	2	3	0	3	2	
Adenocarcinoma	3	0	1	1	1

¹One case was accompanied with ancylostomiasis; ²One case was accompanied with heterotopic pancreas. DBE: Double-balloon enteroscopy.

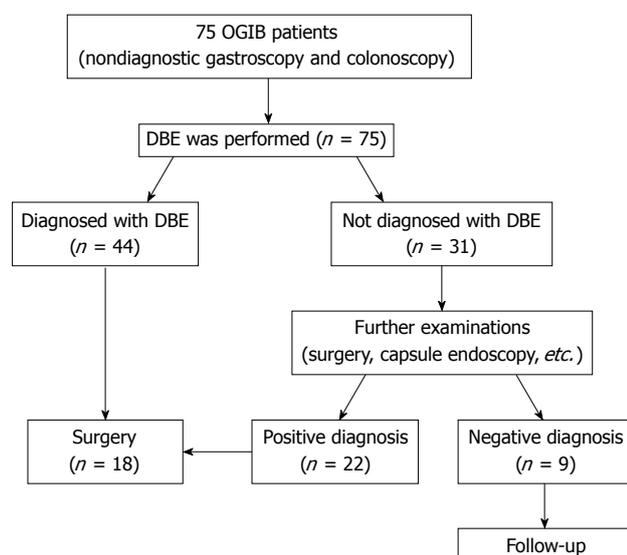

Figure 1 Distribution of obscure gastrointestinal bleeding (OGIB) patients enrolled in this study. DBE: Double-balloon enteroscopy.

enrolled in this study is shown in Figure 1. Among the 66 cases with positive DBE, OGIB was detected in upper digestive tract of 7 cases, in jejunum of 34 cases, in ileum of 24 cases, and at junction of jejunum and ileum of 1 case, respectively. The incidence of OGIB was higher in proximal small bowel (the third and fourth parts of duodenum, jejunum) than in distal small bowel (ileum) (49.3% vs 33.3%, $P = 0.047$). The DBE findings are presented in Table 2.

OGIB was most commonly caused by small bowel tumor (28.0%, 21/75), angiodysplasia (18.7%, 14/75) and Crohn's disease (10.7%, 8/75). Small bowel tumor was detected in duodenum of 3 cases, in jejunum of 14 cases, and in ileum of 4 cases, respectively. The incidence of small bowel tumor was higher in jejunum than in ileum (66.7% vs 19.0%, $P = 0.002$). Histological analysis showed that the tumor was benign in 7 cases (gastrointestinal stro-

mal tumor in 2, lipoma in 3, duodenum adenoma in 1 and angioma in 1) and malignant in 14 cases (gastrointestinal stromal tumor in 6, non-hodgkin lymphoma in 5 and adenocarcinoma in 3) (Figure 1). The detection rate of benign tumor was lower than that of malignant tumor (33.3% vs 66.7%, $P = 0.031$).

Angiodysplasia was detected in jejunum of 9 cases, in ileum of 4 cases, and in dieulafof of gastric fundus of 1 case, respectively, accounting for 18.7% of all the cases with no significant difference between them ($P = 0.128$). Crohn's disease was detected in jejunum and ileum of 2 and 6 cases, respectively, accounting for 10.7% of all the cases with no significant difference ($P = 0.132$). In addition, diverticulum, Henoch-Schönlein purpura, single ulcer, polyp, ancylostomiasis, tuberculosis, and non-specific inflammation were also detected (Figure 2).

DBE detection rate of bleeding and duration of symptoms

Of the 75 cases, 45 presented with melena and 25 (55.6%) with positive DBE. Symptoms of hemafecia were detected in 17 cases with a DBE detection rate of 47.1% (8/17). There was no significant difference between the DBE detection rates of melena and hemafecia (55.6% vs 47.1%, $P = 0.55$). The DBE detection rates of occult bleeding, hematemesis and melena were not compared because of the limited number of cases.

The 75 patients were divided into 3 groups according to their bleeding time. There was no significance between the duration of OGIB symptoms and the DBE detection rates (Table 3).

Operation results

Of the 75 patients, 18 (24.0%) underwent operation. Gastrointestinal stromal tumor, non-hodgkin lymphoma, adenocarcinoma, lipoma and angioma were the most commonly detected tumors. Both gastrointestinal stromal tumor and bleeding from heterotopic pancreas were detected in 1 patient.

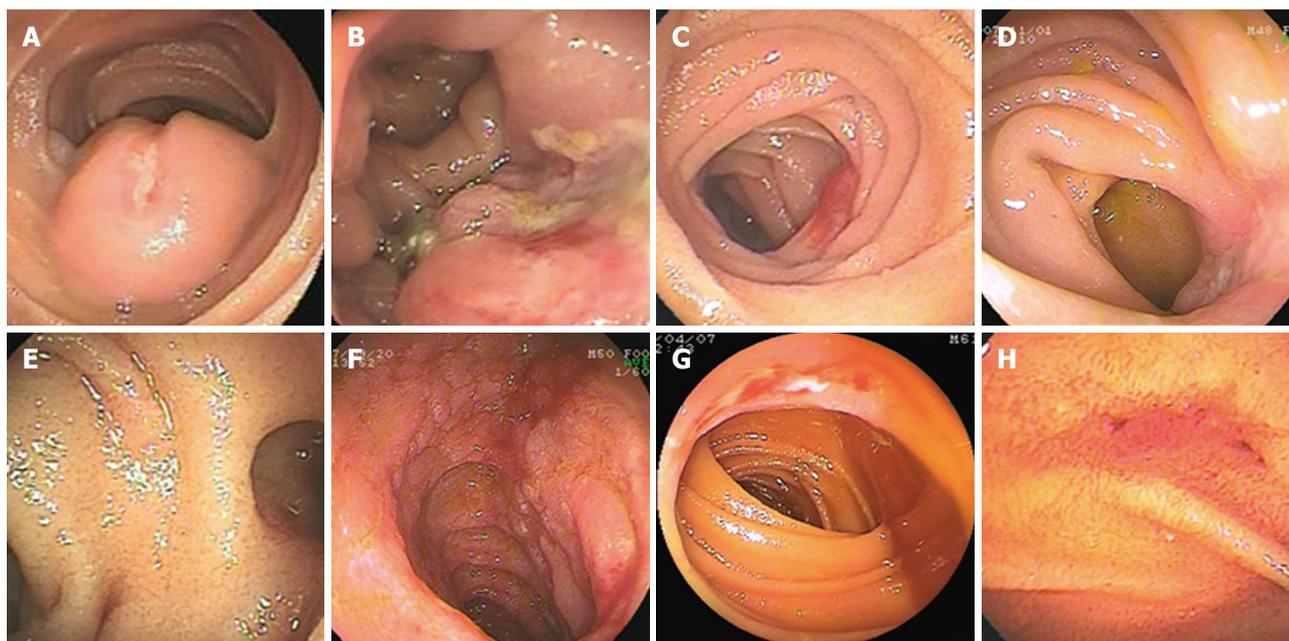

Figure 2 Typical endoscopic imaging. A: Gastrointestinal stromal tumor in jejunum; B: T cell lymphoma in jejunum; C: Angiodysplasia in jejunum; D: Crohn's disease in ileum; E: Diverticulum in jejunum; F: Henoch-Schönlein purpura in jejunum; G: Tuberculosis in ileum; H: Non-specific inflammation in jejunum.

Table 3 DBE detection rate of bleeding and duration of symptoms

	Patients	DBE findings	Detection rate (%)	P
Total	75	44	58.7	-
Causes of OGIB				
Melena	45	25	55.6	0.55 ¹

²Difference between the DBE detection rates of < 1 mo and 1-12 mo;

³Difference between the DBE detection rates of 1-12 mo and > 12 mo;

⁴Difference between the DBE detection rates of < 1 mo and > 12 mo.

DISCUSSION

OGIB is a common problem encountered by gastroenterologists. Its diagnostic rate has been greatly improved due to CE since 2000^[9]. CE has a higher diagnostic rate of OGIB than conventional methods including small bowel barium radiography, push enteroscopy, and cross-sectional imaging^[10]. However, CE may fail to identify lesions such as Meckel's diverticulum, angiodysplasia, and malignancies^[11]. DBE can explore a large part of the small bowel, during which targeted tissue for biopsy can be taken. Moreover, endoscopic treatment procedures, including hemostasis, polypectomy, endoscopic mucosal resection, balloon dilation, and stent placement, can be performed at DBE^[12].

In this study, the diagnostic value of DBE for OGIB

was evaluated. The DBE detection rate of OGIB is consistent with the reported data^[13,14]. No complication occurred in the 75 patients who underwent DBE without anesthesia, suggesting that DBE is a safe, tolerable, and effective procedure for the diagnosis of OGIB.

It was reported that 3%-6% of OGIB events are caused by small bowel tumor^[15,16]. Sun *et al*^[17] showed that the prevalence of gastrointestinal stromal tumor is the highest among different small bowel tumors. DBE can show lesions in about 50%-66% of the small intestine and even in the entire small intestine, thus providing a high diagnostic rate of small bowel tumor^[18].

In this study, angiodysplasia was found to be another common etiology of OGIB, which is also in agreement with the reported data^[19]. The detection rate of lesions was higher in jejunum than in ileum. Since Crohn's disease has been found to be the third commonest etiology of OGIB, and shows a higher incidence in distal intestine, DBE *via* anus is usually recommended^[20].

The selection of DBE is still controversial. For those with no site of lesion indicated, DBE through mouth is preferred because our study and other studies showed that it has a higher diagnostic rate of lesions in proximal small bowel^[21,22] and is relatively easier to perform without twisting the colon, which is also supported by Safatle-Ribeiro *et al*^[23]. However, DBE through anus is also preferred by some endoscopists, since it has a better tolerance^[18].

In summary, DBE is a safe, tolerable, accurate and effective procedure for the diagnosis of OGIB. OGIB is most commonly caused by small bowel tumor and angiodysplasia. Lesions occur more frequently in proximal small bowel and DBE through mouth is recommended as a prior consideration if no evidence indicates the location.

COMMENTS

Background

The diagnosis of obscure gastrointestinal bleeding (OGIB) was rather difficult in the past. Double-balloon enteroscopy (DBE) and capsule endoscopy (CE) have significantly revolutionized the diagnosis of small bowel lesions. Compared with CE, DBE has unique advantages such as handing controllability, biopsy, diagnosis and treatment, *etc.* Few data are available on the diagnostic value of DBE for OGIB.

Research frontiers

The data about 75 OGIB patients were retrospectively analyzed in this article. The DBE detection rate of OGIB and the feasibility of operation were evaluated. The incidence of common diseases in small bowel was compared. The DBE detection rate of lesions in proximal or distal small bowel was different.

Innovations and breakthroughs

Patients could tolerate the whole DBE process with no serious complication. The DBE detection rate of different bleeding events and symptoms of OGIB were compared. DBE through mouth was completed at one time.

Applications

In this study, DBE was proven to be a safe, accurate and effective procedure for the diagnosis of OGIB and can thus be performed in hospital for the diagnosis of OGIB.

Terminology

OGIB is defined as recurrent or persistent gastrointestinal bleeding when gastric and colonic endoscopy is negative. DBE and CE are both new methods enabling diagnostic endoscopy of the entire small intestine, which have their own *pros and cons* in the diagnosis of small bowel diseases.

Peer review

This is an interesting descriptive study concerning a single center experience with DBE for OGIB in China.

Abstract

AIM: To develop a hepatocyte cell line, we immortalized primary porcine hepatocytes with a retroviral vector SSR#69 containing the Simian Virus 40 T antigen (SV40Tag).

METHODS: We first established a method of porcine hepatocyte isolation with a modified four-step retrograde perfusion technique. Then the porcine hepatocytes were immortalized with retroviral vector SSR#69 expressing SV40T and hygromycin-resistance genes flanked by paired loxP recombination targets. SV40T cDNA in the expanded cells was subsequently excised by Cre/LoxP

site-specific recombination.

RESULTS: The resultant hepatocytes with high viability (97%) were successfully immortalized with retroviral vector SSR#69. One of the immortalized clones showed the typical morphological appearance, TJPH-1, and was selected by clone rings and expanded in culture. After excision of the SV40T gene with Cre-recombinase, cells stopped growing. The population of reverted cells exhibited the characteristics of differentiated hepatocytes.

CONCLUSION: In conclusion, we herein describe a modified method of hepatocyte isolation and subsequently established a porcine hepatocyte cell line mediated by retroviral transfer and site-specific recombination.

INTRODUCTION

A virtually unlimited supply of hepatocytes for metabolic studies, bio-artificial livers and cell transplantation would be highly desirable^[1,2]. However, the utility of cultured hepatocytes is hampered by difficulties in timely obtained populations of primary cells, which have a limited life span *in vitro*. An attractive alternative source of hepatocytes would be immortalized cells which could make unlimited supplies of cells feasible and exhibit the characteristics of differentiated hepatocytes^[3]. A series of studies have developed the strategy of cell immortalization^[4,5]. However, the oncogene in the immortalized hepatocytes would expose patients to an unacceptable tumorigenic risk. An attractive solution for this problem could be the use of a novel strategy of reversible immortalization by using Cre/loxP site-specific recombination^[6]. It has been reported that Cre/loxP recombination operates efficiently in primary cells^[7]. The procedure of reversible immortalization was devised by retrovirus-mediated transfer of an oncogene that can be subsequently effectively excised by site-specific recombination^[8].

A series of cells can be immortalized by retrovirus-mediated transfer of an immortalizing oncogene (*SV40T*)^[9]. Although the hepatocytes can be transduced with retroviral vectors, the efficiency of transduction is significantly low^[10]. In the process to successfully and effectively transduce retroviral vectors into hepatocytes, establishing an efficient technique of cell isolation seems to be meaningful.

To address these issues, we herein report an efficient procedure for porcine hepatocyte isolation, and subsequent successful immortalization by retrovirus-mediated transfer of *SV40T* which could be subsequently excised by Cre/LoxP-mediated site-specific recombination. The present study expands the strategy of hepatocyte reversible immortalization and represents an important step toward the development of immortalization of hepatocytes.

MATERIALS AND METHODS

Animals

A mini-pig weighing 13 kg was used in the present study. All procedures performed on the pig were approved by Tongji Medical College Animal Care and Use Committee and were within the guidelines for laboratory animals.

Porcine hepatocyte isolation

Porcine hepatocytes were isolated from a surgically resected liver segment with a modified four-step retrograde perfusion technique using dispase and collagenase (Figure 1). Briefly, the resected liver sample (47 g) was cannulated with a suitable pipette into the visible blood vessel on the cut surface (Figure 2A). Then the sample was flushed with a 500 mL calcium-free buffer solution (Step 1), 500 mL EDTA in buffer solution (Step 2) and another 500 mL of buffer solution at 37°C. Continuous recirculating perfusion was then carried out on the tissue using a pre-warmed

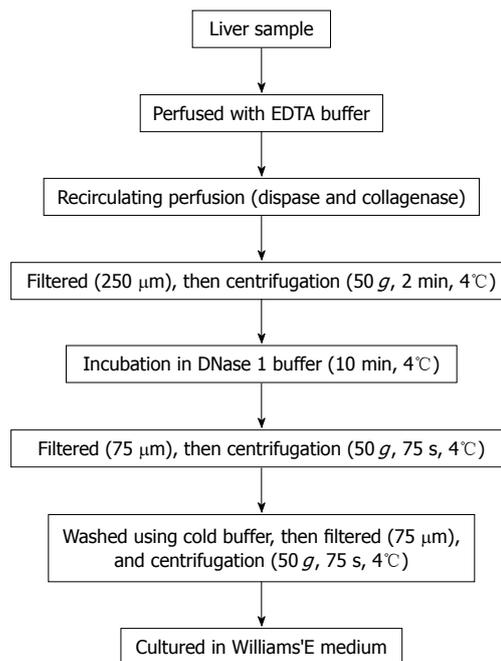

Figure 1 Flow diagram of the preparation of isolated hepatocytes with a modified four-step retrograde perfusion technique.

digestion buffer solution (8.4 g/L dispase II and 0.5 g/L collagenase IV, Sigma, St. Louis, MO, USA) at 37°C (Step 3). When digestion of the parenchyma was visualized, the liver tissue was finally flushed with 500 mL buffer solution (Step 4). Following sufficient digestion, the liver capsule was mechanically disrupted and the emerging cell suspension filtered through 250 μm nylon mesh and centrifuged (50 g, 2 min, 4°C). After that we employed a cell incubation step of 10 min using DNase1 (Sigma, St. Louis, MO, USA) containing buffer solution, during which cell clumps were broken up and damaged cells digested. Then, the resulting suspension was filtered through 75 μm nylon mesh, and the cells were harvested by low speed centrifugation at 50 g for 75 s. This was followed by washes using cold buffer solution and filtration through 75 μm nylon mesh and another centrifugation step (50 g, 75 s, 4°C). The resulting cell clumps were finally resuspended in culture medium (William's medium E, supplemented with 100 mU/mL penicillin, 100 μg/mL streptomycin and 10% fetal bovine serum). Hepatocyte yield and viability was determined using the standard trypan blue exclusion technique. Freshly isolated hepatocytes were seeded at a concentration of 4×10^5 per milliliter in culture flasks. The morphology of the cultured hepatocytes was assessed with a Nikon Diaphot inverted microscope at a magnification of 100 ×.

Porcine hepatocytes immortalization

The retroviral vector SSR#69 (kindly given by Naoya Kobayashi, Okayama University) containing SV40 large TAG and a gene resistant to hygromycin (Figure 3) was cultured in DMEM medium (Sigma, St. Louis, MO, USA) supplemented with 10% newborn calf serum. Freshly isolated primary porcine hepatocytes were transduced with 2 mL of SSR#69 cells supernatant per T25 flask at

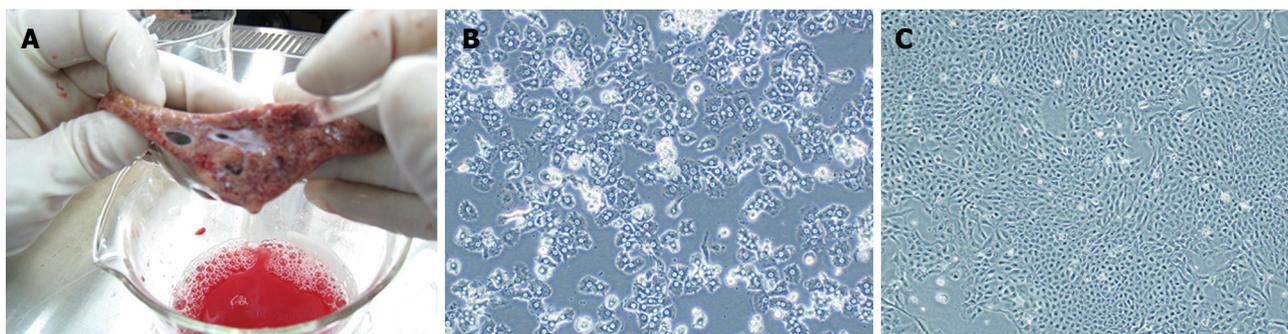

Figure 2 Isolation technique and microscopic appearance of primary and immortalized porcine hepatocytes. A: Perfusion was conducted by inserting a suitable pipette into vessels exposed on a cut surface of the sample; B: Non-immortalized primary porcine hepatocytes grow slowly with low plating efficiency and a short life span; C: Immortalized porcine hepatocytes grow rapidly as islands and had an extended life span. Magnifications: B and C 100 ×.

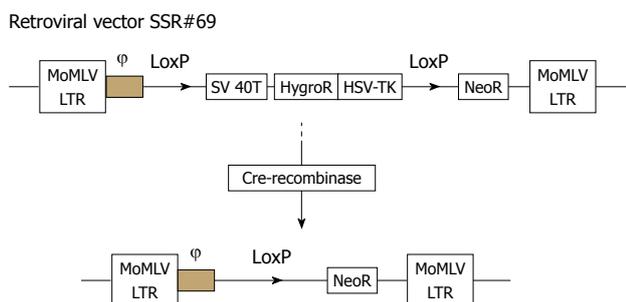

Figure 3 Schematic drawings of the integrating component of retroviral vector SSR#69 before and after Cre-recombination. SSR#69 contains the hygromycin B resistance gene (*Hyg R*) as a positive selectable marker and the herpes simplex virus thymidine kinase gene (*HSV-TK*) as a negative selectable marker. The *SV40T*, *Hyg R* and *HSV-TK* genes are flanked by loxP sites.

37°C for 12 h each day for 5 d. Two days after the final transduction, selection was applied with 100 µg/mL hygromycin. After two weeks hygromycin selection, colonies of transduced hepatocytes emerged. One of the colonies displayed morphological characteristics of the primary hepatocytes, TJPH-1, and was isolated by cloning rings and expanded in culture. Finally, *SV40T* cDNA in the expanded cells was excised by Cre/loxP site-specific recombination.

Immunofluorescent analysis of SV40T antigen (SV40Tag) in immortalized cells

For detection of *SV40Tag*, indirect immunofluorescent staining was performed, using mouse monoclonal immunoglobulin G antibody to *SV40Tag* (Santa Cruz Biotechnology; Santa Cruz, CA, USA) and the second antibody, rhodamine (TRITC)-conjugated sheep anti-mouse IgG (Sigma, St. Louis, MO, USA). DAPI (4',6-diamidino-2'-phenylindole dihydrochloride, Roche, Cat. No. 10236276001) blue-fluorescent dye was used for staining nuclei (double-stranded DNA).

Gene expression of liver-specific functions in immortalized cells

Total RNA was extracted from immortalized cells and reverse transcription-polymerase chain reaction (RT-PCR) was performed according to the manufacturer's

protocol. Primers used were as follows: *SV40T* (422 base pair, bp), CAGGCATAGAGTGTCTGC (5'primer), CAACAGCCTGTTGGCATATG (3'primer); porcine albumin (324 bp), CTTATTCCAGGGGTCTGTTTC (5'primer) and TCGTTTCTCTCAGGCTCTTCT (3'primer); porcine GAPDH (179 bp), CATCATCCCTGCTTCTACCG (5'primer), CCTGCTTCACCACITTTCTTG (3'primer).

RESULTS

Successful porcine hepatocytes isolation resulted in a cell yield of 1.05×10^7 cells/g liver. The viability of hepatocytes immediately after isolation, using the trypan blue exclusion technique, was 97%. The primary hepatocytes attached to the plates showed typical morphological appearance with a polygonal shape, granular cytoplasm and one or more nuclei (Figure 2B).

After transfection of porcine hepatocytes with *SV40T*, several clones (Figure 2C) grew steadily in the culture medium within 2 wk after 100 µg/mL hygromycin selection. One of the surviving cell colonies, TJPH-1, isolated by cloning rings displayed morphological characteristics of primary hepatocytes featuring a large round nucleus with a few nucleoli and multiple granules in the cytoplasm. After treatment with Cre recombination, the expanded TJPH-1 cells reverted to their pre-immortalized state. The reverted cells lost expression of *SV40T* (Figure 4), resulting in loss of proliferation.

The *SV40Tag* was examined by immunofluorescent staining in the nuclei of all immortalized cells, as shown in Figure 5A. Immortalized and reverted cells expressed the albumin gene shown by RT-PCR, similar to normal porcine hepatocytes (Figure 4).

DISCUSSION

Cultured primary porcine hepatocytes provide a valuable tool for various research strategies and clinical applications, such as studying the regulation of cell growth and of certain differentiated hepatocyte functions and BAL (bio-artificial liver) systems^[11,12]. However, the utility of cultured hepatocytes is hampered by difficulties in obtaining populations of primary cells which cannot be expanded *in vitro*.

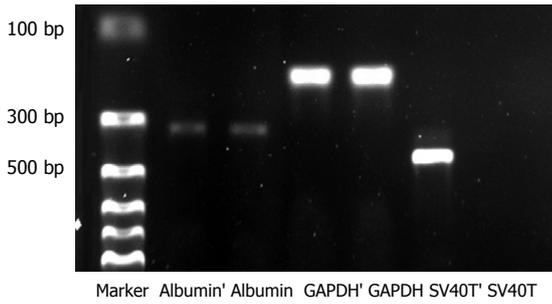

Figure 4 Gene expression of liver-specific functions in immortalized and reverted cells. Lines 1 to 7, from left to right, Marker, Albumin' (immortalized hepatocytes), Albumin (reverted hepatocytes), GAPDH' (immortalized hepatocytes), GAPDH (reverted hepatocytes), SV40T' (immortalized hepatocytes), SV40T (reverted hepatocytes), respectively.

Thus, other alternative sources of hepatocytes have to be explored^[13]. Hepatocytes immortalized with a SV40Tag can make unlimited supplies of cells feasible. However, the continued presence of a SV40Tag in the immortalized hepatocytes would expose patients to an unacceptable tumorigenic risk. To surmount this hurdle, we herein established reversible immortalized porcine hepatocytes to intentionally control population expansion (Figure 5). Use of the Cre/LoxP-based reversible immortalization strategy represents an important step in the development of a potentially novel strategy for resolving the current limits of primary hepatocytes^[2]. Different from a general gene transfer strategy, the novel strategy of reversible immortalization allows temporary expansion of cell populations by transfer of an oncogene which can be subsequently excised by site-specific recombination. Several studies have confirmed the utility, safety and efficiency of the reversible immortalization procedure^[14]. This novel procedure has extended to several cell types, such as liver endothelial cells^[15], hepatic stellate cells^[16] and rat hepatocytes^[17]. The present study expands the work to primary porcine hepatocytes.

Although porcine hepatocytes can be immortalized by retrovirus-mediated transfer of SV40T, the efficiency of transduction was significantly low^[10]. A major challenge of successful transduction is represented by the availability of a sufficient amount of hepatocytes with high post-isolation viability. Thus, in the process to successfully and effectively transduce retroviral vectors into primary hepatocytes, establishing an efficient cell isolation technique would be meaningful.

Hepatocyte isolation started in the mid-1960s, when rat hepatocytes were isolated using a combined mechanical/enzymatic digestion technique^[18]. It was not until 1976, when Seglen^[19] introduced the two-step collagenase perfusion technique, that high-yield preparation of isolated intact hepatocytes was available. After that, different innovative techniques have been introduced to further improve isolation results^[20,21]. In this study, we established a modified four-step collagenase retrograde perfusion technique. The modified four-step method of hepatocyte isolation, compared to the traditional two-step method, can

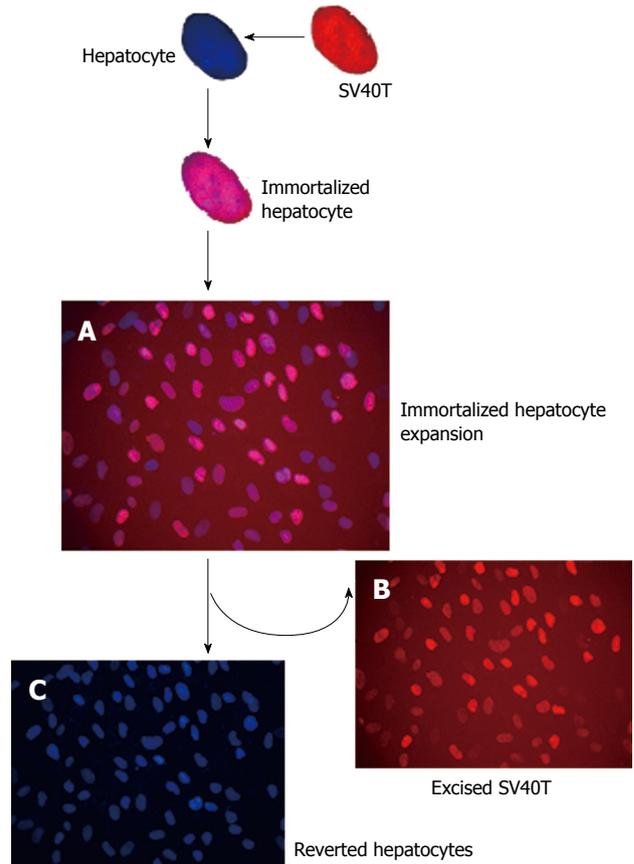

Figure 5 Scheme of reversible immortalization. The primary porcine hepatocytes were immortalized by transfer of an oncogene (SV40T). After expansion of the immortalized cells, Cre/loxP recombination was performed to remove the oncogene (SV40T) and the cells reverted to their pre-immortalized state. (A-C) Double immunofluorescence of immortalized hepatocytes stained with DAPI (blue), which binds, together with monoclonal antibody anti-SV40T revealed with texas red-antibody conjugate (red). Blue and red fluorescence merged as purple. SV40T expression is revealed by intense staining of the cell nucleus.

result in an improvement in cell viability and yield^[22]. After cell isolation, we employed an incubation step of 10 min using DNase 1, during which cell clumps were broken up and damaged cells digested. This method resulted in a hepatocyte yield of 1.05×10^7 cells/g liver. The viability of the cells, using the trypan blue exclusion technique, was 97%.

In summary, we propose that the modified four-step technique would improve research results, allowing large-scale production of hepatocytes of high quality. Furthermore, the present study expanded the novel strategy of reversible immortalization to primary porcine hepatocytes. By permitting temporary and controlled expansion of hepatocyte populations, the reversible immortalized cells may therefore be used for various research strategies and clinical applications.

ACKNOWLEDGMENTS

We thank Dr. Naoya Kobayashi (Okayama University Graduate School of Medicine and Dentistry) for providing SSR#69 cells.

COMMENTS

Background

The limited lifespan of porcine hepatocytes is a major hurdle to their use. Furthermore, the functional activities of primary porcine hepatocytes decline rapidly after several days in culture. An attractive alternative source of liver cells would be reversible immortalized cells that could make unlimited supplies of cells feasible which would exhibit the characteristics of differentiated hepatocytes. Toward this goal, the authors have focused on reversible immortalization by using Cre/loxP site-specific recombination.

Research frontiers

Cre/loxP site-specific recombination was used to reversibly induce the proliferation of primary cells. A reversible immortalization system using the Cre-loxP site-specific recombination system has been widely used in establishing immortalized cell lines.

Innovations and breakthroughs

The authors described a modified four-step retrograde perfusion technique of hepatocyte isolation and subsequently established a porcine hepatocyte cell line mediated by retroviral transfer and site-specific recombination.

Applications

The modified four-step retrograde perfusion technique would improve research results, allowing large-scale production of hepatocytes of high quality. Furthermore, the present study expanded the novel strategy of reversible immortalization to primary porcine hepatocytes. This reversible immortalized cell line could provide an unlimited supply of cells for research and clinical use.

Terminology

Reversible immortalization: The procedure of reversible immortalization was devised by retrovirus-mediated transfer of an oncogene that can be subsequently effectively excised by site-specific recombination.

Peer review

This manuscript appears to be about two separate, but related topics of hepatocyte isolation and "reversible immortalization". In my opinion, by combining the two topics, it weakens the manuscript. It appears they were able to reproduce techniques described by others, which is good.

Abstract

Gastrointestinal perforations are conservatively managed at endoscopy by through-the-scope endoclips and covered self expandable stents, according to the size and tissue features of the perforation. This is believed to be the first report of successful closure of two gastrocutaneous fistulas with over-the-scope clips (OTSCs). After laparoscopic gastric banding, a 45-year old woman presented with band erosion and penetration. Despite surgical band removal and gastric wall suturing, external drainage of enteric material persisted for 2 wk, and esophagogastroduodenoscopy demonstrated two adjacent 10-mm and 15-mm fistulous orifices at the esophagogastric junction. After cauterization of the margins, the 10-mm fistulous tract was grasped by the OTSC anchor, invaginated into the applicator cap, and closed by a traumatic OTSC. The other 15-mm fistula was too large to be firmly grasped, and a fully-covered metal stent was temporarily placed. No leak occurred during the following 6 wk. At stent removal: the OTSC

was completely embedded in hyperplastic overgrowth; the 15-mm fistula significantly reduced in diameter, and it was closed by another traumatic OTSC. After the procedure, no external fistula recurred and both OTSCs were lost spontaneously after 4 wk. The use of the anchor and the OTSC seem highly effective for successful closure of small chronic perforations.

INTRODUCTION

Gastrointestinal (GI) perforations require prompt closure and control of extraluminal fluid collections and sepsis. They have been managed traditionally by surgery^[1-3], but a conservative endoscopic approach has recently been preferred with the advantages of negligible morbidity and mortality, a short hospital stay, and the possibility of prompt resumption of an oral diet^[2,4-6].

Routine endoscopic methods to close GI perforations are endoclips and covered self-expandable stents; the choice being related to the width and tissue features of the margins^[7,8]. Endoclips are metallic double-pronged clips loaded on a deployment catheter introduced through the operative channel of the scope [through-the-

scope (TTS) clips^[7]. Although acute small (< 15 mm) perforations can be successfully closed with TTS clips^[9], these devices achieve controversial results when used for larger perforations^[10,11], and seem technically inadequate for chronic perforations, due to poor grasping ability and insufficient strength to close fibrotic margins^[7]. Therefore, TTS clips have rarely closed chronic leaks^[12-17] and are generally considered only as a supplementary technique^[8].

Covered self-expandable metal stents (SEMSs) or self-expandable plastic stents (SEPSs) are an effective method for sealing and healing more than 80% of chronic GI leaks, but have drawbacks: the removal of partially-covered SEMSs may be difficult due to the ingrowth at uncovered ends and the risk of mucosal tears, hemorrhage and subcutaneous emphysema^[4,18,19], whereas fully-covered stents show a migration rate of up to 50% and often require replacement^[6,20,21].

The present case is the first successful closure of two gastro-cutaneous fistulas with the newly designed over-the-scope-clip (OTSC) (Ovesco Endoscopy, Tubingen, Germany).

CASE REPORT

Twenty-six months after laparoscopic gastric banding, a 45-year-old woman presented severe epigastric pain. The diagnosis of band erosion with penetration through two large tears at the posterior wall of the gastric fundus was established by esophagogastroduodenoscopy (EGD), and a subphrenic abscess was demonstrated by computed tomography (CT). Management included surgical band removal, suturing of the gastric wall with two omental patches, and abdominal drainage.

However, external drainage of enteric material persisted for 2 wk and the barium swallow revealed two fistulas at the esophagogastric junction (Figure 1). EGD showed two opposite perforations of 10 and 15 mm (Figure 2), with fistulous tracts partially and fully negotiable by the 9.8-mm endoscope, respectively.

After cauterization of the margins, the proximal segment of the 10-mm fistula was grasped by the OTSC anchor, invaginated into the applicator cap (Figure 3A), and closed by a 9-mm traumatic OTSC (Ovesco Endoscopy GmbH, Tuebingen, Germany) (Figure 3B). On the contrary, the 15-mm fistula was too wide to be firmly grasped by the anchor and therefore it was closed with a fully-covered esophageal self-expandable metal stent (SEMS; Niti-S, Taewoong, South Korea), which also covered the OTSC.

The barium swallow performed after 24 h confirmed the complete sealing of both fistulas (Figure 3C) and the patient was discharged on an oral diet.

After 6 wk, the fully-covered SEMS was easily removed, and the EGD showed that the OTSC was buried into an intense overgrowth reaction (Figure 4). The 15-mm fistula diameter was reduced to 8 mm, and therefore it was sealed by a second 9-mm traumatic OTSC (Figure 5).

During the following 8 wk, no external fistula or

Figure 1 Barium swallow: two fistulas at the esophagogastric junction.

abdominal collection was observed by barium swallow (Figure 6) or the dye leak test with methylene blue. Both OTSCs were lost within the second and fourth weeks of follow-up after SEMS removal.

DISCUSSION

The OTSC has a different conception from TTS clips: (1) the OTSC is in nitinol with a “leghold trap” memory shape, is loaded on a cap placed on the scope tip, and has the capacity to grasp and compress the tissue more widely and with greater strength, without provoking ischemia or cutting the tissue; and (2) the target tissue needs to be caught and pulled into the cap by specifically developed devices that make addressing tangential lesions easier.

Preliminary small case series suggest that the OTSC is effective for hemostasis of non-variceal bleeding^[22,23]. Moreover, results from a few human cases^[22-24] and animal studies^[25-27] have indicated that this device may be appropriate to close acute gastric and colonic perforations that occur during endoscopic mucosal resection, and natural orifice transluminal endoscopic surgery orifices up to 20 mm in size.

This is the first report of successful closure of two inveterate perforations by OTSCs. In our opinion, the success of the procedure should be attributed both to the anchor used to pull the tissue into the cap and to the OTSC itself. The three rigid hooks of the anchor firmly grasp the perforation margins at three equidistant points, permitting to pull the margins circumferentially into the cap. In the present case, the anchor was opened beyond the luminal margins of the fistulous orifice into the proximal segment of the fistulous tract that was partially invaginated into the cap before the release of the OTSC. This mechanical result would not have been achieved using the other OTSC device, the twin grasper, which has two independently movable branches that grasp the perforation margins at two opposite points. This two-point grasping method may be sufficient for acute perforations with normal elastic tissue margins, but not for fibrotic hard chronic ones that would be only partially invaginated into the cap (Figure 7).

Both traumatic OTSCs placed in the present case were lost after a period between the 2nd and 4th week after SEMS removal. Whether traumatic or atraumatic

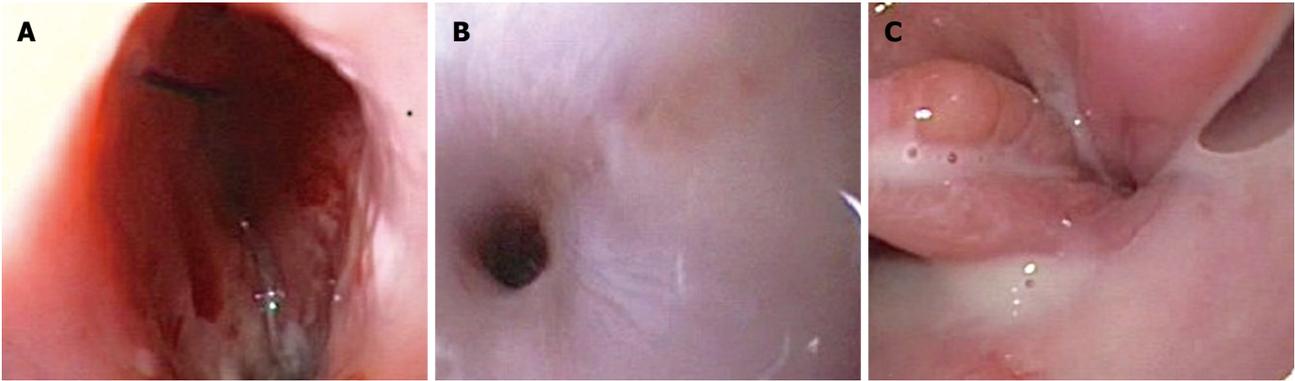

Figure 2 Endoscopic view of the 15-mm (A) and 10-mm (B) fistulous openings on the left and right sides, respectively, above the esophagogastric junction (C).

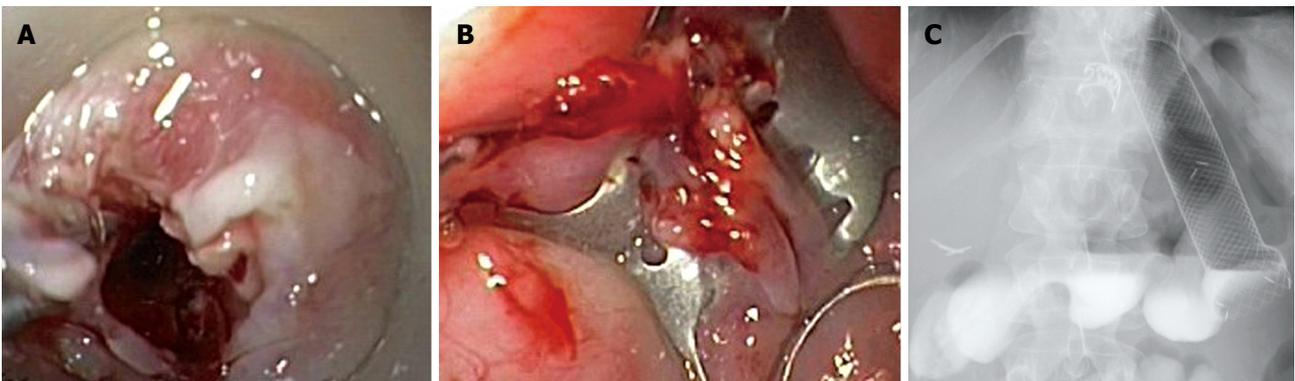

Figure 3 First OTSC placement. A: Invagination of the proximal segment of the 10-mm fistula into the OTSC applicator cap using the anchor; B: Closure of the 10-mm fistula; C: Barium swallow after the first OTSC and stent placement.

jaws have different “stay-in-place” periods is unknown. In previous studies, acute perforations have been successfully closed independently from the OTSC teeth shape after remaining in place for similar periods of time^[22,26], and only occasionally for > 4 wk^[24,26]. Although the traumatic teeth may reduce the possibility of hard tissue slipping out of the OTSC, prolonging its *in situ* stay, strong tissue compression could be more important to determine long-standing closure. Moreover, the use of oversized OTSCs may increase the capacity to grasp and close fibrotic margins of chronic perforations and its permanence.

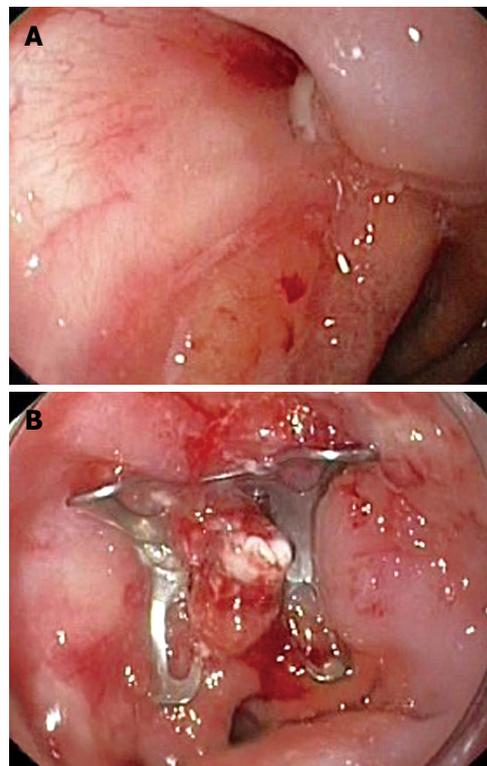

Figure 5 Second OTSC placement. A: Fistula opening reduced in size; B: Fistula closure.

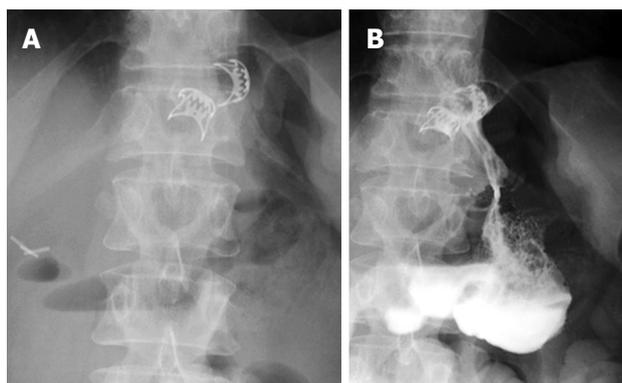

Figure 6 OTSC closure of the two fistulas. A: Two OTSCs in place; B: No leaks from both OTSCs at barium swallow.

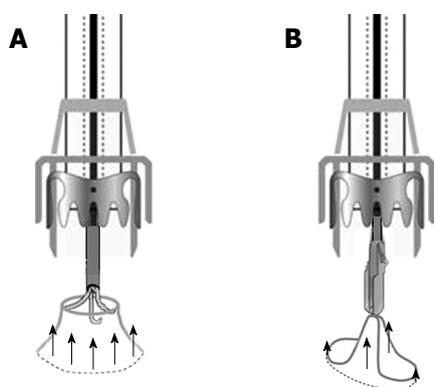

Figure 7 Mechanical results of OTSC devices pulling fibrotic margins of chronic perforations. A: Circumferential invagination using the anchor; B: Two-point invagination with the twin grasper.

Finally, no OTSC-related complications occurred. An intense overgrowth embedded the first OTSC after SEMS removal, but it did not prevent the spontaneous loss of the clip during follow-up. It remains to be established whether the overgrowth reaction would have occurred without the stent. Although endoscopic follow-up was not scheduled in previous studies, OTSC-related overgrowth has not been observed in humans^[22-24], whereas Schurr *et al*^[26] have observed minimal overgrowth in the colon of some pigs after 1 mo.

In conclusion, the OTSC may be the least invasive method to close chronic small fistulas or leaks, if prospective large comparative studies with fully-covered stents will confirm our observation.

Abstract

We present the case of an 18-year-old female transferred to our center from an outside hospital due to persistent gastrointestinal bleeding. Two weeks prior to her transfer she underwent duodenal omentopexy for a perforated duodenal peptic ulcer. The patient underwent a computed tomography angiogram which identified the source of bleeding as a giant gastro-duodenal artery (GDA) pseudoaneurysm. The patient was taken to interventional radiology where successful microcoil embolization was performed. We present this rare case of a giant GDA pseudoaneurysm together with imaging and a review of the medical literature regarding prevalence, etiology and treatment options for visceral arterial aneurysms.

INTRODUCTION

Upper gastrointestinal bleeding (UGIB) is one of the leading causes of admission to the emergency department. While the vast majority of these bleeding episodes resolve spontaneously and most of the remaining cases are successfully managed endoscopically, a small percentage of patients require treatment using more invasive procedures such as therapeutic angiography and surgery. UGIB can be caused by a number of various pathologies. Gastro-duodenal artery (GDA) pseudoaneurysm is a rare but potentially fatal complication of surgery and, hence, early recognition and management of this complication is critical^[1]. Although open surgery has traditionally been the treatment of choice, therapeutic angiography is emerging as an effective treatment modality for selected cases^[2]. In this article we present such a case as well as remarkable images of the giant GDA aneurysm. Additionally, we discuss the pathophysiology of the condition, the treatment options and our rationale for opting for angiographic intervention over surgery.

CASE REPORT

An 18-year-old female was transferred to our surgery department due to unsuccessful treatment of acute upper gastrointestinal bleeding. Seven months prior to this admission she was diagnosed with Crohn's disease of the ileo-cecal region. She was treated with oral steroids and

Figure 1 Computed tomography angiography (CTA). A: CTA arterial late phase showing the giant GDA pseudoaneurysm (arrow); B: CTA eight days post the procedure which shows the reduction in size of the pseudoaneurysm (long arrow), angiographic coils (short arrow) and no perfusion.

mesalamine (Pentasa) with gradual improvement of the disease symptoms. Five months later she was admitted to a local community hospital due to acute abdominal pain. She was taken immediately to the operating theatre. At that time, a perforated duodenal ulcer was identified and treated with duodenal omentopexy (Graham's patch). On post-operative day 14, the patient began bleeding from the surgical wound and experiencing episodes of UGIB. She was transfused with multiple units of packed blood cells and was transferred to a second hospital where she underwent an upper endoscopy (Figure 1A). The endoscopy showed erosive gastritis and blood clots without active bleeding. Due to unsatisfactory explanation for the source of the hemorrhage she underwent computed tomography angiography (CTA) which demonstrated a giant pseudoaneurysm of the GDA, surrounded by fresh clots of blood. The patient was transfused with an additional five units of packed blood cells and transferred to our institution as the initial hospital did not have an interventional radiology unit. Upon arrival at the emergency department, the patient's pulse was 80 bpm and blood pressure was 110/70 mmHg. A pulsatile abdominal mass was palpated at the right upper quadrant. Blood tests showed hemoglobin level of 11.6 mg/dL and normal coagulation studies. A naso-gastric tube was inserted which drained multiple clots of blood, at which time she was treated with intravenous omeprazole and taken to the angiography suite. After cannulation of the celiac trunk and the superior mesenteric artery *via* a right transfemoral approach, the giant pseudoaneurysm emerging from the GDA was demonstrated. Arterial embolization was performed by placement of several detachable micro-coils until flow-arrest was obtained. The procedure was performed without complication. Eight days following the procedure she underwent CTA which showed the angiographic coils surrounded by a small collection of fluid and no signs of perfusion in the GDA (Figure 1B). She was discharged on the 10th d of hospitalization. After two years of follow up, the patient is asymptomatic and has not been hospitalized due to recurrent UGIB.

DISCUSSION

Visceral artery pseudoaneurysms are considered rare

pathologies. Nevertheless, pseudoaneurysm rupture and bleeding can lead to significant morbidity and mortality. The visceral arteries which most commonly develop pseudoaneurysm are the splenic artery, hepatic arteries, gastric and gastroepiploic arteries, gastro-duodenal artery and branches of the mesenteric arteries^[3]. The most common artery involved is the splenic. GDA aneurysms are considered to be extremely rare. Although pseudoaneurysms and aneurysms of splanchnic arteries have traditionally been considered uncommon clinical entities, the prevalence discovered during autopsy study was surprisingly high (10.4%)^[1]. More recent, higher rates of detection are likely related to increased frequency of imaging studies such as ultrasonography and computed tomography. There are multiple etiologies for development of pseudoaneurysms including: atherosclerosis, trauma, surgery, pancreatitis, infection, collagen vascular disease and congenital abnormalities. Infection and trauma are probably the most common causes. Infection can occur as a direct process around the vessel or as lymphatic spread from a primary focus such as *Mycobacterium tuberculosis* located away from the vessel^[4]. Patients with pseudoaneurysm may be asymptomatic or present with symptoms of gastrointestinal bleeding, intraperitoneal hemorrhage, obstructive jaundice due to external pressure by the pseudoaneurysm, hematemesis and rupture into the portal vein.

A review of visceral aneurysms conducted by Moore *et al.*^[5] concluded that 35% of GDA aneurysms are ruptured at presentation, carrying a mortality rate of 21%. In the past, these pseudoaneurysms were treated surgically. However, in the last two decades, radiographic intervention has emerged as an attractive method for treating these patients. Surgical treatments include resection of the aneurysm and placing an interposition graft or performing aneurysmectomy with or without patching using a great saphenous vein. Endovascular treatments used are embolization or stent graft repair of the aneurysm. A laparoscopic procedure has also been reported for treating splenic artery aneurysm^[6]. The potential complications of angiography, aside from those of standard femoral cannulation, include infarction of viscera and abscess

formation. Fortunately, the complication rate regarding the former is relatively low due to rich collateral blood supply. Saltzberg *et al*⁷¹ retrospectively reviewed the outcome of 65 patients diagnosed with visceral aneurysm, 18 of whom were treated by angiography and 9 by surgery. He reported that the initial technical success rate of the endovascular procedures was 94.4% (17/18). Major complications occurred in 22.2% (4/18). However, all four of these were in patients who were treated for splenic artery aneurysms. They concluded from their experience that endovascular management of visceral artery aneurysms is a reasonable alternative to open surgical repair, except for patients with splenic artery aneurysm. Carrafiello *et al*⁸¹ published a case report of a patient with an evolving asymptomatic GDA pseudoaneurysm who underwent a combination of percutaneous, ultrasound-guided thrombin injection directly into the pseudoaneurysm sac and microcoil embolization of the gastro-duodenal artery. They concluded that thrombin injection may reduce the pseudoaneurysm's wall tension and probably diminishes the risk for rupture.

Our patient presumably developed the pseudoaneurysm due to a leak occurring after the omentopexy repair for her perforated duodenal ulcer which initiated an infectious/inflammatory process in the region of the GDA area, causing damage to the vessel wall. Bleeding into the peritoneal space or the gastrointestinal tract beginning several days following an operation should be a cause for suspicion for the possibility of a ruptured pseudoaneurysm. Any operation which involves handling of an infected space or organ is a risk factor for infecting the peritoneal cavity and developing the pseudoaneurysm. Angioembolic occlusion of this giant aneurysm provided an effective treatment with minimal morbidity risk. Sur-

gical repair in this case would have been particularly challenging and possibly morbid as it would have required re-exploring a previously operated space. We conclude that angiographic management is not only a feasible but possibly preferred treatment modality in selected cases of visceral artery aneurysms.

Abstract

The most frequent health problems seen in senility are chronic and degenerative diseases. A 75-year-old male patient with the complaints of weight loss and difficulty in swallowing was admitted to our hospital from a nursing home. Upper system fiber-optic gastrointestinal endoscopy was performed and a mass at the junction of the hypopharynx and esophagus just below recessus piriformis obstructing almost the whole of the lumen and blocking the distal passage was detected. Computed tomography revealed marked narrowing secondary to osseous hypertrophy in the air column of the hypopharynx and proximal esophagus. Diffuse idiopathic skeletal hyperostosis or Forestier's disease is an idiopathic disease characterized by the ossification of the anterior longitudinal ligament of vertebra and some of the extraspinal ligaments. In the present case we aim to discuss an elderly patient who suffered from dysphagia and weight loss and the diagnostic stages.

© 2010 Baishideng. All rights reserved.

INTRODUCTION

Diffuse idiopathic skeletal hyperostosis (DISH) is a common but often unrecognized systemic disorder observed mainly in elderly people^[1]. All papers related to DISH demonstrate a consistent and marked increase of the disease with advancing age^[2]. Various local structural lesions such as oropharyngeal tumors, vascular pathologies, retropharyngeal abscesses, and anterior cervical osteophytes may lead to mechanical esophageal dysphagia^[3-5]. The prevalence of DISH in adults over the age of 50 years is around 25% for men and 15% for women, with an increased incidence in patients with obesity, gout and diabetes^[6].

Although most patients with cervical spine involvement are either asymptomatic or have limited cervical spine movement and unspecified pain, possible complications described in the literature are dysphagia^[7], stridor^[8], dyspnea^[9], ossification of the posterior longitudinal ligament and/or myelopathy^[10] and hoarseness^[11].

CASE REPORT

A 75-year-old male patient was found drunk and unconsci-

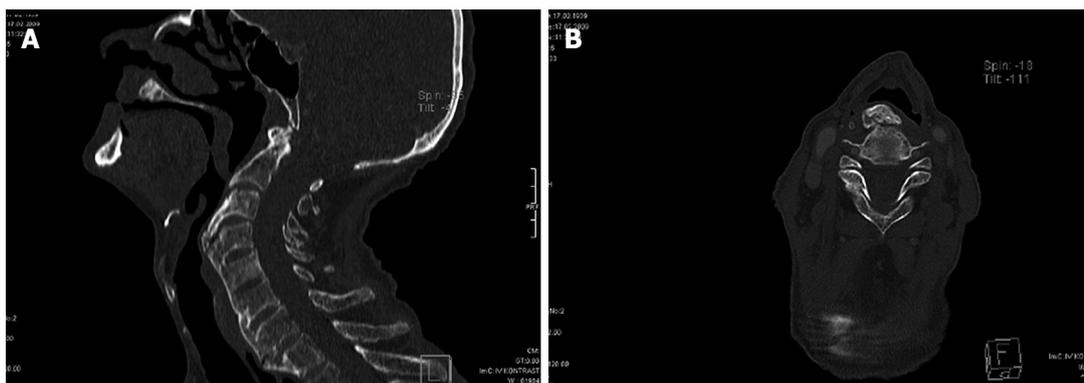

Figure 1 Cervical CT. A: Sagittal section revealed hypertrophic bridging alterations of anterior corpus parts at the level of C3-T1 vertebra and restriction of the esophagus due to osteophytic sprue formations; B: Axial section revealed osteophytic formations on the anterior parts of vertebral corpus.

ous on the street in November 9, 2008 and was transferred to the nearest state hospital. After an operation for intertrochanteric femur fracture he was sent to a nursing home. Because of progressive weight loss and swallowing difficulty, some blood tests were done and Hb and erythrocyte sedimentation rate (ESR) were found to be 9 g/dL and 75 mm/h, respectively. The patient was then transferred to our hospital on 28 January, 2009 with the preliminary diagnosis of malignancy. His height was 160 cm, weight 41 kg and body mass index was 16 kg/m². Physical examination revealed only cachectic appearance and limited neck movements; the other findings were normal, and the thyroid gland was nonpalpable. Due to detected anemia two packs of erythrocyte suspensions were transfused. In the biochemical analyses hepatic and renal functions were normal; he didn't have any electrolyte imbalance or systemic disease (fasting plasma glucose: 79 mg/dL, blood urea nitrogen: 22 mg/dL, creatinine: 1.0 mg/dL, uric acid: 4.8 mg/dL, aspartate aminotransferase: 8 U/L, alanine aminotransferase: 3 U/L, potassium: 4.3 mmol/L, iron: 41 µg/dL total iron binding capacity: 173 µg/L). His vitamin B12 and folic acid levels were 57 pg/mL and 1.46 ng/mL respectively. Total protein value was 5.7 g/dL and albumin was 2.3 g/dL. Evaluation of cognitive functions revealed his Mini Mental State Examination score was 12. There was not any evidence for malignancy in his thoracic and abdominal CT scans. Upper system fiber-optic gastrointestinal endoscopy was performed and a mass at the junction of the hypopharynx and esophagus just below recessus piriformis obstructing almost whole of the lumen and blocking the distal passage was detected. Biopsy couldn't be performed because of the risk of bleeding and aspiration. As a result of ear-nose-throat clinic consultation, and after laryngoscopic examination, anesthesia confirmation and cervical CT was performed for taking a biopsy from the mass thought to have originated from the pharyngeal area. Cervical CT revealed hypertrophic bridging alterations of anterior corpus parts at the level of C3-T1 vertebra (Figure 1A and B). At the hypopharynx and proximal parts of esophagus restriction secondary to osseous hypertrophy was demonstrated and this aspect was evaluated as consistent with DISH or Forrester disease. As a result of

multidisciplinary evaluation, an operation wasn't planned because of the patient's poor general condition. Patient's nutrition was regulated with fluid foods. No problem was established during nutrition with fluids. The patient was sent back to nursing home after recovery of general status.

DISCUSSION

Although mortality decreases and life expectancy gets longer with developing technology and medicine, chronic diseases remain common problems of elderly patients. In the differential diagnosis for dysphagia, larynx, lung and mediastinal tumors, esophagus motility disorders, esophagitis, restriction of esophagus, spinal tumors, vascular abnormalities, Zenker diverticle, Plummer-Vinson syndrome, gastroesophageal reflux and globus histericus should be kept in mind. For differentiating these disorders barium esophagography has a great importance^[12].

A medical history should be taken in detail and questions about anatomical structure and functions of the oral cavity, pharynx, larynx, and esophagus should be examined when a patient complaining of dysphagia applies to ear-nose and throat clinics. Physical examination of the oral cavity, pharynx, larynx and neck should be done for determining the possible pathologies. Esophageal cancer, web, achalasia, diffuse esophageal spasm and esophagitis are common causes of esophageal dysphagia. Rarely, mediastinal tumors pressing the esophagus, vertebral bone processes and impressions due to the aorta can be the causes^[13]. In our case, the patient's complaints were anemia, weight loss and difficulty in swallowing and initially esophageal malignancy was thought to be the cause of these complaints and upper gastrointestinal system endoscopy was planned. As a result of these evaluations, hypertrophic bridging alterations of anterior corpus parts at the level of C3-T1 vertebra were revealed. It was reported that perforation during esophagoscopy improves because of compression due to cervical osteophytes^[14].

Treatment for DISH is primarily conservative, non-steroidal anti-inflammatory drugs and myorelaxants are used. But in refractory cases there are two surgical approaches to remove osteophytes by lateral cervical or

peroral transpharyngeal ways^[15]. In our case, we initially preferred a medical approach and started treatment with anti-inflammatory drugs and nutrition with liquid foods, after recovery of oral intake we maintained with high calorie formulas.

In our case, the patient hadn't applied to any hospital in the period that he lived alone but after he began to stay in the nursing home for elderly these complaints and problems were established and he was transferred to our hospital. At the present time, it is emphasized that without increasing the quality of the life, longer life will have no meaning and health expectancy is more important than life expectancy. Consequently, while treatment is the target in a young population, in a geriatric population the main target is the preservation of quality of life. We avoided the complications of surgical management and anesthesia, we tried nutrition with liquids and facilitated oral intake. Eventually, recovery in our patient's status and weight gain started. Gastrostomy may be planned if necessary and the patient is followed at particular intervals. During the evaluation of elderly patients, social status, cognitive functions and exhaustive physical examination should be performed definitely.

In conclusion, DISH should be considered an important, although rare, cause of dysphagia among older adults. However, it should not be accepted as the cause of dysphagia until all other causes have been ruled out.

Abstract

Lipoma is relatively common in the colon but is less often in the small intestine. Most lipomas are incidentally detected at endoscopy and are usually small and asymptomatic. However, some of them can present with obstruction and/or intussusceptions. Surgical resection is commonly recommended to remove such significant lipomas with a limited pedicle and larger than 2 cm in size, as endoscopic resection may result in unfavorable complications such as intestinal perforations. We report a case of 62-year-old man presenting with hematochezia. Colonoscopy showed a submucosal tumor, about 50 mm in size, in the terminal ileum. A clinical diagnosis of lipoma was established based on the findings of colonoscopy and abdominal computed tomography (CT). As the patient complained of hematochezia and mild iron deficiency anemia associated with repeated tumor prolapse, we decided to remove his lipoma. Consequently, the lesion was completely removed *en bloc*. Although

abdominal CT immediately after removal of the lesion showed a small amount of free air, conservative treatment was successfully carried out for the perforation. Histologically, the removed lesion was a lipoma.

INTRODUCTION

Lipoma is relatively common in the colon (65%-75%) but is less often in the small intestine (20%-25%). Most lipomas are incidentally detected at endoscopy and are usually small (less than 2 cm) and asymptomatic. However, some of them can present with obstruction and/or intussusceptions^[1]. Surgical resection is commonly recommended to remove such lipomas with a limited pedicle and larger than 2 cm in size, as endoscopic resection may result in unfavorable complications such as intestinal perforations^[2]. We herein report a case of a large lipoma, 50 mm in diameter, arising from the end of ileum, which was completely removed with the so-called endoscopic

unroofing technique in combination with endoscopic submucosal dissection (ESD)^[3,4].

CASE REPORT

A 62-year-old man presented with hematochezia. Colonoscopy showed a pedunculated lesion, about 50 mm in size, originating from the ileum end. With peristalsis, the lesion prolapsed through the ileocecal valve into the cecum and ascending colon (Figure 1). The surface was regularly covered with normal mucosa, except for a part of nodular change suggesting hyperplastic mucosa due to repeated prolapse, and “Cushion-sign” was positive^[5]. Moreover, computed tomography (CT) showed a uniform mass with a very low-density in the ileum end corresponding to the above detected lesion (Figure 2A and B). A clinical diagnosis of ileal lipoma was established based on the above findings. Although there was not any symptom of intestinal intussusception, multiple erosions were seen in the ascending colon perhaps caused by the tumor prolapsing with peristalsis. As oozing of blood was also seen, the ileal lipoma was considered as the bleeding source of his hematochezia. Therefore, local resection was decided for treatment. At first, conventional endoscopic mucosal resection (EMR, lift and cut technique) was attempted under CO₂ insufflation. However, the tumor was too large for the largest commercially available snare with a maximum diameter of 33 mm in our department to capture the whole lesion after injection of glycerol at the base of the lesion (Figure 3A). Alternatively, endoscopic submucosal resection (ESD) was conducted with an IT-knife for removal. Unfortunately, the muscle layer was lacerated and serosal membrane was observed during dissection (Figure 3B). Thus, we used the snare to break the mucosal layer on the top of the lipoma, and then dissection from the defect on the top rather than from the base of the lesion was continued. Capsulated fat tissue extruding through the overlying mucosa during dissection (naked fat sign) was seen (Figure 3C)^[5,6]. Finally, the lesion was completely removed *en bloc* (Figure 3D). The vital signs were stable and no abdominal distension or discomfort was found during the whole procedure. The lacerated muscle layer could not be completely but only partially sutured with metallic clips due to the narrow lumen in the terminal ileum. Abdominal CT immediately after removal, however, showed only a small amount of free air around the ileum end without ascites. Conservative treatment including withholding of oral intake, intravenous administration of antibiotics and hyperalimentation was started after consultation with the surgeons. The vital signs were stable except for fever (at the highest degree of 38°C) for 2 d. No sign of peritoneal irritation suggesting diffuse peritonitis was seen on close physical examination. Oral intake was restarted on the fifth day after ESD, and the patient was discharged uneventfully 2 d thereafter. Histologically, the removed lesion was a lipoma.

DISCUSSION

This lipoma could be correctly diagnosed before resec-

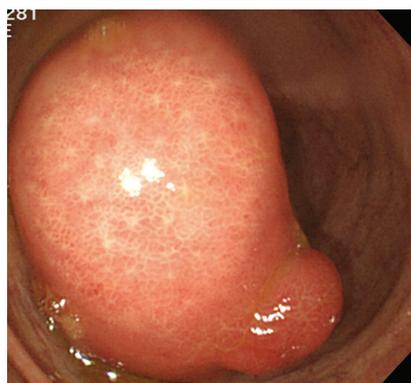

Figure 1 Colonoscopy showing a large pedunculated tumor, 50 mm in size, originating from the ileum end.

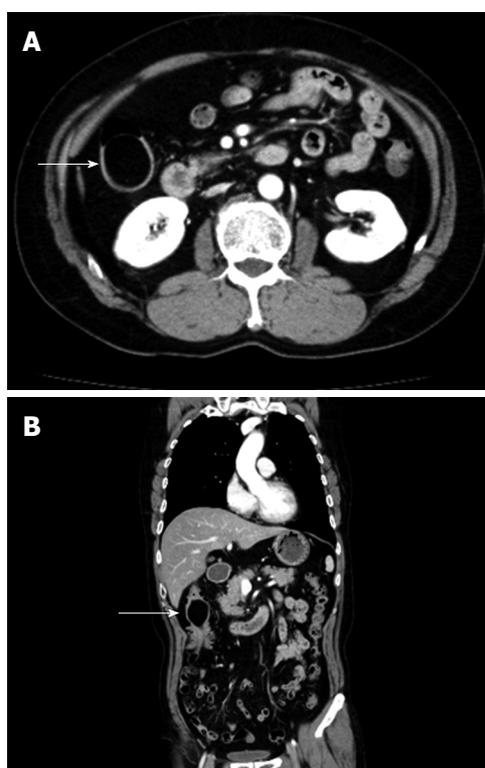

Figure 2 Abdominal CT showing a round, smooth and well-demarcated tumor at the end of the ileum (A) with a fat attenuation coefficient of -116 Hounsfield units (arrows) (B).

tion, as endoscopically it was a submucosal tumor with a positive “Cushion sign”, and moreover computed tomography disclosed a round and smooth, well-demarcated tumor with a fat attenuation^[7,8]. Although, lipohyperplasia, frequently discovered at the right-sided colon (especially in the ileocecal valve), should be included in the differential diagnosis, the encapsulated yellowish adipose tissue detected during endoscopic dissection finally supported the endoscopic diagnosis of a lipoma rather than lipohyperplasia before histological evaluation. We decided to treat this ileal lipoma, as the patient complained of hematochezia and mild iron deficiency anemia associated with erosions caused by repeated tumor prolapse. Various techniques including endoscopic

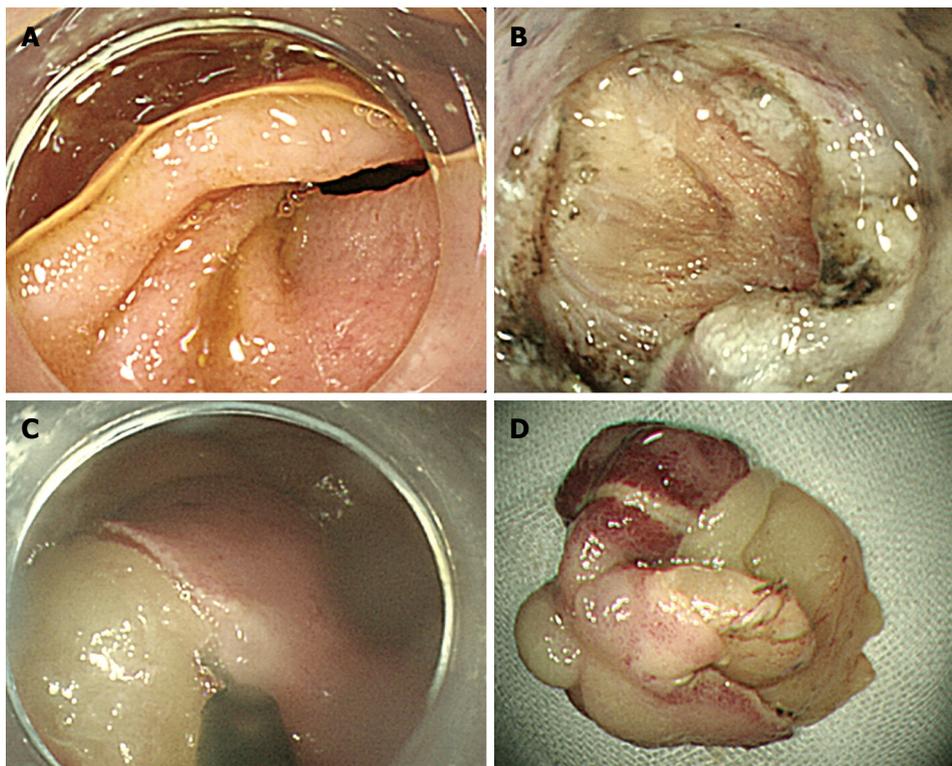

Figure 3 Whole captured lesion after injection of glycerol at the base of the lesion. The base of the lipoma (A), lacerated muscle layer (B), dissected overlying mucosa and capsule (C), and completely removed lipoma (D).

removal and surgical resection have been reported^[9,10]. We firstly attempted conventional EMR. However, unfortunately the tumor could not be completely captured with the largest snare. Piecemeal resection was also tried but failed to electroresect the tumor with the snaring technique. We therefore used the ESD technique to remove this large lesion, as this newly developed technique can remove this kind of large lesions *en bloc*^[11].

During dissection, since laceration of the muscle layer and thereafter the serosa were unfortunately endoscopically identified, we modified the ESD technique for removal. We enrolled the reported unroofing technique in combination with ESD for endoscopic resection^[3,4,12]. At first, the overlying mucosa and capsule of the lipoma were peeled off with the tip of the snare and IT knife from the top to the bottom of the tumor. The underlying adipose tissue was thereafter seen like a peeling banana. This modified technique finally enabled us to completely remove the lipoma *en bloc*. Different from the submucosal direct dissection at the base, we dissected this lipoma from the top to the bottom rather than from the base. We believe that this modified technique can remove large lipomas more safely and quickly than ESD^[11].

Perhaps, perforation is one of the most serious complications associated with endoscopic resection. We did not close the lacerated muscle layer immediately, as the clips in the narrow lumen of ileum would disturb continuing the endoscopic procedure. Fortunately, we could complete the endoscopic removal, as the patient did not develop pneumoperitoneum and the lumen was not collapsed. Furthermore, we could not close the perforation completely with metallic clips. However, conservative treatment was carried out successfully. Our case was

treated successfully without laparotomy. However, the choice of conservative or surgical treatment for iatrogenic colonic perforation remains controversial. In this case, non-surgical treatment was selected because the vital signs of the patient were stable, the abdominal pain was mild and localized, no unexplained peritoneal fluid was found in the abdominal CT, and the colonic preparation was extremely good. We also believe that CO₂ insufflation plays an important role in this successful conservative treatment, as room air insufflation would lead to pneumoperitoneum collapsing the lumen and vital signs (abdominal compartment syndrome)^[13-16].

In conclusion, large ileal lipoma can be completely removed with the modified ESD procedure in combination with endoscopic unroofing technique (from the top to the bottom like peeling a banana).

INTRODUCTION

Superwarfarins are anticoagulants similar to warfarin. As substitutes for acute rodenticides, superwarfarins are usually the first choice of rodenticide, especially in rural areas. Esophagogastroduodenoscopy (EGD) is a common tool for diagnostic and therapeutic goals. Significant bleeding after cold mucosal biopsy is seldom seen. Here, we report a woman with severe upper gastrointestinal hemorrhage after gastroscopic mucosal biopsy, which is a rare and previously unreported complication of superwarfarin poisoning.

CASE REPORT

A 55-year-old woman was referred to our hospital for epigastric pain and abdominal distention. Her medical history and physical examination were unremarkable. She had no history of anticoagulation therapy or use of non-steroid anti-inflammatory drugs. She came to the outpatient department for further evaluation.

Routine EGD revealed an uneven granular mucosa and several erosion lesions scattering in the stomach, covered with fresh blood crusts (Figure 1). Five mucosal biopsies of the stomach, two from the gastric angle and three from the lesser curvature side of gastric antrum, were performed for pathological analysis and *Helicobacter pylori* (*H. pylori*) detection. Gastric biopsy specimens revealed atrophic gastritis accompanying intestinal metaplasia. Rapid urease test was negative for *H. pylori* infection. No active bleeding was seen immediately after endoscopic biopsy and throughout the whole endoscopic procedure. However, she was admitted to the emergency department of our hospital because of hematemesis and melena the next day after EGD examination.

Abstract

Superwarfarins are a class of rodenticides. Gastrointestinal hemorrhage is a fatal complication of superwarfarin poisoning, requiring immediate treatment. Here, we report a 55-year-old woman with tardive upper gastrointestinal hemorrhage caused by superwarfarin poisoning after endoscopic cold mucosal biopsy.

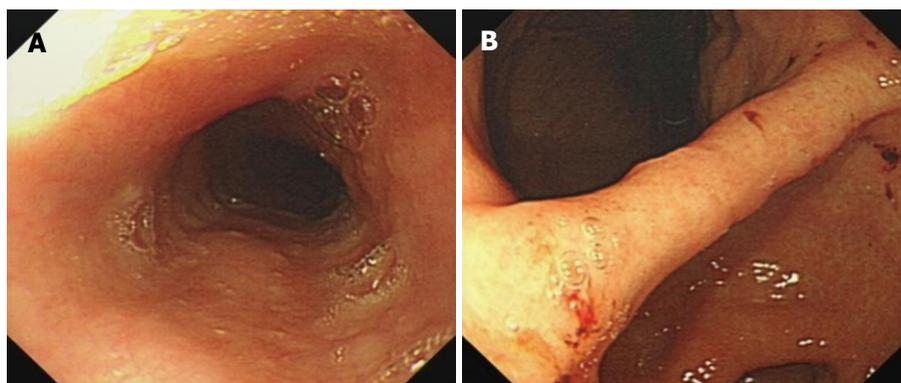

Figure 1 Initial esophagogastroduodenoscopy (EGD) demonstrating normal esophageal mucosa (A) and erosion lesions scattering in the stomach (B).

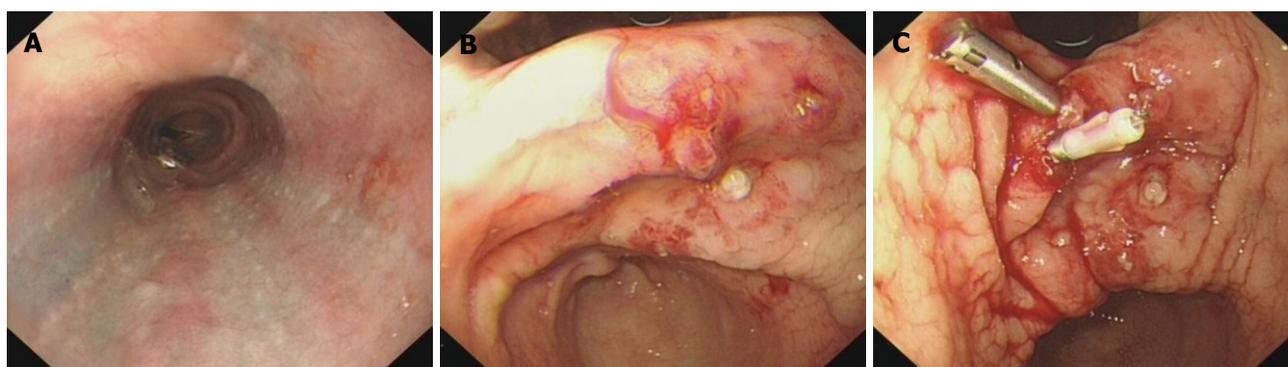

Figure 2 Second EGD showing submucosal congestion in the esophagus (A), active bleeding in the original biopsy sites (B), and titanium clips used for hemostasis (C).

Table 1 Findings in hematologic and coagulation laboratory tests

Variables	Normal range	Day 2	Day 4	Day 8
RBC ($10^{12}/L$)	3.5-5.5	1.7	2.25	2.72
Hemoglobin (g/L)	110-160	55	74	89
Prothrombin time (s)	11.0-14.0	> 180	16.8	13.8
Activated partial thromboplastin time (s)	35.0-55.0	94.3	30.5	26.9

Routine blood test showed 1.7×10^{12} erythrocytes per liter (normal 3.5-4.5 erythrocytes/liter) and 56 g hemoglobin per liter (Table 1). Coagulation function test revealed a prolonged prothrombin time (PT > 180 s) and an activated partial thromboplastin time (APTT = 94.3 s) (Table 1), both of which could be corrected when mixed with normal plasma at a 1:1 ratio. Other blood tests, such as platelet count, fibrinogen, renal function, and liver function, were normal (data not shown).

Superwarfarin poisoning was taken into consideration. The patient's serum and urine specimens were sent to Affiliated 307 Hospital of Academy of Military Sciences of China for toxicology analysis. Laboratory evaluation for some common superwarfarins was performed with the help of reverse-phase high performance enzyme-linked chromatography, showing that the level of brodifacoum and bromadiolone in serum was 1665 ng/mL and 132 ng/mL, respectively, and 216 ng/mL and 15 ng/mL in urine, respectively. The diagnosis of superwarfarin

poisoning was confirmed. The patient was also allowed to have intentionally ingested rodenticides to commit suicide 10 d before the routine EGD examination because of severe depression.

Emergency EGD showed submucosal congestion of the esophagus (Figure 2A), and five hemorrhagic sites in the stomach, which were still bleeding during the endoscopic procedure (Figure 2B). All the bleeding sites were closed with 5 titanium clips to achieve hemostasis (Figure 2C).

The patient was treated with concentrated red blood cells, fresh frozen plasma and intravenous vitamin K (30 mg/d) for 8 d until her coagulation parameters returned to normal, RBC count and hemoglobin concentration were greatly improved (Table 1). She began to have oral vitamin K1 (30 mg/d) from day 9 after admission. Toxicology analysis on day 7 showed a brodifacoum concentration of 986 ng/mL and a bromadiolone concentration of 36 ng/mL in serum. Brodifacoum (7 ng/mL) could only be detected in the urine specimen. On day 10, EGD showed that the submucosal congestion of esophagus was absorbed with no sign of bleeding in the stomach, and titanium clips in good condition (Figure 3). Plain radiography and CT scanning revealed 5 titanium clips in the stomach (Figure 4).

Two days after the last EGD examination, the patient was discharged from our hospital and oral vitamin K1 was prescribed (10 mg/d) for 1 mo. Weekly PT, prothrombin activity and international normalized ratio measurements

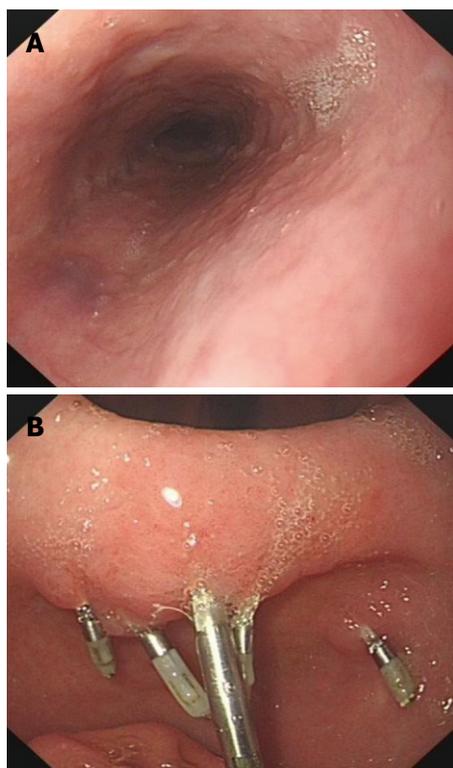

Figure 3 Final EGD showing the absorbed esophageal submucosal congestion (A) and bleeding in the stomach with titanium clips in good condition (B).

were also advised. During the 1-mo following-up after discharge, her coagulation parameters remained normal with no recurrent bleeding.

DISCUSSION

Superwarfarins, a class of rodenticides with brodifacoum and bromadiolone as their representative, are long acting anticoagulants^[1,2] and are 100 times as potent as warfarin. The half life of brodifacoum and bromadiolone can be as long as 24 d^[3] or 30 d^[1] and 31 d^[2], respectively.

Superwarfarins are supposed as the first-line rodenticides all over the world. However, superwarfarin poisoning cases are often reported, especially in rural areas. The number of superwarfarin poisoning cases has also increased in the USA^[4,5]. The causes of superwarfarin poisoning include accidental exposure, suicide intention and occupational exposure. In addition to oral intake, inhalation and skin absorption can also result in superwarfarin poisoning.

Gastrointestinal hemorrhage is a fatal complication of superwarfarin poisoning, requiring immediate treatment. Treatment modalities include use of antidotes, such as vitamin K1, often requiring a high dose (20-125 mg/d) and a prolonged time because of the long half-life of superwarfarins^[2].

Endoscopic treatment for hemostasis is somewhat

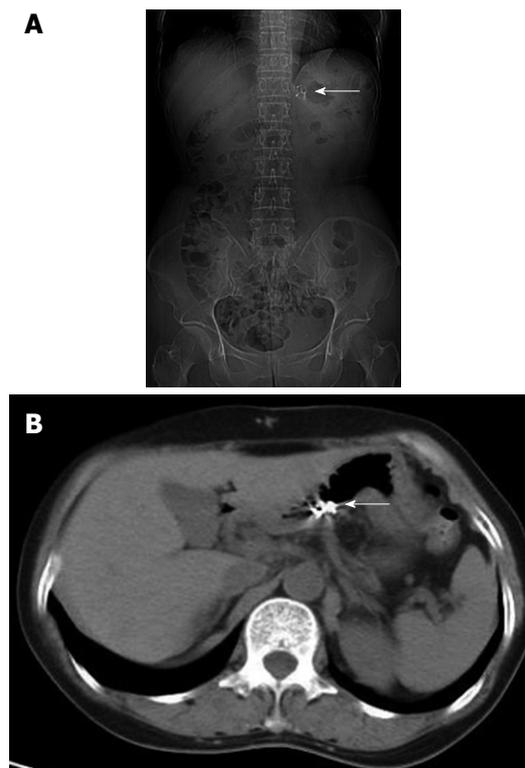

Figure 4 Plain radiography (A) and CT scanning (B) revealing 5 titanium clips in the stomach (arrows).

effective. Due to the extensive bleeding and hemodynamic instability of our patient, blood transfusion and fluid infusion should also be applied to correct the blood volume before emergency endoscopy. In this case, hemostasis was achieved by placing five titanium tips to clip the bleeding sites with the help of an EGD.

In conclusion, with the help of antidotes against superwarfarins and EGD, upper gastrointestinal hemorrhage caused by superwarfarin poisoning after endoscopic cold mucosal biopsy can be successfully and safely controlled.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board

members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Article: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce Consensus and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Instructions to authors

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 $\mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG,

WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-5908-0039

Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

**EDITORIAL**

- 1683 Controlling postoperative ileus by vagal activation
Lubbers T, Buurman W, Luyer M
- 1688 Safe procedure in endoscopic submucosal dissection for colorectal tumors
focused on preventing complications
Yoshida N, Yagi N, Naito Y, Yoshikawa T

TOPIC HIGHLIGHT

- 1696 Recent trends in the treatment of well-differentiated endocrine carcinoma of
the small bowel
Poncet G, Faucheron JL, Walter T

REVIEW

- 1707 Walled-off pancreatic necrosis
Stamatakis M, Stefanaki C, Kontzoglou K, Stergiopoulos S, Giannopoulos G, Safioleas M
- 1713 Pathologic research update of colorectal neuroendocrine tumors
Ni SJ, Sheng WQ, Du X

ORIGINAL ARTICLE

- 1720 Real-time sono-elastography in the diagnosis of diffuse liver diseases
*Gheonea DI, Săftoiu A, Ciurea T, Gorunescu F, Iordache S, Popescu GL, Belciug S,
Gorunescu M, Săndulescu L*
- 1727 Effectiveness of narrow-band imaging magnification for invasion depth in
early colorectal cancer
Fukuzawa M, Saito Y, Matsuda T, Uraoka T, Itoi T, Moriyasu F
- 1735 Expression of nesfatin-1/NUCB2 in rodent digestive system
Zhang AQ, Li XL, Jiang CY, Lin L, Shi RH, Chen JD, Oomura Y

BRIEF ARTICLE

- 1742 Current surgical treatment of diverticular disease in the Netherlands
*Morks AN, Klarenbeek BR, Flikweert ER, van der Peet DL, Karsten TM, Eddes EH,
Cuesta MA, de Graaf PW*
- 1747 Successful antiviral therapy is associated with a decrease of serum
prohepcidin in chronic hepatitis C
Jaroszewicz J, Rogalska M, Flisiak I, Flisiak R
- 1753 *NOD2/CARD15, ATG16L1* and *IL23R* gene polymorphisms and childhood-
onset of Crohn's disease
*Gazouli M, Pachoula I, Panayotou I, Mantzaris G, Chrousos G, Anagnostou NP,
Roma-Giannikou E*

- 1759** Endoscopic submucosal dissection in dogs in a World Gastroenterology Organisation training center
Tanimoto MA, Torres-Villalobos G, Fujita R, Santillan-Doherty P, Albores-Saavedra J, Gutierrez G, Martin-del-Campo LA, Bravo-Reyna C, Villanueva O, Villalobos JJ, Uribe M, Valdovinos MA
- 1765** Hepatitis B-related events in autologous hematopoietic stem cell transplantation recipients
Çeneli Ö, Özkurt ZN, Acar K, Rota S, Akı ŞZ, Yeğın ZA, Yağcı M, Özenirler S, Sucak GT
- 1772** Identification of cerebral response to balloon distention of the bile duct
Sai JK, Suyama M, Kubokawa Y, Matsumura Y, Inami K, Watanabe S, Kirino E
- 1776** Efficacy of early treatment with infliximab in pediatric Crohn's disease
Lee JS, Lee JH, Lee JH, Lee HJ, Kim MJ, Lee HJ, Choe YH
- 1782** Diabetic factors associated with gastrointestinal symptoms in patients with type 2 diabetes
Kim JH, Park HS, Ko SY, Hong SN, Sung IK, Shim CS, Song KH, Kim DL, Kim SK, Oh J
- 1788** Inflammatory cytokine gene polymorphisms increase the risk of atrophic gastritis and intestinal metaplasia
Li ZW, Wu Y, Sun Y, Liu LY, Tian MM, Feng GS, You WC, Li JY

CASE REPORT

- 1795** Does (supra)gastric belching trigger recurrent hiccups?
Hopman WP, van Kouwen MC, Smout AJ
- 1800** Surgical spacer placement and proton radiotherapy for unresectable hepatocellular carcinoma
Komatsu S, Hori Y, Fukumoto T, Murakami M, Hishikawa Y, Ku Y
- 1804** Intestinal anisakiasis can cause intussusception in adults: An extremely rare condition
Miura T, Iwaya A, Shimizu T, Tsuchiya J, Nakamura J, Yamada S, Miura T, Yanagi M, Usuda H, Emura I, Takahashi T
- 1808** Gastrointestinal stromal tumor of stomach with inguinal lymph nodes metastasis: A case report
Zhang Q, Yu JW, Yang WL, Liu XS, Yu JR

ACKNOWLEDGMENTS I Acknowledgments to reviewers of *World Journal of Gastroenterology*

APPENDIX I Meetings
I-IV Instructions to authors

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

FLYLEAF I-VII Editorial Board

EDITORS FOR THIS ISSUE

Responsible Assistant Editor: *Xiao-Fang Liu*
Responsible Electronic Editor: *Xiao-Mei Zheng*
Proofing Editor-in-Chief: *Lian-Sheng Ma*

Responsible Science Editor: *Lin Tian*
Proofing Editorial Office Director: *Jian-Xia Cheng*

Abstract

Postoperative ileus is a frequently occurring surgical complication, leading to increased morbidity and hospital stay. Abdominal surgical interventions are known to result in a protracted cessation of bowel movement. Activation of inhibitory neural pathways by nociceptive stimuli leads to an inhibition of propulsive activity, which resolves shortly after closure of the abdomen. The subsequent formation of an inflammatory infiltrate in the muscular layers of the intestine results in a more prolonged phase of ileus. Over the last decade, clinical strategies focusing on reduction of surgical stress and promoting postoperative recovery have improved the course of postoperative ileus. Additionally, recent experimental evidence implicated antiinflammatory interventions, such as vagal stimulation, as potential targets to treat postoperative ileus and reduce the period of intestinal hypomotility. Activation of nicotinic receptors on inflammatory cells by vagal input attenuates inflammation and promotes gastrointestinal motility in experimental models of ileus. A novel physiological

intervention to activate this neuroimmune pathway is enteral administration of lipid-rich nutrition. Perioperative administration of lipid-rich nutrition reduced manipulation-induced local inflammation of the intestine and accelerated recovery of bowel movement. The application of safe and easy to use antiinflammatory interventions, together with the current multimodal approach, could reduce postoperative ileus to an absolute minimum and shorten hospital stay.

INTRODUCTION

Postoperative ileus is a common pathological condition in the surgical ward and presents as an inability to tolerate enteral nutrition, nausea, abdominal distension, and lack of flatus and defecation. Although all surgical patients are at risk of developing postoperative ileus, the condition is mostly observed after abdominal surgery with manipulation of the gastrointestinal tract^[1]. Cessation of bowel movement and delayed gastric emptying, which can be up to 5 d after colorectal surgery, results in increased morbidity and a prolonged hospital stay^[2-4]. The duration of postoperative ileus has a major financial impact, adding an average of 6.300 US\$ to hospital costs

per patient who develops ileus^[5]. The additional health care costs in the US have been estimated to be 1.5 billion US\$ annually^[6]. Increased insight into the pathophysiology and discovery of novel treatment options could diminish the length of postoperative ileus, decrease patient morbidity, and reduce hospital costs.

PATHOPHYSIOLOGY OF POSTOPERATIVE ILEUS

The pathophysiology underlying postoperative ileus is complex and multifactorial, consisting of endogenous and pharmacological characteristics. Recent experimental studies have demonstrated that the pathogenesis of the endogenous component of postoperative ileus can be grossly divided in two distinct phases^[1]. The first phase, or neural phase, results from activation of mechanoreceptors and nociceptors by stimuli, such as incision of the skin and, more importantly, by direct manipulation of the intestine^[7]. Activation of these receptors initiates a neural reflex, which is dependent on release of mediators, such as α -calcitonin gene-related peptide and substance P, which inhibit gastrointestinal motility and result in generalized intestinal hypomotility^[8-10]. The neural phase of postoperative ileus lasts minutes to hours and resolves after closure of the wound when the noxious stimuli have ceased^[9,11,12]. The motility of the colon in particular depends heavily on input from the autonomic nervous system, which might explain colonic susceptibility to isolated and prolonged ileus^[13].

The second, more protracted, inflammatory phase is caused by formation of an inflammatory infiltrate in the muscular layers of the intestine^[7,14,15]. Manipulation of the intestine initiates an inflammatory cascade starting with activation and degranulation of mast cells^[16-18]. Subsequently, resident macrophages are activated either *via* mast cell-derived mediators or by luminal antigens^[17,19,20]. These activated macrophages produce cytokines and chemokines, which attract neutrophils to the muscular layer of the intestine. Invaded neutrophils directly impair intestinal smooth muscle cell contractility *via* release of nitric oxide and prostaglandins^[21,22]. The formation of an inflammatory infiltrate not only impairs motility in the manipulated areas, but also leads to generalized hypomotility of the gastrointestinal tract *via* activation of inhibitory adrenergic neural pathways. There is emerging evidence that inflammation also plays a vital role in postoperative ileus in humans, therefore a major focus of current research has been directed at the development of antiinflammatory treatments^[18,23,24]. In experimental models of intestinal manipulation, it was demonstrated that administration of antiinflammatory agents, such as mast cell stabilizers^[17], non-steroidal antiinflammatory drugs^[25,26], and interleukin (IL)-10^[27], prevent development of postoperative ileus. In addition, it was recently shown in patients undergoing major abdominal surgery that an intervention with the mast cell stabilizer, Ketotifen, reduced gastroparesis^[24].

CLINICAL STRATEGIES TO TREAT POSTOPERATIVE ILEUS

A number of strategies for preventing postoperative ileus are combined in the so-called fast-track program. The goals of fast-track surgery are reduction of perioperative surgical stress and promotion of postoperative recovery. Adequate pain relief, minimal invasive surgery and early enteral nutrition are important to achieve these goals^[28]. Adequate pain relief can attenuate postoperative ileus in two important ways. First, intraoperative spinal anesthesia and postoperative epidural analgesia with local anesthetics during abdominal surgery reduce the neural phase of ileus by interruption of neural transmission. Second, local anesthetic interventions minimize the use of opioid-derivatives^[29,30]. Both endogenous opioids, released in response to noxious stimuli, and exogenous opioids are notorious for their inhibitory effect on gastrointestinal motility, thereby aggravating postoperative ileus^[31]. Blocking the μ -opioid receptor with Alvimopan, a selective, peripherally active antagonist, has been demonstrated to accelerate recovery of bowel function and decrease hospital stay, without affecting the analgesic effects of opioids^[32,33]. In addition, non-steroidal anti-inflammatory drugs seem promising for their opioid-sparing and antiinflammatory effects^[26,34]. However, caution should be taken as the use of cyclo-oxygenase-2 inhibitors after colonic surgery has been associated with increased anastomotic leakage^[35].

Surgical trauma and direct manipulation of the intestine are major factors in the occurrence of postoperative ileus. The degree of gastrointestinal hypomotility correlates with the degree of manipulation and intestinal inflammation^[19]. The introduction of minimally invasive techniques, such as laparoscopy, significantly reduced the duration of postoperative ileus and length of hospital stay^[36]. This improvement is probably due to minimization of trauma, resulting in less pain and a diminished release of neurotransmitters and inflammatory mediators^[18,28,37].

Finally, enteral nutrition is found to be essential for enhanced recovery after surgery. Ingestion of nutrients elicits various reflexes and releases several neuropeptides that promote gastrointestinal motility^[38,39]. Traditionally however, a nil-by-mouth regime is often enforced starting from several hours before surgery until days postoperatively. Recent studies have demonstrated that early enteral nutrition is safe and well tolerated after abdominal surgery. In addition, early enteral nutrition reduces postoperative ileus and length of hospital stay^[40,41]. Unfortunately, studies investigating the effect of early enteral nutrition on postoperative ileus remain difficult to interpret, as the studies often lack essential information on the type of analgesia that was used^[2]. Enteral nutrition is a promising intervention to treat ileus; however, future well-designed studies are needed to evaluate the effect of early enteral nutrition on intestinal motility. When implementing early enteral nutrition routinely,

caution should be taken, as there is a small chance that enteral nutrition could lead to intestinal ischemia in the circulatory compromised patient^[42,43].

The implementation of fast-track regimes in the surgical field has improved the course of postoperative ileus. However, despite these efforts, it still remains an important clinical challenge. Inhibition of the inflammatory phase, by targeting the cellular and molecular changes underlying postoperative ileus is another focus of treatment.

EXPERIMENTAL STRATEGIES TO CONTROL POSTOPERATIVE ILEUS

The inflammatory phase dominates the course of postoperative ileus. Novel experimental interventions aimed at preventing the activation of inflammatory cells, such as administration carbon monoxide^[44,45], pretreatment with blocking antibodies to intracellular adhesion molecule-1 and lymphocyte function-associated antigen-1^[7,46], inactivating macrophages^[47], and preventing mast cell activation^[17], have displayed promising results in reducing gastrointestinal hypomotility. Borovikova *et al.*^[48] described a novel approach for modulating the inflammatory response; electrical stimulation of the vagus nerve attenuates systemic inflammation in a murine endotoxin model. Stimulation of the vagus nerve modulates inflammation *via* release of acetylcholine that binds to nicotinic receptors on inflammatory cells, hence the term “cholinergic anti-inflammatory pathway”^[49,50]. In addition, the vagus nerve has recently been identified as an important modulator of intestinal health; loss of vagal integrity aggravates intestinal inflammation and augments loss of gut barrier function^[51,52].

In a murine model of intestinal manipulation, electrical stimulation of the vagus nerve ameliorates postoperative gastrointestinal hypomotility *via* inhibition of local intestinal inflammation. Vagal stimulation activates the $\alpha 7$ nicotinic acetylcholine receptor on intestinal macrophages and attenuates release of pro-inflammatory cytokines *via* the Jak2-Stat3 signaling pathway^[53]. Furthermore, administration of the selective $\alpha 7$ receptor agonist, AR-R17779, prevented postoperative ileus in mice^[54]. Although very effective in preventing postoperative ileus in animal models, caution should be taken when implementing electric vagus stimulation and pharmacologic interventions in patients. Electrical stimulation remains an invasive procedure, while pharmacologic stimulation of nicotinic receptors might cause unwanted stimulation of different cell types and organs^[55,56].

A more physiological way to activate the vagal anti-inflammatory pathway is by administration of enteral nutrition enriched with lipids. Administration of lipid-rich nutrition prior to, or following, hemorrhagic shock attenuates systemic inflammation and preserves intestinal integrity^[57,58]. These positive effects of lipid-rich nutrition on gut barrier function and systemic inflammation are specific for the amount of lipids in the nutrition, as a low-lipid control feeding did not exert these protec-

tive effects. The enteral presence of lipids activates the autonomic nervous system *via* cholecystokinin (CCK) receptors. Subsequently, inflammation is inhibited through activation of nicotinic receptors on inflammatory cells *via* the efferent vagus^[59]. Enteral administration of lipid-rich nutrition was demonstrated to reduce postoperative ileus in a rodent model of intestinal manipulation^[16]. Enteral nutrition enriched with lipids prevented degranulation of mast cells, inhibited release of macrophage-derived tumor necrosis factor- α and IL-6, and prevented influx of neutrophils into the intestinal muscularis to a greater extent than the control, low-lipid, nutrition. More importantly, the beneficial effect of lipid-rich nutrition on manipulation-induced local inflammation promoted gastrointestinal transit in a CCK-receptor-dependent manner^[16]. These findings indicate that lipid-rich nutrition reduces postoperative ileus *via* activation of the nutritional anti-inflammatory pathway. Luminal lipids are known to activate the autonomic nervous system *via* CCK-mediated stimulation of peripheral CCK-1 receptors on afferent vagal fibers, resulting in several regulatory digestive functions, such as satiety^[60]. Therefore, the anti-inflammatory potential of lipid-rich enteral nutrition could rely on activation of a nutritional CCK-dependent vagovagal reflex.

Interestingly, sham feeding is another physiological technique that activates the cephalic vagal axis by mimicking food intake, thereby stimulating bowel motility^[38,39]. Furthermore, activation of the cephalic phase elicits digestive functions *via* vagovagal cholinergic reflexes^[61]. Sham feeding by chewing gum has been shown to improve bowel movement and reduce time to first flatus and first defecation after open gastrointestinal surgery, and demonstrates a trend towards a reduced hospital stay^[62,63]. However, the exact mode of action remains to be investigated.

CONCLUSION

Surgical interventions, and abdominal surgery in particular, are frequently accompanied by the occurrence of postoperative ileus. Postoperative ileus is a multifactorial surgical complication that requires a multifactorial treatment approach. Minimal invasive surgery to reduce surgical stress, epidural analgesia to block inhibitory reflexes, minimizing opioid use, and attenuation of intestinal inflammation by anti-inflammatory interventions should reduce postoperative ileus to a minimum. The development of safe and easy-to-use treatments to prevent intestinal inflammation will play a key role in controlling postoperative ileus and deserves further investigation. Stimulation of the vagal anti-inflammatory pathway, by interventions such as enteral administration of lipids, is one of the promising interventions contributing to a further reduction of postoperative ileus.

Abstract

Endoscopic submucosal dissection (ESD) is efficient for *en bloc* resection of large colorectal tumors. However, it has several technical difficulties, because the wall of the colon is thin and due to the winding nature of the colon. The main complications of ESD comprise postoperative perforation and hemorrhage, similar to endoscopic mucosal resection (EMR). In particular, the rate of perforation in ESD is higher than that in EMR. Perforation of the colon can cause fatal peritonitis. Endoscopic clipping is reported to be an efficient therapy for perforation. Most cases with perforation are treated conservatively without urgent surgical intervention. However, the rate of postoperative hemorrhage in ESD is similar to that in EMR. Endoscopic therapy including endoscopic clipping is performed and most of the cases are treated conservatively without blood transfusion. In blood examination, some degree of inflammation is detected after ESD. For the standardization of ESD, it is most important to decrease the rate of perforation. Adopting a safe strategy for ESD and a suitable choice of knife are both important ways

of preventing perforation. Moreover, appropriate training and increasing experience can improve the endoscopic technique and can decrease the rate of perforation. In this review, we describe safe procedures in ESD to prevent complications, the complications of ESD and their management.

INTRODUCTION

Endoscopic mucosal resection (EMR) has been generally performed for colorectal tumors worldwide, including Japan. It is difficult to perform *en bloc* resection by EMR for a colorectal tumor whose size is larger than 20 mm^[1-3]. The rate of *en bloc* resection by EMR for tumors with a diameter of more than 20 mm was reported to be approximately 30%^[2,3]. Piecemeal EMR enables us to remove large colorectal tumors. However, colorectal cancer has a high rate of local recurrence^[2-5]. Moreover, precise histopathological diagnosis is difficult when using separate resected specimens of piecemeal EMR^[6]. Thus, laparoscopic-assisted colectomy (LAC) has been regarded as a standard therapy for large colorectal tumors throughout the world^[7]. However, LAC is more invasive than endoscopic treatment. Endoscopic submucosal

dissection (ESD) has a high rate of *en bloc* resection for large colorectal tumors, and it is less invasive than LAC. The rate of *en bloc* resection for large colorectal tumors has been reported to be 84.0%-98.9%^[8-17]. However, the procedure has not been standardized because of its associated technical difficulties. The colon is winding in nature, and the colonic wall is thinner than the gastric wall. Moreover, there are many folds in the colorectum. Therefore, the rate of perforation in ESD is reported to be higher than that in EMR. A safe strategy, suitable knife, and adoption of other equipment are necessary while performing ESD in order to prevent its associated complications, including perforation.

In Japan, a special working group consisting of experts in ESD suggested specific indications for ESD^[6]. Briefly, ESD is suitable for a tumor when it is difficult to use a snare EMR for *en bloc* resection. ESD should be performed for tumors that are diagnosed as carcinomas with intramucosal to shallow submucosal invasion. Moreover, ESD is performed for lesions with submucosal fibrosis that cannot be removed by conventional EMR even if the size of the lesion is less than 20 mm. However, tumors in a location where the endoscope will not be able to be operated smoothly should not be removed by ESD.

METHOD OF SAFE ESD

Preparation and equipment

ESD is performed using a general lower gastrointestinal endoscope with a single channel. In our institution, EC 590 MP (Fuji Film Medical, Tokyo, Japan) or PCF Q260AI (Olympus Medical Systems Co., Tokyo, Japan) are used. ESD requires a high-frequency generator with an automatically controlled system. In our institution, VIO300D or ICC200 (Erbe Elektromedizin Ltd., Tübingen, Germany) are used. An upper gastrointestinal endoscope is adopted in some institutions because it is slim and can be used in the retroflexed position^[10]. A transparent short hood (Olympus Medical Systems Co., Tokyo, Japan) is fitted at the tip of the endoscope. A mixture of 1% hyaluronic acid solution (Mucoup; Johnson & Johnson K.K., Tokyo, Japan) and 10% glycerin solution (Glyceol; Chugai Pharmaceutical Co., Tokyo, Japan) is used as the injection liquid to induce a higher elevation of the submucosa and to lengthen the duration of the continuous elevation of the submucosa^[18,19].

Before ESD, residual feces and liquid are removed from the entire colon even if the tumor is located at the rectum. The ESD procedure should be abandoned if the residual feces can not be removed enough. Residual feces prevent smooth submucosal dissection. Moreover, it is essential to remove residual feces in order to prevent the outflow of feces into the abdomen in the case of perforation.

Various knives are used in ESD for colorectal tumors (Figure 1A-F). Among the obtuse short-tipped types are the Flush knife (Fujifilm Medical, Tokyo, Japan), Dual knife (Olympus Medical Systems Co., Tokyo, Japan), B-knife (Zeon Medical, Tokyo, Japan), and Splash needle

(Pentax Co., Tokyo, Japan)^[9,15,20]. The Flush knife and Splash needle are capable of injecting substances into the submucosa. They enable us to omit switching between the knife and the injection needle^[13,15]. A Dual knife has a ball disk at the tip of the knife, enabling us to hook the submucosa. The B-knife and Flush knife both have a new type of ball tip. The insulated tipped (IT) knife (Olympus Medical Systems Co., Tokyo, Japan), whose efficacy has been reported to be satisfactory in ESD for gastric tumors, is used in certain institutions^[21]. Speedy dissection can be performed with the IT knife, but it may cause large perforations due to its long blade. A Hook knife (Olympus Medical Systems Co., Tokyo, Japan) is used particularly when the dissection of the submucosa is difficult due to poor elevation of the submucosa^[12]. The B-knife is the only bipolar knife; burning of the muscularis propria layer is considered to be less with this knife than with other monopolar knives. A grasping-type scissor forceps has been reported as an original knife^[22]. In our institution, the Flush knife is mainly used because it can be effectively used to administer local injections, while the Hook knife is used when the risk of perforation is high due to the poor elevation of the submucosa^[12,23].

Mucosal incision (initial complete circumferential incision and partial circumferential incision)

The border of the tumor is observed carefully by applying indigo carmine dye. It is generally unnecessary to make placement of borders by coagulation because in the majority of cases, the borders of the tumor are clearly visible. Injection into the submucosa for its elevation is performed with a 23-25 gauge needle (TOP Co., Tokyo, Japan) after observation of the border of the tumor. Then, a mucosal incision is taken. An initial complete circumferential incision or a partial circumferential incision is made according to the institution's procedure and the lesion's characteristics, as reported previously (Figure 2A and B)^[8,12]. In initial complete circumferential incision, injection of hyaluronic acid solution into the submucosa is performed from the oral edge of the tumor. A mucosal incision is made after adequate elevation of the submucosa is obtained. Simultaneously, an incision up to the deep submucosa is made. Then the solution is injected into the anal edge of the tumor and the mucosal incision is made. Thus, a mucosal incision is made all around the tumor. On the other hand, in partial circumferential incision, the anal side of the tumor is the first to be incised after the injection of hyaluronic acid solution for submucosal elevation. Both types of mucosal incisions are performed with the endocut mode (e.g. Output 40W, effect 2 in ICC200; or endocut I, effect 2, duration 2, interval 1 in VIO300D). However, each incision has its own merits and demerits.

In initial complete circumferential incision, leakage of injection fluid can easily occur following which submucosal elevation cannot be obtained. Moreover, injection of the fluid into the oral side of the tumor causes the position of the tumor to be perpendicular to the endoscope (Figure 3A and B). This makes submucosal dissection difficult. In addition, the uncut residual mucosa on the oral

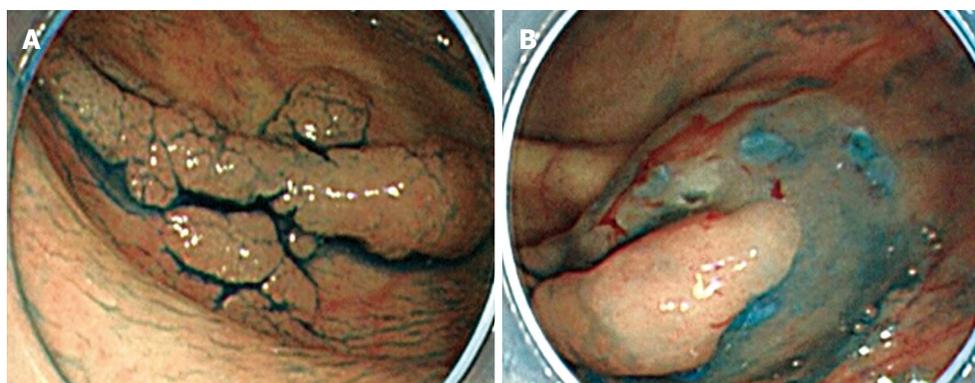

Figure 3 A case of the tumor perpendicular to the endoscope. A: Colonic tumor, 0-IIa 20 mm in the ascending colon; B: The position of the tumor became vertical with respect to the endoscope following injection into the proximal side.

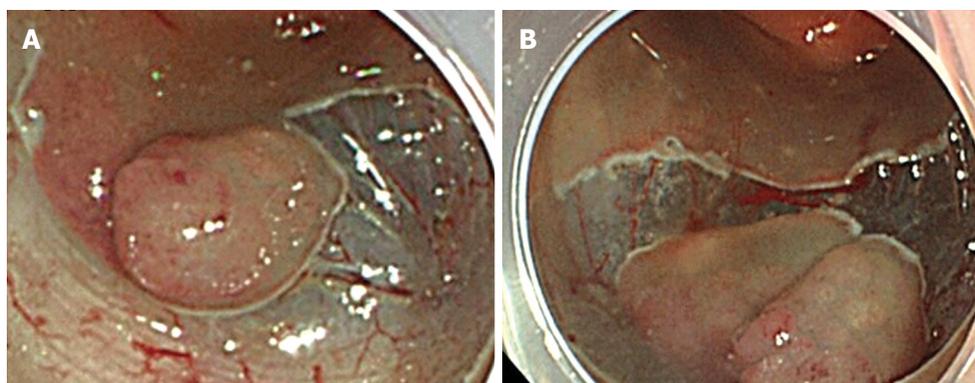

Figure 4 Another case of the tumor perpendicular to the endoscope. A: Residual mucosa on the oral side pulled the tumor upward; B: The substance caused by the residual mucosa was lost during full mucosal resection, and the position of the tumor became vertical with respect to the endoscope.

side pulls the tumor upward (Figure 4A); however, this substance caused by the residual mucosa is lost in initial complete circumferential incision, and the tumor becomes perpendicular to the endoscope (Figure 4B). These fac-

tors are experienced frequently in tumors whose size is less than 50 mm. In partial circumferential incision, higher elevation of the submucosa can be maintained because the uncut residual mucosa on the oral side of the tumor

prevents the leakage of injected fluid. However, in partial circumferential mucosal incision, it is sometimes difficult to resect the residual mucosa on the oral side owing to the presence of the partially resected tumor. Thus, each type of mucosal incision has its own merits and demerits; the type of incision to be used should be decided according to the tumor size, location of the tumor, and types of knives being used. In our institution, partial circumferential incision is performed for tumors measuring less than 50 mm or for which fluid injection into the tumor's oral side would likely negatively influence the position of the tumor.

Dissection of the submucosa below the tumor

After mucosal and submucosal incisions are made around the tumor, the submucosa below the tumor is dissected from the anal side of the tumor. Dissection of the submucosa is performed using the Endocut (e.g. Output 40W, effect 2 in ICC200; endocut I, effect 2, duration 2, interval 1 in VIO300D) or the coagulation mode (e.g. Forced coagulation, Output 40W in ICC200 or Forced coagulation, Output 40W, effect 3 in VIO300D). To achieve submucosal elevation, the glycerin solution or the mixture of hyaluronic acid solution and glycerin solution is injected with the injection needle or knife with the function of injection, as appropriate. Then continuing to dissect with prevention of perforation and hemorrhage, *en bloc* resection of the tumor is performed.

COMPLICATIONS

Perforation

Perforation following ESD for colorectal tumors can be fatal because peritonitis caused by colorectal bacteria and feces is known to be more severe than peritonitis occurring after gastric perforation.

The rate of perforation has been reported to be 1.4%-10.4% (Table 1). In our experience with perforations, there were no statistical differences regarding the location of the tumor, i.e. in the colon or in the rectum^[23]. Another report has revealed that perforation is associated with large tumor size (> 30 mm) and the presence of fibrosis^[17]. The rate of perforation of ESD is dramatically high when compared with that observed for EMR^[1-3]. One of the reasons for the high rate of perforations is the thinness of the colorectal wall as compared to the gastric wall. Knife coagulation is the most common cause of perforation^[23]. The paradoxical movement of the endoscope during ESD due to the winding nature of the colorectum causes coagulation in the muscularis propria. A longer operation time increases the amount of air in the abdomen, causing greater paradoxical movement of the endoscope. This situation is experienced specifically in tumors located in the cecum up to the descending colon. Obtuse short-tipped knives such as the Dual knife and the Flush knife can easily cause this type of perforation. In contrast, it is difficult to cause perforations while using the Hook knife because it enables us to hook and separate the submucosa from the muscularis propria and thereby cut safely. Rare

¹This study included mild hemorrhage cases which did not need endoscopic treatment. ESD: Endoscopic submucosal dissection.

reasons for perforation include resection by using a snare, coagulation by special hemostat forceps with soft coagulation, and endoscopic clipping onto coagulated submucosa^[23]. Further, endoscopic clipping is also performed when perforation is detected. Multiple endoscopic clipping is performed to close the perforation depending upon its size. Small perforations can be closed by endoscopic clipping^[24,25]. If abdominal distention due to air leakage is severe, decompression of the pneumoperitoneum must be performed using a 20-gauge puncture needle^[14]. The majority of cases with perforation are treated conservatively without emergency surgery. Recently, it has been shown that large perforations can be closed using a new closure device consisting of a clip with loop^[26]. On the other hand, there are cases in which perforation is not detected by endoscopy, but free air is detected by computed tomography (CT). The possible reasons for this are that small perforations cannot be detected during ESD or that very small perforations may occur during deep injection by the injection needle. However, these cases are generally not clinically serious because they can be successfully treated by withholding oral intake; no abdominal pain is typically detected after ESD.

Severe abdominal tympanic fullness, emphysema, and severe abdominal pain are possible symptoms of perforation. A high index of suspicion should be maintained when these symptoms are observed; moreover, the patient, nurse and physician should all watch out for these symptoms.

On the other hand, delayed perforation has been reported as a serious complication after ESD^[10]. The rate of delayed perforation is reported to be 0.3%-0.7%^[10,17,27]. The reasons for delayed perforation are unknown, but it is reported to be related to excessive coagulation in the muscularis propria. It has been reported that delayed perforations are typically large in size and require treatment by emergency surgery^[10,17,27].

The rate of perforation is reported to be decreased with the increased experience of the endoscopist^[8,9]. It is important to actively prevent perforations when the endoscopist does not have much experience with ESD. The indication of ESD according to endoscopist's skill, appro-

priate strategy of ESD and the choice of a suitable knife in each case is important in preventing perforations^[8].

Hemorrhage during ESD and postoperative hemorrhage

To prevent hemorrhage during ESD, when a vessel less than 2 mm in diameter is detected in the submucosa it is cut with a knife in the coagulation mode (e.g. Forced coagulation, Output 40W in ICC or Forced coagulation Output 40W, effect 3 in VIO300D). When a vessel more than 2 mm in diameter is detected, special hemostat forceps (e.g. Coagrasper; FD-410LR, Olympus Optical Co, Tokyo, Japan) are used in the soft coagulation mode (e.g. Output 50W in ICC; Output 60W, effect 5 in VIO300D) to prevent hemorrhage during ESD^[12]. These forceps can be rotated and they are used to gently catch and lift the vessels upward from the muscularis propria. In our institution, a unique use of the hemostat forceps has been adopted for resecting vessels. In brief, a vessel is coagulated using hemostatic forceps in the soft coagulation mode and then resected with the forceps in the endocut mode. Moreover, the coagulated submucosa surrounding the vessel is also resected with the forceps. Removing the coagulated vessel and the surrounding submucosa ensure that the subsequent submucosal dissection is safer and easier than otherwise (Figure 5A-D). When massive bleeding that cannot be stopped by the knife occurs during ESD, special hemostat forceps are used in the soft coagulation mode as described above. Endoscopic clipping is performed when bleeding cannot be controlled with the special forceps.

The rate of postoperative hemorrhage in ESD is reported to be 0%-12.0% (Table 1)^[8-17]. This rate is comparable to that reported for EMR^[1-3]. A study has reported the rate of postoperative hemorrhage to be 12.0%, including mild cases^[13]. Most cases of postoperative hemorrhage are treated only by endoscopic clipping and withholding oral intake without emergency surgery or blood transfusion.

Restlessness

Severe restlessness of the patient owing to abdominal fullness and pain have rendered submucosal dissection impossible in some cases. Conscious sedation is effective for some patients for the prevention of restlessness. Carbon dioxide insufflations have been reported to be effective for the prevention of abdominal fullness^[28]. In our institution, conscious sedation is performed with midazolam (Dormicum; Astellas Pharma Inc., Tokyo, Japan) and pentazocine (Pentajin; Daiichi Sankyo Co., Tokyo, Japan) with monitoring using an automatic blood pressure monitor. In our ESD study that included 105 cases, there were 22 patients for whom the operation time exceeded 2.5 h, and patient restlessness occurred in 15 out of these 22 cases (68.1%) despite conscious sedation. In contrast, in cases with an operation time less than 2.5 h, patient restlessness occurred in only 10 out of 83 cases (12.0%). Thus, restlessness due to abdominal fullness and pain occurs frequently in cases with an operation time exceeding 2.5 h. Therefore, according to our experience, ESD is indicated when the operation time is expected to be less than 2.5 h. On the other hand,

the use of propofol for conscious sedation extends the possibility of longer operation times than 2.5 h without causing restlessness and discomfort^[14]. However, this drug requires further examination before its standardized use in ESD procedures.

Other complications

Inflammation has been reported to a certain degree in some cases. In our previous report, the mean amount of C-reactive protein 2 d after ESD was 5.82 ± 12.10 mg/L in cases with perforation and 1.27 ± 2.00 mg/L in cases without perforation^[29]. Fever and abdominal pain were also reported without perforation. A rare complication was acute colon obstruction after ESD of a colonic tumor located at the cecal base^[30].

CASE PRESENTATION

We present here the case of a 71-year-old male with a tumor graded 0-IIa, measuring 20 mm, and located in the ascending colon (Figure 6A). The surface of the tumor was slightly depressed and the deformity of the colonic wall was detected with indigo carmine dye. Magnifying endoscopy revealed a V₁ pit pattern^[31]. The tumor was diagnosed as early colonic cancer with invasion up to the mucosa, and ESD was performed. Injection was first performed from the anal side of the tumor. However, the elevation of the tumor by injection was poor on the oral side of the tumor (Figure 6B). Therefore, either severe fibrosis or submucosal invasion was suspected. A mucosal incision was made and submucosal dissection was performed below the tumor using a Flush knife from the anal side of the tumor (Figure 6C). After that, a mucosal incision was made on the oral side of the tumor. Severe fibrosis was detected at the oral side of the tumor (Figure 6D). Then submucosal dissection was then performed with a Hook knife. However, owing to a thin submucosa, perforation was caused while hooking the submucosa (Figure 6E). Endoscopic clipping was performed minimally as the clipping did not prevent resection of the tumor, and the tumor was immediately resected using a snare. Then several endoscopic clippings were performed (Figure 6G). A small amount of free air was detected by abdominal CT after ESD. The patient had neither abdominal pain nor severe inflammation following surgery and was discharged 5 d after ESD. The resected specimen was fixed and the tumor was diagnosed by histopathological examination as early colonic cancer. The macroscopic tumor type was 0-IIa and the tumor was 20 mm in diameter. Invasion of the tumor was limited to the mucosa. Lymphatic and venous invasion was not detected. Lateral and vertical margins of the tumor were histopathologically free of the tumor (Figure 6F).

THE STANDARDIZATION OF ESD FOR COLORECTAL TUMORS

ESD is a feasible endoscopic treatment because of its

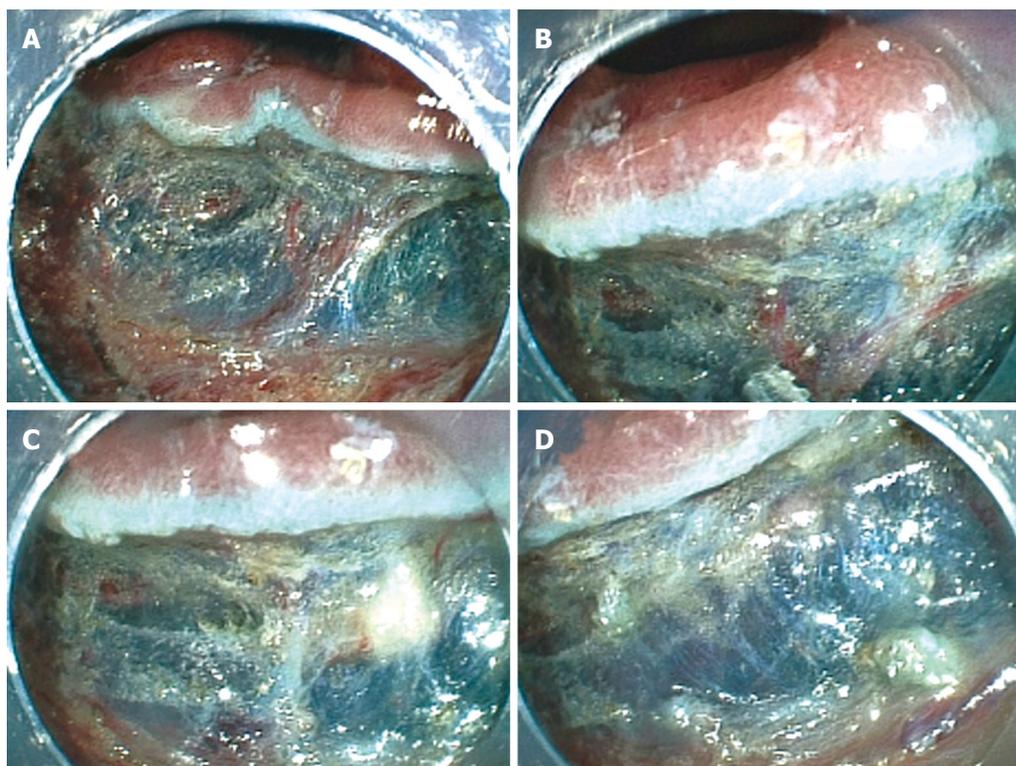

Figure 5 A unique use of hemostat forceps. A: Thick vessels were detected in the submucosa; B: The vessels were grasped by the hemostat forceps; C: The vessels and surrounding submucosa were coagulated and became whitish. The view of the submucosa was obscured; D: The coagulated vessels and submucosa were resected using the hemostat forceps, following which the view was restored.

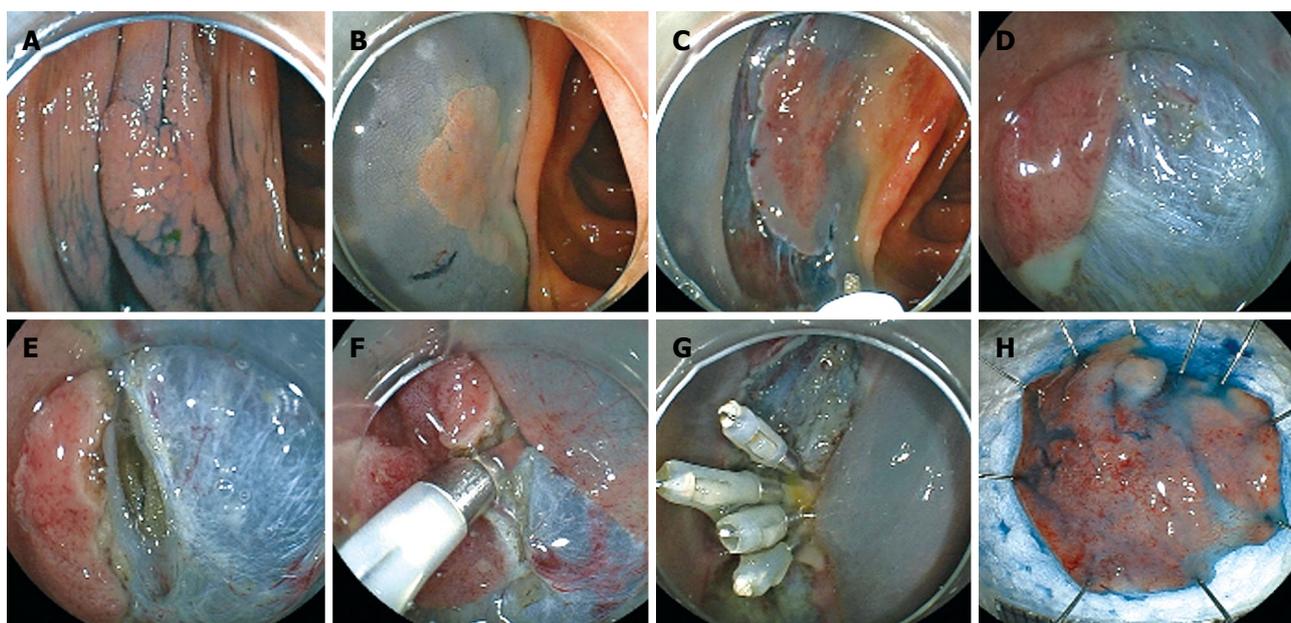

Figure 6 A case with perforation. A: The tumor in this patient was graded 0-II a, measured 20 mm, and was located in the ascending colon. The surface of the tumor was slightly depressed and the deformity of the colonic wall was detected with indigo carmine dye; B: Injection was performed on the anal side of the tumor. However, the elevation of the tumor following the injection was poor on the oral side of the tumor; C: Mucosal incision and submucosal dissection below the tumor were performed with the Flush knife from the anal side of the tumor; D: Mucosal incision on the oral side of the tumor was performed. Severe fibrosis was detected on the oral side of the tumor; E: Submucosal dissection was then performed with the Hook knife. However, owing to the thin submucosa, perforation occurred during hooking; F: Endoscopic clipping was performed minimally as clipping did not prevent the resection of the tumor; G: Several endoscopic clippings were performed after resection of the tumor; H: The resected specimen was fixed and the tumor was diagnosed by histopathological examination as early colonic cancer. The tumor was 20 mm in diameter. Tumor invasion was limited to the mucosa. Lateral and vertical margins of the tumor were histopathologically free of the tumor.

high rate of *en bloc* resection for large colorectal tumors. Hospitalization after ESD is less than that after LAC^[8,9,12]. However, ESD has disadvantages, with longer operation times and the possibility of perforation^[32]. In-

creased experience in the procedure can, however, solve these problems^[8,9].

Visits to other institutions with ESD experts and observation of such experts at work is an important compo-

ment of training in performing ESD procedures. Adequate practice at performing ESD may be obtained by using animal models. Systematic training systems for use of ESD in colorectal tumors are essential for the prevention of perforation and long procedure times. Acquiring experience in gastric ESD prior to attempting colorectal ESD is reported to be a safer way to prevent perforation^[8]. In our institution, EMR with circumferential mucosal incision has been used as training for ESD^[15]. Moreover, better devices that are particularly suitable for ESD, such as knives, endoscopes, and other new equipment, need to be designed for shortening the operation times and to prevent perforation^[33-36]. The indication of ESD should be decided according to the technique of the endoscopists in each institution. ESD for colorectal tumors is now improving, and a standardized method is expected to be developed in the near future. However, it is extremely important to diagnose the colorectal tumor correctly with suitable modalities, such as magnifying endoscopy; further, based on the diagnosis, the most appropriate methods of therapy should be considered, such as ESD, piecemeal EMR, and LAC.

CONCLUSION

In this review, we have assessed technical aspects and complications of ESD for colorectal tumors. For the standardization of ESD, it is most important to decrease the rate of perforation. Adopting a safe strategy of ESD and a suitable choice of knife are both efficient in the prevention of perforation. Moreover, appropriate training and increasing experience can improve the endoscopic technique and decrease the rate of perforation. We hope that standardization of ESD will be established in the near future, and that ESD will be performed in US and Europe where ESD is not widely adopted.

ACKNOWLEDGMENTS

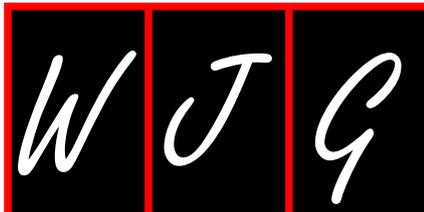

We thank all members of our department for support. We also thank Dr. Akio Yanagisawa for histopathological advice about ESD.

Abstract

Well-differentiated endocrine carcinomas of the small bowel are fairly rare neoplasms that present many clinical challenges. They secrete peptides and neuroamines that may cause carcinoid syndrome. However, many are clinically silent until late presentation with major effects. Initial treatment aims to control carcinoid syndrome with somatostatin analogs. Even if there is metastatic spread, surgical resection of the primitive tumor should be discussed in cases of retractile mesenteritis, small bowel ischemia or subocclusive syndrome in order to avoid any acute complication, in particular at the beginning of somatostatin analog treatment. The choice of treatment depends on the symptoms, general health of the patient, tumor burden, degree of uptake of radionuclide, histological features of the tumor, and tumor growth. Management strategies include surgery for cure (which is rarely achieved) or for cytoreduction, radiological interventions (transarterial embolization or radiofrequency ablation), and chemotherapy (interferon and somatostatin analogs). New biological agent and radionuclide targeted therapies are under investigation. Diffuse and non-evolving lesions should also be simply

monitored. Finally, it has to be emphasized that it is of the utmost importance to enroll these patients with a rare disease in prospective clinical trials assessing new therapeutic strategies.

INTRODUCTION

Neuroendocrines tumors (NETs) of the small bowel account for 23%-28% of all gastroenteropancreatic (GEP) NETs and about 2% of all gastrointestinal (GI) tumors. Incidence rates of 0.28 to 0.8 per 100 000 population per year have been reported^[1,2]. Their prevalence has increased in the last 3 decades as awareness and diagnostic techniques have improved^[3]. A recent study showed a significant increase in their reported annual age-adjusted incidence from 1973 (1.09/100 000) to 2004 (5.25/100 000) in the US population^[4]. Most of these tumors are well-differentiated and have an indolent course. As a consequence of the long delay between onset of symptoms and final diagnosis, many patients have advanced disease at the time

of diagnosis. Jejunio-ileal (JI) NETs originate from the diffuse endocrine system (enterochromaffin cells), located in the GI tract that may produce serotonin. Clinical and biological features are heterogeneous^[2]. This explains that classification is a critical point and is evolving. The recent World Health Organization (WHO) classification is based on clinical pathological criteria^[5]. The WHO classification subdivides JI NETs, similar to other GEP endocrine tumors, into 3 general categories^[5]: (1) well-differentiated endocrine tumor (carcinoid) of benign behavior (confined to the mucosasubmucosa, non-angioinvasive, < 1 cm in size) or uncertain behavior (non-functioning, confined to mucosasubmucosa, > 1 cm in size, or angioinvasive); (2) well-differentiated endocrine carcinoma (malignant carcinoma) with low-grade malignant behavior, deeply invasive (muscularis propria or beyond) or with metastases; and (3) poorly-differentiated endocrine carcinoma (small-cell carcinoma), high-grade malignant. However, because of its prognostic limits, a need for development of a TNM classification has been identified and such work is underway^[6]. A proposal for a TNM classification for tumors of the lower jejunum and ileum, where T1-4 describes the size of the tumor (with T2 tumors > 1 cm) and the depth of involvement of the intestinal wall, was discussed. Stage I comprises T1 tumors with limited growth. Stage II identifies tumors that are larger in size or more invasive, i.e. T2 or T3, but without metastases. Stage III encompasses tumors invading surrounding structures (III A), T4, or the presence of regional lymph node metastases (III B), whereas stage IV indicates distant metastases. In the proposal, a grading system is also included, in which the G1 tumor category has a mitotic count < 2 or Ki-67 < 2%, G2 tumors a mitotic count 2-20 or Ki-67 2%-20%, and G3 tumors mitotic count > 20 or Ki-67 > 20%. Clinical features of JI NETs are heterogeneous: they can either remain asymptomatic for years, or occur with obstructive symptoms, or with liver metastases diagnosed by abdominal computed tomography (CT) or magnetic resonance imaging (MRI) for other purposes, or as incidental terminal ileum tumors by colonoscopy, or less frequently occur with symptoms related to hormonal hypersecretion ("functioning tumors"). The term "carcinoid" should be reserved for a characteristic clinical syndrome that results from the intermittent release of serotonin and other substances, such as tachykinins, prostaglandins and bradykinins, into the systemic circulation that occurs in about 10%-20% of patient with JI NETs^[2]. Signs and symptoms of the carcinoid syndrome can include one or any of the following: flushing, diarrhea, carcinoid heart disease (CHD), and intermittent bronchoconstriction. These tumors are commonly metastases to the liver. Tumor size is an unreliable predictor of metastatic potential, and metastases can occur with primary tumors that are smaller than 1 cm in diameter^[7].

Survival of JI NETs correlates closely with the stage of the disease at presentation with a 5-year survival of 65% in patients with localized or regional disease and 36% in those with distant metastases^[8,9]. Pape *et al*^[10] reported

on 75 JI NETs, with more than 90% metastatic and 97% low-grade malignant; the 5-year survival rate was 90%. In addition, recent studies demonstrated the prognosis relevance of the WHO classification and the newly proposed TNM classification system for NETs^[10-13].

Treatment should be highly individualized based on the diverse range of symptoms, general health of the patient, tumor burden, degree of uptake of radionuclide, histological features, and tumor growth. Critical assessment of every treatment option is difficult because of the complexity, heterogeneity, and rarity of GEP NETs. There is a paucity of relevant randomized trials. However, some different groups (Nordic NE Tumour Group^[14,15], European Neuroendocrine Tumour Society^[9,16], National Comprehensive Cancer Network guidelines in the United States, Canadian National Carcinoid Expert Group^[17], United Kingdom NETwork^[18]) have recently published guidelines for the management of NETs. The treatment of carcinoid syndrome by somatostatin analogs is the first priority. Then the minimally required imaging studies and biochemical tests to decide any treatment include chromogranin A and urinary 5-hydroxyindoleacetic acid (5-HIAA)^[9]. Imaging studies are essential to localize the primary tumor as well as to guide management by staging, to monitor tumor growth, and for follow-up evaluation after therapy. The standard imaging procedures for JI NETs include abdominal ultrasonography, contrast-enhanced helical CT or MRI of the abdomen, pelvis and thorax, somatostatin receptor scintigraphy (SSRS), endoscopy, echocardiography, and bone scan or spine MRI to prove bone metastases if SSRS is negative^[9]. Capsule endoscopy and double balloon enteroscopy can be useful to detect the intestinal primary tumors^[9].

Management strategies include surgery for cure (which is rarely achieved) or cytoreduction, radiological interventions (by chemoembolization or radiofrequency ablation), chemotherapy and new biological agents, interferon, somatostatin analogs and peptide-receptor radionuclide therapy. Tumor growth is evaluated from clinical symptoms, repeated biological tests and imaging studies (every 3 to 6 mo), allowing decision-making between a curative treatment including aggressive treatment of metastatic disease, a palliative or symptomatic treatment, or a simple follow-up.

DIAGNOSIS AND TREATMENT OF CARCINOID SYNDROME

Presence of carcinoid syndrome, occurring in about 10%-20% of patients with JI NETs^[2], must be treated as a priority. Urinary 5-HIAA has a sensitivity of 73% and a specificity of 100% in predicting the presence of a carcinoid syndrome in the midgut area^[19]. 5-HIAA should be collected with strict dietary restrictions to avoid false positive levels. Somatostatin analogs remain the mainstay of symptomatic treatment for JI NETs. They could be started immediately in patients with inoperable disease or preoperatively in patients who have operable

disease (liver resection with or without resection of the primary tumor). They are administered subcutaneously every 6-12 h. Long-acting formulations require infrequent administration and have contributed to an improved quality of life for patients. To date, the most effective formulations include long-acting octreotide (10, 20 or 30 mg) and lanreotide autogel (60, 90 or 120 mg), which are widely accepted as effective in controlling tumor-related symptoms in about 50%-80% of patients and in reducing serum concentration of tumor markers by 40%-60%^[20]. These drugs are well tolerated and safe, with mild adverse effects and high tolerability after sustained use. However, tachyphylaxis and resistance to octreotide or lanreotide are known to occur. Toumpanakis *et al.*^[21] reported that in 17% of patients with loss of symptomatic response with the initial dose, symptoms were controlled by just an increase of somatostatin analogs dose, whilst the other patients required additional treatment (interferon, or transarterial hepatic embolization, *etc.*). Also, for all patients with a functioning carcinoid tumor, a potential carcinoid crisis should be prevented by prophylactic administration of octreotide, given by constant intravenous infusion at a dose of 50 mg/h for 12 h before and at least 48 h after surgery or other stress arising from invasive treatment (e.g. embolization, radiofrequency ablation)^[22]. A phase II trial, reported in 2005, aimed to examine the efficacy of a novel somatostatin analog, pasireotide (SOM-230), in 45 patients with carcinoid syndrome who were refractory to octreotide therapy^[23]. SOM-230 is a hexapeptide compound with 30 to 40 times higher binding affinity than octreotide to somatostatin receptors (SSR) subtype 1 and 5 and has a similar binding affinity to SSR 2^[24,25]. Treatment with SOM-230 was well tolerated except for a few episodes of hyperglycemia. This trial established a 27% rate of symptom improvement in patients who switched from octreotide to SOM-230. A 2-stage, randomized *vs* placebo, multicenter study of SOM-230 followed by SOM-230 LAR in patients with malignant carcinoid tumors whose disease-related symptoms are inadequately controlled by somatostatin analogs is currently underway (www.clinicaltrials.gov).

In addition to the presence of SSR, the expression of dopamine D2 receptors in GEP NETs has recently been studied^[26,27]. BIM23A760 is a new chimeric compound that selectively interacts with these receptors. The development of this drug is ongoing for the control of pituitary adenomas and Cushing's syndrome^[28,29] and a phase II study to assess the efficacy of this drug in patients with carcinoid syndrome is currently underway (www.clinicaltrials.gov). Another novel approach for the management of the carcinoid syndrome is LX1032, produced by Lexicon Pharmaceuticals. LX1032 is an orally bioavailable small molecule designed to inhibit peripheral serotonin synthesis^[30]. Its use in a phase 1 clinical study of 87 subjects has been reported by the European Neuroendocrine Tumors Society^[31]. A dose-dependent reduction in urinary 5-HIAA levels and whole blood serotonin concentration was observed. The development

of LX1032 continues in a phase II clinical trial (www.clinicaltrials.gov). Patients not responding to somatostatin analogs may also be candidates for other therapeutic measures, such as debulking surgery, hepatic embolization, and radiofrequency ablation^[32]. Other agents, such as loperamide or diphenoxylate for diarrhea and H1 or H2 blockers (or both) for histamine-secreting tumors may be administered as required.

Finally, patients with carcinoid syndrome should have an echocardiogram at diagnosis, permitting detection of cardiac involvement, which occurs in more than 50% of cases. The use of somatostatin analogs, titrated to manage symptoms or to normalize 5-HIAA levels, can help to prevent or minimize CHD, but CHD may continue to progress even if 5-HIAA is carefully controlled^[33]. If CHD develops, heart failure rather than metastatic disease may be the cause of death. Medical therapy for heart failure should be introduced when necessary. Cardiac surgery with valvular replacement should be considered for patients with symptomatic CHD, which can significantly increase survival^[34,35]. Cardiac surgery should be performed before major liver surgery or liver embolization.

ANTITUMOR TREATMENT

The aim of treatment should be curative whenever possible but is palliative in the majority of cases. These patients often maintain a good quality of life for a long period of time despite having metastases. Although the rates of growth and malignancy are variable, the aim should always be to maintain a good quality of life for as long as possible.

SURGICAL TREATMENT

The treatment of non-metastatic cases (stage I-III of the TNM classification) is based on a complete surgical resection to obtain a microscopic healthy margin (R0), the only way to significantly improve the 5-year survival rate^[3]. However, in cases of retractile mesenteritis, metastatic disease or peritoneal carcinomatosis, removal of the primary tumor should still be considered as this might prevent subsequent local complications of small-bowel obstruction or mesenteric ischemia^[9,36,37]. During laparotomy, a careful exploration of the entire abdominal cavity including the entire small bowel must be performed in order not to miss a second localization, which occurs in 30% of cases^[3]. This surgery requires a lymphadenectomy as wide as possible toward the mesenteric artery origin, associated with a prophylactic cholecystectomy because of possible future treatment with somatostatin analogs or future arterial embolization of hepatic metastases. No positive phase III studies in an adjuvant situation are available. Given the rarity of these tumors and the poor results of anti-tumoral treatment in metastatic disease (chemotherapy, interferon), these tumors only necessitate forward monitoring, except in cases of trial inclusion.

Only 15% of patients had unilobar or bilobar liver metastases without extrahepatic spread. These patients should be assessed for the possibility of aggressive approaches with curative surgical resection. The 5-year survival rate is around 60% in patients who undergo resection of liver metastases compared with 30%-40% in patients with unresected liver metastases^[38,39]. However, the recurrence risk is high, increasing from 55% to 84% within 5 years. Hepatic metastasis resection should be proposed for fit patients who have no extra-hepatic metastasis or tricuspid valve deficiency, and when complete resection of the primary tumor is possible. Concerning synchronous metastases, surgical management should be discussed according to several parameters including general health, number, size, and localization of liver metastases. Radiofrequency ablation can also be performed either before or during surgery^[40]. A 2-stage hepatectomy can be proposed in patients with liver metastases in both lobes. The first step associates the resection of the primary tumor with the resection of the left liver metastases (+/- radiofrequency ablation) and the ligation of the right branch of the portal vein. The second step consists of a right hepatectomy 4 or 6 wk later, when left liver hypertrophy is obtained: the hepatectomy can be extended to segment I and IV^[41]. As liver metastatic recurrences are nearly systematic in the course of the disease, major hepatectomy must be weighted against medical or isotopic therapy. In rare individuals such as young patients with no extra-hepatic metastasis and low Ki67, a liver transplantation may be proposed. The 5-year survival rate is about 45%, with a 5-year survival rate without recurrence of around 25%^[42].

Palliative resection should also be considered in patients who remain symptomatic despite the use of medical therapy if more than 90% of the tumor load can be removed, as this can achieve survival benefit and good symptom control^[16,38]. Liver metastasis cytoreduction can also be required in the case of a voluminous compressive mass (gastric compression).

RADIOLOGICAL TREATMENT

Hepatic artery embolization and transarterial chemoembolization

Many patients with JI NETs have liver metastases at the time of diagnosis, most of them being hypervascular. Selective hepatic trans-catheter arterial embolization (TAE) or chemoembolization (TACE) may be used to treat liver metastases in patients where surgery is not feasible. These modalities are effective in the control of symptoms and tumor growth. The intra-arterial injection of a cytotoxic drug, such as doxorubicin, streptozotocin, cisplatin or mitomycin C, is administered together with non-polar contrast^[43-47]. Embolization with gelatine sponge particles or microspheres is used until evidence of a marked decrease in blood flow. Although TACE has been used for 20 years, no current evidence exists that TACE is superior to TAE. TACE has been proved to be effective

in symptom relief in 63%-100% of patients^[43,44,48-51]. Long-term palliation can be achieved with repeated TACE sessions^[43]. Objective tumor response rates are noted in 33%-86% of patients^[43,44,48-51]. Median time to progression is about 15 mo; 5-year survival is about 50%^[40]. Contraindications for embolization are complete portal vein obstruction, liver insufficiency, and previous biliary reconstruction. Concomitant antibiotics and somatostatin analogs are used to avert a carcinoid crisis and diminish the possibility of hepatic abscess. Adverse events include a post-embolization syndrome (nausea, fever, elevated liver enzymes, and abdominal pain) which occurs in 90% of patients. Major side effects, including acute liver or renal failure, carcinoid crisis, cholecystitis, or bleeding peptic ulcers, occur in about 10% of patients. Treatment-related deaths are very rare. More recently, the radiocontrast agent lipiodol has become available with ¹³¹I instead of cold iodine, permitting embolization with radioactive material. Radioembolization using resin ⁹⁰Y-microspheres is also currently increasingly used. It can deliver high doses of radiation preferentially to hepatic metastases of NETs. In comparison to published reports of other local treatments of liver metastases from NETs, radioembolization shows a similar safety profile and improvement in debulking of tumor and survival^[52,53]. Another interesting modality of TACE is to use drug-eluting beads (DEBs). de Baere *et al.*^[54] reported in 20 patients that TACE plus DEBs loaded with 100 mg doxorubicin were well tolerated and appeared effective. This new procedure may increase the necrosis and reduce side effects from chemotherapy. Comparative studies with standard TAE, TACE, radioembolization and TACE with DEBs are warranted to define the best protocol for transarterial treatment of NET liver metastases. In addition, as not all patients are responsive to TAE or TACE, better selection criteria are still needed to obtain better responses to the procedure.

Radiofrequency ablation

Radiofrequency ablation has been used percutaneously or laparoscopically^[55], with some effect in reducing tumor size, but randomized trials are lacking. Response rates from 80% to 95% are reported. It may be indicated in patients with inoperable bilobar metastases in whom hepatic artery embolization has failed^[56]. Radiofrequency ablation can be used to reduce hormone secretion if at least 90% of the visible tumor can be destroyed or to reduce tumor burden. The main limitation for radiofrequency ablation is the size (only tumors < 3-5 cm in diameter should be treated) and number of tumors (less than 3-5 tumors should be treated per session), which are often small, and numerous in NETs. Radiofrequency ablation morbidity is low.

MEDICAL TREATMENT

Somatostatin analogs

Although the inhibitory effects of octreotide on hormonal secretion are well established, the effects on cell

proliferation and tumor growth are somewhat controversial. However octreotide has not yet been registered in any country as an antitumor agent. Their effects on tumor growth are limited: less than 5% of patients have objective radiological tumor regression, although 35%-70% of patients have stabilization of tumor size^[57-65]. The first placebo-controlled, double-blind, phase III study on the effect of octreotide LAR (long-acting release) in the control of tumor growth in patients with well-differentiated metastatic midgut NETs has been reported recently^[66]. The median time to tumor progression in the octreotide LAR and placebo groups was 15.6 and 5.9 mo (hazard ratio = 0.34, $P = 0.000072$), respectively. However, only a limited group of patients—those with less than 10% tumor mass in the liver along with resected primary tumors—responded to treatment^[67]. Therefore the effectiveness of octreotide LAR for control of growth in patients with a larger tumor burden is unproven. Also, we did not know whether patients had progressive disease at the beginning of the treatment. Another similar multicenter, placebo-controlled European Phase III study is currently underway to assess whether lanreotide autogel prolongs time to disease progression in patients with non functioning GEP-NETs (www.clinicaltrials.gov).

Interferon

Interferon- α is given for the same indications as somatostatin analogs, with the exception of carcinoid crisis. A biochemical response and symptomatic improvement could be noted in 40%-60% and 49%-70% of patients, respectively, whereas partial tumor size responses could be demonstrated in 10%-15%^[9,68,69]. The duration of response was 12 to 36 mo. Because of more pronounced side effects, interferon is generally used as second-line therapy for symptomatic control^[9]. Interferon, usually recombinant interferon- α , is given subcutaneously at 3-5 MU 3-5 times per week. A pegylated formulation, given once a week is available but not yet registered^[70]. Minor side effects include flu-like symptoms, weight loss and fatigue. Major side effects include autoimmune reactions, depression and mental disturbances. Bone marrow toxicity is usually mild as is hepatotoxicity, which can be managed by dose adjustments. There is no evidence that addition of interferon to somatostatin analogs increases the tumor response^[71,72]. However patients progressing on monotherapy of either drug may benefit from the addition of the other^[9].

Peptide receptor radionuclide therapy

Most JI NETs express SSR, especially subtype 2. Targeting these receptors with radiolabeled somatostatin analogs may not only be used for imaging, but also for radiotherapy. Since the early 1990s, different radiolabeled analogs have been used for tumor-targeted therapy. For metastatic disease with evidence of avid uptake on OctreoscanTM, radionuclide targeted therapies (for example, ¹³¹I metaiodobenzylguanidine, ⁹⁰Y or ¹⁷⁷Lu labeled soma-

tostatin analogs for peptide receptor targeted therapy) show promising results^[73]. Randomized studies of peptide receptor radionuclide therapy (PRRT) are lacking, making comparison of published data difficult. A symptomatic response in up to 80% of patients, a partial tumor response in up to 35% of patients and a disease stabilization in up to 56% of patients have been reported. Side effects are limited as long as radiation dose to the kidney and bone marrow are kept within dose limits; the use of kidney protection by co-infusion of amino acids (lysine and arginine) allows the administration of higher doses of the radiopharmaceuticals^[9]. The most recent data indicate a partial or complete response in 28% of patients with a median time to progression of more than 36 mo for Lutate^[74,75]. These radiopharmaceuticals are only available in a few centers. PRRT is recommended in SSRS-positive tumors in symptomatic patients refractory to medical treatment with inoperable disease.

External radiation therapy

Carcinoid tumors have often been regarded as being radioresistant. However, external beam radiotherapy is recommended for some brain and symptomatic bone metastases.

Traditional chemotherapy

Although pancreatic NETs seem to be moderately sensitive to systemic cytotoxic chemotherapy, well-differentiated JI NETs are generally considered to be chemoresistant. Single agents [5-fluorouracil (5-FU), doxorubicin, DTIC] and combinations (streptozotocin + doxorubicin or 5-FU) generally produce responses in less than 15% of patients^[76-79]. Dahan *et al.*^[80] reported no significant difference in progression-free survival and overall survival between interferon and 5-FU plus streptozotocin (even a trend in favor of interferon) in a phase III randomized trial in patients with metastatic carcinoid tumors. Based on the activity of dacarbazine and 5-FU in NETs^[81,82], there is a rationale for the study of the oral agents temozolomide, which is converted as dacarbazine into the active alkylating agent MTIC^[83-85] and capecitabine (an oral pro-drug for 5-FU)^[86]. Kulke *et al.*^[84] reported on the combination of temozolomide with thalidomide in a variety of NETs, documenting an objective response rate of 45% in pancreatic NETs *vs* only 7% in carcinoid tumors. Interestingly, the response to temozolomide-based therapy appeared to be correlated with O6-methylguanine DNA methyltransferase deficiency^[87]. Combining capecitabine and temozolomide may be an interesting association in patients with NETs^[88]. Oxaliplatin seems to be also an interesting drug in NETs^[86,89]. Even if some new drugs are coming, there is a general consensus that chemotherapy with agents available today is not recommended in patients with well-differentiated JI NETs^[9,36].

Angiogenesis inhibitors and other novel targets

Currently, there are a number of new drugs undergoing

evaluation in the clinic. These could be divided into 3 groups as follows: (1) drugs targeting vascular endothelial growth factor (VEGF), such as the VEGF monoclonal antibody bevacizumab and a more recent related compound, VEGF-trap; (2) small molecules that inhibit the intracellular tyrosine kinase domain of vascular endothelial growth factor receptor or other growth factor receptors, such as sunitinib, sorafenib, imatinib and valatinib; and (3) other compounds inhibiting different signaling pathway components such as epithelial growth factor receptor, insulin-like growth factor 1 receptor, phosphoinositide-3-kinase, RAC- α serine/threonine-protein kinase (AKT), and mammalian target of rapamycin (mTOR).

The first reported phase II trial of bevacizumab in NETs was performed in 44 patients with advanced carcinoid tumors. Patients were randomly assigned to 18 wk of treatment with either octreotide plus bevacizumab or octreotide plus pegylated interferon^[90]. At week 18, the progression-free survival rate was 96% in the group receiving bevacizumab *vs* only 68% in the group receiving pegylated interferon. Moreover, a rapid reduction in blood tumor perfusion measured by functional CT scan was demonstrated in the bevacizumab-treated patients. Based on the promising results in the bevacizumab study, a confirmatory randomized phase III trial is underway by the Southwest Oncology Group, comparing octreotide plus bevacizumab or interferon in advanced carcinoid tumors, with progression-free survival as the primary endpoint. The experience with bevacizumab in other solid tumors such as colorectal cancer has shown that its addition to chemotherapy can significantly improve outcome, whereas it has very little clinical activity as a single agent. The combination of temozolomide and bevacizumab has recently been reported in a small phase II trial with 0% of objective response rate in carcinoid tumors *vs* 24% in pancreatic NETs^[91]. Currently, different combination are ongoing: a phase I - II trial of FOLFOX plus bevacizumab in refractory carcinoid and pancreatic endocrine tumors in the USA; a phase II trial of capecitabine plus bevacizumab in chemotherapy-naïve patients with carcinoid tumors in France; a phase II trial of bevacizumab plus 2-methoxyestradiol (Panzem) in patients with locally advanced or metastatic carcinoid tumors (www.clinicaltrials.gov).

Similarly, a multi-institutional phase II study of sunitinib, a novel tyrosine kinase inhibitor with activity against VEGFR-1 to 3, PDGFR, FLT-3, c-Kit and RET, was also conducted among patients who had advanced NETs^[92]. In this trial on 66 patients with pancreatic NETs and 41 patients with carcinoid tumors^[92], the treatment was well tolerated and a partial response occurred in 11 (17%) of pancreatic NETs and 1 (2%) of carcinoid tumors. Rates of stabilized disease were high in both groups (68% in pancreatic NETs and 83% in carcinoid tumors). Raymond *et al*^[93] reported the first phase III randomized, double-blind study, with the efficacy of sunitinib given daily as a continuous dose *vs* placebo in patients with advanced islet

cell tumors. The median disease-free survival was 11.1 mo in the sunitinib group *vs* 5.5 mo in the placebo group. No similar phase III trial is ongoing for carcinoid tumors. In addition, a pending phase II trial will investigate the use of sunitinib after TAE in the treatment of NETs with liver-predominant metastases. The purpose of the trial will be to assess whether angiogenesis inhibition assists in prolonging the time to disease progression following liver embolization. Previously, use of sorafenib, an oral and multitarget agent with potent activities against VEGF-FGR-3, PDGFR-b, FLT-3, c-Kit and fibroblast growth factor receptor-1, has also been reported in 50 carcinoid tumors, but with more than 40% of grade 3-4 toxicity^[94]. Other trials testing different tyrosine kinase inhibitors are currently underway (e.g. vatalanib).

The third approach for new drugs has focused on inhibiting different signaling pathway components. For example, mTOR is an intracellular serine/threonine kinase that acts as a central regulator of multiple signaling pathways (IGF- I , EGF, VEGF) that participates in the regulation of apoptosis, angiogenesis, proliferation and cell growth through modulation of cell cycle progression^[95]. Two rapamycin derivatives have recently been evaluated in NETs: temsirolimus^[96] and everolimus^[97,98]. The results of a first phase II study combining everolimus (RAD001) at 5 or 10 mg orally daily and depot octreotide at 30 mg intramuscularly every 28 d in low-grade NETs have been recently reported^[97]. Of the 60 patients, there were 30 with carcinoids and 30 with islet cell carcinomas. Toxicities were mild to moderate, including those expected from everolimus such as stomatitis and myelosuppression. Tumor response rates were higher in the group with RAD001 at the 10 mg dose level *vs* the 5 mg dose level, and in the islet cell carcinoma (27%) *vs* the carcinoid tumor (17%) group^[97]. Tumor response was low, but control of disease was very promising (97% in the carcinoid tumor group). Based on these encouraging results, 3 large trials were sponsored by Novartis (RADIANT-1,-2,-3). RADIANT-1 is an open-label, stratified, single-arm phase II study of RAD001 in patients with advanced pancreatic NETs after failure of cytotoxic chemotherapy^[98]. Two further phase III, placebo-controlled, randomized trials in patients receiving depot octreotide recently closed: RADIANT-2 in patients with advanced carcinoid tumors and RADIANT-3 in patients with advanced pancreatic islet cell tumors. In contrast, interest in EGF receptor inhibitors, such as gefitinib, on carcinoid tumors seems to be poor^[99].

ALGORITHMS OF TREATMENT IN PATIENTS WITH JI WELL- DIFFERENTIATED ENDOCRINE CARCINOMAS

Recently, management algorithms have been proposed by several experts^[16-18,37,100]. Treating these tumors needs collaboration of different types of physicians including

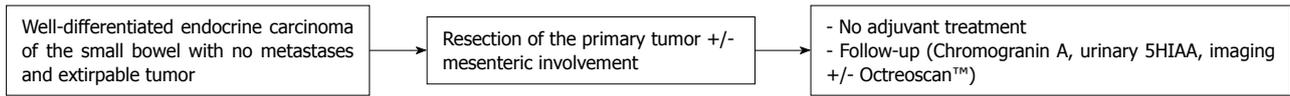

Figure 1 Management algorithm for patients with non metastatic well-differentiated endocrine carcinoma of the small bowel (stage I-III of TNM classification). 5HIAA: 5-hydroxyindoleacetic acid.

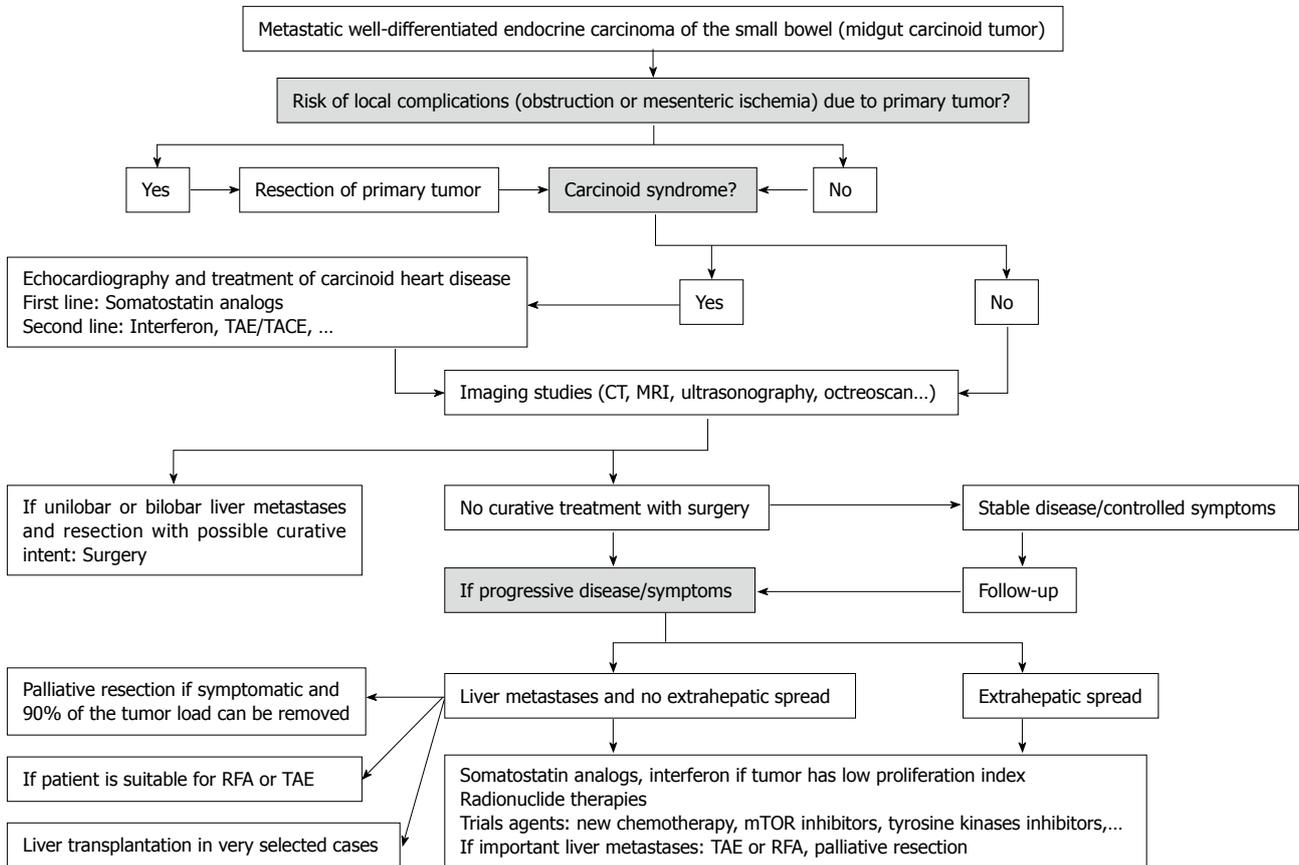

Figure 2 Management algorithm for patients with metastatic well-differentiated endocrine carcinoma of the small bowel (stage IV of TNM classification). TAE: Transarterial embolization; TACE: Transarterial chemoembolization; RFA: Radiofrequency ablation; mTOR: Mammalian target of rapamycin; CT: Computed tomography; MRI: Magnetic resonance imaging.

endocrinologists, gastroenterologists, oncologists, interventional radiologists, pathologist, and surgeons. Only a complete surgical resection permits cure of localized well-differentiated endocrine carcinoma of the small bowel (stage I-III of TNM classification). After curative surgery, there is no indication for medical therapy other than pre- and peri-operative somatostatin analogs to avoid a carcinoid crisis (Figure 1). The strategy for treatment of metastatic tumors (stage IV of TNM classification) is more complicated and varies depending on tumor spread, general health of the patient, predominant symptoms, and tumor growth (Figure 2). Somatostatin analogs remain the primary treatment for carcinoid syndrome. Since the PROMID study, they may be also considered for asymptomatic patients with low hepatic tumor load. TAE, TACE, radioembolization or TACE with DEBs are indicated for patients with non-resectable multiple metastases and persistence of carcinoid syndrome despite treatment with somatostatin analogs,

with the intention of reducing tumor size and hormone output. In patients with disabling carcinoid syndrome who are still refractory, interferon is frequently used in second-line treatment; the novel somatostatin analog SOM-230 could be useful in the near future for palliation of carcinoid syndrome^[101]. Perhaps the most promising avenue of research is the field of PRRT. Moreover, it is very probable that angiogenesis inhibitors and therapy targeting mTOR will become a new standard treatment for these vascular malignancies; however, as in pancreatic NETs with sunitinib, randomized phase III trials will be needed to demonstrate improvements in time to progression or overall survival.

CONCLUSION

Finally, the development of centers of excellence and NET clinical teams to coordinate multicenter studies, extend clinical and tissue databases, and ultimately develop

molecularly targeted therapeutics are needed to advance treatment and survival for patients with GEP NETs.

Abstract

Walled-off pancreatic necrosis (WOPN), formerly known as pancreatic abscess is a late complication of acute pancreatitis. It can be lethal, even though it is rare. This critical review provides an overview of the continually expanding knowledge about WOPN, by review of current data from references identified in Medline and PubMed, to September 2009, using key words, such as WOPN, infected pseudocyst, severe pancreatitis, pancreatic abscess, acute necrotizing pancreatitis (ANP), pancreas, inflammation and alcoholism. WOPN comprises a later and local complication of ANP, occurring more than 4 wk after the initial attack, usually following development of pseudocysts and other pancreatic fluid collections. The mortality rate associated with WOPN is generally less than that of infected pancreatic necrosis. Surgical intervention had been the mainstay of treatment for infected peripancreatic fluid collection and abscesses for decades. Increasingly, percutaneous catheter drainage and endoscopic retrograde cholangiopancreatography have been used, and encourag-

ing results have recently been reported in the medical literature, rendering these techniques invaluable in the treatment of WOPN. Applying the recommended therapeutic strategy, which comprises early treatment with antibiotics combined with restricted surgical intervention, fewer patients with ANP undergo surgery and interventions are ideally performed later in the course of the disease, when necrosis has become well demarcated.

INTRODUCTION

Since the first interdisciplinary symposium on acute pancreatitis in Marseille in 1964 remarkable progress has been gained in creating a uniform classification system for the variable clinical features of this disease. The most important and frequent definitions in terms of pancreatic infection are as follows: (1) Pancreatic infection: the presence of microbes including bacteria or fungi overgrowing the pancreas or the peripancreatic space and causing pathologic changes. Pancreatic infection usually occurs secondary and time-dependently to acute pancreatitis. This definition includes infected necrosis, pancreatic

abscesses and infected pancreatic pseudocysts; (2) Infected necrosis: intrapancreatic or extrapancreatic necrosis with a positive smear or culture for bacteria or fungi. Usually no major collection of pus is present; (3) Pancreatic abscess: a localized collection of purulent material with little or no necrosis in the region of the pancreas, which is delineated by a wall of collagen and granulation tissue; and (4) Infected pancreatic pseudocyst: a localized collection of infected fluid in the region of the pancreas and, like an abscess, also walled off by a membrane of collagen and granulation tissue. Usually the presence of bacteria or fungi is of no clinical significance and represents contamination only. There may be communication with the pancreatic ductal system; pus or necrosis is generally not found^[1]. The term “Walled-off pancreatic necrosis (WOPN)” was first introduced by Connor *et al*^[2] in 2005. This term was officially established later, on the 2006 Digestive Disease Week during the American Gastroenterological Association Clinical Symposium, “Problems and Pitfalls of Atlanta Classification for acute pancreatitis: American Gastroenterological Association, American Pancreatic Association and International Association of Pancreatology to revisit,” chaired by Dr. Peter Banks^[3]. WOPN, formerly known as pancreatic abscess is uncommon and usually occurs in the setting of pancreatitis, usually in complicated cases of pseudocysts or sterile pancreatic necrosis. Infections outside this setting are extremely uncommon but they have been reported to occur with perforation of the bowel into the pancreas^[4] or splenic parenchymal involvement^[5]. It embodies a quite late complication of pancreatitis, chronic or acute, commonly, after the formation of pseudocysts. In pancreatitis, enzymes can be walled off by granulation tissue, by developing pseudocysts or *via* bacterial seeding of pancreatic or peripancreatic tissue, leading to development of WOPN^[6]. Even if WOPN constitutes 1%-9% of all acute pancreatitis complications, it still remains a lethal surgical entity, which can be alleviated through early detection and application of the indicated therapeutic measures^[7]. The aim of this article is to review WOPN, its etiology, epidemiology, clinical features, diagnosis and new clues, as they are presented, in the latest articles of the literature.

EPIDEMIOLOGY

In the US, the incidence of pancreatitis is approximately 185 000 cases per year. At least 80% of cases are due to alcohol and cholelithiasis, and all the rest are associated with other triggering conditions, as illustrated in Table 1. Acute necrotizing pancreatitis (ANP) is reported by some to occur in approximately 20% of all episodes of pancreatitis. Although sterile necrosis may occur, a variable percentage develops infection of the necrotic tissue. Bacterial contamination of the necrotic pancreas occurs in as many as 70% of cases, and the mortality rate approaches 100% if surgical intervention and drainage are not undertaken for WOPN. A difference in the rate of WOPN formation between men and women has not been clearly demonstrated^[8,9]. WOPN

Table 1 Etiology of pancreatitis

Biliary tract disease	Obstruction of the pancreatic duct at the level of the ampulla of Vater
Excessive alcohol consumption	Direct toxic effect
Hyperlipidemia	Restricted blood flow (atherosclerotic emboli, hypoperfusion, vasculitis) results in ischemic disturbance to the acinar structures and an increasingly acidic environment
Hypercalcemia	Induces pancreatic injury <i>via</i> a secretory block, accumulation of secretory proteins and possibly activation of proteases
Hereditary	Cationic trypsinogen mutations
Trauma	Acute release of toxic factors (resulting from inflammatory response) into the systemic circulation
Ischemia	Similar to hyperlipidemia
Pancreatic duct obstruction	Similar to biliary tract disease
Viral infections	Mumps or cytomegalovirus
Scorpion venom	Direct toxicity
Idiopathic	Develops without readily identifiable cause
Drugs	Frequently 6-Mercaptopurine Azathioprine Corticosteroids Synthetic estrogens Furosemide Mesalamine Methyldopa Sulphonamides Tamoxifen Occasionally Asparaginase Chlorothiazide Cisplatin Hydrochlorothiazide Interferon- α Sulindac Tetracycline Valproic acid

occurs in 1%-9% of the cases of acute pancreatitis, usually 4 to 6 wk after the initial episode and is heralded by pain, fever and chills^[10]. The mortality rate of ANP (about 25% of acute pancreatitis) has been reported to be between 10% and 30%^[7,11].

ETIOLOGY-PATHOPHYSIOLOGY

ANP is the most severe end of a spectrum of inflammation associated with pancreatitis. During the past decade, significant progress has been achieved in our understanding of the inflammatory response in pancreatitis^[12], see also Table 1^[13-24]. By contrast, very little is known about the mechanisms mediating another major pathologic response in pancreatitis, the parenchymal cell death. In experimental models of acute pancreatitis, acinar cells have been shown to die through both necrosis and apoptosis^[25]. The apoptosis/necrosis ratio varies in different experimental models of pancreatitis. Of note, the severity of experimental pancreatitis directly correlates with the extent of necrosis and inversely with that of

apoptosis^[26]. Inflammation causes cell death with resultant devitalized tissue, which is likely to become infected. The amount of necrotic tissue is the strongest predictor of mortality in ANP. After pancreatic necrosis occurs, 3 potential outcomes exist, resolution, pseudocyst, or WOPN. Pseudocysts may result in prolonged abdominal pain, rupture leading to acute peritonitis, fistula formation, and erosion into vessels with acute hemorrhage^[27,28]. Pancreatic ascites or pleural effusion may be developed. Pseudocysts or WOPN may also cause hollow viscus obstruction by compression of surrounding structures, including the colon, stomach, duodenum and the common bile duct. The role of proinflammatory cytokines in this process is being vigorously examined^[27]. WOPN forms through various mechanisms, including fibrous wall formation around fluid collections, penetrating peptic ulcers, and secondary infection of pseudocysts. A pseudocyst arises as a local complication of ANP. Over a period of 3–4 wk, sequestration of necrotic tissue occurs, forming a fibrous capsule without an epithelial lining. At any point after the initial injury in ANP, infection of necrotic tissue may occur, leading to WOPN development. When this occurs prior to the formation of the fibrous wall, it is termed infected necrosis. WOPN can be located in single or multiple locations and vary greatly in size^[3]. Of note, pseudocyst formation is directly related to the degree of necrosis present. Approximately 3% of patients with acute pancreatitis develop WOPN. Baltazar and Ranson's radiographic staging criteria predict the formation of pseudocysts and, therefore, WOPN development. Grade A: normal pancreas; Grade B: focal or diffuse enlargement; Grade C: mild peripancreatic inflammatory changes; Grade D: single fluid collection; Grade E: two or more fluid collections or gas within the pancreas or within peripancreatic inflammation. In grade A, B, C, or D, the probability of WOPN development is less than 2%. With grade E disease (2 or more collections of peripancreatic fluid), the probability rises to 57%^[29]. WOPN should be distinguished from infected pancreatic necrosis in that little or no necrotic material is present. WOPN also typically appears later in the course of pancreatitis, often 4 wk or more after the start of the attack^[30].

PRESENTATION

Diagnosed pancreatitis with an unexpectedly prolonged course, hemodynamic instability, fever, failure of medical therapy, or the presence of fluid collections on a computed tomography (CT) scan all point to the possibility of necrosis and, potentially, WOPN later in the course. Abdominal pain with or without a mass on palpation of the epigastrium is suggestive of parietal peritoneal irritation. Classic physical examination findings, such as Grey-Turner sign or Cullen sign, are supposedly characteristic of pancreatitis but rarely are noted in clinical practice. Other physical findings are nonspecific and include abnormal vital signs consistent with sepsis, abdominal

guarding, and rebound tenderness^[31]. Peripancreatic fluid encased in a fibrinous capsule defines pseudocysts. Superinfection of pseudocysts is one way that WOPN may be developed, even if pseudocysts are not a prerequisite. Evidence suggests that colonic translocation of bacterial flora accounts for many cases of local infected fluid formations^[32]. The most typical organisms isolated from infected necrosis and abscesses are gut flora-associated and *Candida spp*^[33].

DIAGNOSIS

No specific hematologic studies define WOPN. A persistently elevated white blood cell count with a left shift and positive blood cultures is suggestive of this diagnosis. The degree of pancreatic enzyme elevation does not directly indicate the degree of necrosis^[34]. The presence of air in necrotic tissue in a pseudocyst on imaging studies is also specific for infection. Abdominal CT scan with IV contrast; ultrasound, either endoscopic or transabdominal; and magnetic resonance imaging (MRI) (with gadolinium) are potential modes for imaging pancreatic necrosis or abscess^[35]. MRI is becoming the imaging study of choice because of concerns regarding the use of iodinated contrast, which is said, by some, to devitalize marginal tissue, increasing the burden of necrotic tissue. The current criterion standard for initial evaluation is contrast-enhanced CT scan, which may reveal ischemic pancreatic tissue as evidenced by the lack of uptake of contrast. Contrast-enhanced CT scan (and in particular a contrast-enhanced thin-section multidetector-row CT scan) is the best imaging technique to exclude conditions that masquerade as acute pancreatitis, to diagnose the severity of acute pancreatitis, and to identify complications of pancreatitis^[35-37]. MRI may be of some additional benefit in the acute evaluation of ANP; gadolinium does not cause a worsening of ischemia in experimental models^[38]. Demonstrable necrotic tissue in the pseudocyst may exist. Typically, this develops more than 3 wk after the initial bout of pancreatitis^[39]. The presence of either bacterial or fungal flora in pancreatic fluid collections usually aspirated *via* CT-guided needle biopsy is the sine qua non of WOPN. The presence of organisms either on Gram stain or culture is essential for WOPN.

TREATMENT

Generally, medical care is supportive, with attention paid to blood pressure and volume status. Patients frequently are transiently bacteremic, so antibiotics are routinely administered. The choice of antibiotics is thoroughly guided by the likely flora and degree of antibiotic penetration into the locations of WOPN and the other necrotic tissue. The most commonly isolated bacteria in WOPN are gut flora, by means of translocation^[40]. The most common pathogens are *Escherichia coli*, *Klebsiella pneumoniae*, *Enterococcus faecalis*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Proteus mirabilis* and *Streptococcus spp*^[41]. In

several trials, imipenem^[42] has been shown to have good penetration into pancreatic tissue, and it has a good activity against all likely pathogens^[43]. Other antibiotics that have been shown to be efficacious in ANP include cefuroxime^[44] and a regimen of ceftazidime, amikacin and metronidazole^[45]. It must be emphasized that the ultimate treatment for WOPN is complete removal by surgical resection or drainage^[46]. Primary drainage is the treatment of choice for WOPN. Cases of WOPN have been reported of treatment, in which death has not resulted; however, the standard of care is drainage involving an open procedure^[47]. Case series have been reported of WOPN patients, who have been treated with CT-guided drainage tube placement, but these seemed to show inferior results to open drainage^[48]. Recent advances in endoscopic treatment using endoscopic ultrasound (EUS) have made guided transgastric treatment of the complications of ANP possible^[49]. EUS-guided necrosectomy has been promising to date. The introduction of formal widespread pancreatic and peripancreatic necrosectomy with a following procedure to manage the peripancreatic space, allowing continued drainage and debridement, has markedly decreased the mortality associated with infected necrosis. In specialized centers, this is rapidly becoming the treatment of choice^[50]. CT-guided drainage has a role in some patients, who cannot tolerate an open procedure. EUS with trans-gastric drainage is another option. Consideration can be given to medical management of nonsurgical candidates until their clinical status improves^[51]. Other forms of aspiration, including endoscopic drainage of WOPN, are currently being investigated, with controversial results^[3,52,53]. Surgical drainage of WOPN is the procedure for cure. Placement of indwelling drains after the initial procedure may be necessary for complete resolution^[54,55]. Nil *per os* or a jejunal feeding tube is initially recommended for ANP; however, no contraindication for enteral feeding exists if the pancreatitis has resolved. If the course is prolonged, the institution of total parenteral nutrition can be of benefit^[56]. Antibiotics are the primary medical therapy in WOPN, used for the control of bacteremia and sepsis. Supportive care with fluids is needed, and the use of vasopressors may be required, in hemodynamically unstable patients. Overall, it can be presumed that WOPN is an entity that can lead to several complications such as fistula formation, recurrent pancreatitis, bowel obstruction or death. Studies, including the present review based on retrospective observations, have demonstrated that non-operative management has been associated with a favorable outcome in patients with this dreaded complication^[57]. If bacteremia and sepsis can be restrained with prolonged antibiotic therapy along with antifungal agents, the need for necrosectomy associated with high morbidity and mortality in these patients can be avoided. Applying the recommended therapeutic strategy, which comprises early application of antibiotics combined with restricted indication for surgical intervention, fewer patients with ANP undergo

surgery, and the interventions are performed later in the course of the disease, ideally when necrosis has become well demarcated^[58]. Endoscopic sphincterotomy plays a role in patients with a dilated common bile duct from an impacted stone at risk of impending cholangitis. Surgery in acute pancreatitis is used for cholecystectomy in the patient with gallstone pancreatitis, as well as for infected pancreatic necrosis, WOPN, pseudocysts and traumatic pancreatitis with a ruptured duct system^[7,59].

CONCLUSION

Today, treatment of acute pancreatitis is mainly conservative and surgery is on the retreat. Infection of pancreatic necrosis is still the main risk factor of morbidity and mortality in the course of necrotizing disease. A prophylactic treatment with antibiotics can reduce both infectious complications and mortality. Thus, antibiotics should be administered in severe pancreatitis. If pancreatic infection is suspected, fine needle aspiration should be performed. Today, WOPN is a well accepted indication for open surgery, when minimal invasive treatment is not efficient^[60]. Natural orifice transluminal endoscopic surgery (NOTES) has emerged as an innovation in endoscopic access that allows incisionless surgery. Integral techniques used in NOTES have developed in part through advances in endoscopic retroperitoneal access to pancreatic pathology over the past 2 decades. In 2004, Kalloo *et al*^[61] described peroral endoscopic access to the peritoneal cavity for a liver biopsy, reporting a new access technique for surgical procedures. In actuality, transluminal endoscopic access by Kozarek *et al*^[62] was well documented as early as 1985 for the treatment of pancreatic pseudocysts. A study^[23] reviewing the senior author's (Gary C Vitale) 15-year experience with natural orifice transluminal endoscopic retroperitoneal access for the drainage of pancreatic abscesses showed that the optimal approach to pancreatic abscess drainage has yet to be studied by a randomized controlled trial, but the literature demonstrates that endoscopic therapy has greatly reduced morbidity and mortality rates compared with surgery.

The natural orifice transluminal approach to pancreatic fluid collections has evolved to address complicated cases that previously would have necessitated surgery^[23]. The development of EUS has expanded the safety and efficacy of this modality by allowing one to access and drain more challenging fluid collections^[7]. The aim of the surgical procedure is to remove the septic focus by debridement of the infected pancreatic and peripancreatic necrosis^[3]. The optimal timepoint for the surgical intervention is when necrotic tissue is well demarcated. Therefore bleeding complications and removal of vital tissue can be avoided. Today, surgical procedures should combine the necrosectomy with a postoperative method to continuously remove necrosis and debris. This is the case with the following 2 techniques: postoperative continuous lavage and closed packing. Fulminant acute pancreatitis is a rare subgroup of acute pancreatitis,

characterized by a rapidly progressive multiple organ failure in the first days following the onset of the disease with a high probability of death despite intensive care unit therapy. There is a poor outcome with both, surgical and conservative therapies. Thus, surgery should only be performed as a last resort^[63]. If left untreated, WOPN precipitates to sepsis and death. Adequate drainage of a pancreatic pseudocyst may help prevent some cases of WOPN. However, in many cases the disorder is not preventable^[64]. Until now, there are no official established guidelines for the treatment of WOPN. That is a major consideration for the future.

Abstract

Colorectal neuroendocrine tumors (NETs) originate from neuroendocrine cells in the intestinal tract, and represent a small area within oncology, but one which has provided increasing new data during the past years. Although the World Health Organization has determined clinical and histological features to predict prognosis for such tumors, they may not be valid on an individual basis. We aim to give an overview of the recent findings with regard to pathology, molecular genetics and diagnosis of NETs.

INTRODUCTION

Neuroendocrine (NE) cells are distributed throughout the human body, including the gastrointestinal (GI) tract, pancreas, lung, thyroid, adrenal gland and many other organs^[1-4]. The GI tract has the largest population of NE cells^[5]. However, neuroendocrine tumors (NETs) of the colon and rectum are rare. Results from analyses of the Surveillance, Epidemiology and End Results database demonstrated that the age-adjusted incidence of carcinoids of the small intestine and digestive system has increased by 460% and 720%, respectively, in the past 30 years due to, at least in part, the improvements in diagnostic technology such as endoscopy, as well as doctors' increased awareness^[6]. In 2003, Modlin *et al*^[7] reported that the incidence of NETs in the GI tract was 2.5-5 cases per 100 000 population annually. Males are more often affected than females, with a proportion of 1.8:1^[8]. In the large intestine, NETs are more commonly found in the rectum (54%), then in the cecum (20%), sigmoid colon (7.5%), rectosigmoid colon (5.5%) and ascending colon (5%)^[9].

Colon NETs usually appear as large tumors and often already have regional lymph nodes or liver metastasis at the time of diagnosis, therefore the prognosis is poor. On the other hand, NETs occurring in the rectum are often diagnosed incidentally during colonoscopy, therefore they are typically small, localized, non-functioning tumors with rare metastasis, probably as a result of early detection^[6,8,10,11].

CLASSIFICATION

Colorectal NETs are traditionally classified as typical

Table 1 Classification of NETs of the colon and rectum^[14,15]

Well-differentiated neuroendocrine tumor (carcinoid)
Benign: Non-functioning, confined to mucosa-submucosa, non-angioinvasive, < 1 cm in size (ileum) or ≤ 2 cm colon and rectum
Serotonin-producing tumor
Enteroglucagon-producing tumor
Benign or low-grade malignant (uncertain malignant potential): non-functioning, confined to mucosa-submucosa, angioinvasion, or < 1 cm in size (ileum) or ≤ 2 cm colon and rectum
Serotonin-producing tumor
Enteroglucagon-producing tumor
Well-differentiated neuroendocrine carcinoma (malignant carcinoid)
Low-grade malignant: invasion of the muscularis propria and beyond or metastases
Non-functioning or functioning serotonin-producing carcinoma (with carcinoid syndrome)
Non-functioning enteroglucagon-producing carcinoma
Poorly-differentiated neuroendocrine carcinoma
High-grade malignant

NETs: Neuroendocrine tumors.

carcinoid, atypical carcinoid and undifferentiated cancer according to the differentiation of the disease^[12,13]. The term carcinoid can no longer characterize the entire morphologic and biologic spectrum of neoplasms of the disseminated NE cell system. The updated World Health Organization (WHO) classification of 2000 adopted the neutral and inclusive terms, tumor and carcinoma. In this classification, it is clearly explained how to characterize well-differentiated NETs (benign behavior or uncertain malignant potential), well-differentiated NE carcinoma (low-grade malignancy), and poorly-differentiated NE carcinoma of high-grade malignancy [small cell carcinomas (SCCs)]^[14,15]. The morphologic/biologic criteria including tumor size, angioinvasion, proliferative activity, histological differentiation, metastasis, invasion, and hormonal activity (association with clinical syndromes or diseases) have also been added (Table 1).

Well-differentiated NE tumor was referred to as typical carcinoid historically, and well-differentiated NE carcinomas were termed atypical carcinoid. Although this framework is helpful, lesions of uncertain behavior are poorly defined. In the WHO classification, SCC is synonymous with the term “poorly-differentiated NE carcinoma”, but there is no clear differentiation between large cell NE carcinomas (LCNECs) and mixed endocrine-glandular neoplasms. No coincident repeat diagnosis could be made by different pathologists or by different institutions, although the WHO classification of colorectal NETs has been used for several years. The main reason is that the WHO classification has not been closely adhered to^[1]. Pathological recognition of these tumors is critical, as the treatment strategy, particularly chemotherapy for a particular subtype, largely depends on the underlying pathology^[16,17].

Well-differentiated NE tumor-carcinoid

Colorectal carcinoids account for approximately 6% of

all GI NETs, often accompanied by chronic inflammatory disease such as ulcerative colitis or Crohn's disease. The tumors are usually multiple when complicated by these diseases^[18]. In Crohn's disease, the incidence of carcinoids may increase, by a recent estimation of 15-fold^[19,20]. In most instances, colorectal carcinoids present without obvious signs or symptoms and remain undetectable for years^[8]. Most of the diagnoses are made incidentally at the time of surgery for other abdominal disorders. Their relatively high incidence in large autopsy series has provided evidence for this observation^[21].

The tumors with NE differentiation have classical histological architecture of trabecular, insular, or ribbon-like cell clusters, and have no or minimal cellular pleomorphism and sparse mitoses^[8,22,23]. Colorectal carcinoids display moderate neurofilament staining. They stain positive for chromogranin A (CgA) in more than 70% of cases, positive for neuron specific enolase (NSE) in more than 50% of cases, and prostatic acid phosphatase is expressed in 80%-100% of cases. However, the staining pattern is variable^[8]. Other markers such as synaptophysin (Syn), somatostatin, 5-HT, or CD56 may be present as well. The Ki-67 index is higher in carcinoids of a size more than 5 mm, as compared to those sized less than 5 mm in diameter^[24].

Rectal carcinoids are usually discovered incidentally during colonoscopy examinations. The tumors are usually small, non-functional and without regional or distant metastasis^[25,26]. The 5-year overall survival rate of patients with rectal carcinoids is 88%. However, the prognosis of colon carcinoids is worse than that of its rectal counterpart^[8,10,26,27]. There are data showing that there is a high frequency of combined adenocarcinoma and NETs in the proximal colon^[28,29]. Perhaps this is one of the reasons explaining the worse prognosis in colon carcinoids than for their rectal counterpart.

Well-differentiated NE carcinoma-malignant carcinoid

Malignant carcinoid was termed as atypical carcinoid, historically. Only a few cases have been reported as malignant carcinoid of the large intestine due to uncertainty of its definition.

Well-differentiated NE carcinomas have histological features and a biological behavior that fall between well-differentiated NE tumors and poorly-differentiated NE carcinomas^[8]. These are aggressive lesions and represent forms poorly differentiated from carcinoid with increased mitotic activity and presence of necrosis. Mitoses range from 1 to 10/10 high power field (hpf). The presence of necrosis serves as an important character of malignant carcinoid^[8,30,31]. The cells range in appearance from uniform, large, polygonal, or fusiform types with abundant eosinophilic granular cytoplasm and round to oval nuclei similar to the cells seen in typical carcinoid, to pleomorphic cells with scanty cytoplasm and hyperchromatic variably sized and shaped nuclei^[32]. The tumors are nonargentaaffinic but strongly argyrophilic and they are

stained with the usual immunohistochemical markers of NE cell differentiation.

There are few reports of the clinical outcome of colorectal malignant carcinoids. It has been reported, however, that a patient with an atypical carcinoid of the lung has a significantly worse prognosis than those with typical carcinoids^[33,34].

Poorly-differentiated NE carcinoma (small cell carcinoma)

Colorectal SCCs constitute 0.2%-0.8% of all colorectal tumors, mostly located in the right colon^[1,35]. They are clinically aggressive; therefore have extremely poor prognosis, even when diagnosed at an early stage. Most patients present with overt distant metastases. Sometimes they are discovered in the background of colon inflammatory diseases, or in the background of NE cell proliferation^[36,37].

Colorectal SCCs are identical to lung SCCs morphologically. These small blue cell tumors present the character of densely packed, small, and oval-, spindle-, fusiform-shaped anaplastic cells with minimal amounts of cytoplasm and granular nuclear chromatin. The size of the nuclei measures approximately twice the size of mature lymphocytes^[38]. Solid sheets, nests, and rosettes as well as ribbon-like structures composed of small cells and intermediate cells form, which all exhibit more than 10/10 hpf mitoses^[1].

In cases with classic histological features, it is unnecessary to demonstrate NE differentiation to establish the diagnosis. However, further analysis may be necessary in puzzling cases. SCCs typically express CgA, Syn, NSE, and CD56 by immunohistochemistry. Pan cytokeratin (AE1/AE3) and low molecular weight keratin are also reported to be positive in all SCCs^[1,39]. Shida *et al.*^[40] reported that 70% of GI SCCs expressed human achaete-scute homologue gene-1 protein (hASH1), which is usually absent in normal GI NE cells, carcinoid and adenocarcinoma. The sensibility and specificity of hASH1 is better than other classic markers, such as CgA and Syn, and this protein may serve as a new biomarker for GI SCC diagnosis. There are also some reports demonstrating that cytokeratin is positive in these tumors and the Ki-67 index beyond 75% is often seen in SCCs^[1].

As mentioned above, the prognosis of patients with GI SCCs is usually extremely poor. Most patients present with regional or overt distant metastases. Up to 80% of patients already have regional lymph nodes and/or distant metastases at the time of diagnosis^[41]. When tumor size is larger than 5 cm, the median survival time for patients is usually less than 4 mo, and the median survival of those with smaller tumor is around 12 mo^[1].

LCNEC

LCNECs are rare, poorly-differentiated NE carcinomas. LCNECs are amongst the worst studied group of colorectal NETs and their diagnostic criteria are briefly described in many standard texts^[14]. The features of these tumors are similar to their counterpart in the

lung^[42]. They are malignant neoplasms composed of large cells structured in organoid, nested, trabecular, rosette-like, and palisading patterns that suggest NE differentiation. Compared to SCCs, LCNECs have more cytoplasm, nuclei are more vesicular, and nucleoli are prominent^[42]. Focal necrosis is often observed. These tumors exist alone or associated with adjacent adenomas or conventional adenocarcinomas^[43]. LCNECs are defined through both NE morphology and immunohistochemical positivity of NE markers.

CK20 is expressed in colorectal LCNECs; a generally acknowledged marker in adenocarcinoma which is rarely found in other NETs^[44,45]. This phenomenon may indicate that there is some relationship between LCNECs and adenocarcinomas.

LCNECs have a similar prognosis to colorectal SCCs. Kumarasinghe *et al.*^[46] suggested that LCNECs should be included in the poorly-differentiated NE carcinoma category based on their poor prognosis.

Mixed endocrine-glandular neoplasm

Mixed endocrine-glandular neoplasms constitute a heterogeneous group of rare neoplasms. These tumors are composed of at least two distinct tumor populations, with the NE part containing at least 30% of obviously endocrine cells^[14,47,48]. The degree of NE cell differentiation varies between tumors and between different tumor areas. The most common component is carcinoid, while poorly-differentiated NE type also exists, and another component can be adenocarcinoma or squamous carcinoma^[14,15,49]. The NE component is usually well-differentiated, and easily recognized by its suggestive histological features; the NE nature of the tumor cells can be verified by the immunodetection of specific NE markers (such as CgA and Syn). Especially when the NE component is poorly differentiated, the demonstration of NE markers to confirm the diagnosis is needed^[50]. More often, the diagnosis cannot be made until the tumors are stained with NE cell markers when the endocrine cells are inconspicuous and the quantity present is not obvious^[1].

Because of their rarity and unusual presentation, the optimal strategy of management of mixed endocrine tumors is largely unknown. The more aggressive component of the mixed endocrine tumors must be taken into account when considering their treatment. Mixed tumors containing a well-differentiated NE component and an adenocarcinoma component are suggested to be treated as adenocarcinoma. Mixed tumors containing a poorly-differentiated NE component must be treated as poorly-differentiated NE carcinomas^[50]. Some researchers report mixed NETs as having worse prognosis, thus the ascertainment of the NE component is important to predict the prognosis^[48].

MOLECULAR GENETICS OF COLORECTAL NETs

The molecular mechanisms of NET tumorigenesis are

Table 2 Proposed staging system for rectal and colon NETs^[62,63]

	Rectal	Colon
Depth of invasion and size		
T1	Up to and into muscularis propria, ≤ 1 cm	Any depth of invasion, ≤ 1 cm
T2	Up to muscularis propria, > 1 to ≤ 2 cm Beyond muscularis propria, ≤ 1 cm Into muscularis propria, > 1 to ≤ 2 cm	Up to or including muscularis propria, > 1 to ≤ 4 cm Beyond muscularis propria, > 1 to ≤ 4 cm Up to or including muscularis propria, > 4 cm
T3	Up to and into muscularis propria, > 2 cm Invasion beyond muscularis propria, > 1 cm	Beyond muscularis propria, > 4 cm
Lymph node		
N0	No lymph node metastasis	
N1	Regional lymph node metastasis	
Distant metastasis		
M0	No distant metastasis	
M1	Distant metastasis	
Stage		
I	T1; N0; M0	
II	T1; N1; M0 or T2; Any N; M0	
III	T3; N0; M0 or T3; N1; M0	
IV	Any T; Any N; M1	

unclear; however, these aspects have been focused on in many recent reports^[51]. Increased knowledge of the molecular background for the development of NETs may improve the management of these tumors in the future. A number of genetic syndromes including multiple endocrine neoplasia syndrome-type 1 (MEN1), von Hippel-Lindau syndrome, and neurofibromatosis-type 1 may be associated with intestinal NETs^[8,52]. Some studies have demonstrated neither classic oncogenes (*src*, *ras*, *myc*, *fos*, *jun*) nor suppressor genes (*P53*, *RB*) present in NETs^[52,53]. However, there are reports of other gene site deletions. For example, *PDCD4* was found to be absent in NETs; this is a gene which is interrelated with cell proliferation, located at 11q13 close to *MEN1*^[54].

The microsatellite instability (MSI) caused by mismatch repair (MMR) damage is an important cause of tumorigenesis in hereditary nonpolyposis colorectal cancer (HNPCC)^[55-58]. Stelow *et al.*^[59] discovered the loss of *MMR* genes in colorectal SCCs, but not along with HNPCC. The chromosome instability caused by the loss of *MMR* genes possibly follows a different pathway from MSI in SCC tumorigenesis. Arnold *et al.*^[60] studied 34 poorly-differentiated colorectal NETs, 38 well-differentiated benign or malignant fore-/midgut NETs, and 150 sporadic colorectal cancers with known MSI status and found that 20/34 (59%) colorectal NETs *vs* 11/38 (29%) fore-/midgut NETs were CpG island methylator phenotype (CIMP) positive. The Ki-67 index was significantly higher in poorly-differentiated colorectal NETs compared with the less malignant fore-/mid-gut NETs. However the CIMP status did not correlate with survival.

Research in NET molecular genetics should target early detection, prognosis predicting, or treatment selection. Currently, new technologies should be used to find new sensitive and specific biochemical and tissue markers for colorectal NETs.

PROPOSED TNM STAGE AND RISK FACTORS

NETs are a challenging group of diseases, and the lack of a widely accepted staging system limits the clinician's ability to provide meaningful prognostic information to the patients. In October 2009, the 7th edition of the AJCC for the first time gave a detailed TNM description for NETs, classifying primary tumor (T), regional lymph nodes (N), and distant metastasis (M), respectively. However, no clarified TNM staging has been established for colon and rectal NETs^[61].

In 2008, Landry *et al.*^[62,63] proposed a different staging system from that of conventional colorectal adenocarcinomas in the study of 4710 rectal NETs and 2459 colon NETs (Table 2). In their report^[62], it was revealed that rectal NETs were the only primary malignancy in 82% of patients, 17% patients had one additional malignancy and 1% had two or more additional malignancies. The mean and median sizes of primary tumor were 1 and 0.6 cm, respectively. About 4.1% had regional lymph node metastases, and 2.4% presented with distant metastases at the time of diagnosis. The 5-year survival rates for patients with stages I and II disease were 97% and 84%, respectively. The 5-year survival rate for stage III patients was 27% with a median survival time of 45 mo. The 5-year survival rate for stage IV patients was 20% with a median survival time of 31 mo. The 10-year survival rates of the disease for stages I through IV were 91%, 56%, 14%, and 2.5%, respectively.

In another study^[63] of colon NETs, the researchers demonstrated that there were regional lymph node metastases in 48% of patients, and distant metastases in 24% of patients at the time of diagnosis. The 5-year survival rates for stages I and II were 97% and 69%, respectively. Similarly, the 5-year survival rate for stage III disease was 21%, with a median survival time of 27 mo.

The 5-year survival rate for stage IV disease was 17%, with a median survival time of 20 mo. The 10-year survival rates for stages I through IV were 92%, 47%, 15%, and 5.4%, respectively.

Some studies have suggested some risk factors of colorectal NETs related to poor outcome, such as tumor size, depth of wall penetration, presence of lymphatic or venous invasion, and mitotic rate of metastasis in colorectal NETs^[64-69]. The tumor size is related to prognosis. Most rectal NETs are less than 1 cm at the time of diagnosis^[70,71]. The malignancy rate increases when the tumor grows larger than 1 cm. However, for small-sized tumors less than 1 cm at detection with predominant submucosal invasion there is usually a relatively high incidence of distant metastasis, about 1.7%-3.4%^[71,72]. Some reports have shown that cancer-specific survival of patients with colorectal NETs without metastasis was better than that of those with adenocarcinomas. However, the survival rate is similar between carcinoid and adenocarcinoma if the tumors have lymph node or distant metastases^[65]. On the other hand, colorectal NE carcinomas behave aggressively and are associated with a worse prognosis than that of conventional colorectal adenocarcinomas of the same stage^[16,39].

CONCLUSION

The complexity, heterogeneity and scarcity of NETs, rare colorectal neoplasia, account for almost no improvement of survival rates in the past 30 years. The diagnosis for colorectal NETs mostly depends on pathology with the aid of immunohistochemistry. As we have summarized here, the 2000 WHO classification of colorectal NETs provides a solid basis for localization, biology and prognosis of individual NETs, but there are still some types of tumors not properly described. More studies will be needed with regard to diagnosis, treatment and prognosis.

Abstract

AIM: To analyze whether computer-enhanced dynamic analysis of elastography movies is able to better characterize and differentiate between different degrees of liver fibrosis.

METHODS: The study design was prospective. A total of 132 consecutive patients with chronic liver diseases and healthy volunteers were examined by transabdominal ultrasound elastography. All examinations were done by two doctors.

RESULTS: Due to the limitations of the method, we obtained high-quality elastography information in only 73.48% of the patients. The κ -means clustering method was applied to assess the inter-observer diagnosis variability, which showed good variability values in accordance with the experience of ultrasound examination of every observer. Cohen's κ test indicated a moderate agreement between the study observers ($\kappa = 0.4728$). Furthermore, we compared the way the two observers clustered the patients, using the test for comparing two proportions (t value, two-sided test). There was no statistically significant difference between the two physicians, regardless of the patients' real status.

CONCLUSION: Transabdominal real-time elastography is certainly a very useful method in depicting liver hardness, although it is incompletely tested in large multi-center studies.

INTRODUCTION

Palpation continues to be of great value in modern medicine, both practiced by doctors and as a technique

for self-examination. However, palpation is limited to a few accessible organs, and the interpretation of the information sensed by the fingers is highly subjective. Recently, elastography has emerged as an option in several commercial ultrasound systems, and is starting to prove clinically valuable in many areas, particularly for example in assisting breast cancer diagnosis^[1,2], or in guiding minimally invasive treatment of prostate cancer^[3,4]. The technique reveals the physical properties of the tissue by characterizing the difference in hardness between diseased and surrounding tissue^[5,6]. The method measures mechanically induced deformation (strain) of structures in the B mode image to quantify the elasticity of the tissue. By measuring the tissue strain induced by compression, it is possible to estimate the tissue hardness. The region of interest for the elastography calculations is selected manually and should include the targeted area and the surrounding tissues^[7].

Elasticity measurements have been reported to be useful for the diagnosis and differentiation of many tumors, which are usually harder than normal surrounding tissues^[8-10]. Furthermore, different solid tumors situated near the gastrointestinal tract might be also visualized by endoscopic ultrasound (EUS) elastography and potentially characterized by this technique. EUS elastography has been used in several studies for the characterization and differentiation of benign and malignant lymph nodes, with variable sensitivity, specificity, and accuracy, with better results than those obtained by conventional EUS criteria^[11-13]. Furthermore, the feasibility of EUS elastography has been tested in pancreatic diseases, with very good results^[14,15].

Recently, transabdominal real-time elastography was proposed as a new method for noninvasive staging of liver fibrosis^[16-18]. For many years, liver biopsy was the only method to evaluate liver fibrosis and it has traditionally been considered as the gold standard^[19]. However, it is a painful invasive method associated with poor patient compliance, discomfort and, in very rare cases, with serious complications^[16,20]. High inter-observer variability has been reported between two pathologists when analyzing the same biopsy sample^[19,21]. Therefore, recent research has been focused on the evaluation of noninvasive methods for the assessment of liver fibrosis, both by biochemical tests as well as imaging methods^[22], as an alternative to liver biopsy.

The aim of this study was to analyze whether computer-enhanced dynamic analysis of elastography movies is better able to characterize and differentiate between different degrees of liver fibrosis. We previously have reported that analysis of selected elastography images is operator-dependent, therefore, our approach was to use a dynamic analysis of several frames of elastography movies that might reduce possible selection bias or artifacts.

MATERIALS AND METHODS

Patients

The study design was prospective. A total of 132 conse-

cutive patients with chronic liver diseases and healthy volunteers were examined by transabdominal ultrasound elastography during an 18-mo period in the Research Center of Gastroenterology and Hepatology, University of Medicine and Pharmacy Craiova, Romania. Patients (73 men and 59 women) were 26-74 years old. As a result of the limitations of the method, only 97 patients were considered for further elastography analysis as follows: healthy volunteers ($n = 27$), chronic viral B and C hepatitis ($n = 26$), and liver cirrhosis ($n = 29$), fatty alcoholic liver disease ($n = 21$). Chronic viral hepatitis was proven by the presence of hepatitis C virus antibodies or hepatitis B surface antigen in serum and the persistence of liver inflammation or liver parameter alterations for > 6 mo. In all the patients with chronic viral hepatitis, liver biopsy was performed 1-3 d before real-time elastography. Liver cirrhosis was proven by clear demonstration of portal hypertension signs (including esophageal and/or gastric varices) in a clinical suggestive setting. Patients with ascites were excluded from the study. Fatty alcoholic liver disease was diagnosed by ultrasound aspects of the liver and excessive alcohol intake (> 30 g daily), in the absence of viral infection and any doubt of cirrhosis. The control group consisted of healthy adult volunteers [normal levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST); negative tests for blood viral markers] who did not have a history of relevant concomitant illness or cancer. None of the healthy volunteers had an excessive daily alcohol intake (< 10 g daily).

Examination protocol

EUS elastography equipment includes a Hitachi EUB 8500 ultrasound system with an embedded elastography module (Hitachi Medical Systems Europe Holding AG, Zug, Switzerland) and a 6.5-MHz linear probe. The same conditions of brightness, contrast, intensity, and gain of the ultrasound system were used in all examinations. However, because the numeric elastography information is displayed using a rainbow color-coded scale, with values from 1 to 256, changes in the system settings did not affect the subsequent post-processing analysis.

All examinations were done by two doctors with different degrees of experience in ultrasound, a proficient physician (SA) and a physician beginner in ultrasound technique (GDI), in a typical clinical setting with previous knowledge of the patient's underlying disease. The ultrasound probe was placed in a convenient right intercostal space and elastography information was gathered during breath holding at the end-expiration phase. Three 10-s movies were recorded by each examiner for every patient, with a region of interest set to include the liver and surrounding tissues (Figure 1A-C). The movies were stored uncompressed at maximum quality for further accurate computer-enhanced analysis.

Liver biopsy was performed through the right intercostal space in the right liver lobe after transabdominal ultrasound found the most useful area. After betadine disinfection and local anesthesia, liver biopsy was per-

formed at the previously marked site. Liver fibrosis stages were evaluated semi-quantitatively according to the Metavir scoring system^[23-25]. Liver fibrosis was staged on an F0-F4 scale: F0-no fibrosis, F1-portal fibrosis without septa, F2-portal fibrosis with few septa, F3-numerous septa without cirrhosis, and F4-cirrhosis.

Computer-enhanced elastography movies analysis

The elasticity of tissue was reconstructed within the region of interest and translated into a color signal that overlay the grey scale image. To visualize tissue elasticity patterns, different elasticity values were marked with different colors (on a scale of 1 to 256). The system was set-up to use a hue color map (red/green/blue), where hard tissue areas were marked with dark blue, medium hard tissue areas with cyan, intermediate tissue areas with green, medium soft tissue areas with yellow, and soft tissue areas with red. The complete spectrum from blue to red was applied to every elastography record and indicated the graduation of relative elasticity within the region of interest. The quality of tissue compression was indicated by a numeric scale from 1 to 7 within the image.

Each recorded elastography movie was subjected to a computer-enhanced dynamic analysis using a public domain Java-based image processing tool (Image J)^[26] with a special plug-in developed by the IT Department of the University of Medicine and Pharmacy, Craiova. The plug-in was used to compute and dynamically analyze the individual hue histograms of each frame from an elastography movie; all programmers and statisticians being blinded to the clinical and pathological information to minimize the human bias. Shortly, every color frame was transformed into numerical form, and characterized by a single average hue histogram vector. Each individual value of the vector corresponded to the number of pixels of each color, in other words, to the number of pixels that corresponded to each elasticity level, from 1 to 256. The numeric values displayed by computer were offered to the statistical team and analyzed.

Statistical analysis

A prospective cross-sectional study was carried out on 97 samples of elastography records from chronic hepatitis patients and healthy volunteers recorded by two doctors. Using all clinical and laboratory test data, expert doctors (Săftoiu A and Gheonea DI) diagnosed the patients into four types (normal, liver steatosis, chronic hepatitis, and cirrhosis). First, an a priori power analysis determined the acceptability of the patient record sample size. Second, the κ -means clustering algorithm was applied to assess the inter-observer diagnosis variability. Basically, we used the κ -means algorithm to cluster automatically the 97 patients into four groups that corresponded to the four types of diseases; furthermore we compared these clusters with the final diagnosis. Finally, the analysis of variance, comparison of the proportions of well-diagnosed patients, Cohen's κ statistics, the proportion of agreement between the two examiners, and

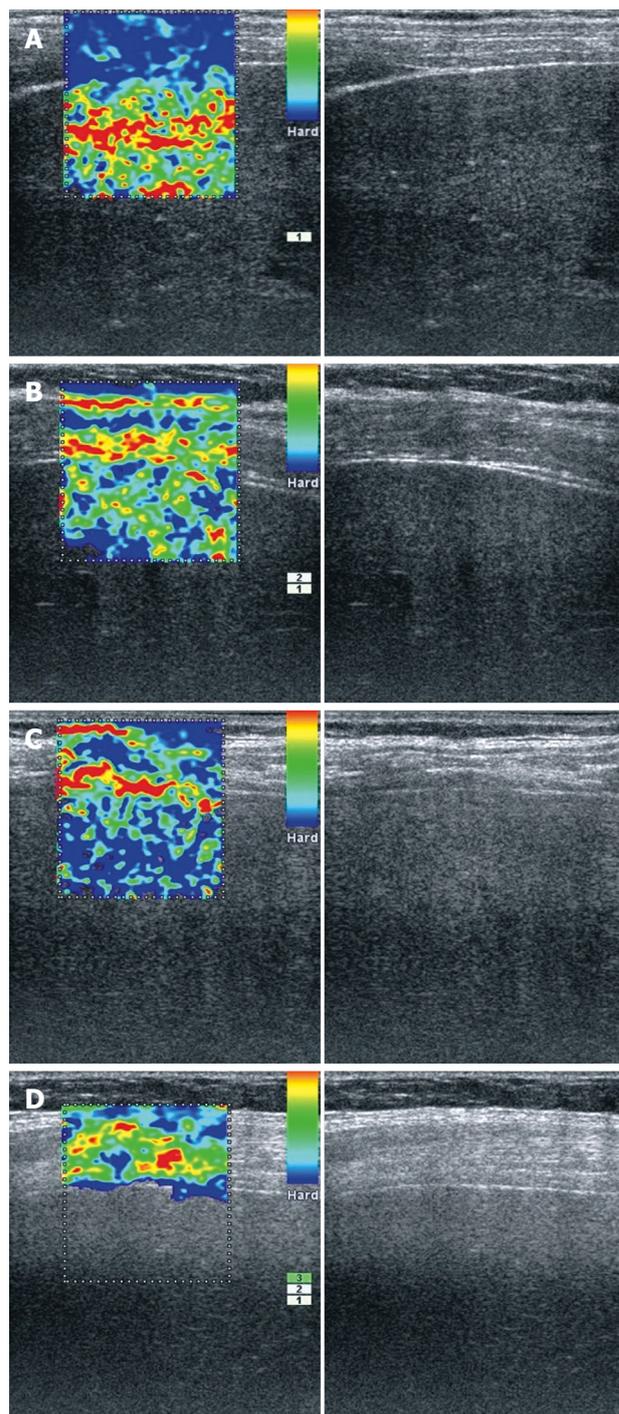

Figure 1 Real-time elastography images of right liver lobe. A: 58-year-old patient with alcoholic liver steatosis - a very soft liver parenchyma (red/yellow/green) in contrast with hard intercostal muscles and diaphragm (blue); B: 56-year-old patient with chronic hepatitis C - parenchyma with mixed appearance (green/blue) indicative of elasticity; C: 57-year-old patient with alcoholic cirrhosis - very hard liver parenchyma (predominantly blue); D: 67-year-old obese woman with chronic hepatitis. The elastography software was not able to characterize elasticity inside liver.

Stuart-Maxwell's statistics were performed to evaluate the appropriateness of each doctor's diagnosis and the inter-observer reliability between expert doctors.

Furthermore, statistical analysis concerning the liver biopsy Metavir scores (F1, F2, F3) compared with the

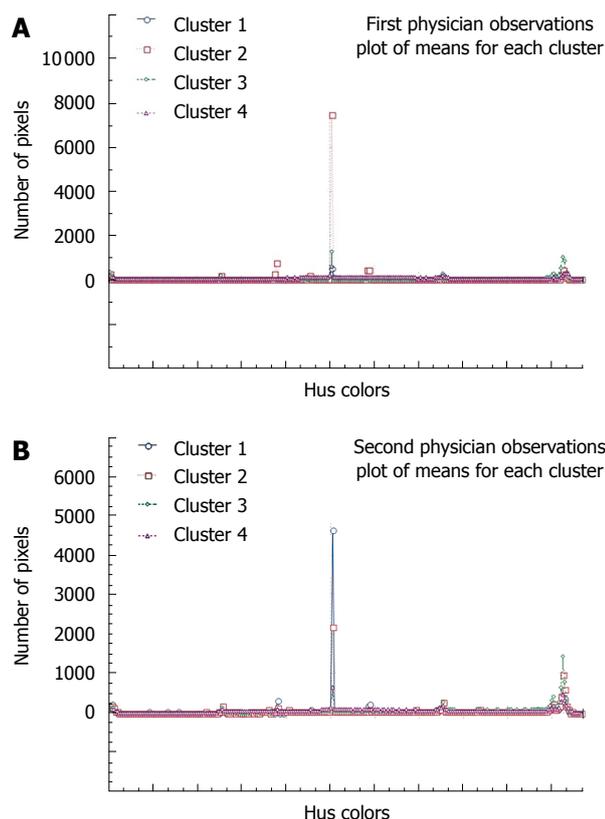

Figure 2 Graphs showing the way the first (A) and the second investigator (B) clustered the patients.

elasticity value (determined by computer-enhanced elastography movies assessment) was performed using Spearman's correlation coefficient.

RESULTS

A total of 132 consecutive patients were examined by real-time elastography using the right intercostal space as an acoustic window for gathering elasticity information about the liver. Due to the limitations of the method concerning the low penetrability of elastography into the tissues (Figure 1D), we obtained high-quality elastography information in only 97 patients (73.48%). The two examiners categorized the study patients into four groups (cirrhosis, chronic hepatitis, alcoholic steatosis, healthy volunteers) in accordance with the determined clinical status. Furthermore, the results of computer-enhanced analysis of the elastography movies were compared statistically.

First, we performed a power analysis to determine the acceptability of the patient record sample size, because one of the main goals of this study was to investigate the appropriateness of each observer examination and the inter-observer reliability between expert doctors. Accordingly, a sample of 97 records were considered, which provided a statistical power of 95% (type I error rate $\alpha = 0.10$).

Second, the κ -means clustering method was applied to assess the inter-observer diagnosis variability. It aimed to distinguish between different groups of patients and

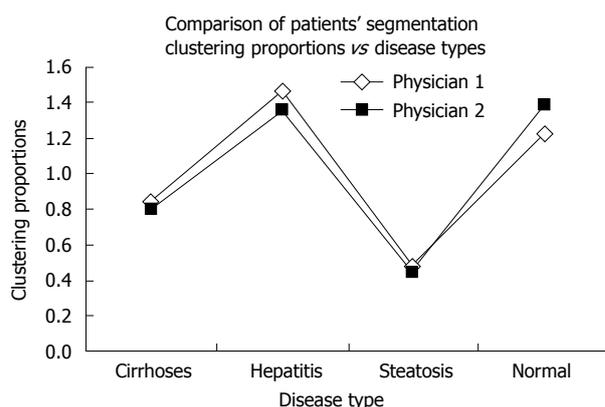

Figure 3 Patient segmentation across the four types of status, showing a similar manner of clustering the patients, irrespective of examiner.

can therefore be used to enhance knowledge of diseases and make automatic diagnosis predictions. Technically, based on each observer film computer analysis, we have used the κ -means algorithm to cluster automatically the 97 patients into four groups corresponding to the four types of status. Next, we compared the results of the two segmentations of patients, which corresponded to each doctor's diagnosis, to investigate the possible differences between them. To evaluate the appropriateness of each examination, we used the well-known analysis of variance, which compared the within-cluster variability (small if the classification was good) to the between-cluster variability (large if the classification was good). Thus, we obtained a very good classification for Săftoiu A ($P = 0.014$) and a poorer classification for Gheonea DI ($P = 0.15$), which meant that the first decision was better than the second one (more homogeneous clusters and more different from each other). This implied that the first observer was much more experienced than the second in performing elastography. We also considered the two graphs of the means across clusters, which corresponded to each examiner (useful for visually summarizing the differences in means between clusters). As we saw from these two graphs (Figure 2A and B), there was no significant visual difference between the two doctors' ways of clustering the patients, even if the previous analysis of variance showed a difference between them. Moreover, we considered the patients' segmentation across the four types, which showed a similar way of clustering the patients, irrespective of examiner (Figure 3). Besides the above approaches used to assess the inter-observer variability, we applied the test for comparing two proportions (t value, two-sided test). We found that there was no statistically significant difference between the two physicians' computer-enhanced movie analysis, regardless of disease type: cirrhosis ($P = 0.54$), chronic hepatitis ($P = 0.85$), steatosis ($P = 0.81$), and healthy subjects ($P = 0.78$).

Another way of analyzing the agreement between the two observers was application of Cohen's κ test as a measure of association between the two measurements (categorical variables), which consisted of the real-time elastography examinations performed by the two doctors.

Table 1 Cohen's κ test as a measure of association between the two measurements showed moderate agreement ($\kappa = 0.4728$) for the two study examiners

Observed κ	Standard error	95% CI	
		Lower limit	Upper limit
0.4728	0.0762	0.3235	0.6221

We considered for each examiner only one examination per patient, which gave a sample of 97 records. Each examiner classified each patient into one of the following categories: steatosis, normal, hepatitis, cirrhosis, thus, the 97 records referred to the above four categories. The four categories were nominal, therefore, Cohen's simple unweighted coefficient κ was the only form that could meaningfully be used (Table 1). According to Landis and Koch^[27], $\kappa = 0.4728$ indicated a moderate agreement between the two doctors. Thus, we conclude that, of all the decisions that we would have expected to be non-concordant if nothing more than coincidence were operating, 47.28% of the decisions were in fact concordant.

Independently of the Cohen's κ value, it is also possible to measure the proportion of agreement between the two observers^[28] within each of the four categories separately (confidence intervals for proportions are calculated according to the Wilson efficient-score method, corrected for continuity). Table 2 shows that the greatest agreement concerned normal patients (84.85%), while the smallest was for patients with cirrhosis (33.33%). In addition, we used Stuart-Maxwell's test for the four categories as a measure of the overall disagreement between the two doctors. The null hypothesis H_0 was that the distribution of diagnosis type among the four categories was the same for the two observers. Using the corresponding χ^2 statistics with 4-1 (3) degrees of freedom, the corresponding significance level ($P = 0.001$) showed that we could reject hypothesis H_0 , that is, there seemed to be a significant overall disagreement between the two doctors.

Although all the correlation methods applied for determining the correspondence between real status of the examined patients (normal, liver steatosis, chronic hepatitis, cirrhosis) and elasticity assessed by real-time elastography were positive, we could not establish a good correlation between the Metavir score (chronic hepatitis patients) and the results of elastography movies analysis (results not shown).

DISCUSSION

Recently, elastography has been presented as a new ultrasound-associated technology for the assessment of tissue elasticity. Computer-enhanced dynamic analysis of liver elastography movies was the objective of our current study. Furthermore, we studied the inter-observer variability and the correspondence between elastography and clinical (final) diagnosis. This approach would also eliminate the selection bias induced by analysis of static

Table 2 Wilson efficient-score method, corrected for continuity to measure the proportion of agreement between the two observers

Decision	Proportions of agreement			95% CI	
	Maximum possible	Chance expected	Observed	Lower limit	Upper limit
Normal	0.8485	0.2169	0.5250	0.3634	0.6818
Steatosis	0.5789	0.1961	0.3953	0.2537	0.5555
Hepatitis	0.5517	0.1381	0.5000	0.3168	0.6832
Cirrhosis	0.3333	0.0089	0.3333	0.0177	0.8747
Composite	0.7882	0.3084	0.6353	0.5232	0.7350

The greatest agreement concerned normal patients (84.85%), while the smallest concerned cirrhosis patients (33.33%).

images^[7], because it takes into account the information contained in several frames of a liver elastography movie.

The first goal of our statistical analysis was to see if percutaneous elastography of the liver was able to diagnose correctly the real status of the patients. We analyzed three independent cine-loop elastography examinations recorded by two separate examiners who were blinded to each other. For each patient, we thus recorded six real-time cine-loop elastography examinations, which were further analyzed through hue histogram analysis, with averaged values for a 10-s cine loop. Although the aspects of the images suggested the correct diagnosis (Figure 1A-C), we automatically analyzed every frame of the movies recorded by the two investigators. To evaluate the appropriateness of each examination, the κ -means clustering method was performed, which showed agreement between the clinical diagnosis and the results of computer analysis of the recorded movies. The results were very good, especially for the first investigator (Săftoiu A), thus proving that experience in performing ultrasound is important in obtaining quality and accurate recordings of the study patients.

As we previously suggested^[7], the region of interest for all the movies was set to include also the surrounding liver tissue (fatty tissue, intercostals muscles, diaphragm, peritoneum), which were considered to have the same elasticity in all patients despite their subsequent disease. We do not believe that inclusion of hepatic vein branches^[29] would be very useful as a reference structure, because the presence of vessels induces clear artifacts in the elastography images (Figure 4A), similar to the presence of ascites (Figure 4B). This is easily understandable if we look at the colors displayed by the real-time elastography software in the region of interest. In the presence of a very highly elastic structure such as the hepatic vein or ascites, the rest of the liver would be depicted as hard, irrespective of its elasticity. However, the development of ascites is a strong indicator for the presence of cirrhosis, which makes noninvasive staging of fibrosis unnecessary.

Liver biopsy is an important diagnostic tool and helps therapeutic decision making in chronic liver diseases patients^[30]. Histopathological examination was considered the most appropriate method in chronic hepatitis for assessing changes after antiviral therapy^[31], and is considered

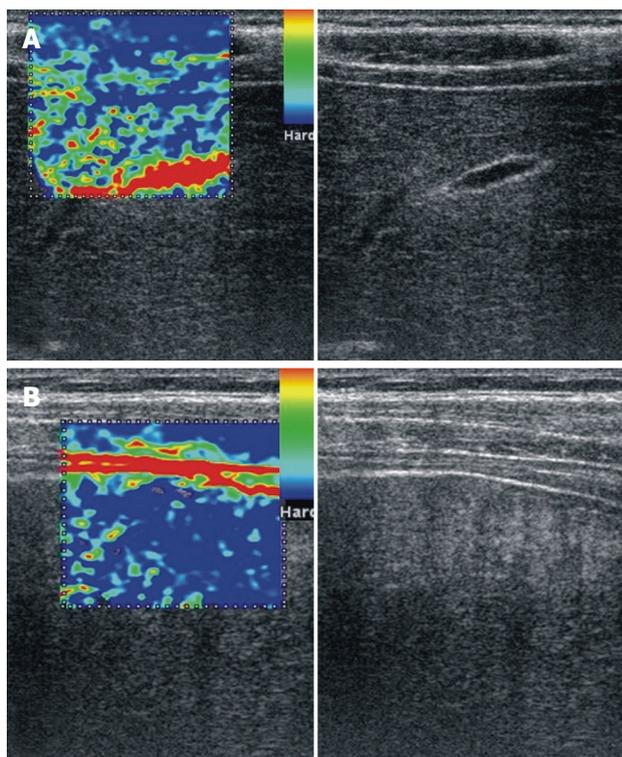

Figure 4 Real-time elastography images of right liver lobe. A: 45-year-old patient with alcoholic liver steatosis. Region of interest include a large vessel, therefore, the liver parenchyma had a hard appearance (blue/green) in contrast with the extremely compressed (red) vessel; B: 52-year-old patient with liver cirrhosis and small amount of ascites surrounding the liver. There was very compressive and elastic fluid (red), and the liver parenchyma was depicted as very hard (blue). Consequently, other types of ascites might possibly induce similar artifacts, even in the presence of normal liver tissue.

mandatory for grading and staging in most patients. The question is whether liver biopsy can be regarded as the gold standard for the staging and grading^[32] of diffuse liver diseases when risks of biopsy, inadequate sampling, and intra-observer and inter-observer error are taken into account^[30]. Our elastography statistical results showed a very good inter-observer variability analyzed by all three methods presented above. Therefore, computer-aided diagnosis of elastography calculations can be a very useful and reproducible method in depicting the hardness of the liver.

Even so, we were not able to distinguish between intermediate degrees of liver fibrosis (F1, F2, F3) in the chronic hepatitis patients subgroup in which we performed liver biopsy. To the best of our knowledge, there is only one published study^[16] that has succeeded partially in correlating the degree of fibrosis with real-time elastography calculation, especially in patients with $F \geq 2$. Unfortunately, the obtained values were calculated as means of static images selected by the examiner, which could have had a significant influence on the results. Furthermore, it is not clear if the region of interest was set to include also the surrounding tissues of the liver as a reference area.

One important limitation of our approach was the examination of the liver with a linear transducer of 6.5 MHz, which might be too high to examine the right

liver lobe correctly and consistently. We did not select only patients with a normal body mass index, therefore, in only 73.48% of the examinations did we obtain constant and high quality elastography information from the area of interest. The penetration of real-time elastography is limited to 3-4 cm, therefore, it is difficult to record useful elastography information inside the liver if the thoracic wall is thicker than 2-3 cm. A better option might be represented by the use of a lower frequency linear transducer, or another means of performing elastography of the liver, for example, by using EUS with the transducer placed in the stomach near the left liver lobe. Development of a pressure gauge is certainly necessary because manual application of pressure cannot be standardized. Usually, a small deformation ($< 2\%$) of the tissues is needed, and this is very difficult to obtain, even by experienced doctors.

In conclusion, transabdominal real-time elastography is certainly a very useful method in depicting liver hardness, although it has been tested incompletely in large multicenter studies and should be compared with other noninvasive methods (blood markers, transient elastography). We also suggest an improvement of the examination methodology, which should take into account previous observations made by different authors (better transducers, improved elastography software) to establish real-time elastography as a new revolutionary method that can replace liver biopsy for assessment of different stages of fibrosis in patients with chronic hepatitis.

COMMENTS

Background

Chronic liver diseases are marked by the gradual destruction of liver tissue over time, which eventually causes liver cirrhosis. Cirrhosis is the seventh leading cause of death in the United States, according to the National Institute of Diabetes and Digestive and Kidney Diseases. Liver biopsy is still the gold standard in many centers for quantifying liver fibrosis.

Research frontiers

Recently, research has focused on the evaluation of noninvasive methods for the assessment of liver fibrosis: routine hematological and biochemical tests, surrogate fibrosis markers in the blood and their algorithms, glycomics, proteomics, transient elastography, and real-time elastography.

Innovations and breakthroughs

Elasticity measurements have been reported to be useful for the diagnosis and differentiation of different diseases. Recently, transabdominal real-time elastography was proposed as a new method for noninvasive staging of liver fibrosis. The present study clearly demonstrated that computer-enhanced dynamic analysis of elastography movies is better able to characterize and differentiate between different degrees of liver fibrosis.

Applications

Transabdominal real-time elastography is certainly a very useful method in depicting liver hardness and allows the replacement of other invasive methods, such as liver biopsy, which are associated with patient discomfort and mortality in some cases.

Terminology

Transabdominal real-time elastography is an imaging technique, completely noninvasive, that visualizes the tissue strain during compression that characterizes the difference in hardness between diseased and normal tissues. Tissue compression produces strain within the tissue. The strain is smaller in harder compared with softer structures.

Peer review

In the present study, the authors aimed to analyze whether computer-enhanced

dynamic analysis of elastography movies is better able to characterize and differentiate between different degrees of liver fibrosis. The topic is interesting, and novel.

[odds ratio (OR) = 402.5, 95% confidence interval (CI): 12.4-1313.1] and vessel regularity: negative (OR = 15.9, 95% CI: 1.2-219.1). Both of these findings when combined were an indicator of sm-d invasion with sensitivity, specificity and accuracy of 81.4%, 100% and 92.9%, respectively. Pit pattern diagnosis sensitivity, specificity and accuracy, meanwhile, were 86.0%, 98.6% and 93.8%, respectively, thus, the NBI with magnification findings of non-dense vessel density and negative vessel regularity when combined together were comparable to pit pattern diagnosis.

CONCLUSION: Non-dense vessel density and/or negative vessel regularity observed by NBI with magnification could be indicators of ECC sm-d invasion.

Abstract

AIM: To evaluate the surface microvascular patterns of early colorectal cancer (ECC) using narrow-band imaging (NBI) with magnification and its effectiveness for invasion depth diagnosis.

METHODS: We studied 112 ECC lesions [mucosal/submucosal superficial (m/sm-s), 69; sm-deep (sm-d), 43] ≥ 10 mm that subsequently underwent endoscopic or surgical treatment at our hospital. We compared microvascular architecture revealed by NBI with magnification to histological findings and then to magnification colonoscopy pit pattern diagnosis.

RESULTS: Univariate analysis indicated vessel density: non-dense ($P < 0.0001$); vessel regularity: negative ($P < 0.0001$); caliber regularity: negative ($P < 0.0001$); vessel length: short ($P < 0.0001$); and vessel meandering: positive ($P = 0.002$) occurred significantly more often with sm-d invasion than m/sm-s invasion. Multivariate analysis showed sm-d invasion was independently associated with vessel density: non-dense

INTRODUCTION

Magnified colonoscopy and the development of pit pattern diagnosis^[1] not only permits us to distinguish neoplastic from non-neoplastic colorectal lesions^[2-5], but also helps to assess the invasion depth of early colorectal cancers (ECC)^[6-9]. Similarly, vascular findings on the surface of gastric lesions have also been observed by

magnification endoscopy, and the usefulness in predicting the histological nature of such lesions and assessing their invasion depth has also been reported in the upper gastrointestinal (GI) tract^[10-12].

The recently developed narrow-band imaging (NBI) system is a noninvasive optical technique that uses reflected light that provides clearer images of surface microvascular architecture than the conventional observation modality^[13]. To date, the use of magnification endoscopy with the NBI system has been studied in the upper GI tract^[14-20] and the suitability of this new modality for differentiating neoplastic from non-neoplastic lesions and its potential for pit pattern diagnosis have also been reported for the lower GI tract^[21-30].

As previously indicated, colorectal lesions with mucosal (m) or submucosal (sm) superficial invasion $< 1000 \mu\text{m}$ (sm-s) have an extremely low risk of lymph-node metastasis and are good candidates for endoscopic treatment^[31]. It is helpful therefore, to differentiate endoscopically between m/sm-s and deeper sm invasion (sm-d $\geq 1000 \mu\text{m}$) lesions. There have been only a few reports concerning invasion depth diagnosis using NBI with magnification in a large series of cases, however, a number of questions remain regarding the comparative effectiveness of a diagnosis based on NBI observation and one using pit pattern analysis by dye chromoendoscopy for determining invasion depth.

Using magnification colonoscopy with the NBI system, we evaluated the characteristics of the surface microvascular architecture of ECC and investigated the effectiveness of this new optical modality for the diagnosis of invasion depth. In addition, we evaluated the comparative relationship between NBI with magnification and pit pattern diagnoses.

MATERIALS AND METHODS

NBI system

NBI is a novel technique that uses spectral narrow-band optical filters instead of the full spectrum of white light. It is based on the phenomenon that the depth of light penetration depends on its wavelength, with a short wavelength penetrating only superficially and a longer wavelength penetrating into deeper layers. In the NBI mode, optical filters that allow narrow-band light to pass at wavelengths of 415 and 540 nm are mechanically inserted between a xenon arc lamp and a red/green/blue rotation filter. Thin blood vessels such as capillaries on the mucosal surface can be seen most clearly at 415 nm, which is the wavelength that corresponds to the hemoglobin absorption band, while thick vessels located in the deep layer of the mucosa can be observed at 540 nm. Current NBI technology limits mucosal surface light penetration, thereby enhancing visualization of the fine capillary vessel structure on the surface layer.

Patients and evaluation methods

We studied a total of 112 ECC lesions ≥ 10 mm analyzed with NBI with magnification colonoscopy examination, which then underwent endoscopic or surgical treatment at the National Cancer Center Hospital between January 2006 and February 2007. All colonoscopies were per-

formed with a PCF-Q240ZI or CF-H260AZI endoscope (Olympus Optical Co. Ltd., Tokyo, Japan) by three experienced endoscopists (MF, YS, TM) each of whom had annually performed more than 1000 magnifying chromoendoscopy examinations and at least 500 NBI examinations per year. Endoscopic images of each lesion were taken in the following order: conventional colonoscopy, NBI with magnification, chromoendoscopy and magnification chromoendoscopy. When a lesion was detected by conventional colonoscopy, its surface was washed with proteinase to remove excess mucus. Magnification NBI views of the microvascular architecture concentrated on those portions of the lesion where invasion seemed to have permeated the deepest regions, such as depressed areas and large nodules^[32,33].

After completion of NBI with magnification, the pit pattern of each lesion was assessed with magnification chromoendoscopy performed using 0.4% indigo-carmin (IC) dye spraying. When high magnification observation with IC dye did not permit us to determine adequately the surface structure for pit pattern analysis, 0.05% crystal violet was applied for staining^[7]. The visible pit pattern was then assessed during the course of the examination by the endoscopist conducting the procedure. All lesions were resected subsequently endoscopically or surgically and histological diagnosis was performed by three experienced pathologists based on the Vienna classification^[34,35]. The depth of sm invasion was determined as being either sm-s $< 1000 \mu\text{m}$ or sm-d $\geq 1000 \mu\text{m}$ ^[31]. After pathological diagnosis was completed on all resected lesions, three endoscopists (Fukuzawa M, Saito Y and Matsuda T) who performed the examination individually reviewed the endoscopic images of the NBI findings that were taken prior to treatment. All endoscopic images were chosen by one of these endoscopists. Their evaluation of the NBI images of the m/sm-s and sm-d lesions focused on the suspected areas, respectively, of higher grade dysplasia and deepest suspected invasion. Each characteristic of microvascular architecture was finally determined based on the agreement of at least two of the three reviewing endoscopists. Microvascular findings with a high frequency of sm-d were assessed as to whether those were significant sm-d indicators by univariate and multivariate analysis. In addition, sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and diagnostic accuracy were calculated for each microvascular architectural feature observed during NBI, as well as every pit pattern diagnosis determined by magnification chromoendoscopy. We then compared the various types of microvascular architecture characteristics revealed by NBI with magnification to the chromoendoscopy pit pattern diagnoses.

The protocol for this study was approved by our institutional review board and all patients gave written informed consent.

Chromoendoscopy with magnification

Our pit pattern evaluation method relied on the clinical classification system proposed by Fujii *et al*^[7] and Matsuda *et al*^[8], with reference to the Kudo Classification System. Lesions were categorized into noninvasive and invasive

patterns. The noninvasive pattern included regular crypts with or without a demarcated area (e.g. depression, large nodule, or reddened area) and irregular pits without a demarcated area, and are usually observed in Kudo's types III_s, III_l, IV and V_l without demarcated areas (e.g. adenomatous polyps, m and sm-s cancers), with endoscopic resection being the appropriate treatment. The invasive pattern was characterized by irregular and distorted crypts in a demarcated area, as observed in Kudo's type V_N and V_l with a demarcated area (e.g. sm-d), and should be treated by surgical resection. As indicated, Kudo's type V_l can be observed in either noninvasive or invasive patterns. Those differences are dependent on the presence or absence of a demarcated area.

Microvascular architecture of ECC

Microvascular architectural images taken during magnification colonoscopy with NBI were reviewed retrospectively by three endoscopists who referenced the microvascular architectural features of superficial esophageal carcinoma^[15], and included the following characteristics: (1) caliber, narrow or wide; (2) caliber regularity, positive or negative; (3) meandering, positive or negative; (4) vessel regularity, positive or negative; (5) vessel length, short or long; and (6) vessel density, non-dense or dense. These characteristics were evaluated by comparing the NBI with magnification images to representative photographs of model examples (Figure 1).

Statistical analysis

We compared microvascular architecture as revealed by NBI with magnification to histological findings using the χ^2 test of independence or Fisher's exact test for univariate analysis. Variables with a *P* value of < 0.05 in our univariate analysis were subsequently included in a logistic regression multivariate analysis. The StatView program, version 5.0 (SAS Institute, Cary, NC, USA), was used for data analysis and *P* < 0.05 was considered to be statistically significant.

RESULTS

Clinicopathological features of patients and lesions

The clinicopathological details of the patients and colorectal lesions involved in this study are shown in Table 1.

Univariate analysis

Univariate analysis indicated characteristics involving vessel density: non-dense (*P* < 0.0001); vessel regularity: negative (*P* < 0.0001); caliber regularity: negative (*P* < 0.0001); vessel length: short (*P* < 0.0001); and vessel meandering: positive (*P* = 0.002) occurred significantly more often with sm-d invasion than m/sm-s invasion (Table 2).

Multivariate analysis

Multivariate analysis demonstrated that sm-d invasion was independently associated with vessel density: non-dense [odds ratio (OR) = 402.5, 95% confidence interval (CI): 12.4-13133.1]; and vessel regularity: negative (OR = 15.9, 95% CI: 1.2-219.1) (Table 2). The sensitivity, speci-

¹Update on the Paris classification of superficial neoplastic lesion in the digestive tract^[36]. LST-G: Laterally spreading tumor-granular type; LST-NG: Laterally spreading tumour-non granular type; m/sm-s: Mucosal/submucosal superficial; sm-d: Submucosal-deep.

ficity, PPV, NPV and diagnostic accuracy rate for each characteristic are shown in Table 3. The two vascular findings that were confirmed by multivariate analysis had the highest values for specificity, PPV and accuracy (non-dense vessel density: specificity 0.99, PPV 0.95, accuracy 90.2%; negative vessel regularity: specificity 0.99, PPV 0.95, accuracy 90.2%).

Pit pattern diagnosis

The pit patterns of 21 m/sm-s lesions were evaluated following IC dye spraying, whereas the pit patterns of the other 48 m/sm-s lesions and all 43 sm-d lesions were assessed after crystal violet staining. We subsequently calculated the sensitivity, specificity, PPV, NPV and accuracy in differentiating m/sm-s from sm-d for: (1) the pit patterns that were diagnosed as being invasive; and (2) the NBI with magnification characteristic findings of (a) non-dense vessel density and/or negative vessel regularity and (b) non-dense vessel density and negative vessel regularity, which were both considered to be indicators for sm-d invasion. Pit pattern analysis sensitivity, specificity, PPV, NPV and diagnostic accuracy were 0.86 (95% CI: 0.72-0.95), 0.99 (0.92-0.99), 0.97 (0.86-0.99), 0.92 (0.83-0.97) and 93.8%, respectively. The NBI with magnification characteristic findings of non-dense vessel density and negative vessel regularity were comparable to pit pattern diagnosis results [0.81 (0.67-0.92), 1.00 (0.95-1.00), 1.00 (0.90-1.00), 0.90 (0.81-0.95), 92.9%] (Table 4). Seven of the lesions in this study were incorrectly diagnosed using pit pattern analysis including six sm-d lesions mistakenly diagnosed as m/sm-s invasion depth. In two of these cases, however, both non-dense vessel density and negative vessel regularity had also been observed by magnification NBI, which suggests its potential use as a supplementary diagnostic tool to pit pattern diagnosis (Figures 2 and 3).

DISCUSSION

It has been reported previously that observation of intra-

Invasion depth diagnosis using NBI with magnification was correct, based on findings of non-dense vessels and negative vessel regularity, but pit pattern diagnosis of this lesion was inaccurate.

nifying endoscopy. In cancerous lesions, characteristic changes of the intrapapillary capillary loops can be seen in the superficial mucosa according to the depth of tumor

invasion. There have been few studies to assess invasion depth in cancerous lesions from microvascular architecture. However, the NBI system enabled observation of

microvascular architecture of the tumor surface in the GI tract. In a similar fashion, we used NBI with magnification to investigate whether or not quantitative ECC invasion depth diagnosis was possible based on analysis of capillary vessel patterns instead of pit patterns. Based on our results, it appeared that non-dense vessel density and negative vessel regularity, as observed by NBI with magnification, could be diagnostic indicators of sm-d invasion, as effectively as pit pattern analysis.

Regular hexagonal or honeycomb-like capillary patterns are formed around the crypts of normal colorectal mucosa. In contrast, it has been reported that these capillaries are larger in tumor adenomas, whereas vascular disruption, caliber irregularity and dense vessels have been observed in severe atypical cases^[37]. In addition, vascular changes do not generally occur in non-neoplastic lesions such as hyperplastic polyps, with the exception of inflammatory polyps^[38]. The NBI technique provides clearer observation of microvascular architectural characteristics, therefore, it has been reported that differentiation of neoplastic from non-neoplastic lesions on the basis of different vascular patterns is equally possible using NBI or chromoendoscopy^[21-30], and pit pattern diagnosis has likewise been explored using NBI^[21,24,27,28]. Previous studies have shown that the accuracy of pit pattern diagnosis of invasion depth by magnification endoscopy was 98.8%^[8], whereas such diagnostic accuracy in this study was 93.8%.

The area surrounding crypts in the superficial layer of the mucosa is covered with capillaries and has previously been recognized as a pit using the NBI technique. Machida *et al.*^[21] have reported that NBI pit pattern diag-

nosis is significantly more useful ($P < 0.001$) than conventional observation, but inferior to chromoendoscopy ($P < 0.05$). Hirata *et al.*^[24] have reported that overall diagnostic consistency in pit patterns between magnification NBI and dye-spraying observations was 84%, but even higher for types II, III, IV and V_N pit patterns, although somewhat lower at 78%, for the type V_I pit pattern. In addition, Tischendorf *et al.*^[27] have reported that there is no significant difference in the PPV for neoplastic lesions as determined by pit pattern and vascular findings using NBI. There was a discrepancy, however, between two endoscopists in their NBI pit pattern diagnosis of types III-V neoplastic lesions^[27]. This may have been because the actual pit structure was not observed using the NBI technique, unlike the results from the contrast and staining methods; or, it could have been caused by the NBI pit pattern diagnosis of types III-V lesions, which are considered particularly important in determining the most suitable method of treatment, not having been performed accurately.

More recently, Katagiri *et al.*^[30] have reported that capillary patterns observed by NBI with magnification are highly accurate in distinguishing between low-grade and high-grade dysplasia/invasive cancer, and thus could be used to predict the histopathological features of colorectal neoplasia. In addition, Hirata *et al.*^[25] have reported vascular findings of significant sm-d invasion based on their NBI observation of thick blood vessels with irregularity on the surface of tumors. This differs somewhat from the results of our investigation, but the difference could be caused by a number of factors, such as variations in our respective definitions of vascular findings, and the macroscopic types of lesions involved in the two studies.

Magnification observation with dye spraying and staining, in particular crystal violet staining, however, can be time-consuming. Patient symptoms including abdominal discomfort and peristalsis are more likely to appear in longer duration colonoscopy examinations, which may render detailed observation more problematic. In contrast, the press of a single button on the handle of the endoscope with the NBI system can almost immediately change from NBI to the conventional view and back again, thereby shortening examination times and reducing the burden on patients and endoscopists alike. A mucous attachment on the endoscope can also interfere with diagnosis, and washing the surface of a lesion with pronase solution takes additional time during pit pattern diagnosis by magnification colonoscopy with IC dye spraying or crystal violet staining. Hirata *et al.*^[24] have further reported that NBI observation results in more accurate pit pattern diagnosis than dye spraying observation in cases with mucous attachment.

Our study suffered from some limitations. First, the NBI assessments were made on still images by three endoscopists, whereas the pit pattern diagnosis was done in real time after initial inspection with NBI, which could account for some further bias. Second, the different NBI features of the microvasculature are not independent: the endoscopist is not blinded to one feature if he scores the other. In addition, lesions that were diagnosed histologically as cancer had a diameter of at least 10 mm, thus lesions < 10 mm in diameter were not assessed in this study. Accordingly, future prospective studies will require that relevant data be accumulated and analyzed on a more objective basis.

In conclusion, the results of this study indicated that two microvascular architectural characteristics, non-dense vessel density and negative vessel regularity, observed using NBI with magnification during colonoscopy examinations could be reliable indicators of ECC sm-d invasion.

COMMENTS

Background

The intra-papillary capillary loops can be seen in the normal esophageal mucosa by magnifying endoscopy. In cancerous lesions, characteristic changes of the intrapapillary capillary loops can be seen in the superficial mucosa according to the depth of tumor invasion. Narrow-band imaging (NBI) enables detailed observation of microvascular architecture of the tumor surface.

Research frontiers

NBI provides clearer observation of microvascular architectural characteristics, and it has been reported that differentiation of neoplastic from non-neoplastic lesions on the basis of different vascular patterns is equally possible using NBI or chromoendoscopy. However, there have been only a few reports concerning invasion depth diagnosis using NBI with magnification in a large series of cases. This study clarifies the efficiency of NBI with magnification colonoscopy for invasion depth diagnosis of early colorectal cancer (ECC).

Innovations and breakthroughs

Some studies have already reported the clinical usefulness of pit pattern

diagnosis using magnifying chromoendoscopy for predicting the depth of invasion of ECC. The authors' results indicate that NBI with magnification findings were comparable to pit pattern diagnosis results.

Applications

Magnification observation with dye spraying and staining, in particular crystal violet staining, however, can be time-consuming. In contrast, the press of a single button on the handle of the endoscope with the NBI system can almost immediately change from NBI to the conventional view and back again, thereby shortening examination times and reducing the burden on patients and endoscopists alike.

Peer review

The authors present a trial analyzing the impact of NBI colonoscopy on assessing the invasion depth in ECC. Overall, 112 patients were included; additionally pit pattern analysis was performed in 64 patients. The study investigated interesting questions.

Abstract

AIM: To observe the regional distributions and morphological features of nesfatin-1/nucleobindin-2 (NUCB2) immunoreactive (IR) cells in the rodent digestive system.

METHODS: Paraffin-embedded sections of seven organs (pancreas, stomach, duodenum, esophagus, liver, small intestine and colon) dissected from sprague-dawley (SD) rats and institute of Cancer Research (ICR) mice were prepared. The regional distributions of nesfatin-1/NUCB2 IR cells were observed by immunohistochemical staining. The morphological features of the nesfatin-1/NUCB2 IR cells were evaluated by hematoxylin and eosin (HE) staining. Fresh tissues of the seven organs were prepared for Western blotting to analyze the relative protein levels of NUCB2 in each organ.

RESULTS: Immunohistochemical staining showed that the nesfatin-1/NUCB2 IR cells were localized in the central part of the pancreatic islets, the lower third and middle portion of the gastric mucosal gland, and the submucous layer of the duodenum in SD rats and ICR mice. HE staining revealed that the morphological features of nesfatin-1/NUCB2 IR cells were mainly islet cells in the pancreas, endocrine cells in the stomach, and Brunner's glands in the duodenum. Western blotting revealed that NUCB2 protein expression was higher in the pancreas, stomach and duodenum than in the esophagus, liver, small intestine and colon ($P = 0.000$).

CONCLUSION: Nesfatin-1/NUCB2 IR cells are expressed in the pancreas, stomach and duodenum in rodents. These cells may play an important role in the physiological regulation of carbohydrate metabolism, gastrointestinal function and nutrient absorption.

INTRODUCTION

Nesfatin-1, an anorexigenic peptide derived from nucleobindin-2 (NUCB2), is the latest addition to the surprisingly large number of chemical messengers telling the body that the "tank (appetite) is full"^[1]. Nesfatin-1

injected directly into the brain of rats promotes anorexia, whereas an antibody specific to nesfatin-1 injected into the brain potently stimulates feeding^[1]. Previous studies have shown that nesfatin-1/NUCB2 immunoreactive (IR) cells are present in a number of discrete neuronal populations or nuclei, including the hypothalamic arcuate nucleus (ARC), paraventricular nucleus (PVN), supra-optic nucleus, lateral hypothalamic area, and the dorsal motor nucleus of the vagus and nucleus tractus solitarius in the brain stem^[1-5]. Energy homeostasis-regulating circuits are found within and connect these nuclei. NUCB2 gene expression and the nesfatin-1 concentration in the PVN were reduced after a fast of 24 h^[1]. Nesfatin-1 alters the membrane potential of different subpopulations of neurons within the PVN^[6]. In the ARC, nesfatin-1 exerts its anorexigenic effects by inhibiting the orexigenic neuropeptide Y neurons^[7]. In mice, 5-hydroxytryptamine (5-HT) systems, *via* 5-HT_{2c} receptors, upregulate the expression of hypothalamic NUCB2 and induce anorexia *via* a leptin-independent pathway^[8]. These observations indicate a physiological role of central nesfatin-1 in the regulation of food intake.

Two different groups have demonstrated that peripherally injected nesfatin-1 crosses the blood-brain barrier in a non-saturable way to reach brain tissues^[9,10]. Central and peripheral administration of nesfatin-1 resulted in a reduced food intake^[1,11]. These observations, and the fact that various centrally active regulatory neuropeptides are also produced in the periphery, particularly the digestive system^[12], raise the question as to whether peripheral sites also express nesfatin-1/NUCB2.

Therefore, in the present study, we investigated the regional distributions and morphological features of nesfatin-1/NUCB2 IR cells in various organs of the digestive system of sprague-dawley (SD) rats and institute of Cancer Research (ICR) mice, to lay a foundation for the further investigation of its functions in the digestive system.

MATERIALS AND METHODS

Ethics

All procedures strictly adhered to the guidelines of the Institution Council of Animal Care and were approved by the Ethics Committee of Nanjing Medical University.

Materials

Adult male SD rats, weighing 220-250 g, and adult ICR mice, weighing 22-25 g, were obtained from the Experimental Animal Center of Nanjing Medical University (China). Animals were housed in groups of three per cage under controlled illumination (12:12 h light/dark cycle, lights on/off: 6 h/18 h), humidity (60%) and temperature (22 ± 2°C). Animals were fed a standard rodent diet and tap water *ad libitum*.

Antibodies

Mouse anti-nesfatin-1 monoclonal antibody [1:40 000, diluted in 0.3% Triton X-100 in phosphate-buffered

saline (PBS) for immunohistochemistry and 1:1000, diluted in Tris-buffered saline (TBS) in 5% (g/L) nonfat milk for Western blotting], was purchased from Alexis Biochemicals Company, USA. The SP Eivision™ plus kit used for immunohistochemistry, was purchased from Maixin_Bio Fuzhou, Co., Ltd., China. Mouse anti-β-actin monoclonal antibody [1:5000, diluted in TBS/5% nonfat milk for Western blotting], was purchased from Sigma-Aldrich, Co., Inc., USA. Horseradish peroxidase (HRP)-conjugated goat anti-mouse IgG antibody [1:5000, diluted in TBS/5% nonfat milk for Western blotting], was purchased from KPL Gaithersburg, MD, USA.

Immunohistochemistry

Animals (fed *ad libitum*) were euthanized at 09:00 am by intraperitoneal injection of 10% chloral hydrate anesthetic and the pancreas, stomach, duodenum, esophagus, liver, small intestine and colon were quickly resected and transferred to 4% paraformaldehyde and fixed at 4°C for 24 h. After being dehydrated through an ethanol-xylene series, the specimens were embedded in paraffin. Sections were cut (5 μm thick) and mounted on polylysine-coated slides.

Each representative section was immunostained using the streptavidin-peroxidase method^[13]. Sections were de-waxed in xylene and dehydrated with a gradient alcohol series, then incubated for 20 min at 100°C in citrate buffer (pH 6.0) for antigen retrieval^[14]. Endogenous peroxidase was blocked by incubating the sections with 0.3% hydrogen peroxide for 15 min and non-specific binding was reduced by pretreatment with 3% normal goat serum for 20 min. The sections were then incubated with primary antibody (mouse anti-nesfatin-1 monoclonal antibody) overnight at 4°C. After washing in PBS, the sections were incubated for 20 min at room temperature (RT) with polymer enhancer and then incubated with the secondary antibody (polymerized HRP-conjugated anti-mouse IgG antibody) supplied with the SP Eivision™ plus kit for 30 min at RT. The peroxidase reaction was carried out in 3,3'-diaminobenzidine tetrachloride solution (MaiXin_Bio, Fuzhou, Co., Ltd., China) for 2 min and regularly checked under a light microscope. After being lightly counterstained with Mayer's hematoxylin for 1 min, the section was mounted on a slide, dehydrated with absolute alcohol followed by xylene, air-dried and coverslipped with Permount. Sections were observed and photomicrographed under a confocal microscope (Zeiss, AxioCam MRc5, Germany).

To investigate the specificity of the nesfatin-1 antibody under our conditions, the same protocol was applied for immunostaining after pre-absorption of the anti-nesfatin-1-antibody. Recombinant rat nesfatin-1 (50 μg ALX-522-116 Alexis Biochemical, USA) was incubated with mouse monoclonal anti-nesfatin-1 antibody at 1:40 000 in 0.3% Triton X in PBS for 2 h at RT followed overnight at 4°C. The solution was centrifuged for 15 min at 12 000 × g and the supernatant was used for staining as described above, as a negative control. For the positive

control, we used tissue sections obtained from the hypothalamus of three *ad libitum*-fed male SD rats, which had been confirmed to express the peptides of interest^[1]. Cells expressing these peptides were colored brown.

Hematoxylin and eosin staining

The paraffin specimens used for immunohistochemical staining were also used for hematoxylin and eosin (HE) staining. Each section was de-waxed in xylene and dehydrated with a graded alcohol series. After being washed with distilled water for 3 min, the sections were counterstained with Mayer's hematoxylin for 15 min, washed in distilled water for 3 min and incubated in the eosin staining solution for 3 min. Finally, the sections were mounted on a slide, dehydrated with absolute alcohol followed by xylene, air-dried and coverslipped with Permount. All specimens were observed and photomicrographed under a confocal microscope.

Sodium dodecylsulfate polyacrylamide gel electrophoresis and Western blotting analysis

Tissue specimens from seven digestive organs of SD rats and ICR mice were kept on ice and ultrasonicated in the presence of one tablet of protease split cocktail [20 mmol/L Tris buffer pH 6.8, 4 mmol/L ethylene diamine tetraacetic acid pH 8.0 and 2% sodium dodecylsulfate (SDS)]. The crude protein fractions were obtained by centrifugation of the homogenates in a Sorvall centrifuge at 12000 × *g* for 20 min at 4°C to remove cell debris and nuclei. The supernatant was used as the protein fraction. The final protein concentrations of the protein fractions were determined using a BCA protein assay (Pierce Biotechnology, Rockford, IL, USA).

Gel samples were prepared by mixing protein samples with gel sample buffer [10% SDS, 0.05% bromophenol blue (g/L), 25% glycerol (g/L), 10% mercaptoethanol (mL/L) in 0.1 mmol/L Tris buffer pH 6.8]. The samples were boiled at 100°C for 5 min before gel electrophoresis. Forty micrograms of each protein sample was loaded on a 5%-10% SDS polyacrylamide gel and run in a running buffer [25 mmol/L Tris-HCl, 192 mmol/L glycine, 0.1% SDS (g/L)]. After SDS-polyacrylamide gel electrophoresis, the proteins were transferred by electrophoresis to polyvinylidene difluoride membranes (Roche Diagnostics Indianapolis, IN, USA) in a transfer buffer [48 mmol/L Tris-HCl, 39 mmol/L glycine, 0.037% SDS] for 60 min on ice. The membranes were washed twice with TBS [10 mmol/L Tris-HCl, 150 mmol/L NaCl, 0.05% Tween-20 (mL/L)]. Non-specific binding sites were blocked by incubation in TBS containing 5% nonfat milk (Guangming, Co., Ltd., Shanghai, China) for 1 h at RT. The membranes were then incubated with the primary antibodies [mouse anti-nesfatin-1 monoclonal antibody (1:1000) and mouse anti-β-actin monoclonal antibody (1:5000)] overnight at 4°C. β-actin, a house-keeping protein, served as an internal control for the Western blotting. The next day, the membranes were washed three times with TBS and then incubated with the secondary

antibody [HRP-conjugated goat anti-mouse IgG antibody (1:5000)] for 2 h at 37°C. After the membranes were washed three times in TBS, enhanced chemiluminescence detection of the target protein was performed using the ECL plus Western blotting detection system (Pierce Biotechnology, Rockford, IL, USA) and exposed using a Kodak autoradiography system (Kodak, Image Station 2000 mm, USA). Densitometry was performed using Kodak Molecular Imaging software. The relative protein levels of NUCB2 in each organ were represented as the density ratio *vs* β-actin (NUCB2/β-actin). All Western blotting analyses were repeated at least three times.

Statistical analysis

Statistical analysis was performed using SPSS 11.5 software (SPSS Inc., Chicago, IL, United States). Data were expressed as means ± SD. Comparisons between groups were made using one-way analysis of variance (ANOVA) followed by Student-Newman-Keuls (SNK) *post hoc* tests for multiple comparisons. *P* values less than 0.05 were considered statistically significant.

RESULTS

Nesfatin-1/NUCB2 IR cells in pancreas, stomach and duodenum detected by immunohistochemical and HE staining

Nesfatin-1/NUCB2 IR, visualized as brown granules, was exclusively localized in the cytoplasm, but not in the nucleus or cell membrane. No brown granules were detected in the negative control sections stained with pre-absorbed anti-nesfatin-1-antibody, indicating that the immunostaining was specific for the target protein.

In the SD rats, nesfatin-1/NUCB2 IR cells were detected in the center of the pancreatic islets, but no immunopositive cells were detected in the pancreatic exocrine cells (Figure 1A). Nesfatin-1/NUCB2 IR cells were also found in the lower third and the middle portion of the gastric oxyntic glands (Figure 1B) and the submucosa of the duodenum (Figure 1C).

In the ICR mice, nesfatin-1/NUCB2 IR cells were also detected in the center of the pancreatic islets (Figure 1D). However, in the stomach, they were only localized in the lower third of the gastric oxyntic glands (Figure 1E). In the duodenum, nesfatin-1/NUCB2 IR cells were also expressed in the submucosal layer glands (Figure 1F). No nesfatin-1/NUCB2 IR cells were detected in the esophagus, liver, small intestine or colon in either the SD rats or in the ICR mice (data not shown).

We further observed the features of nesfatin-1/NUCB2 IR cells in the SD rats (Figure 2A-C) and the ICR mice (Figure 2D-F) using HE staining. The IR cells in the pancreas were islet cells. In histological sections of the pancreas, the islets were seen as relatively pale-staining groups of cells embedded in a region of darker-staining exocrine tissues (Figure 2A and D). In the stomach, they were endocrine cells. These cells were round, oval, triangular, spindle-, shuttle- or flask-like in shape and

located between the glandular cells and the basement membrane at the basal portion of the gastric oxyntic glands (Figure 2B and E). The submucosal glands in the

duodenum were Brunner's glands, which were compound tubular submucosal glands consisting of epithelial tubules with frequent distal branches (Figure 2C and F).

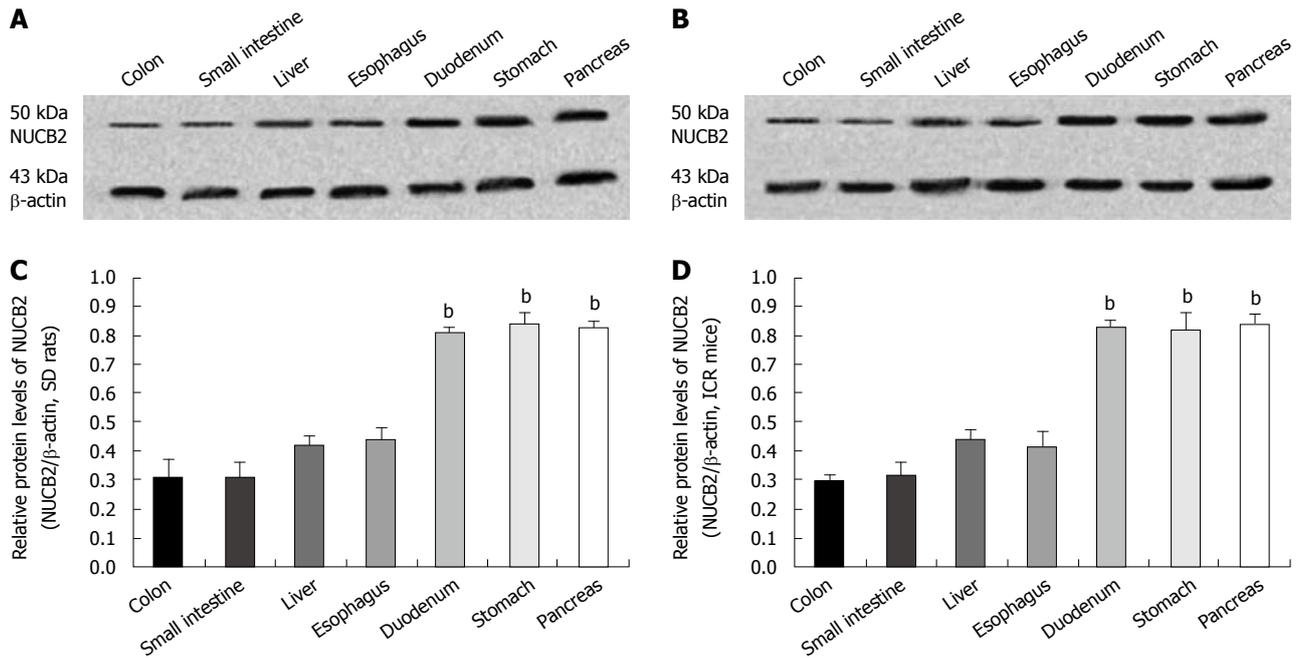

Figure 3 Western blotting for NUCB2 protein in the digestive system of the SD rats (A, C) and ICR mice (B, D). A, B: The predicted band for full-length NUCB2 protein (50 kDa) and β -actin (43 kDa) were observed in all organs; C, D: The relative protein levels of NUCB2 were significantly higher in the pancreas, stomach and duodenum than in the esophagus, liver, small intestine and colon. ^b $P < 0.001$. Data are mean \pm SD. analysis of variance (ANOVA) followed by Student-Newman-Keuls (SNK) test.

Protein levels of NUCB2 in the seven digestive organs

Western blotting of crude proteins of the seven digestive organs with the mouse anti-nesfatin-1 monoclonal antibody, which targets nesfatin-1 and its precursor NUCB2, showed a band corresponding to full-length NUCB2 protein (50 kDa). By contrast, no band corresponding to nesfatin-1 (9.7 kDa) was detected in either SD rats (Figure 3A) or the ICR mice (Figure 3B). In SD rats ($n = 6$), NUCB2 protein was highly expressed in the pancreas (relative expression; 0.82 ± 0.03), stomach (0.84 ± 0.04) and duodenum (0.80 ± 0.02), with lower expression in the esophagus (0.43 ± 0.05), liver (0.42 ± 0.03), small intestine (0.31 ± 0.05) and colon (0.31 ± 0.06) (Figure 3C). A similar pattern of expression was found in the ICR mice ($n = 6$), with high expression of NUCB2 in the pancreas (0.84 ± 0.03), stomach (0.82 ± 0.06) and duodenum (0.83 ± 0.02), and lower expression in the esophagus (0.42 ± 0.05), liver (0.43 ± 0.04), small intestine (0.31 ± 0.05) and colon (0.29 ± 0.02) (Figure 3D). The relative protein levels of NUCB2 in each immunopositive organ (pancreas, stomach and duodenum) were significantly higher than that in the immunonegative organs (esophagus, liver, small intestine and colon) in the SD rats and ICR mice ($P = 0.000$; ANOVA followed by SNK test).

DISCUSSION

Although the function of nesfatin-1/NUCB2 remains largely unknown, its sequence is highly conserved from rats and mice to humans, indicating an important biological role^[1]. NUCB2 is proteolytically processed by prohormone convertase to nesfatin-1 (residues 1-82), nesfatin-2 (residues 85-163) and nesfatin-3 (residues 166-396).

However, of these, only nesfatin-1 was effective in the reduction of food intake^[1]. The initial reports by several researchers have described a wide distribution of nesfatin-1 in the central nervous system of rats. In the present study, our findings expand these reports to the digestive system of SD rats and ICR mice. We found an abundant distribution of nesfatin-1/NUCB2 IR cells in the pancreatic islets, gastric endocrine cells and the duodenal Brunner's glands of the rodents. In particular, our results have revealed that nesfatin-1/NUCB2 IR cells are located in the submucosal Brunner's glands of the duodenum, which has not been previously reported in rats^[15]. Because the number of Brunner's glands in the duodenum is relatively small, which are restricted to a small region of the duodenum, they may have been overlooked in the earlier studies. Thus, to the best of our knowledge, this is the first report to show the presence of nesfatin-1/NUCB2 IR cells in the Brunner's glands of the duodenum. The Brunner's glands are primarily confined to the duodenal bulb and their number gradually decreases to absent in the duodenojejunal flexure^[16]. The main function of Brunner's glands is to produce an alkaline secretion containing bicarbonate and mucus to: (1) protect the duodenum from the acidic content of chyme, which is introduced into the duodenum from the stomach; (2) provide an alkaline condition for the intestinal enzymes to be active, thus enabling absorption to take place; and (3) lubricate the intestinal walls^[17]. Although the functional role of nesfatin-1/NUCB2 in the duodenum is currently unknown, the abundant expression of nesfatin-1/NUCB2 IR cells in the Brunner's glands found in this study suggests that nesfatin-1/NUCB2 may be involved in the regulation of intestinal

enzyme activation, nutrition absorption and preservation of the intestinal walls. To verify this hypothesis, further studies should focus on the molecular mechanism underlying nesfatin-1/NUCB2 IR cells in the Brunner's glands to gain a basic understanding of their pathobiology.

The immunohistochemical analysis also showed abundant nesfatin-1/NUCB2 IR cells in the center of the pancreatic islets, but none in the pancreatic exocrine cells. The islets of Langerhans in the pancreas regulate blood glucose levels. Islets consist of four types of secretory cells: glucagon-producing α -cells, insulin-producing β -cells, somatostatin-producing δ -cells, and PP cells, which contain pancreatic polypeptide. Interestingly, the different cell types within an islet are not randomly distributed. β -cells occupy the central portion of the islet and are surrounded by a layer of α - and δ -cells^[18]. In our experiment, we found that the nesfatin-1/NUCB2 IR cells were principally concentrated in the central region of the islets. Therefore, based on this localization, we speculated that they were β -cells. This is consistent with a recent study, which demonstrated that insulin-producing β -cells in mice and rats co-express nesfatin-1 immunoreactivity^[19]. These findings suggest possible roles of nesfatin-1/NUCB2 in carbohydrate metabolism.

A recent study has shown the presence of nesfatin-1/NUCB2 IR cells in the stomach of rats^[15]. Furthermore, the expression of NUCB2 mRNA in gastric endocrine cells is significantly down-regulated after a 24-h fast^[15]. That study suggested a regulatory anorexigenic role of peripheral nesfatin-1/NUCB2 in energy homeostasis. Similarly, in the present study, we found abundant nesfatin-1/NUCB2 IR cells in the lower third and middle portion of the gastric oxyntic glands in SD rats but only in the lower third of the gastric oxyntic glands in ICR mice. These results suggest fine distinctions in species-specific expression patterns of nesfatin-1/NUCB2 in the rodent stomach. The morphological features of these cells were endocrine cells. Therefore, it is assumed that nesfatin-1/NUCB2 in the stomach may play an important role in the regulation of gastric functions.

In the present study, the 50-kDa NUCB2 protein was detected ubiquitously in all digestive organs, but the protein was only detected in appreciable amounts in the pancreas, stomach and duodenum by immunohistochemistry, which is consistent with the higher levels of NUCB2 protein detected in these three tissues by Western blotting. Nesfatin-1 consists of 82 amino acids and has a predicted molecular weight of 9.7 kDa^[1]. Although the antibody we used in the Western blotting is targeted against the nesfatin-1 and its precursor NUCB2, the Western blottings of all tissues studied here only detected a single band of approximately 50 kDa representing NUCB2, but failed to show a band at 9.7 kDa. Therefore, as described by Stengel *et al.*^[15], the protein identified in this study was called nesfatin-1/NUCB2.

Taken together, the findings of this study demonstrate the presence of nesfatin-1/NUCB2 IR cells in the pancreas, stomach and duodenum but not in the esophagus, liver,

small intestine or colon of the SD rats and the ICR mice and the relative protein levels of NUCB2 were significantly higher in pancreas, stomach and duodenum. Like many other feeding behavior regulatory peptides, nesfatin-1 was expressed both centrally and in the periphery. The broad distributions of nesfatin-1/NUCB2 in the digestive system suggest a possible regulatory role of peripheral nesfatin-1/NUCB2 in carbohydrate metabolism, gastrointestinal function and nutrition absorption. Going forward, it will be crucial to understand the site and mechanism of action for the anorectic signal mediated by nesfatin-1. Identifying a receptor or non-classical binding partner for nesfatin-1 will be an important first step in this journey.

COMMENTS

Background

In 2006, Oh-I and his colleagues discovered a new feeding inhibitory molecule, and named it nesfatin-1. They initially found the novel anorexigenic peptide expressed in a number of discrete neuronal populations or nuclei, which are involved in feeding behavior. Subsequently, several researchers have expanded the distributions of nesfatin-1 in the central nervous system. It is well known that various centrally active food regulatory neuropeptides are also produced in the periphery, particularly the digestive system. The authors investigated the regional distributions of nesfatin-1/nucleobindin-2 (NUCB2) in various organs of the digestive system of sprague-dawley (SD) rats and institute of Cancer Research (ICR) mice.

Research frontiers

Although the function of nesfatin-1/NUCB2 remains largely unknown, its sequence is highly conserved from rats and mice to humans, indicating an important biological role. The nesfatin-1 signaling pathway might be associated with the melanocortin signaling pathway in the hypothalamus. The hypothalamic leptin signaling pathway does not exist downstream of the pathway by which nesfatin-1 causes anorexia. Nesfatin-1 can cross the blood-brain barrier without saturation. Nesfatin/NUCB2-immunoreactivity was recently identified in the rat gastric mucosa. Systemic or local administration of nesfatin-1-related drugs may improve metabolic disorders by reducing the body weight of patients with obesity and metabolic syndrome.

Innovations and breakthroughs

This is the first study to report the expression of nesfatin-1/NUCB2 in the duodenal Brunner's glands. Furthermore, a quantitative analysis with Western blotting studies showed higher protein levels of NUCB2 in the immunopositive organs than in the immunonegative organs.

Applications

By understanding where nesfatin-1/NUCB2 is expressed and by quantitatively analyzing its expression in the digestive system, this study may lay a foundation for the further investigation of its functions in the digestive system. In addition, this may help understand the relationship between the peripheral and the central nervous system.

Peer review

The authors examined the expression of nesfatin-1/NUCB2 in seven organs of the digestive system in SD rats and ICR mice. The study not only confirmed that nesfatin-1/NUCB2 is expressed in the pancreas and stomach, but is also for the first time to reveal that nesfatin-1/NUCB2 is expressed in the duodenal Brunner's gland. The authors conducted a quantitative analysis to determine the protein levels of NUCB2 in the seven organs. The results are interesting and may lay a foundation for the further investigations of its functions in the digestive system.

Abstract

AIM: To evaluate the development of diagnostic tools, indications for surgery and treatment modalities concerning diverticular disease (DD) in the Netherlands.

METHODS: Data were collected from 100 patients who underwent surgery for DD in three Dutch hospitals. All hospitals used the same standardized database. The collected data included patient demographics, patient history, type of surgery and complications. Patients were divided into two groups, one undergoing elective surgery (elective group) and the other undergoing acute surgery (acute group).

RESULTS: Two hundred and ninety-nine patients were admitted between 2000 and 2007. One hundred

and seventy-eight patients underwent acute surgery and 121 patients received elective operations. The median age of the 121 patients was 69 years (range: 28-94 years), significantly higher in acute patients ($P = 0.010$). Laparoscopic resection was performed in 31% of elective patients. In the acute setting, 61% underwent a Hartmann procedure. The overall morbidity and mortality were 51% and 10%, and 60% and 16% in the acute group, which were significantly higher than in the elective group (36% and 1%). Only 35% of the temporary ostomies were restored.

CONCLUSION: This study gives a picture of current surgical practice for DD in the Netherlands. New developments are implemented in daily practice, resulting in acceptable morbidity and mortality rates.

INTRODUCTION

Diverticular disease (DD) accounts for 14 000 hospital admissions annually in the Netherlands. The incidence of DD is rising, mainly among younger patients^[1]. The treatment depends on the severity of the disease, vary-

ing from light symptomatic diverticulosis to perforated diverticulitis. For years it was thought that the risk of perforation and other complications increased after each recurrence. Therefore, the American Association of Colorectal Surgeons suggested to perform an elective sigmoid resection after two episodes of acute diverticulitis, after a single episode in young patients or when complications, such as stenosis or fistulae, occur^[2].

However, new insights in the natural course of DD resulted in a more conservative approach. Severe complicated diverticulitis, leading to acute surgical intervention, is most often the primary presentation of the disease^[3]. More recent studies highlight the benign course of recurrent episodes of diverticulitis with a low complication rate in patients treated conservatively for an acute episode of diverticulitis^[4-6]. It is suggested that elective, prophylactic sigmoid resections based on the number of episodes is not always indicated.

New diagnostic tools and therapeutic techniques have improved the treatment of DD. For instance, the ability to treat large abscesses by computed tomography (CT)-guided percutaneous drainage prevents the emergency surgery and can form a bridge to an elective resection when indicated^[7]. The rise of laparoscopic surgery since the 90s resulted in decreased morbidity and mortality rates, making it the preferred approach in elective sigmoid resections^[8].

Whether a laparoscopic approach can also be applied to patients with perforated diverticulitis and generalized peritonitis remains to be confirmed. Laparoscopic sigmoid resection cannot be accomplished completely because of extensive pericolic infiltration and faecal or purulent contamination. Hartmann's procedure is the treatment of first choice for most surgeons. However, several recent studies showed that a primary anastomosis with or without a deviating ileostomy could be performed safely under these circumstances^[9,10]. Even laparoscopic lavage can be a safe alternative for Hartmann's procedure in case of perforated purulent diverticulitis^[11].

The aim of this study is to evaluate development of diagnostic tools, indications for surgery and treatment modalities concerning DD in the Netherlands. We analyzed the results of 299 patients with DD treated in three Dutch hospitals. Since the patients treated for acute diverticulitis have a worse prognosis compared with electively treated patients, we analyzed them in separate groups.

MATERIALS AND METHODS

In January 2008, we collected and pooled the data in the last 100 patients with DD treated surgically in three Dutch hospitals. The hospitals were the VU University Medical Center in Amsterdam, the Deventer Ziekenhuis in Deventer and the Reinier de Graaf Gasthuis in Delft, evenly distributed over the country. Patients were selected using national coding systems (i.e. ICD-9) and the national pathology database (PALGA).

The following data were collected: gender, age, ASA-grade (American Society of Anesthesiologists), type of admission (elective or acute), previous episodes of diverticulitis, results of radiological tests (CT-scan, ultrasound and contrast enemas), operative technique, duration of operation, type of surgeon [gastrointestinal (GI)-surgeon, resident or general surgeon], Hinchey classification^[12], intensive care unit (ICU) admission, complications, creation/restoration of ostomies and mortality. The data were collected in a standardized database by retrospective analysis of the medical records.

Minor complications include urinary tract infections, conservatively treated ileus, small wound infection and/or postoperative delirium. Anastomotic leakages, evisceration, necrotic ostomy, re-operation for other reasons and/or cardiopulmonary distress were considered to be major complications. Mortality was defined as death within 30 d after operation or during initial hospital admission.

Statistical analysis

Data of the three hospitals were combined into one database. Patients were divided into two groups: one undergoing elective surgery and the other undergoing acute surgery. Statistical analysis was performed using SPSS 15.0.1 (SPSS Inc., Chicago, IL, USA). Values were expressed as median and range for continuous variables. Distributions of dichotomous data were given in percentages. Continuous variables with normal distribution were compared using Student's *t* test. Wilcoxon *W* test was employed for continuous variables. Pearson χ^2 test was used for the analysis of discrete variables.

RESULTS

Population

The last 100 patients with DD treated surgically in the three hospitals were included, all were admitted between April 2000 and December 2007. After combining the datasets, one patient was excluded because the indication for surgery was revised. Two hundred nineteen-nine patients with complicated DD were analyzed. Patient characteristics are shown in Table 1. The median age was 69 years (range: 28-94 years), the patients in the acutely admitted group were 8 years older ($P = 0.010$) than the elective group. Only 5% of patients were younger than 40 years and 46% over 70 years of age. The male to female ratio was 42% to 58%. No differences were found in ASA-grade between groups. Sixty percent was of ASA-grade two.

Patient history and diagnostic procedures

Data on history and diagnosis are depicted in Table 1. Over half of the patients (52%) with an acute indication for surgery, had no history of diverticulitis. In the elective group, 54% of patients underwent a sigmoid resection after one episode of diverticulitis, the others had a history of two or more episodes. Conservative treatment

CT: Computed tomography.

of a mild episode of diverticulitis usually consisted of dietary advice and sometimes antibiotic therapy. Percutaneous drainage of abscesses was only reported in 20% of Hinchey II patients.

CT-scan seemed the most valuable diagnostic tool in an acute setting, being performed in 58% of patients. In the preoperative work-up for an elective intervention, CT-scan (81%) and colonoscopy (63%) were performed. Severity of the disease was classified by the Hinchey classification, knowing that Hinchey III and IV perforated diverticulitis can only be distinguished during surgery; and 65% of elective patients were Hinchey I and 35% Hinchey II. Indications for elective sigmoid resection were: recurrent episodes of acute diverticulitis, persistent complaints, colovesical or colovaginal fistulae and symptomatic stenosis of the sigmoid colon.

Perforated diverticulitis with generalized peritonitis was the main indication for an acute intervention (Hinchey III 43% and Hinchey IV 11%). Other acute indications were total bowel obstruction, very large or persisting abscesses and failure of conservative treatment. In 54% of the acute patients, surgery was performed on the day of admission, and in 15% the following day.

Operation

Operative data are shown in Table 2. Laparoscopic sigmoid resection was performed in 31% of the elective patients, with a conversion rate of 15%. A deviating ileostomy was created in 12%. There was a wide inter-hospital variety in the preferred elective approach.

ICU: Intensive care unit; GI: Gastrointestinal.

In the acute setting, Hartmann's procedure was performed in 61% of patients. The other patients were treated by means of resection and primary anastomosis, 14% of them received a deviating ileostomy. Laparoscopic approach was attempted in 4% of the patients, with a high conversion rate (63%).

Median operating time in acute operations was significantly shorter than in an elective setting (125 min *vs* 160 min, *P* = 0.000). Results, complications and operating time may largely depend on the operating surgeons, i.e. GI-surgeon, general surgeon or resident. This distribution was determined by the setting in which an operation was performed (acute or elective). Most of the elective surgeries were performed by GI-surgeons (65%), whereas general surgeons and residents (under supervision) performed most of the acute operations (82%). In total, 36% of all interventions for DD were performed by residents, 37% by GI-surgeons and 27% by general surgeons.

Complications and follow-up

The overall morbidity and mortality of the total cohort

were 51% and 10%, respectively, in which elective surgery was associated with significantly better outcomes (Table 2). Following elective surgery, 36% of patients had postoperative complications, 16% having minor and 20% having major complications. After acute operation, the morbidity was 60%, including 20% minor and 40% major complications. The mortality in the acute group was 16% in contrast with 1% in elective group.

Twenty-nine percent of elective patients were admitted to the ICU after operation, 79% of these patients returned to the normal surgical ward within 1 d after operation. In the acute setting, the ICU admission rate was 73%, 48% of the patients stayed in ICU for more than 2 d.

A total of 133 ostomies were created, 86% of which used Hartmann's procedure. Only 35% of these ostomies, 50% of the ileostomies and 33% of Hartmann's procedures were actually reversed. The median interval until reversal was 29 wk (6-213 wk).

DISCUSSION

This study describes the current surgical practice in DD in the Netherlands. DD is associated with substantial postoperative morbidity (51%) and mortality (10%). A morbidity rate of 60% and a mortality rate of 16% are especially high in the acute setting. These numbers are comparable to other recent series, and little improvement has been seen over the past years^[9,13,14]. This could have been expected because acute interventions remained the same for decades, especially the Hartmann's procedure. No apparent reduction of these adverse outcomes has been achieved by improvement in peri-operative care, better patient selection and enhanced guarding on the ICU when needed.

Significantly more complications were seen in the acute group, mostly major complications. Usually a prominent share of morbidity and mortality is accounted for by anastomotic leakages although in this series a low percentage of 5% was found. None of these anastomotic leakages resulted from a primary anastomosis in Hinchey III or IV patients. Moreover, the majority of anastomotic leakages occurred in elective operations (7%) and not in acute interventions (3%). As can be expected, the total number of primary anastomosis was higher in the elective group than in the acute group. Perhaps primary anastomosis in the acute setting was only considered under favorable conditions, resulting in a positive selection bias.

Elective sigmoid resections are progressively approached laparoscopically. It is not only a safe alternative for open techniques, several advantages have been demonstrated in recent trials^[8]. Postoperative pain is reduced, duration of hospital stay is shortened and morbidity rates are decreased. Surprisingly, only 31% of all elective patients in this study underwent a laparoscopic sigmoid resection. This might be explained by differences in laparoscopic experience among different hospitals. In

one clinic, a laparoscopic sigmoid resection is always attempted, whereas the other center has a preference for the open technique. In this context, it has to be realized that the beneficial effects of laparoscopic surgery are exclusively generated in high-volume centers by experienced laparoscopic surgeons. Patients may benefit more from an open sigmoid resection than a laparoscopic approach when the surgeon is at the beginning of his 'learning curve'^[15,16].

More recently, alternatives for Hartmann's procedure have been proposed. The technique of laparoscopic lavage is being evaluated in a prospectively randomized study in the Netherlands and no patient in this study was treated by this promising technique. Furthermore, laparoscopic resection was only attempted in 4% of the acute patients, resulting in a considerable conversion rate (63%). The number of primary anastomoses in the acute setting is increasing, with or without deviating ileostomy. In this series, 39% of the acute patients received a primary anastomosis, which is a substantial rise when compared to 27% in another Dutch study on 291 patients between 1995 and 2005^[17].

New insights in the natural history of DD have resulted in an increasingly conservative approach to this disease. It seems that uncomplicated, conservatively treated diverticulitis has a good prognosis, with a low recurrence rate and a rather benign course^[3-6]. Nevertheless in this series, 48% of the acute patients had an earlier episode of diverticulitis. When considering more than 5 d ICU stay in 21% of the acute patients and a mortality rate of 16%, some of these patients may have benefited from early elective sigmoid resection. Further research of this substantial group might reveal high-risk patients to be associated with a more hazardous course of DD, and certain comorbid conditions (auto-immune diseases and chronic renal failure), medication (steroids and non-steroidal anti-inflammatory drugs) or younger age are suggested factors^[18-20].

In a retrospective multi-center study, bias is unavoidable, and data collection is dependent on the individual search strategies and interpretation of different researchers. In this study, patient data were collected in a standardized fashion in all three hospitals by means of retrospective analysis of the medical records. Because of the deliberate choice to invite three different types of hospitals (university and teaching) in different parts of the Netherlands to participate in the study, extrapolation of the results to a broader perspective seems possible. These results are likely to reflect the national policy on DD.

It seems that Dutch hospitals are up-to-date, new developments are implemented in daily practice, resulting in acceptable morbidity and mortality rates. Indications for elective surgery are based on complaints and complications of DD, and not so much on the number of episodes. Furthermore, when elective surgery is indicated, the laparoscopic approach has been adopted in some hospitals, dependent on the experience of the surgeons.

In the acute setting, Hartmann's procedure is no longer the only option in generalized peritonitis. For further enhancement of the treatment of DD, national audits and prospective trials are needed. We can conclude that DD is a common disease which necessitates surgery in acute as well as in elective settings. Currently, no directives are available concerning best treatment strategies for acute and elective DD. Different treatment strategies are applied leading to an acceptable morbidity and mortality rate.

COMMENTS

Background

Diverticular disease (DD) accounts for 14 000 hospital admissions in the Netherlands annually. The incidence of DD is rising, mainly among younger patients.

Research frontiers

The aim of this study is to evaluate developments in diagnostic tools, indications for surgery and treatment modalities concerning DD in the Netherlands. Therefore, the authors analyzed the results of 299 patients treated for DD in three Dutch hospitals.

Innovations and breakthroughs

Recent studies highlight the usually benign course of recurrent episodes of diverticulitis with low complication rates, in patients treated conservatively for an acute episode of diverticulitis. It is suggested that planned, prophylactic sigmoid resections based on the number of episodes is not always indicated. New diagnostic tools and therapeutic techniques have improved the treatment of DD.

Applications

This study gives a picture of current surgical practice of DD in the Netherlands. New developments seem to be implemented in daily practice, resulting in acceptable morbidity and mortality rates.

Peer review

This article shows the current surgical treatment for DD in the Netherlands. The aims of this work are well delineated; the patients and methods are clearly described and appropriate statistical measures are indicated. The results are well reported and support the aims of the work. Discussion section is concise and well organized.

Abstract

AIM: To assess serum concentrations of prohepcidin in chronic hepatitis C individuals and evaluate their associations with disease activity and efficacy of pegylated interferon (PEG-IFN)/ribavirin (RBV) therapy.

METHODS: Prohepcidin was measured in sera of 53 chronic hepatitis C patients. Concentrations of prohepcidin and other iron metabolism markers were analyzed at 9 time points before, during and after the end of antiviral therapy.

RESULTS: In hepatitis C virus (HCV) genotype 1-infected individuals, a gradual decrease of prohepcidin during antiviral therapy was observed in responders (88.8 ± 14.7 ng/mL before therapy vs 60.6 ± 0.3 ng/mL in the 48th wk, $P = 0.04$). In contrast, no decrease was observed in non-responders. A similar association was

observed in HCV genotype 3a individuals, with a statistically significant decline in serum prohepcidin only in the responder group (99.5 ± 5.2 ng/mL at baseline vs 72.7 ± 6.1 ng/mL in the 24th wk, $P = 0.01$). Moreover, HCV-RNA at week 12 of therapy was positively correlated with baseline ($R = 0.63$, $P < 0.005$) and week 12 ($R = 0.60$, $P = 0.01$) serum prohepcidin concentrations in HCV genotype 1 infection.

CONCLUSION: Successful PEG-IFN/RBV therapy results in a decline of serum prohepcidin concentration in chronic hepatitis C, which may suggest a direct effect of HCV on iron metabolism at the prohormonal level of hepcidin.

INTRODUCTION

Liver iron overload is a well described, but not completely understood, feature of hepatitis C virus (HCV) infection. Several lines of evidence have suggested its negative influence on chronic hepatitis C outcome. Recent reports have emphasized the strong association between hepatic iron storage markers and oxidative DNA damage in

persistent HCV infection. In the study by Fujita *et al*^[1], phlebotomy resulted in a significant decrease of oxidatively generated DNA damage markers with concomitant reduction in serum transaminases as well as iron-related markers in chronic hepatitis C. Iron accumulation has also been linked with insulin resistance and liver steatosis in HCV-infected patients^[2,3]. Furthermore, experimental data have shown that iron deposits may trigger hepatic stellate cell activation and thus induce liver fibrosis^[4]. Among other potential links between iron metabolism and chronic hepatitis C, the possibility of enhancing HCV replication by serum iron has been postulated in experimental settings^[5].

Fujita *et al*^[1] found that total iron score correlated positively with transaminase activity, histological grading and staging in chronic hepatitis C subjects. Interestingly, in this study baseline iron metabolism alterations were more pronounced in non-sustained viral response (non-SVR) than in SVR to interferon (IFN)/ribavirin (RBV) treatment, therefore suggesting the association between iron deposition and resistance to anti-HCV therapy. This observation has been further confirmed in a recent study^[6] showing inadequate hepcidin expression in chronic HCV, which could be restored by eradication of the virus.

The mechanisms of iron metabolism deregulation in chronic hepatitis C are not fully elucidated. Takeo *et al*^[7] showed significantly higher liver mRNA expression of transferrin receptor 2 (TfR2) and ferroportin in chronic hepatitis C than in hepatitis B virus (HBV)-infected patients, which additionally correlated with the total hepatic iron score during the HCV infection. Authors have suggested that upregulation of hepatic iron transporters may contribute to the hepatic iron accumulation. Recently discovered iron regulatory hormone, hepcidin, synthesized predominantly in the liver, has changed the understanding of iron metabolism regulation^[8]. Hepcidin has been found to suppress intestinal absorption of iron through the binding to ferroportin, which is robustly expressed by enterocytes and liver macrophages^[9]. Synthesis of hepcidin is increased by iron overload and decreased by anemia, hypoxia-inducible factors and reactive oxygen species. Moreover, it may be induced by infection and inflammatory responses, which result in rapid plasma iron decrease^[10-12]. Recent results have shown hepcidin deregulation in chronic hepatitis C and have suggested the pivotal role of this hormone in the pathogenesis of iron overload^[1,6,13].

In the current study, levels of prohepcidin, a hepcidin precursor protein predominantly synthesized in the liver, were measured. In the hepatocytes, prohepcidin undergoes two cleavages and is rapidly secreted from cells as the mature, 25 amino acid peptide, hepcidin. It has been shown that, to some extent, prohepcidin is also secreted by hepatocytes^[14]. Recently, we have suggested the association between serum prohepcidin levels and liver function impairment in liver cirrhosis patients^[15]. The aim of the study was to assess the serum concentration of this hepcidin prohormone in chronic hepatitis C and evaluate its possible association with the

disease activity as well as the efficacy of pegylated IFN (PEG-IFN)/RBV therapy.

MATERIALS AND METHODS

Patients

Prohepcidin levels were measured in sera of 53 chronic hepatitis C patients (15 females and 38 males; median age: 46.5 years, min: 20 years, max: 67 years) before and during PEG-IFN- α /RBV therapy. Twenty-nine of them were infected with HCV genotype 1 and 24 with HCV genotype 3a. All patients had chronic hepatitis C proven through the presence of anti-HCV antibodies and HCV-RNA in sera for at least 6 mo. Quantitative HCV-RNA and HCV genotyping were performed by two-step real-time quantitative RT-PCR using TaqMan. Disease activity was evaluated by liver biopsy (Hepafix System, Braun, Melsungen, Germany) performed before the start of anti-HCV therapy. Paraffin-embedded biopsy specimens were stained and evaluated using Scheuer's scoring system^[16]. None of the included patients had liver cirrhosis diagnosed, nor HBV, hepatitis delta virus or human immunodeficiency virus co-infections. Clinical characteristics of the studied population are presented in Table 1.

Patients received a combination therapy with a weekly dose of PEG-IFN- α 2a administered subcutaneously and RBV administered orally at daily doses of 1000 or 1200 mg/d based on body weight (< 75 or \geq 75 kg, respectively) for genotype 1 and 800 mg/d for genotype 3a. The total duration of treatment was 48 wk for genotype 1 and 24 wk for genotype 3a. Patients were divided into two groups: responders, defined as undetectable HCV-RNA at week 24 after the end of therapy, and non-responders, defined as HCV-RNA positive at week 24 after the end of therapy.

Prohepcidin serum concentrations were measured at baseline, in the 4th, 12th, 24th and 48th (genotype 1) wk of antiviral therapy and in the 24th wk after termination of the treatment (week 72). During the same visits, liver function tests and the serum iron metabolism markers, serum iron, total iron binding capacity (TIBC), transferrin saturation, and ferritin, were measured. Moreover, serum iron saturation was calculated using the following formula: (serum Fe/TIBC) \times 100%. Serum prohepcidin values were compared with those collected from 15 healthy volunteers (7 females and 8 males, median age: 40 years).

Hepcidin prohormone measurement

Venous blood was collected on ice using vacutainer tubes and centrifuged at 2500 \times g at 4°C within 30 min of collection. Serum samples were assayed for prohepcidin with the quantitative sandwich enzyme immunoassay kit (DRG Instrument GmbH, Marburg, Germany) according to manufacturer instructions. The employed antibody detects both the pro-region and pro-hepcidin (aa 25-84). The sensitivity of assay is 3.95 ng/mL, intra-

assay variation coefficient of variation (CV) 4.69% and inter-assay variation CV 4.82%.

Statistical analysis

Values were expressed as mean \pm SE of mean. The significance of differences was calculated by non-parametric Mann-Whitney *U*, Kruskal-Wallis and Friedman ANOVA tests. For correlation analysis, the Spearman non-parametric correlation was used. A $P < 0.05$ value was considered as statistically significant. Statistical analyses were performed with Statistica 7.0 for Windows software (Statsoft Inc., Tulsa, USA).

Informed consent was obtained from each patient. The procedures followed were in accordance with the Helsinki Declaration of 1975, as revised in 1983. The study was approved by the Bioethical Committee of the Medical University of Bialystok.

RESULTS

Serum concentration of prohepcidin measured before PEG-IFN/RBV therapy in chronic hepatitis C individuals slightly, but not significantly, exceeded values observed in healthy controls (93.2 ± 5.3 ng/mL *vs* 84.1 ± 7.8 ng/mL, respectively, $P = 0.46$). Interestingly, we observed a higher concentration of serum prohepcidin in HCV genotype 3a compared to genotype 1 (98.8 ± 4.7 ng/mL *vs* 88.5 ± 8.9 ng/mL, respectively, $P = 0.02$). In the latter group the values were also significantly higher than in controls ($P = 0.04$) (Figure 1).

Baseline serum prohepcidin concentration showed a positive correlation with serum ferritin in chronic hepatitis C ($R = 0.50$, $P = 0.02$) (Table 2). In HCV genotype 1 the positive correlation between prohepcidin and ferritin was even stronger ($R = 0.63$, $P = 0.001$). Furthermore, an association with alanine aminotransferase (ALT) activity ($R = 0.38$, $P = 0.04$) was observed. We did not notice correlations between serum prohepcidin and either age,

sex, liver histology, baseline HCV viral load, serum iron or TIBC.

Serum prohepcidin concentrations showed an association with PEG-IFN/RBV therapy effectiveness. In the first 7 d after the introduction of PEG-IFN/RBV, a gradual and reversible decrease in serum prohepcidin was observed regardless of HCV genotype (Tables 3 and 4). In the following phase, a further decrease of prohepcidin during antiviral therapy was noted in the HCV genotype 1 responder group, from 88.8 ± 14.7 ng/mL before therapy to 60.6 ± 2.3 ng/mL in the 48th wk (Friedman ANOVA test, $\chi^2 = 9.6$, $P = 0.04$). Such an association was not revealed in non-responders, with serum prohepcidin showing stable values (88.3 ± 11.4 ng/mL at baseline *vs* 82.3 ± 4.4 ng/mL in 48th wk) (Table 3 and Figure 2). A similar relationship was observed in genotype 3a individuals, with a statistically significant decrease in serum prohepcidin only in responders (99.5 ± 5.2 ng/mL

at baseline *vs* 72.7 ± 6.1 ng/mL in the 24th wk, *P* = 0.01) (Table 4 and Figure 2).

The above mentioned observations were further confirmed by the significant association between serum prohepcidin and HCV viral load during the treatment. HCV-RNA at the 12th wk was positively correlated with baseline (*R* = 0.63, *P* < 0.005) and 12th wk (*R* = 0.60, *P* = 0.01) serum prohepcidin concentrations in genotype 1 HCV-infected individuals. A similar analysis was not possible for genotype 3a since HCV-RNA was detectable only in 6 of 24 patients at the 12th wk.

To assess the possibility of the interference of RBV-induced anemia with prohepcidin synthesis we performed a correlation analysis between hemoglobin concentration and prohepcidin. We found no association between these parameters at baseline (Table 1) or at different time points during the PEG-IFN/RBV therapy (data not shown).

DISCUSSION

Recent years have brought to light new facts concerning the pathogenesis of iron metabolism alterations in chronic liver diseases. The discovery of hepcidin has linked inflammatory disorders and iron turnover disturbances^[8].

The name of hepcidin originated from its antimicrobial properties and the predominant production of this protein in the liver. Following infectious, inflammatory stimuli or iron-overload its production increases, resulting in the decrease of plasma iron by negative regulation of iron uptake by duodenal enterocytes and sequestration by macrophages^[12,17]. In contrast, down-regulation of hepcidin is an important factor facilitating iron deposition in parenchymal organs, especially in the liver. The regulation of hepcidin production is multilateral and still not fully understood. Main pathways involved include iron-storage, hypoxic and inflammatory-related^[18]. Hemochromatosis protein (HFE) seems to maintain the basal expression of hepcidin, probably *via* Tfr2 and hemojuvelin, acting as a body iron store sensor^[19]. In contrast, inflammatory-related

hepcidin induction appears to be independent of HFE, Tfr2 and mainly relies on interleukin-6 (IL-6) *via* STAT-3 activation^[20,21].

It is only in the last years that some insights into the role of hepcidin in chronic hepatitis C have been presented. Nagashima *et al*^[13] found significantly lower concentrations of serum prohepcidin in chronic hepatic C compared to chronic HBV infection and healthy individuals, suggesting that failure of prohepcidin regulation may be induced by HCV infection. More recently, Fujita *et al*^[22] evaluated hepatic hepcidin mRNA expression in chronic hepatitis B and C individuals. They showed significant positive correlations between hepatic hepcidin expression, serum iron, and ferritin, as well as liver total iron score. However, liver hepcidin mRNA expression was comparable in chronic hepatitis B and C in this study. Only after adjustment for serum ferritin were hepcidin indices significantly lower in HCV infection. The same group^[23] found a positive correlation between hepatic oxidatively generated DNA damage and serum ferritin, total iron score and liver hepcidin mRNA in chronic hepatitis C. Interestingly, they also showed more prominent baseline hepatic oxidative stress markers in non-SVR to IFN/ribavirin therapy.

We investigated the association between PEG-IFN/ribavirin therapy and iron metabolism parameters, especially hepcidin prohormone, prohepcidin, concentrations in chronic hepatitis C. We found comparable levels of serum prohepcidin in chronic hepatitis C and healthy individuals. Interestingly enough, baseline prohepcidin was significantly higher in HCV genotype 3a than in HCV-1. This new finding could be possibly explained by differences in iron metabolism in patients with genotype 3. Sebastiani *et al*^[3] showed that hepatic iron deposits were significantly more frequent in HCV-3-infected individuals and strongly associated with viral-induced hepatic steatosis.

Baseline serum prohepcidin in this current study showed a strong positive correlation with serum ferritin. Moreover, an association between baseline serum prohepcidin and ALT activity was found. These observations are in accordance with other reports^[22] and probably reflect above mentioned pathways of hepcidin regulation. The new finding of this study is the association between serum prohepcidin and PEG-IFN/ribavirin efficacy in chronic hepatitis C. We showed a statistically significant, gradual decrease of serum prohepcidin during successful antiviral treatment in HCV-1 and 3a individuals. The reduction in prohepcidin concentration for genotype 1 was 31% in the 48th wk of treatment (Table 3) and 27% in the 24th wk for HCV-3a (Table 4) in the SVR groups. In contrast, in non-SVR the prohepcidin serum concentrations did not change significantly compared to baseline values. This finding seems to contradict findings of a recent clinical study performed by Fujita *et al*^[6], however it has to be underlined that the current study measured a hepcidin precursor, not an active hormone. In the aforementioned work^[6], serum hepcidin was measured by mass spectrometry in 73 untreated chronic hepatitis C patients

and in 27 patients during PEG-IFN + RBV therapy. The baseline serum hepcidin was higher in chronic hepatitis C compared to healthy individuals but only in those with hyperferritinemia. On the other hand, HCV-infected individuals with normal ferritinemia had comparable serum prohepcidin with the control group. Interestingly, the most recent analysis by Girelli *et al*^[24] showed that in a rigorously selected population with HFE genotyping performed, serum hepcidin was significantly reduced in chronic hepatitis C in comparison to healthy controls and strongly associated with body iron deposits, regardless of IL-6 concentrations.

The current study applied a different approach. The assay used detected a hepcidin prohormone, not a mature peptide. It has been shown that serum assessment of prohepcidin does not reflect the levels of biologically active mature hepcidin peptide^[14]. On the contrary, it may give some insight into the mechanisms of hepcidin maturation. Hepcidin is almost exclusively synthesized in the liver as a 84 amino acid prepropeptide, which is further processed in hepatocytes to the mature form^[25]. Recent evidence showed that the proteolytic cleavage of prohepcidin to hepcidin is regulated by the hepatic prohormone convertase furin^[14]. The mechanism involved in the transport of hepcidin to the extracellular zone is not fully understood. Valore *et al*^[14] showed that a larger hepcidin precursor protein undergoes two cleavages (the signal sequence, then the pro-region) and is rapidly secreted from the cell. Moreover, in primary human hepatocytes, prohepcidin was transiently detected in culture supernatant immediately after labeling but it appeared to be present at low levels compared to mature hepcidin. Of interest, the inhibition of furin activity prevented the conversion of prohepcidin to hepcidin but also appeared to stabilize the prohepcidin peptide both in the cell and the media. In situations of liver function impairment the prohepcidin synthesis as well as activity or expression of converting enzymes might be altered and affect circulating prohepcidin concentrations. This finding could also suggest that HCV interference with hepcidin synthesis may occur at the step of prohormone synthesis or maturation in the liver.

In conclusion, we found an association between successful PEG-IFN/ribavirin therapy and serum prohepcidin concentration decrease in chronic hepatitis C patients. This may suggest a direct link between HCV and hepcidin maturation in the liver.

COMMENTS

Background

Iron accumulation in the liver has a negative influence on chronic hepatitis C outcome. It has been linked with oxidative DNA damage, insulin resistance and liver steatosis, but may also trigger hepatic stellate cell activation and thus induce liver fibrosis. Recently, a key iron regulatory hormone, hepcidin, was discovered. This hormone has been found to suppress intestinal absorption of iron through its binding to ferroportin. Hepcidin is synthesized in the liver from its precursor protein, prohepcidin.

Research frontiers

The mechanisms of iron metabolism deregulation in chronic hepatitis C are

not fully elucidated. Hepcidin, a versatile regulator of iron homeostasis is likely engaged in this process. Nevertheless, the factors influencing maturation of hepcidin in the setting of chronic liver injury are unclear. Recently, the authors have suggested the association between serum prohepcidin levels and liver function impairment in liver cirrhosis patients. The aim of the current study was to assess the serum concentration of hepcidin prohormone in chronic hepatitis C and evaluate its possible association with disease activity as well as with the efficacy of pegylated interferon (PEG-IFN)/ribavirin therapy.

Innovations and breakthroughs

In the present study, comparable levels of serum prohepcidin in chronic hepatitis C and healthy individuals were noted. Interestingly, baseline prohepcidin was significantly higher in hepatitis C virus (HCV) genotype 3a than in HCV genotype 1. The new finding of the study is the association between serum prohepcidin and PEG-IFN/ribavirin efficacy in chronic hepatitis C. A statistically significant, gradual decrease of serum prohepcidin during successful antiviral treatment in HCV-1 and 3a individuals was shown, which was not the case in patients who did not respond to anti-HCV therapy.

Applications

The results of this study may suggest that in situations of liver function impairment prohepcidin synthesis, as well as activity or expression of converting enzymes, might be altered and affect circulating prohepcidin concentrations. This finding could also suggest that HCV interference with hepcidin synthesis may occur at the step of prohormone synthesis or maturation in the liver.

Peer review

This study was conducted to elucidate the effect of HCV and the influence of PEG-IFN/ribavirin combination therapy on the iron metabolism in patients with chronic hepatitis C. The manuscript was well prepared. The data analysis was appropriate. The authors obtained a reasonable result and the discussion was good.

Abstract

AIM: To assess whether the polymorphisms of *NOD2/CARD15*, autophagy-related 16-like 1 (*ATG16L1*), and interleukin-23 receptor (*IL23R*) genes play a more critical role in the susceptibility of childhood-onset than in adult-onset Crohn's disease (CD).

METHODS: Polymorphisms R702W, G908R, and 3020insC of *NOD2/CARD15*; rs2241880 A/G of *ATG16L1*, and rs11209026 (R381Q) of *IL23R* gene were assessed in 110 childhood-onset CD, 364 adult-onset CD, and 539 healthy individuals. Analysis of polymorphisms R702W, G908R, and 3020insC of *NOD2/CARD15* genotyping was performed by allele specific polymerase chain reaction (PCR) or by PCR-restriction fragment length polymor-

phism analysis. The polymorphisms rs2241880 A/G of the *ATG16L1*, and rs11209026 (R381Q) of the *IL23R* gene in the children's cohort were genotyped by PCR and melting curve analysis whereas adult group genotyping was performed using the Affymetrix Genome-Wide Human SNP Array 5.0 (500K).

RESULTS: The 3020insC allele in *NOD2/CARD15* was significantly higher in childhood than in adult-onset CD ($P = 0.0067$). Association with at least 1 *NOD2/CARD15* variant was specific for ileal disease (with or without colonic involvement). Even if the frequency of G allele of the rs2241880 *ATG16L1* polymorphism was increased in both paediatric and adult CD patients compared to controls ($P = 0.017$ and $P = 0.001$, respectively), no difference was observed between the childhood and the adult cohort. The rare Q allele of *IL23R* rs11209026 polymorphism was underrepresented in both paediatric and adult CD cases ($P = 0.0018$ and $P = 0.04$, respectively) and no difference was observed between the childhood and the adult cohort. The presence of the rs2241880 *ATG16L1* and rs11209026 *IL23R* polymorphisms did not influence disease phenotype.

CONCLUSION: Polymorphism 3020insC in *NOD2/CARD15* occurs statistically significantly more often in patients with childhood-onset CD than in patients with adult-onset CD. The *ATG16L1* and *IL23R* variants are associated with susceptibility to CD, but not early-onset disease.

INTRODUCTION

Inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC) are characterized by chronic relapsing inflammation of the digestive tract. As a multifactorial disorder, IBD is caused by a complex interaction of genetic, microbial, and immunological factors. Approximately 10%-20% of all IBD will present either in childhood or adolescence^[1].

Although age of onset seems to be a random event, recent data have shown that a subgroup of patients with early-onset IBD may have specific phenotypes that differs from adult onset IBD, suggesting that the pathogenesis of pediatric IBD and adult IBD may differ^[2-4]. A compelling speculation is that pediatric-onset IBD is more likely to be influenced by genetics compared to late onset, as there is less time for environmental modifiers to influence the onset of the disease. Adult-onset IBD is more likely to be confounded by abundant environmental exposure compared to childhood-onset IBD populations^[5].

Genetic risk factors for IBD have been extensively studied during the last year. *NOD2/CARD15* polymorphisms R702W, G908R, and 3020insC are independently associated with an increased risk of developing CD^[6-8]. Existing data remain conflicting as to whether *NOD2/CARD15* polymorphisms are associated with the age of onset of IBD, with some studies showing an effect toward a younger age of onset^[9,10], and others showing no effect^[11,12].

Recently, genome wide association studies (GWAS), in addition to offering further confirmation of the importance of the *NOD2/CARD15* gene, provided evidence for several determinants, including genes encoding autophagy-related 16-like 1 (*ATG16L1*) and interleukin-23 receptor (*IL23R*)^[13]. Moreover, Kugathasan *et al*^[14], by employing GWAS in a cohort of individuals with pediatric-onset IBD, provide further insights into disease pathogenesis.

Hampe *et al*^[15] were the first group to implicate the autophagy pathway in CD. The association of the Ala197Thr (rs2241880 A/G) variant of the *ATG16L1* gene with susceptibility to CD, has now been replicated in several independent cohorts^[16,17]. Recent studies have explored genotype associations in adult-onset IBD, and to a more limited extent in pediatric disease. Prescott *et al*^[18] suggested an association between the Ala197Thr variant allele and early-onset CD, as well as an effect of *ATG16L1* genotype on age at diagnosis. Baldassano *et al*^[19] replicated this association in a pediatric cohort. In contrast, Van Limbergen *et al*^[20] reported that the *ATG16L1* variant is not associated with early-onset IBD in a pediatric population in Scotland.

The *IL23R* gene is located on chromosome 1p31 and its corresponding ligand IL23 is a key component of the immunoregulatory pathway. The identification of an association between the R381Q variant of *IL23R* and CD is thus an important step toward the delineation of pathways related to inflammation to chronic inflammatory cascade characteristics of CD. Recent studies suggest that the R381Q variant in *IL23R* is associated with pediatric-onset CD^[21,22].

In view of these discrepant data regarding the association of key regulatory genes with CD susceptibility, the purpose of our study was investigate whether the known DNA polymorphisms in the *NOD2/CARD15*, *ATG16L1*, and *IL23R* genes determine susceptibility for CD in Greek children, and to compare these data with the frequency of these gene polymorphisms in adult-onset CD.

MATERIALS AND METHODS

Patients and controls

We examined 110 Greek children with CD, diagnosed before the age of 17, who attended the First Department of Pediatrics of Athens University, "Aghia Sophia" Children's Hospital between January 2007 and December 2008. The diagnosis of CD was based on standard clinical, endoscopic, radiologic and histopathologic criteria^[23]. Cases of UC and indeterminate colitis were excluded. Also excluded were children who had concomitant immune-mediated diseases such as asthma, diabetes type 1, juvenile diabetes, or juvenile arthritis. Blood samples from 364 adult CD patients were collected at the Inflammatory Bowel Disease (IBD) Outpatient Clinic of the Evagelismos Hospital. Most of them had already been used for genotype studies on *NOD2/CARD15*^[24]. The main clinical characteristics of IBD patients are detailed in Table 1. This cohort was compared to 539 healthy controls (94 children and 445 adults). Before commencement of the study, the Ethics Committee at the participating centers approved the recruitment protocols. All participants were informed of the study.

Genotyping

DNA was isolated from blood with the NucleoSpin blood kit (Macherey-Nagel, Germany). Patients were genotyped for the 3 common *NOD2/CARD15* polymorphisms i.e. R702W, G908R, and 3020insC using previously described methods^[8,24]. Polymorphisms rs2241880 A/G of the *ATG16L1*, and rs11209026 (R381Q) of the *IL23R* gene in the children's cohort were genotyped by PCR and melting curve analysis, using a pair of fluorescence resonance energy transfer (FRET) probes in LightCycler[®] 2.0 Instrument (Roche Diagnostics, Mannheim, Germany) as previously described^[25,26]. The adult group genotyping was performed using the Affymetrix Genome-Wide Human SNP Array 5.0 (500K)^[27].

(90%) were calculated using the <http://sampsizem.sourceforge.net/iface/s3.html#cc> software. Statistical analysis was done using the software package GraphPad v. 3.00 (GraphPad Software, San Diego, CA). The Hardy-Weinberg equilibrium was tested by comparing the expected and observed genotypes in 2×3 chi-square tables. All the samples were in Hardy-Weinberg equilibrium ($P > 0.1$). For comparison between categorical variables, the Fisher's exact test or χ^2 test was used where appropriate. Single marker allelic tests were performed with Fisher's exact test. Odds ratios (OR) were calculated for the minor allele at each polymorphisms.

RESULTS

Genotype and allele frequencies of the *NOD2/CARD15* polymorphisms R702W, G908R, and 3020insC are detailed in Table 2.

The R702W polymorphism frequency did not differ significantly between child- and adult-onset CD. However, a statistically significant association was found between the R702W polymorphism and adult-onset CD only. The T allele frequency, leading to heterozygous and homozygous R702W polymorphisms, was increased in the adult CD population (9.1%) compared to controls (5.47%) ($P = 0.004$). In pediatric-onset CD, T allele frequency was also increased (8.18%), but no statistical significant difference was observed when compared to controls.

The C allele frequency, encoding the G908R variant, was also found significantly elevated (10%) in adult patients ($P = 0.014$), but was slightly reduced (9.54%) in childhood CD patients and in controls (6.77%).

For the 3020insC polymorphic allele, a significantly increased prevalence was found both in paediatric (16.36%), and in adult (9.47%) CD patients as compared, with the controls ($P < 0.0001$ in both cases). The

frequency of 3020insC polymorphism was significantly higher in the paediatric cohort than in the adult-onset cohort ($P = 0.0067$).

Concerning the genotype-phenotype correlation ileal involvement was more frequent in individuals with at least one *NOD2/CARD15* polymorphism (78.25%) than in wild-type carriers (59%), in both cases of child- and adult-onset CD (OR = 2.46, 95% CI: 1.33-4.57, $P = 0.006$). The examined variants did not influence CD behavior in the present study.

Concerning the rs2241880 A/G polymorphism of the *ATG16L1* gene, the frequency of the G allele was increased in both pediatric and adult CD patients compared to controls ($P = 0.017$ and $P = 0.001$, respectively) as shown in Table 3. No association of the *ATG16L1*

polymorphism with early-onset CD was seen in our childhood-onset CD case-control analysis *vs* adult-onset CD analysis (Table 3). Furthermore, *ATG16L1* polymorphism did not influence the disease location and behaviour in the population studied.

The minor allele (Q) of the rs11209026 (R381Q) polymorphism of the *IL23R* gene was underrepresented in both childhood-onset and adult-onset CD, compared to controls ($P = 0.0018$ and $P = 0.04$, respectively) as shown in Table 3. No genotype-phenotype correlations were found among the CD patients studied with *IL23R* rs11209026 (R381Q) polymorphism.

DISCUSSION

Our present survey represents the first Greek study to document the frequency of the *NOD2/CARD15*, *ATG16L1*, and *IL23R* gene polymorphisms in childhood-onset CD, and compare them to those in an adult-onset CD cohort.

Our results confirm the previously reported association of *NOD2/CARD15* 3020insC mutation with early-onset CD^[9,28,29]. In our study, only the *NOD2/CARD15* 3020insC mutation was strongly associated with childhood-CD susceptibility, and its frequency was significantly

higher in the childhood cohort than in the adult-onset cohort, whereas in previous studies of early-onset CD patients, significantly higher carrier rates were found either for all the 3 *NOD2/CARD15* mutations^[10] or for G908R and/or 3020insC only^[12,30]. Others did not find any differences in the frequency of the 3 major *NOD2/CARD15* mutations between a childhood-onset and an adult-onset CD cohort^[31]. Both ileitis and ileocolitis were more frequent in carriers of *NOD2/CARD15* polymorphisms, indicating an association of *NOD2/CARD15* polymorphisms with ileal involvement. This confirms previous findings in both pediatric and adult patients^[8,10,12,30,32]. In contrast to other studies indicating an association between *NOD2/CARD15* polymorphisms and stricturing behaviour^[12] we did not find any significant association between *NOD2/CARD15* polymorphisms and CD phenotype. These conflicting results can be explained by the regional and ethnic differences in genotypes, and the relatively small numbers of patients included in these studies.

Recent studies have reported *ATG16L1* rs2144880 variant genotype association with adult-pediatric onset CD. So far, reports in the literature have been conflicting. Specifically, Prescott *et al.*^[18] and Baldassano *et al.*^[19] demonstrated an association of this variant with diagnosis at an earlier age. Van Limbergen *et al.*^[20] and Latiano *et al.*^[31] have suggested that the *ATG16L1* rs2144880 variant is associated with susceptibility to adult CD in Scotland, but not to early-onset disease. In our study in the Greek population, we were able to demonstrate an effect of this *ATG16L1* polymorphism on both paediatric and adult CD susceptibility. However, the allele and genotype frequencies in childhood-onset CD were comparable to that seen in adults and therefore, we can not support an association of *ATG16L1* with early-onset CD in Greece. In agreement with previous studies, in the genotype-phenotype analysis, no association was detected in the cases tested^[25,33].

Regarding the rs11209026 (R381Q) polymorphism of the *IL23R* gene, our study confirms the recently described associations between variants in the *IL23R* gene in both pediatric and adult-onset CD^[19-21,31]. Recently Yamazaki *et al.*^[34] did not find any positive association of the *IL23R* gene polymorphism with CD in the Japanese population. Furthermore, in agreement with previous studies we did not observe any association of the rs11209026 (R381Q) polymorphism of the *IL23R* gene with the disease location and phenotype^[33,35]. This finding can be attributed to the distinct ethnic difference of genetic backgrounds of CD that has been reported previously for other genes between Japanese and Caucasian populations. It should be noted that the different results in allele frequencies between the studies can be explained by large regional and ethnic differences in genotypes, by the broad spectrum of clinical phenotypes of patients with CD, and by the relatively small numbers of cases included in most studies.

In conclusion, this study demonstrates that the 3020insC mutation in *NOD2/CARD15* gene is associated with CD in a Greek childhood-onset CD cohort. Moreover, the 3020insC mutation occurred significantly more often in childhood onset patients with CD than in

adult-onset CD patients. Our results provide an independent confirmation of the association of the *ATG16L1* rs2144880 and the *IL23R* rs11209026 (R381Q) polymorphisms with susceptibility to CD without supporting their implication in early-onset disease. Therefore, further studies are needed to specifically identify gene variants that predispose children to early paediatric onset disease.

COMMENTS

Background

As a multifactorial disorder, inflammatory bowel disease (IBD) is caused by a complex interaction of genetic, microbial, and immunological factors. Approximately 10%-20% of all IBD will present either in childhood or adolescence. Recent data have shown that a subgroup of patients with early-onset IBD may have specific phenotypes that differ from adult onset IBD, suggesting that the pathogenesis of paediatric IBD and adult IBD may differ. The study assesses whether the polymorphisms of *NOD2/CARD15*, autophagy-related 16-like 1 (*ATG16L1*), and interleukin-23 receptor (*IL23R*) genes play a more critical role in the susceptibility of childhood-onset than adult-onset Crohn's disease (CD).

Research frontiers

Although several gene loci have been associated with susceptibility to CD in adults, the aetiology of childhood CD is still unknown. The current study is one of the first studies assessing the impact of candidate gene's polymorphisms and disease susceptibility in childhood CD in a Greek cohort.

Innovations and breakthroughs

It is important to investigate the genetic variation in susceptibility to CD and identify markers that will facilitate identification of individuals at risk of developing this disease. The results suggest that the polymorphism 3020insC in *NOD2/CARD15* occurs statistically significantly more often in patients with childhood-onset CD than in patients with adult-onset CD. The *ATG16L1* and *IL23R* variants are associated with susceptibility to CD, but not early-onset disease.

Applications

The results of this study will help us to further understand the genetic determinants of childhood CD.

Peer review

The present study demonstrates that the 3020insC mutation in *NOD2/CARD15* gene is associated with CD in a Greek childhood-onset CD cohort. Moreover, the 3020insC mutation occurred significantly more often in childhood onset patients with CD than in adult-onset CD patients.

Abstract

AIM: To evaluate if canine models are appropriate for teaching endoscopy fellows the techniques of endoscopic submucosal dissection (ESD).

METHODS: ESD was performed in 10 canine models under general anesthesia, on artificial lesions of the esophagus or stomach marked with coagulation points. After ESD, each canine model was euthanized and surgical resection of the esophagus or stomach was carried out according to "The Principles of Humane Experimental Technique, Russel and Burch". The ESD specimens were fixed with needles on cork submerged in a formal solution with the esophagus or stomach, and delivered to the pathology department to be analyzed.

RESULTS: ESD was completed without complications using the Hook-knife in five esophageal areas, with a procedural duration of 124 ± 19 min, a length of 27.4 ± 2.6 mm and a width of 21 ± 2.4 mm. ESD was also completed without complications using the IT-knife2 in five gastric areas, with a procedural duration of 92.6 ± 19 min, a length of 32 ± 2.5 mm and a width of 18 ± 3.7 mm.

CONCLUSION: ESD is feasible in the normal esophagus and stomach of canine models, which are appropriate for teaching this technique.

INTRODUCTION

The incidence of esophageal adenocarcinoma is currently rising in Western countries and Latin America. Also, gastric cancer is the second leading cause of cancer-related death worldwide. Endoscopic submucosal dissection (ESD) has provided a new alternative for minimally invasive treatment of gastrointestinal (GI) early-stage cancer^[1-10].

With the purpose of preserving gastrointestinal function and obtaining specimens for precise histological evaluation, ESD^[11,12] has been developed for lesions ≥ 2 cm that are not amenable for endoscopic mucosal resection (EMR) because of their size^[11,13,14]. Adequate training is essential, because complications^[11,12] such as perforation are more likely with ESD than with EMR^[2,4,15-18]. In selected cases, ESD may replace surgery and provide clean margins for accurate histological diagnosis of the lesion borders and a complete curative treatment unlike other techniques such as piecemeal EMR^[2,4,15,16], cryotherapy, laser, argon plasma and photodynamic therapy because of their local recurrence rates.

There are few training centers around the world in which an endoscopy fellow can be trained in the ESD technique. There is probably only a formal ESD training program in Asian countries^[4,7,12,16], Germany^[8,9], recently in Portugal^[10] and at one site in Colombia. Animal models have been used to test ESD devices and new technology in this field, but a formal training program is still necessary to teach this technique in western countries and Latin America. For this reason, animal models are an invaluable learning resource.

Our aim was to evaluate if canine models are appropriate to teach endoscopy fellows the ESD technique.

MATERIALS AND METHODS

Ethics

This study was carried out in accordance with "The Principles of Humane Experimental Technique, Russel and Burch"^[19]. After receiving approval for the protocol from the ethics and animal research committees at our institution (GAS-14-09/09-1), the procedures were conducted on 10 mongrel dogs that weighed 18-20 kg that

had previously passed the quarantine period. All the procedures were done by a staff member of the Gastroenterology Department, who was trained at the Fujigaoka Hospital of the Showa University, Yokohama, Japan.

Cutting devices

Hook knife: The hook-type knife KD-620LR (Olympus Optical, Tokyo, Japan) was used to perform ESD in the esophagus^[6] of the canine models. It was right-angled 1 mm at the tip. Safety is improved compared with the use of a needle knife, because the submucosal tissue is hooked and pulled before incision. Safety is further improved when used in conjunction with a transparent soft cap D-201-11804 (Olympus Optical) because the tissue can then be pulled inside the hood (Figure 1E). The knife had a rotating function so that the operator could select the optimal direction of the hook.

Modified insulated-tipped knife 2: The modified insulated-tipped diathermic knife2 (IT-knife2) (KD-611L; Olympus Optical) was used to perform ESD in the stomach^[14] of the canine models. This knife consisted of a small ceramic ball attached to the tip of the blade, which functioned as an insulator so that the incision and dissection of the mucosa and submucosa could be performed safely.

A specialized feature of the modified IT-knife2^[6], which differs from the original IT-knife and other incision instruments, is that the portion between the insulator tip and the sheath, on the base of the ceramic ball, has a combination of the original IT-knife and the triangular knife that is used for removing the tissue with the electrodes on the distal side of the blade. This feature allows a less horizontal cutting position, which was necessary with the previous knife model.

Injection solution for mucosal and submucosal elevation

For all the canine models, we used normal saline solution with diluted epinephrine (1:10 000) and indigo carmine^[3,4,15], which were injected to elevate the lesion and separate the submucosal layer from the muscular layer, as required during all the steps of the ESD procedure, at a volume of 10-30 mL, depending on the size of the lesion. Also, this solution was used for small bleeding sites during ESD^[11,12], or when the cushion of the submucosal layer was insufficient for good dissection. Too much infiltration can obstruct good vision of the circumferential cutting, which interferes with the final cut of the lesion.

Electrosurgical HF-generator

The new electrosurgical HF-generator (ESG-100; Olympus Optical) allowed us to set the power for preprogrammed coagulation and cutting modes.

Endoscopic unit and video-endoscope

All the procedures were done with a CV-145 endoscopy unit (Olympus Optical) and a GIF-Q1145 video-endoscope (Olympus Optical).

A, B: Artificial lesion marked with coagulation points; C: Injection of normal saline with epinephrine and indigo carmine; D: Knife cutting of a circumference around the lesion; E: Transparent softcap provides lesion counter-traction; F: Soft cap attached to the tip of the endoscope during endoscopic submucosal dissection (ESD); G: Grasping forceps during retrieval of ESD specimens.

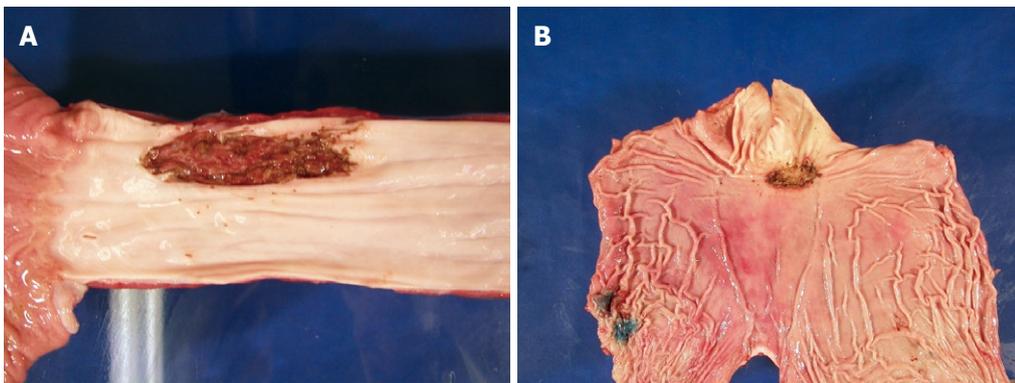

Figure 2 Photographs of the retrieved surgical specimens. Esophagus (A) and stomach (B) after ESD.

ESD procedure

The initial step was to produce an artificial lesion marked with coagulation points (Figure 1A and B) in the esophagus or stomach of 10 canine models (one at a time), under general anesthesia. The settings for marking the points with the precutting knife (KD-10Q-1; Olympus Optical) for the artificial lesions were: power, 20, and force coag2 mode. After marking, the above-mentioned solution was injected so that the peak of the lifting was outside of the markings (Figure 1C). ESD was performed with the Hook-knife in the esophagus or the IT-knife2 in the stomach. After that, we cut a circumference around the lesion with the knife (Figure 1D). We then used another injection to elevate the submucosal layer of the center of the lesion. The settings for the mucosal cutting of the circumference were power at 80 in pulse cut slow mode. Afterwards, we performed submucosal dissection using a soft cap D-201-11804 attached to the tip of the endoscope (Figure 1E) using the same settings as in the circumferential cut. This transparent soft cap provided lesion counter-traction (Figure 1F), which is similar to a surgeon's left hand, which made it easy to dissect the submucosal layer. The grasping forceps (FG-49L-1; Olympus Optical) were used to retrieve the ESD specimens (Figure 1G).

After ESD, each dog was euthanized and surgical resection of the esophagus or stomach (Figure 2A and B) was carried out according to “The Principles of Humane Experimental Technique, Russel and Burch”^[19]. The ESD specimens were fixed with needles on a piece of cork (Figure 3A and B) submerged in formol solution, together with the resected esophagus or stomach, and delivered to the pathology department for investigation.

RESULTS

The ESD procedure was completed without complications using the Hook-knife in five esophageal areas, with a procedural duration of 124 ± 19 min, a length of 27.4 ± 2.6 mm, and a width of 21 ± 2.4 mm. The ESD procedure was also completed without complications using the IT-knife2 in five gastric areas, with a procedural duration of 92.6 ± 19 min, a length of 32 ± 2.5 mm, and a width of 18 ± 3.7 mm.

There was no perforation in either group. This fact was corroborated by an expert pathologist^[8] after histological and macroscopic study of the specimens.

Descriptive statistics of the pilot study are shown in Table 1. The size of each specimen, the procedural duration, the site of ESD, and its complications are shown

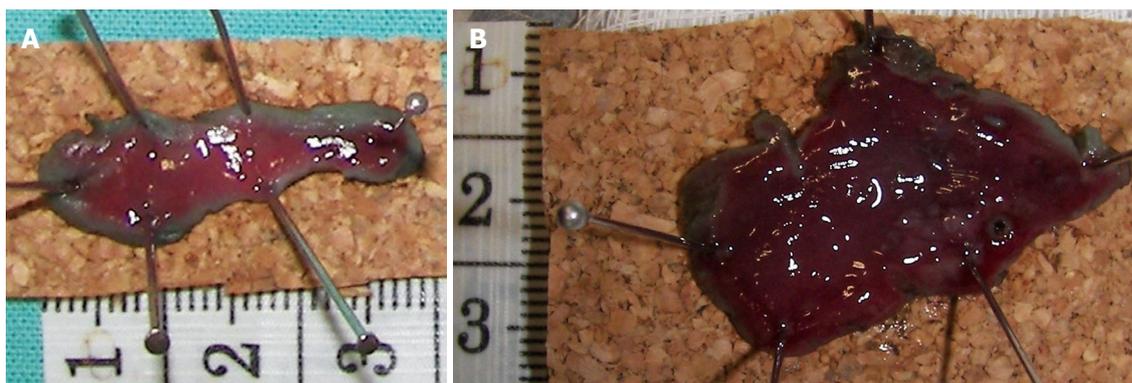

Figure 3 ESD specimens (A and B) fixed with needles in cork.

Table 1 Descriptive statistics of the endoscopic submucosal dissection (ESD) pilot study

Group	Values	Procedural duration (min)	Specimen length (mm)	Specimen width (mm)
Hook-knife (Esophagus)	n = 5

DISCUSSION

ESD has provided a new alternative for minimally invasive treatment of gastrointestinal early-stage^[13] (T1mN0) cancer lesions > 2 cm, with minimal risk of deeper wall-layer involvement or lymph node metastases, as confirmed by endoscopic ultrasonography (EUS)^[1-7]. This technique provides a curative alternative that preserves gastrointestinal function and offers an accurate histological T stage that replaces, in selected cases, surgery or other therapeutic attempts like piecemeal EMR^[2,4,15,16], cryotherapy, laser, argon plasma and photodynamic therapy because of their local recurrence rates.

Multiple factors make esophageal, small intestine and colon ESD more difficult compared with gastric ESD, including difficulties in maintaining the position of the endoscope, the thinness of their walls, the luminal angulations, and peristalsis. To avoid complications such as perforation during the ESD procedure requires adequate training^[4-10,12,16], and for this reason, animal models are invaluable as a learning resource.

Injection of indigo carmine^[3,4,15] and the consequent blue staining of the submucosal tissue (Figure 1B) was used to identify the submucosal layer and the deep margin during the resection process.

Although there are several injection solutions commercially available in Japan for the submucosal cushion (Artz, 3.8% NaCl^[15], Suvaniel, 20% glucose, and glyceol), we decided to standardize the use of normal saline with epinephrine and indigo carmine for all the ESD procedures, and reserve for difficult cases the use of Suprahyl (Asofarma de Mexico S.A. de C.V., Mexico) and sodium hyaluronate^[17] (Meiji Seika Kaisha LTD, Tokyo, Japan).

Also, the solution of normal saline, epinephrine and indigo carmine was used in cases with small bleeding sites during ESD. Fortunately, we did not have any bleeding complications^[11,12] during ESD. It is also very important to use hemostatic forceps as the submucosal dissection progresses for all the visible vessels below the lesion, to prevent bleeding obstructing vision of the cutting direction and post-ESD bleeding.

The electrosurgical HF-generator allowed us to set the power for preprogrammed coagulation and cutting

modes, which proved to be very important in performing the ESD without bleeding or perforation.

The right amount of infiltration always allows visualization of the circumference of the lesion for the final cut. Also, it is important to keep in mind how the muscular layer runs and to observe accurately the accumulation of liquids, to plan the cutting direction so that gravity can assist with the total dissection of the lesion.

Histopathological examination of the ESD specimens by an expert pathologist is essential to confirm clean margins, and complete removal of the mucosa and submucosa in all cases.

The limitations of this research were that it involved artificial non-neoplastic lesions and a small number of specimens in a pilot study.

ESD is a feasible technique in the normal esophagus and stomach of dogs and the use of these models is appropriate for teaching this technique.

ESD is a procedure that requires not only endoscopic skills, but also a good understanding of the endoscopy devices, techniques and technology to identify and treat EGC lesions. The minimum proficiency required by an endoscopy fellow to start ESD training is achieved after the appropriate knowledge is acquired. To begin with, the trainee assists an expert in the field, and eventually, he/she is assisted by an expert. Team work and coordination between the endoscopist and their assistants is also essential to perform ESD successfully.

Further studies and practice are needed to improve performance in canine models and to evaluate when the learning curve has been completed and a trainee is ready to perform ESD in patients. Also, in western countries and Latin America, multicenter studies are necessary before this technique can become a routine procedure.

The implementation of an ESD course at a WGO training center^[1] will not only help to open numerous research areas that could contribute to the treatment of early GI cancer lesions, but will also help the worldwide dissemination of these techniques.

COMMENTS

Background

The incidence of esophageal adenocarcinoma is currently rising in Western countries and Latin America. Also, gastric cancer is the second leading cause of cancer-related death worldwide. Endoscopic submucosal dissection (ESD) has provided a new alternative for minimally invasive treatment of gastrointestinal early-stage cancer, with the preservation of gastrointestinal (GI) function. Because of possible complications, such as perforation, adequate training is necessary to perform ESD successfully.

Research frontiers

Complete curative treatment of early GI cancer with ESD has been demonstrated in the Asian countries. However, after many years of investigation in this field, there are still a lack of multicenter studies that have incorporated this technique into the everyday practice in Western countries and Latin America. In the present study, the authors demonstrated the feasibility of using animal models as a learning resource to teach the ESD technique.

Innovations and breakthroughs

There are few training centers around the world at which an endoscopy fellow can be trained in the ESD technique. There is probably only a formal ESD training program in Asian countries, Germany, recently in Portugal, and at one site in

Colombia. Completion of the learning curve and implementation of training in the ESD technique at a health institute and World Gastroenterology Organisation training center that annually receives trainees from all over Mexico and Central and South America will not only help to open numerous research areas that could contribute to the treatment of early GI cancer, but will also help the worldwide dissemination of these techniques.

Applications

Until now, ESD has been considered technically difficult, hazardous and time consuming. However, new technology is allowing us to overcome these drawbacks. Animal models have been used to test ESD devices and new technology but a formal training program is still necessary to teach this technique in western countries and Latin America. For this reason, animal models are an invaluable learning resource.

Terminology

ESD is a technique that allows *en-bloc* resection of early GI cancers > 2 cm, with minimal risk of deeper wall-layer involvement or lymph node metastases, as confirmed by endoscopic ultrasonography. In selected cases, ESD may replace surgery and provide clean margins for accurate histological diagnosis of the lesion borders and complete curative treatment.

Peer review

This is an interesting investigation that presents the feasibility of using canine models for ESD training.

Abstract

AIM: To investigate the frequency of occult hepatitis B, the clinical course of hepatitis B virus (HBV) reactivation and reverse seroconversion and associated risk factors in autologous hematopoietic stem cell transplantation (HSCT) recipients.

METHODS: This study was conducted in 90 patients undergoing autologous HSCT. Occult HBV infection was investigated by HBV-DNA analysis prior to transplantation, while HBV serology and liver function tests were screened prior to and serially after transplantation. HBV-related events including reverse seroconversion and reactivation were recorded in all patients.

RESULTS: None of the patients had occult HBV prior to transplantation. Six (6.7%) patients were positive

for HBV surface antigen (HBsAg) prior to transplantation and received lamivudine prophylaxis; they did not develop HBV reactivation after transplantation. Clinical HBV infection emerged in three patients after transplantation who had negative HBV-DNA prior to HSCT. Two of these three patients had HBV reactivation while one patient developed acute hepatitis B. Three patients had anti-HBc as the sole hepatitis B-related antibody prior to transplantation, two of whom developed hepatitis B reactivation while none of the patients with antibody to HBV surface antigen (anti-HBs) did so. The 14 anti-HBs- and/or anti-HBc-positive patients among the 90 HSCT recipients experienced either persistent (8 patients) or transient (6 patients) disappearance of anti-HBs and/or anti-HBc. HBsAg seroconversion and clinical hepatitis did not develop in these patients. Female gender and multiple myeloma emerged as risk factors for loss of antibody in regression analysis ($P < 0.05$).

CONCLUSION: Anti-HBc as the sole HBV marker seems to be a risk factor for reactivation after autologous HSCT. Lamivudine prophylaxis in HbsAg-positive patients continues to be effective.

INTRODUCTION

Hepatitis B virus (HBV) infection is one of the major human health problems in the world. It is estimated that 350-400 million (approximately 5%) people worldwide are affected by HBV infection^[1,2]. Turkey is one of the endemic areas for HBV infection. The spectrum of HBV-related disease ranges from asymptomatic HBV carrier state, chronic hepatitis B, acute hepatitis B, to rarely fulminant hepatitis. Chronic HBV infection is also associated with cirrhosis and hepatocellular carcinoma^[1]. A new clinical status of persistence of HBV genomes in the liver tissue and/or serum in HBV surface antigen (HBsAg)-negative individuals is designated as "occult HBV infection"^[3,4]. Though suspected to exist since the early 1980s, this peculiar form of chronic viral infection has been better identified during the past 10 years. The availability of highly sensitive molecular biology techniques made it possible to disclose several of its virological aspects and to show its worldwide distribution, as well as revealing its possible implications in various clinical contexts^[5,6].

Intensive chemotherapy, radiotherapy, monoclonal antibody treatment and autologous and allogeneic hematopoietic stem cell transplantation (HSCT) give rise to immune dysfunction which consequently exposes the patients to the risk of many infections, including viral hepatitis^[7,8]. Exacerbation of hepatitis B is a serious cause of morbidity and mortality in patients undergoing cytotoxic or immunosuppressive therapy, particularly in areas where chronic HBV infection is endemic^[9]. Iwai *et al*^[10] reported lethal hepatic failure in an immunosuppressed patient after allogeneic bone marrow transplantation due to reactivation of latent HBV. The patient had antibody to HBV surface antigen (anti-HBs) and no viral DNA detected in the serum prior to transplantation^[10]. Carpenter *et al*^[11] described a patient with chronic myelogenous leukemia whose pretransplantation evaluation revealed normal serum aspartate and alanine aminotransferase levels, a negative serum for HBsAg, anti-HBs, antibody to HBV core antigen (anti-HBc), and HBV-DNA assessed by a sensitive real-time polymerase chain reaction (PCR). The donor was seropositive for anti-HBc, but serum HBV-DNA was negative by PCR. This case went on to develop acute HBV infection 7 mo after transplantation^[11].

To date, there have been several reports of reverse seroconversion/HBV reactivation in patients previously positive for anti-HBs after allogeneic or autologous HSCT^[12-19]. There is also growing evidence regarding increased frequency of occult HBV infection in areas where hepatitis B is endemic^[5,20-22]. However, information pertaining to prevalence of occult hepatitis B prior to HSCT and frequency of reverse seroconversion/HBV reactivation after HSCT has been scant.

This study aimed to determine: (1) prevalence of occult HBV infection in patients with various hematologic malignancies who are candidates for autologous HSCT; (2) frequency, course and results of HBV reactivation

and reverse seroconversion after autologous HSCT; and (3) risk factors for HBV reactivation and reverse seroconversion in patients undergoing autologous HSCT for various malignancies.

MATERIALS AND METHODS

Study population

Ninety consecutive patients who underwent autologous HSCT at the Stem Cell Transplantation Unit of Gazi University with the diagnosis of various hematological malignancies from September 2003 through July 2008 were included in the study.

Detection of hepatitis markers and HBV-DNA

HBV serology and liver function tests were screened before transplantation, at day +30 and every 3 mo thereafter. HBV-DNA was tested in all patients prior to transplantation, and after transplantation in the patients who had reverse seroconversion/reactivation of HBV or acute HBV infection. HBV serology (HBsAg, anti-HBs, anti-HBc, HBeAg, anti-HBe) was tested by ELISA. HBV-DNA was extracted using the MagAttract Virus Mini M48 kit (Qiagen, Hamburg, Germany) on the Bio-Robot M48 workstation (Qiagen, Hamburg, Germany) following the manufacturer's instructions. Besides HBV markers, all patients were screened for antibody to hepatitis C virus (anti-HCV) and anti-human immunodeficiency virus antibodies prior to transplantation.

Definitions of HBV-related events

Hepatitis was defined as a serum alanine aminotransferase level greater than 100 IU/mL on two consecutive determinations more than 5 d apart^[23].

Occult hepatitis B was defined as the presence of HBV-DNA and the absence of HBsAg in plasma^[3].

HBV reactivation was defined as seroconversion from HBsAg-negative to positive for HBsAg with an increase in HBV-DNA levels compared with baseline HBV-DNA levels, in the absence of clinical and laboratory features of acute infection with hepatitis A, hepatitis C, or other systemic infection^[24].

Reverse seroconversion was defined as appearance of HBsAg and disappearance of anti-HBs after HSCT in patients who had no HBsAg but did have anti-HBs or anti-HBc before transplantation^[14,19].

Loss of antibody was defined as disappearance of anti-HBs and/or anti-HBc after transplantation.

Lamivudine prophylaxis

All patients with a positive HBsAg received 100 mg/d lamivudine prophylaxis before the transplantation conditioning regimen. Lamivudine prophylaxis was maintained for at least 1 year after transplantation. Liver function tests were within normal limits in all patients before starting the conditioning regimen.

This study was approved by the Institutional Board of Gazi University Medical School.

Statistical analysis

Statistical analysis was performed using the program of SPSS for Windows, version 11.5. Relative risks for reactivation of HBV and loss of antibodies were calculated by logistic regression analysis. $P < 0.05$ was considered to be statistically significant.

RESULTS

Patient characteristics

Among the ninety (59 male and 31 female) patients included in the study, forty-six had multiple myeloma (MM), 23 Hodgkin's lymphoma (HL), 15 non-HL (NHL), 4 acute myeloblastic leukemia, 1 acute lymphoblastic leukemia, 1 primitive neuroectodermal tumor (PNET). The median age at transplantation was 48 years (range: 16-71 years). The median follow-up after autologous HSCT was 15 mo (range: 6-36 mo). Patients with MM comprised the most common subgroup (46 patients, 51.1%) as shown in Table 1.

Changes in HBV serologic markers

Pre-transplantation surveillance of HBV infection showed that 6 patients (6.7%) were HbsAg-positive; three of these patients were HBV-DNA-positive. None of the patients in our cohort had occult hepatitis B. Total numbers of patients with anti-HBs and anti-HBc were 30 (33.3%) and 23 (25.6%), respectively. Forty-nine patients (54.4%) had neither anti-HBs nor anti-HBc; 12 patients (13.3%) had both (Table 2).

Clinical hepatitis B infection was detected in three patients. Two of these infections were HBV reactivation while one patient developed acute hepatitis B. While none of the patients with positive HBsAg reactivated after autologous HSCT, 2 of the 3 patients with negative HBsAg and positive anti-HBc had hepatitis B reactivation. On the other hand, none of the patients with negative HBsAg and positive anti-HBs reactivated.

Six patients with pretransplantation HBsAg received prophylactic lamivudine. Autologous HSCT was performed under lamivudine prophylaxis in those 6 patients; none of whom had HBV reactivation in the post-transplantation period.

Reactivation case 1: A 55-year-old male patient with MM had anti-HBc antibody as the sole HBV-related marker at pretransplantation screening. HBsAg, anti-HBs, HBeAg, anti-Hbe and HBV-DNA were all negative. The patient had received four cycles of VAD (vincristine, adriamycin, dexamethasone) as first line treatment, and four cycles of thal-dex (thalidomide-dexamethasone) as second line treatment. Cyclophosphamide-etoposide and melphalan were administered as mobilization and conditioning regimens, respectively. At day 110 after autologous HSCT, HBsAg and HBV-DNA became positive. He was in partial remission at the time of hepatitis B reactivation. Lamivudine treatment was started on the same day. Although ALT was within normal limits ini-

Table 1 Clinical characteristics of patients

Thiotepa-Cy-Bu	1 (1.1)
Z-BEAM	1 (1.1)

BEAM: The combination of Carmustine (BCNU), Etoposide, Cytarabine (Ara-C) and Melphalan; Z-BEAM: The combination of Ybritumomab Tiuxetan (Zevalin®), Carmustine (BCNU), Etoposide, Cytarabine (Ara-C) and Melphalan; Cy: Cyclophosphamide; TBI: Total body irradiation.

tially, it increased to 590 U/L (0-49 U/L, reference value) at day 225 post-transplantation. Subsequently ALT levels decreased gradually and normalized within 2 wk. Anti-HBc was still positive at the time of HBV reactivation and it remained positive during follow-up period. Anti-HBe and anti-HBs have not become positive during the follow-up. HBsAg and HBV-DNA disappeared in the first year after autologous HSCT. HBV-DNA titer was 1.1×10^6 copies/mL at day +110, 1.9×10^6 copies/mL at day +183, 0.9×10^6 copies/mL at day +225, 1100 copies/mL at day +256 and negative at day 365 after autologous HSCT.

Reactivation case 2: A 55-year-old male patient with MM had anti-HBc antibody as the sole HBV-related marker at pretransplantation screening. HBsAg, anti-HBs, HBeAg, anti-Hbe and HBV-DNA were all negative in this patient as well. At day 148 after autologous HSCT, HBsAg and HBV-DNA became positive. Lamivudine treatment was started the same day. ALT level was normal initially, but it was measured as 1157 U/L at day +198. Subsequently, ALT level decreased gradually and returned to normal limits within 2 wk. HBV-DNA titer was 1000 copies/mL at the time of reactivation, then decreased gradually and it became negative at day +225. HBsAg also disappeared in patient's serum on day 365 after autologous HSCT. Anti-HBc was still positive at the time of HBV reactivation and it remained positive during follow-up. Anti-HBe and anti-HBs became positive at day +198 and day +457 after autologous HSCT, respectively. He was in complete remission at the time of hepatitis B reactivation.

Acute HBV infection case 1: A 48-year-old female

MM: Multiple myeloma; NHL: Non-Hodgkin's lymphoma; PNET: Primitive neuroectodermal tumor.

patient with MM received methylprednisolone for autologous graft-versus-host disease (GVHD) treatment at day 18 post-transplantation. HBsAg, anti-HBs, anti-HBc, HBeAg, anti-Hbe and HBV-DNA were all negative prior to transplantation in this patient. On day +210 post-transplantation, HBsAg, HBeAg and HBV-DNA became positive. Lamivudine treatment was started. ALT level, which initially was normal, gradually increased to 534 U/L at day 287 post-transplantation. She remained on steroid treatment for the treatment of grade IV chronic dermal GVHD. HBV-DNA titer was 5.3×10^7 copies/mL on the day of reactivation, 1×10^6 copies/mL at day +287, 3.3×10^4 copies/mL at day +365, and 2000 copies/mL at day 580 after autologous HSCT. On day 580 post-transplantation when the data of this study were analyzed, she was positive for HBsAg, HBeAg and HBV-DNA (gradually decreasing titer, YMDD mutation negative).

Loss of antibody

The 14 anti-HBs- and/or anti-HBc-positive patients who underwent autologous HSCT experienced persistent (8 patients) or transient (6 patients) disappearance of anti-

HBs and/or anti-HBc. Interestingly, neither seroconversion for HBsAg nor clinical hepatitis developed in these patients. Eleven of these 14 patients had MM, 1 had NHL, 1 had HL, and 1 had PNET. Anti-HBs or anti-HBc reappeared in 5 of these patients within 6 to 8 mo. Characteristics of these patients and details of the changes in serologic markers are shown in Table 3.

Possible risk factors for reactivation and loss of antibodies, including age, gender, underlying disease, the number of pre-transplant chemotherapy cycles and the mobilization and conditioning regimens, were tested both in univariate and multivariate logistic regression analysis. No specific risk factors were found for reactivation of HBV. Female gender ($P = 0.04$, OR = 3.4, CI: 1.17-9.81) and MM ($P = 0.035$, OR = 4.29, CI: 1.29-16.2) emerged as risk factors for loss of antibody in univariate analysis; whereas only MM was an independent risk factor in multivariate analysis ($P = 0.043$, OR = 3.6, CI: 1.1-14.4).

DISCUSSION

HBV carriers have increased liver-related morbidity and

mortality during chemotherapy of hematological disorders^[25]. Reactivation in patients supposedly immune to hepatitis B has also become an emerging problem during the treatment of various hematologic disorders with chemotherapeutic agents, monoclonal antibodies, immunosuppressive agents and HSCT^[26]. HBV is a latent virus which may persist for a long time despite the presence of anti-HBs and/or anti-HBc antibodies. Reverse seroconversion/reactivation may occur which results in increased liver-related morbidity and mortality^[25], particularly in areas with high hepatitis B prevalence. Turkey is among the middle-endemic regions for hepatitis B with a mean seroprevalence for hepatitis B among healthy blood donors reported as 4.19% (3.9%-12.9%)^[2,27].

Occult HBV infections are defined as the presence of HBV-DNA and the absence of HBsAg in liver tissue, plasma or serum of HBV-infected patients^[3-5]. The risk of reactivation and fulminant course is particularly high in this group of patients. We investigated the prevalence of occult HBV infection in patients with various hematologic malignancies who were candidates for autologous HSCT. We also investigated the frequency and the risk factors associated with HBV reactivation/reverse seroconversion after autologous HSCT.

Pre-transplantation surveillance of HBV infection showed that six patients (6.7%) were HbsAg-positive, three of whom were also HBV-DNA-positive. The 6.7% HBsAg seropositivity among patients with hematologic malignancies in the presented study seems to be similar to the frequency in the normal population.

There are several reports describing effective lamivudine prophylaxis in HbsAg-positive patients receiving chemotherapy or HSCT^[9,28-30]. None of our patients with HBsAg, with or without positive HBV-DNA, had hepatitis reactivation under lamivudine prophylaxis. Our study results might suggest an efficacy of lamivudine prophylaxis in HbsAg-positive patients undergoing autologous HSCT, although lamivudine resistance has also been reported in other series^[23,31,32].

Reactivation of HBV in patients previously positive for anti-HBs and/or anti-HBc, so called “reverse seroconversion”, has been reported in immunosuppressed patients including patients with acquired immunodeficiency and recipients of organ transplantation or HSCT^[14,33,34]. In particular, patients with lymphoma receiving rituximab with or without chemotherapy have an increased risk of reactivation^[26]. The precise frequency of reactivation in the setting of HSCT in anti-HBs- and/or anti-HBc-positive and HbsAg-negative patients is not known, though previous reports mention a frequency of 7% to 12%^[18,35,36]. Two among the 3 patients (66.7%), who had anti-HBc as the “only” hepatitis B-related marker prior to transplantation developed HBV reactivation after autologous HSCT. The cause of the hepatitis in the two patients presented above seems to be reactivation of a previous infection. Similarly, Matsue *et al*^[37] found an increased risk of reactivation in their patients who had anti-HBc antibodies, while none of the patients in their

series with anti-HBs developed a reverse seroconversion. In the absence of HBV-DNA prior to transplantation, patients with anti-HBc as the sole HBV-related marker might be a variant or subgroup of patients with occult hepatitis where the infection is limited to the liver. Our results suggest that patients with anti-HBc in the absence of anti-HBs seem to be a high risk group requiring monitoring and even prophylaxis, though these data warrant verification with further prospective randomized studies. In contrast to the patients presented by Matsue *et al*^[37], whose HBV reactivation was after corticosteroid therapy for chronic GVHD, our patients who had HBV reactivation were not receiving corticosteroids and were in remission from their underlying diseases. The immunosuppressive effect of autologous HSCT *per se* might be responsible from the reverse seroconversion in our cases.

At present, HBV serological markers including HBsAg, anti-HBs and anti-HBc may not be adequate to perceive the existence of HBV. Recent studies have demonstrated that improvement of PCR methods have favored the recognition of occult HBV infections in an increasing number of clinical settings and geographical areas. To date, documentation of occult HBV prevalence rates has been limited to blood or organ donors and selected patient populations such as hemodialysis patients with HCV^[38-40], AIDS patients and hemophiliacs. The prevalence of HBV viremia in adult hemodialysis patients is 3.8%-15%, or 4-20 times higher than what standard monoclonal antibody-based HBsAg testing would have suggested. It is possible that host immune mechanisms and viral interactions can maintain HBV infection in a latent state until more profound immunosuppression ensues^[38-40]. Recently, occult HBV prevalence has also been investigated in community-based populations^[21]. The prevalence of occult hepatitis was found to be 15.3% in a cohort of 124 consecutive HbsAg-negative stem cell donors in Hong Kong, which suggests occult hepatitis is a matter of concern in endemic areas^[13].

None of the patients presented in this study with various hematological malignancies had occult hepatitis B prior to transplantation. Uhm *et al*^[7] similarly have not detected occult HBV infection in their patients with hematologic malignancies in Korea, which is also an endemic area for HBV infection. Absence of occult hepatitis in a relatively high risk group of patients requires further elucidation. On the other hand, patients with anti-HBc as the only HBV marker might be a variant subgroup with occult hepatitis. More sensitive methods such as detection of covalently closed circular DNA - the key intermediate of replication of the virus - in liver biopsy specimens may be required in patients with immunosuppression, in order to exclude occult infection.

The rates of disappearance of anti-HBs, anti-HBc, and both (loss of antibody) were 40% (12/30 patients), 6.7% (2/30 patients), and 6.7% (2/30 patients), respectively, in our series. Total rate of disappearance of anti-HBs and/or anti-HBc was 46.7% (14/30 patients). Loss

of antibody was transient in 6 of these patients. Anti-HBs reappeared after 8-18 mo (median 15 mo) in 4 patients and anti-HBc reappeared after 6 mo in 2 patients (Table 3). The most common underlying disease among the patients who had loss of antibody (11/14 patients) was MM. MM was discovered to be an independent risk factor for loss of antibody in multivariate analysis ($P = 0.043$, OR = 0.27). The reason why the loss of antibody emerges more in MM patients who have undergone autologous HSCT remains to be elucidated.

None of the patients who lost their hepatitis B antibodies developed HBsAg seroconversion or clinical hepatitis during the median 15 mo follow up period. The actual risk of disappearance of anti-HBs and reverse seroconversion was estimated to be 75% and 39.8% at 2 years, and 100% and 70% at 5 years, respectively, in allogeneic HSCT recipients in the study of Onozawa *et al.*^[19]. Lower rates of disappearance of antibody and reverse seroconversion in our study could be explained by the fact that our study population consisted of patients who had undergone autologous HSCT which is less immunosuppressive than allogeneic HSCT.

In conclusion, HBV-related events such as reactivation, acute hepatitis and loss of antibody can develop in patients undergoing autologous HSCT. Patients with anti-HBc antibody as the only HBV-related serologic marker might be a special risk group where antiviral prophylaxis should be considered. Loss of anti-HBs and/or anti-HBc after transplantation is not a rare complication of autologous HSCT, especially in MM patients, and does not necessarily progress to reverse seroconversion and clinical hepatitis. Further prospective and randomized studies are required to validate the prognostic significance and treatment of anti-HBc-positive patients.

COMMENTS

Background

Hepatitis B virus (HBV) infection is one of the major human health problems in the world. Turkey is one of the endemic areas for HBV infection. Intensive chemotherapy, radiotherapy, monoclonal antibody treatment, and autologous and allogeneic hematopoietic stem cell transplantation (HSCT) give rise to immune dysfunction which consequently expose the patients to the risk of many infections, including viral hepatitis. Exacerbation of hepatitis B is a serious cause of morbidity and mortality in patients undergoing cytotoxic or immunosuppressive therapy, particularly in areas where chronic HBV infection is endemic.

Research frontiers

This study aimed to determine the prevalence of occult HBV infection in patients with various hematologic malignancies who are candidates for autologous HSCT. Frequency, course of disease, results of HBV reactivation and reverse seroconversion after autologous HSCT, and the risk factors for HBV reactivation and reverse seroconversion in patients undergoing autologous HSCT for various malignancies were also determined.

Innovations and breakthroughs

HBV-related events such as reactivation, acute hepatitis and loss of antibody can develop in patients undergoing autologous HSCT. Patients with anti-HBc antibody as the only HBV-related serologic marker might be a special risk group where antiviral prophylaxis should be considered. Loss of antibody to HBV surface antigen (anti-HBs) and/or anti-HBc after transplantation is not a rare complication of autologous HSCT, especially in multiple myeloma patients, and does not necessarily mean progression to reverse seroconversion and clinical

hepatitis. Further prospective and randomized studies are required to validate the prognostic significance and treatment of anti-HBc-positive patients.

Applications

Presence of anti-HBc as the sole HBV-related marker seems to be a risk factor for reactivation. Loss of anti-HBs and anti-HBc are frequently seen after autologous HSCT, not necessarily having a poor prognostic significance. Lamivudine prophylaxis in HBV surface antigen (HBsAg)-positive patients, and treatment in patients with HBV reactivation, continues to be effective.

Terminology

HBV reactivation was defined as seroconversion from HBsAg-negative to positive for HBsAg with an increase in HBV-DNA levels compared with baseline HBV-DNA levels, in the absence of clinical and laboratory features of acute infection with hepatitis A, hepatitis C, or other systemic infection. Reverse seroconversion was defined as appearance of HBsAg and disappearance of anti-HBs after HSCT in patients who had no HBsAg but did have anti-HBs or anti-HBc before transplantation. Loss of antibody was defined as disappearance of anti-HBs and/or anti-HBc after transplantation.

Peer review

In this paper, the authors provide consistent data which may help better understanding of the yet unsolved topic of HBV reactivation after immunosuppression, even if they do not change significantly current practices in this field.

Abstract

AIM: To identify the brain loci that process human biliary sensation.

METHODS: In 6 patients (age range: 42-74 years; 4 men), who underwent percutaneous transhepatic biliary drainage (PTBD), the distal biliary tract was stimulated by repeatedly inflating the balloon of the PTBD catheter so that it reached volumes that produced a definite painless sensation. The functional magnetic resonance imaging (fMRI) of the cortical response to biliary sensation was examined.

RESULTS: Biliary balloon stimulation elicited activation of the insular cortex, prefrontal cortex, and somatosensory cortex ($P < 0.001$).

CONCLUSION: Biliary balloon stimulation evoked a cerebral cortical response detectable by fMRI.

INTRODUCTION

Elevated pressure of the extrahepatic bile duct may elicit a variety of symptoms ranging from various degrees of abdominal distention, discomfort, dyspepsia, and pain. However, there is no information concerning the cerebral cortical response to sensory signals that originate in the biliary tract in humans. On the other hand, the cortical response to esophageal, stomach or rectal stimulation has been studied using several different modalities including evoked potentials^[1], functional magnetic resonance imaging (fMRI)^[2], and positron emission tomography^[3].

In the present study, we used fMRI to investigate the cerebral cortical response to biliary stimulation in humans.

MATERIALS AND METHODS

Patients

Six patients who underwent percutaneous transhepatic biliary drainage (PTBD) participated in this study after the study protocol was approved by the Institutional

Review Board of Juntendo University, and the patients provided their informed consent. The study population consisted of 4 men and 2 women with an average age of 58 years (range: 42-74 years). The indication for PTBD in these patients was the presence of intrahepatic stones. A balloon-affixed 18 French PTBD catheter was used in every patient to perform lithotripsy of intrahepatic stones under percutaneous transhepatic cholangioscopy.

Extrahepatic bile duct distention

Bile duct distention was achieved using the balloon-affixed 18 French PTBD catheter. Before each study, the balloons were inflated in 1 mL increments to determine the volume of air necessary to induce a definite but painless sensation, and the condition was confirmed by magnetic resonance cholangiopancreatography beforehand. The balloon catheter was located at 4 cm proximal to the papilla of Vater and inflated to the desired diameter by manually injecting the predetermined volume of air. Balloon distention was done by the same investigator in all studies. The subjects were asked to confirm the sensation of distention before and after the fMRI study.

MRI scanning

Functional MRI has been shown to accurately detect cortical activity with the use of the blood oxygenation level-dependent (BOLD) technique. The BOLD technique is based on the fact that deoxygenated and oxygenated blood have subtly different magnetic susceptibilities. This change in magnetic susceptibility alters the microscopic distribution of the magnetic field within a single MRI pixel and results in a change in signal intensity, greater oxygenation being associated with a brighter pixel contrast. Thus, the time course of gradient echo MRI images shows subtle changes in brightness in regions of altered oxygenation rate. Neuronal activity is associated with increased venous oxyhemoglobin levels; consequently, the anatomic location of the cortical regions that increase in brightness during application of a stimulus is associated with the sensation of that stimulus^[2,4].

Magnetic resonance images were acquired using a 1.5-Tesla Toshiba VISART EX system with a standard quadrature head coil. BOLD imaging was performed using a field-echo echo planar imaging (EPI) sequence [repetition time (TR) = 2000 ms, echo time (TE) = 45 ms, matrix = 96 × 96, flip angle 70° and field of view (FOV) = 26 cm]. EPI-MRI images were acquired in the axial plane for 13 contiguous slices, 8 mm in thickness, covering the whole brain.

Study protocol

After positioning the subject, echo planar MRI images were captured as follows: for a total of 180 s were captured over a period of 180 s with three 60 s cycles (30 s rests alternated with 30 s periods of sustained balloon distention). In the same subjects, sham biliary balloon distention was performed for control.

Statistical analysis

The functional data processing was performed on personal

Table 1 Cerebral cortical regions associated with biliary balloon distention

Subjects	Regions of activation				
	OFC	Ins	PFC	S	POC
1			B		L
2		B	R		
3				B	
4		B			
5	L	B		B	
6			B	R

computer (PC) workstations (Dynabook, Toshiba, Tokyo) using Statistical Parametric Mapping (SPM99) (Wellcome Department of Imaging Neuroscience) implemented in Matlab (Mathworks). We used SPM99 software to perform realignment for motion correction, normalization or deformation using the standard brain template from the Montreal Neurological Institute and conversion to the standard stereotaxic atlas of Talairach space and performing data analysis (using a threshold of $P < 0.01$) for individual subjects. A typical boxcar model convolved with a hemodynamic response of SPM was used. Data analysis was performed using the amplitude estimates (percent signal change) from the 6 patients.

RESULTS

The volume threshold of bile duct balloon distention at which a sensation of abdominal discomfort was induced was 4.5 ± 0.8 mL; the mean diameter of the balloon was 15.0 ± 1.7 mm, which was $159.0\% \pm 11.6\%$ greater than the bile duct diameter before balloon dilation. All subjects reported they felt a definite painless sensation when the balloon was inflated, before and after fMRI scanning. Bile duct balloon distention produced a cortical fMRI response in all subjects. At the corrected P level of less than 0.01, the cortical response was mostly observed in the insular cortex, prefrontal cortex, and somatosensory cortex (Table 1 and Figure 1). The fMRI signal increased to an average maximum value of $4.1\% \pm 0.6\%$ above the average baseline signal intensity.

With sham biliary balloon distention, all subjects felt no sensation during, before and after fMRI scanning, and the fMRI signal was not observed in all subjects.

DISCUSSION

In this study we characterized the cerebral cortical response to bile duct balloon distention. The technique used in this study is based on measurable changes in magnetic signal intensity due to changes in cerebral blood oxygenation, and the percent average signal change in our study was $4.1\% \pm 0.6\%$; the percent change in signal intensity accepted as significant has been reported for

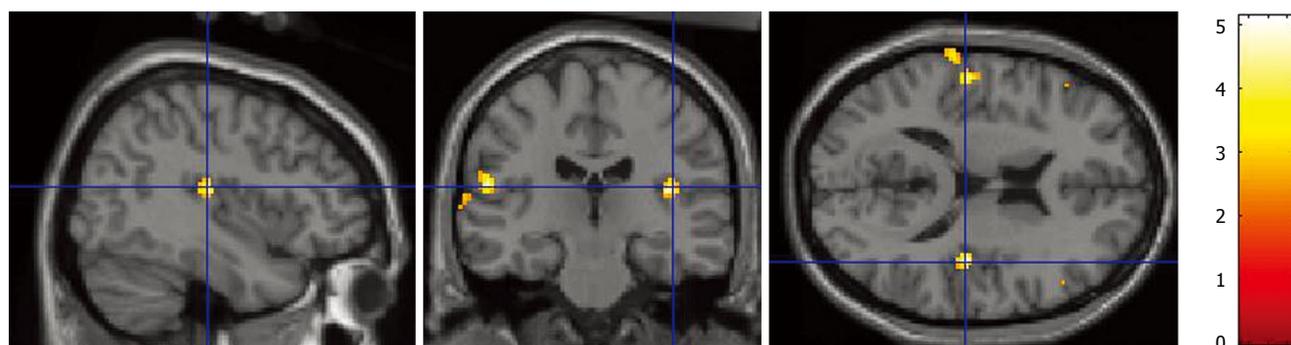

Figure 1 Sagittal, coronal and axial section showing increased activation in the bilateral insular cortex ($P < 0.01$).

simple motor tasks ($4.3\% \pm 0.32\%$)^[5], visual stimulation ($3\%-5\%$)^[6], and psychotropic drug effects ($2\%-3\%$)^[4].

The findings of the present study indicated that balloon stimulation of the bile duct at the definite sensation was relayed to the cerebral cortex and induced neuronal activity detectable by fMRI. Functional MRI technique has been previously used to study the cortical response to balloon dilation of the esophagus, stomach, and rectum^[2,7-9]. The present findings are the first step in the evaluation of cerebral response to bile duct balloon distention, and show the possibility of the presence of pressure sensitive vagal afferents in the biliary tract and the cortical relay of these afferents beyond the brainstem.

The cerebral cortical response to biliary balloon distention was mostly observed in the insular cortex, pre-frontal cortex, and somatosensory cortex. The spread of activation around these regions was comparable to that observed in a meta-analysis of studies on noxious somatic stimulation^[10]. Furthermore, insular activation was found to be the most consistent finding in visceral stimulation research^[9,11]. As described by Neafsey *et al.*^[12], electrical stimulation of the insula in rats, cats, dogs, monkeys, and human elicits changes in blood pressure, heart rate, respiration, piloerection, papillary dilation, gastric motility, peristaltic activity, salivation, and adrenalin secretion, and the insula is regarded as a key integrative visceral sensory area, mediating affective response to visceral stimulation^[11].

Visceral hypersensitivity, a condition characterized by lower thresholds for discomfort, pain, or other sensations during intraluminal balloon distention, has been demonstrated by fMRI in patients with different functional gastrointestinal disorders including functional dyspepsia, irritable bowel syndrome, and noncardiac chest pain^[8,9,13]. The present study suggests the possibility to detect hypersensitive conditions in functional biliary disorder using fMRI.

Potential weaknesses of this study include, first, the small number of patients. The current data need to be confirmed in larger groups of patients. Secondly, manual control of the volume used to induce biliary distension rather than barostat pressure controlled inflations was used due to difficulties with the use of a barostat in the MRI scanner room. A third limitation of this study was

the introduction of the PTBD catheter that may cause not only emotional distress, but also vagal activation. The possible impact of this on registered brain activation patterns was minimized by allowing at least 2 wk between introduction of the PTBD catheter and the MRI scan. However, a certain amount of stimulation at baseline by the presence of the catheter is unavoidable^[9,14].

In summary, biliary balloon stimulation, inducing painless distention, evokes a cerebral cortical response detectable by fMRI. Further functional imaging studies of biliary sensation are required to improve the confidence of interpretation of results.

COMMENTS

Background

Elevated pressure of the extrahepatic bile duct may elicit a variety of symptoms ranging from various degrees of abdominal distention, discomfort, dyspepsia, and pain. However, there is no information concerning the cerebral cortical response to sensory signals that originate in the biliary tract in humans.

Research frontiers

In the present study, the authors used functional magnetic resonance imaging (fMRI) to investigate the cerebral cortical response to biliary stimulation in humans.

Innovations and breakthroughs

The present findings are the first step in the evaluation of cerebral response to bile duct balloon distention.

Applications

The present study suggests the possibility to detect hypersensitive conditions in functional biliary disorder using fMRI.

Peer review

It is an interesting study. The authors are congratulated on making the first observation on the relay of mechanosensitive information from the biliary tract presumably *via* vagal afferents, the brain stem and on to specific regions of the cerebral cortex.

Abstract

AIM: To investigate the effectiveness of early infliximab use for induction and maintenance therapy in pediatric Crohn's disease.

METHODS: We performed a retrospective chart review of 36 patients with Crohn's disease. Ten patients (group A) were treated with mesalamine after induction therapy with oral prednisolone, and 13 patients (group B) were treated with azathioprine after induction therapy with oral prednisolone. Thirteen patients (group C) received infliximab and azathioprine for induction and maintenance therapy for the first year, and were treated with azathioprine after 1 year. All patients were followed for at least 24 mo. Efficacy was determined by the relapse rate using the pediatric Crohn's disease activity index score in each group at 12 and 24 mo.

RESULTS: At the 1 year follow-up, the relapse rate
