At admission, all the patients classified as having SAP were admitted to the intensive care unit (ICU) where resuscitation was commenced. The patients were started on antibiotics, which were usually fluoroquinolones and metronidazole during the initial few years. However, the choice of antibiotic was changed to carbapenems (meropenem 500 mg 6 hourly, for 7 to 14 d) thereafter, owing to the sensitivity of the local microbiological flora and based on the reports of the ability of carbapenems to penetrate the necrosus^[28]. Antifungals were commenced if the duration of antimicrobial therapy went beyond 7 d.

In patients with SAP, contrast-enhanced computed tomography (CECT) scan was performed for assessing the local severity by the Balthazar computed tomography (CT) severity index^[29]. A CT severity index of ≥ 7 was considered indicative of SAP. Nutrition was maintained by nasojejunal intubation and feeding. Percutaneous interventions were performed when clinically indicated, particularly in unstable patients as a temporizing measure or a bridge to surgery. The aim was to try and delay any intervention beyond the first 21 d.

Indications for surgery^[23,30,31]: (1) Sepsis syndrome - clinical deterioration that is progressive with or without organ system failure and accompanied by fever and leucocytosis; (2) IPN - confirmed by fine needle aspiration (FNA) cytology and microbiological examination; (3) CECT showing extensive pancreatic necrosis with air pockets diagnostic of IPN; and (4) "Persisting unwellness" - in the form of abdominal pain, malaise, inability to tolerate a diet, general lack of well being, and continuing weight loss.

Figure 1 Contrast-enhanced computed tomography of the abdomen showing a large hypodense collection with air pockets in the location of the pancreatic body and tail (white arrow) indicative of an infected pancreatic necrosis.

The necrosectomy was planned as a single stage. Surgery was defined as delayed if it was performed at least 21 d after the onset of pain, which was considered as Day 0 of the attack. Fresh imaging in the form of CECT was obtained just prior to the exploration. The areas of necrosis and fluid collection were carefully mapped. The patient underwent a laparotomy through a transverse upper abdominal incision. Free fluid was aspirated, and the lesser sac was exposed either through the transgastrocolic or transmesocolic route. All the pus and fluid were removed and sent for microbiological examination. The necrotic debris was also removed carefully with blunt finger dissection and sponge-holders, with an attempt not to damage any of the normal tissue. Particular care was taken not to divide bands across the cavity, especially in areas where known vessels could cross, e.g. middle colic artery. Copious lavage with warm normal saline was performed, which also helped to separate the necrotic tissue from the normal tissue. Bleeding was controlled with temporary packing, after which specific vessels were underrun with non-absorbable sutures. Other areas were explored, depending on the CT interpretation. These included the right and left paracolic gutters, head of the pancreas, gastrophatic omentum, pelvis, small bowel mesentery and the splenic hilum. Two 28 Fr tube drains were placed in the lesser sac and necrotic cavity. Loop ileostomy was performed selectively in the presence of extensive pericolic necrosis. Figure 1 is an abdominal CECT showing IPN. Figure 2 shows necrotic pancreas post-necrosectomy.

Post-operatively the patients were managed in the ICU. There was no attempt to perform post-operative lavage or flushing of the drains and the drains were removed once the output became minimal.

RESULTS

The 61 patients who required a necrosectomy for IPN included 49 male and 12 female patients. The mean age was 43 years (range 18-73 years). The predominant etiology for AP was gallstones (25 patients). Other etiologies included alcohol-induced (14 patients), idiopathic (13 pa-

Figure 2 Post-operative photograph demonstrating a complete necrotic pancreas.

tients), traumatic (3 patients), post-endoscopic retrograde cholangio-pancreatography (3 patients), and metabolic (3 patients).

The median time of patient transfer to our institute, which is a tertiary care center, was 9 d (range 4-40 d). No patient had surgical intervention prior to transfer, but 4 patients had already undergone percutaneous ($n = 2$) or endoscopic ($n = 2$) drainage for fluid collections prior to transfer.

Fifty-nine patients underwent an open necrosectomy while 2 patients had a laparoscopic necrosectomy. Patients underwent surgery at a median of 29 d (range 13-46 d) from the onset of symptoms. In only one patient, the necrosectomy had to be performed on day 13 for unresponsive multiple organ dysfunction syndrome (MODS). Delayed necrosectomy could be performed in the other 60 patients (98.3%). Re-exploration was required in five (5/59, 8%) patients for ongoing necrosis. In these patients further exploration was required on an average 2.4 occasions (range 2-3 occasions). The rate of re-exploration was 8%. Two patients required subsequent percutaneous drainage for residual intra-abdominal collections. Overall, a single-staged open necrosectomy was successful in 55 (90%) patients.

The microbiological cultures obtained from the necrotic tissue showed evidence of organism growth in 51 patients (83.6%). Mixed gram-positive and -negative organisms were encountered in 9 cases. Of the organisms isolated, 46 cultures were positive for gram-negative organisms, predominantly *E. coli*, *Klebsiella*, *Acinetobacter* and *Pseudomonas* and 11 grew gram-positive organisms. Fungi were isolated in 9 cases, all of which were in bacterial-positive cultures.

The various complications encountered have been listed in Table 1. The most common complication encountered was pancreatic fistula. Other complications were bowel fistulae, bleeding, recurrent sepsis, wound infection and secondary fungal infection.

The diagnosis of pancreatic fistula was based on amylase estimation of the drain fluid, which ranged from 9000 to 104000 U/mL. The drainage tube was maintained *in situ* and the patient was managed on an outpatient basis. Complete healing was achieved in 20 patients after an average

Table 1 Complications encountered in the 61 patients and their management

Complication	n (%)	Management
Pancreatic fistula	31 (50.8)	Tube drainage-20 Stenting-11 Fistulojejunostomy-1 Distal pancreatectomy-1
Enteric fistula	11 (18.0)	
Small bowel	2 (3.2)	Tube drainage-2

Pseudocyst	2 (3.2)	Cystojejunostomy-1 Open drainage-1
Pelvic abscess	1 (1.6)	Pig tail drainage-1

DIC: Disseminated intravascular coagulation.

of 2 mo. Endoscopic stenting of the pancreatic duct was performed in 11 patients in whom the leak persisted for > 2 mo. Two patients required re-surgery in the form of a fistulojejunostomy and a distal pancreatectomy, as stent placement could not be achieved across the leak. Of the 11 patients who developed enteric fistulae in the post-operative period, 4 had undergone prophylactic ileostomy creation during the primary surgery due to the presence of extensive pericolic necrosis. Five patients required a loop ileostomy later. In 4 patients the colonic fistula healed without any sequelae, while 5 patients required segmental colectomy for colonic stricture or persistent leak for more than 6 mo. One patient died after colonic resection due to sepsis. The two patients with small bowel fistulae were managed conservatively with tube drainage. In 3 of the 4 patients who had post-operative hemorrhage, the source could be localized on angiography to pseudoaneurysms (splenic artery: 2, middle colic artery: 1) and this was managed by angioembolization. Another patient died due to coagulopathy and acidosis. Fifteen patients (24.5%) required readmission. The reasons for readmission included persistent pancreatic fistula (5 patients), colonic stricture (4 patients), intestinal obstruction (3 patients), pseudocyst formation (2 patients), and pelvic abscess formation (1 patient).

There were 6 deaths in the perioperative period with a mortality rate of 10%. These included 3 (of the five) patients who underwent re-explorations; 1 patient with post-operative hemorrhage, 1 patient with a colonic fistula and the patient who required an early necrosectomy. The cause of death was sepsis and MODS in all cases except the patient with hemorrhage. The median post-operative ICU stay was 7 d (range 3-30 d) and the median duration for which the patient required ventilatory support was 3 d (range 2-7 d). The median duration of hospital stay

following surgery was 23 d (range 11-88 d). The time to return to daily activity (defined as ability to perform daily personal activities, including feeding oneself and combing hair) was 16 d (10-20 d). The average time to return to regular activity was 110 d (60-140 d).

DISCUSSION

The ideal timing for a necrosectomy for IPN is a matter of debate. In our patients, we carried out a conservative management regimen with supportive care, antibiotics, early enteral feeding, and care of the patient in the ICU.

Using this management strategy we were able to perform a delayed necrosectomy, i.e. after 21 d, with potential benefits as follows: (1) Separation of viable from non-viable tissues making the operation technically easier; (2) Operating on a more hemodynamically stable patient; (3) Reduced bleeding as only non-viable tissue is removed^[12]; (4) Removal of less normal pancreas resulting in reduced long-term morbidity^[9]; and (5) Reduced local complications such as erosion into blood vessels/small bowel that could lead to post-operative hemorrhage or fistulae.

Mier *et al.*^[15] had previously put forward this principle of delayed surgery for IPN. The success of the approach was subsequently confirmed by other studies^[6,13,21].

With this strategy of delaying surgery, in our series necrosectomy was performed as a single stage in all but 6 patients. In patients where the initially severe clinical course improved and the patient developed signs of sepsis in the third week, CT scan was repeated to map the extent of necrosis. At this time the pancreatic and peripancreatic necrosis tended to be localized with a resolution of the changes during the acute attack, such as acute fluid collections, stranding of the mesentery, *etc.*

The mortality rate in our study following the performance of a delayed single-staged necrosectomy was 9.8%. This compares favorably with the mortality rate of 11%-38% reported for open, as well as minimally invasive, necrosectomy for IPN over the last few years^[8,10-12,17,18,23,32,33]. The indication for intervention in our patients was not solely based on an FNA as has been described previously^[12]. We feel that FNA plays a role in the early period after SAP where it helps to differentiate systemic inflammatory response syndrome (SIRS) from infection. However, since we did not operate on the patients in this period, we did not find the need to apply the use of FNA as routine. Our decision to intervene was based on clinical parameters that included features such as persistent "unwellness", persistent pain in the abdomen, leucocytosis, appearance of a new fever especially after the second week when SIRS would not be a cause of raised temperature and infection of the pancreatic necrosis would be the only likely possibility, and the CT scan appearance of pancreatic necrosis^[23,30,31].

The concept of delayed surgery has definitely been facilitated by improvements in critical care, fluid resuscitation and organ support that have contributed to the fall in the early mortality associated with SAP^[34,35]. These have contributed by targeting one of the most important de-

terminants of poor outcome in SAP, i.e. the early development and persistence of organ dysfunction^[36].

We have used carbapenems, in particular meropenem, based on the proven efficacy of the drug for prophylaxis in patients with SAP^[37]. The rationale for using antibiotics was that mortality for IPN is higher than that for sterile necrosis and antibiotic usage decreases the risk of infection^[38,39]. The use of antibiotics indiscriminately, however, can lead to a 12%-35%^[40,41] risk of opportunistic fungal infections, e.g. *Candida albicans* and *Aspergillus fumigatus*^[42], which further increase the mortality rate^[43,44]. The accepted indications for antibiotics in AP are: newly developed sepsis or SIRS, failure of two or more organ systems, proven infection, or an increase in serum C reactive protein in combination with other evidence supporting the presence of infection, e.g. CT scan^[45]. We isolated fungal cultures in only 9 patients, i.e. 15% of cases, which was quite similar to the findings of Grewe *et al.*^[46] who reported similar fungal superinfections after using a four-drug regimen for a mean of 23 d.

The incidence of enteric fistulae in our study (18%) was comparable to that reported by Howard *et al.*^[47]. The incidence of developing a colonic fistula is high in patients with pericolic spread of necrosis into the left paracolic gutter, as seen in our patients, and we strongly advocate the use of prophylactic loop ileostomy in these patients. These results, along with those for pancreatic fistulae (50.8%), however, fall within the range of studies reporting post-necrosectomy gastrointestinal and pancreatic fistula rates of 1%-43% and 3%-72%, respectively^[47]. The use of minimally invasive surgery has also been associated with enteric fistulae. In their series of 5 patients who underwent minimally invasive retroperitoneal necrosectomy, Lakshmanan *et al.*^[24] reported a 40% pancreatic fistula rate, while Connor *et al.*^[23] reported a 17% pancreatic fistula rate in their 24 patients. These results support the idea that such complications could largely be dependent on the nature of the disease rather than the procedure employed to treat it (open *vs* laparoscopy).

In our study we found that as a result of delaying the procedure beyond the first 3 wk, we were able to perform only a single, but effective, exploration in the vast majority of patients. Our re-operation rate was 8.2%, unlike that reported in other studies (22%-79%) where semi-open and open techniques of debridement, as well as early surgery, was practised^[8,17,48-50].

The ideal time for intervening, as well as the number of interventions, has been shown to play a significant role on the mortality rate^[6,21], as was seen in our study. Previous studies have stressed the significance of delayed necrosectomy. However, the best time for intervention continues to be controversial, though most studies have set the ideal time to be after 2-3 wk^[6,13,15,51-56].

The value of a single-staged procedure is that it helps to avoid the risk of bleeding and fistula formation, as seen in patients undergoing open packing or re-operations^[11,50,57]. The incidence of systemic complications is greater in patients who undergo re-operations^[49].

Finally, benefit was also seen when we compared the duration of hospital stay with other studies (23 d *vs* 30-93 d)^[8,17,23,32,40,49].

Our series provides further evidence to support the role of delayed open necrosectomy for IPN. The results are comparable, if not better, than reported smaller series using minimally invasive techniques. The results indicate that a multi-pronged conservative strategy aimed at supporting the patient, with timely intervention, may actually reduce the need for further interventions, reducing not only morbidity but also mortality in these patients.

In conclusion, this series provides further support to the concept of delayed single-stage open pancreatic necrosectomy for IPN. Advances in critical care, effective antibiotic therapy with carbapenems, the availability of interventional radiology and good supportive care have played a complementary role to surgery in improving outcomes in IPN. Prophylactic ileostomy may be considered in patients with necrosis extending into the paracolic gutters.

ACKNOWLEDGMENTS

We wish to thank Professor John Windsor for healthy discussion.

COMMENTS

Background

Infected pancreatic necrosis (IPN) continues to have a high morbidity and mortality. Delayed necrosectomy has been shown to have reduced mortality. This paper illustrates a method of delayed necrosectomy performed in a single stage.

Research frontiers

The ideal technique of necrosectomy continues to be debated (open, endoscopic, laparoscopic). Reports regarding minimally invasive surgery for IPN are now being published. Thus, if we are to develop evidence-based guidelines for the management of IPN, rather than comparing outcomes with the relatively higher mortality encountered in some reports published a few decades ago, a more balanced comparison should particularly include results from larger series, and include some of the more recent series in which surgery for IPN has been complemented by advances in critical care, interventional radiology and broader spectrum antibiotics.

Innovations and breakthroughs

Previously described methods of necrosectomy have employed open packing, closed packing or post-operative lavage, which have high morbidity, cost and prolonged hospital stay. This single-stage delayed necrosectomy attempts to treat the patients in a single-stage approach, helping to reduce the hospital stay and morbidity.

Applications

This procedure helps to treat patients who have IPN with a high success rate, in addition to acceptable morbidity and low mortality. As it is carried out in delayed fashion, the necrotic debris has separated out and is well organized, leading to less intraoperative bleeding. This helps to pave the way for minimally invasive methods to further improve results.

Peer review

This is a well conducted retrospective study in agreement with the standard surgical approach to necrotic pancreatitis.

Abstract

AIM: To evaluate the factors associated with liver function alterations after laparoscopy-assisted gastrectomy (LAG) for gastric cancer.

METHODS: We collected the data of gastrectomy patients with gastric cancer and divided them into 2 groups: open gastrectomy (OG) and LAG. We also collected the data of patients with colon cancer to evaluate the effect of liver manipulations during surgery on liver function alterations. Serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin, and alkaline phosphatase were measured on the pre-operative day and postoperative day 1 (POD1), POD3, POD5, and POD7.

RESULTS: No changes in liver function were observed after the operation in patients with colon cancer ($n = 121$). However, in gastric cancer patients ($n = 215$), AST and ALT levels increased until POD5 compared to those in colon cancer patients and these findings were observed both in the LAG and OG without a sig-

nificant difference except at POD1. The mean hepatic enzyme levels at POD1 in the LAG group were significantly higher than those in the OG group ($P = 0.047$ for AST and $P = 0.039$ for ALT). The factors associated with elevated ALT on POD1 in patients with gastric cancer were body mass index ($P < 0.001$), operation time ($P < 0.001$), intraoperative hepatic injury ($P = 0.048$), and ligation of an aberrant left hepatic artery ($P = 0.052$) but not type of operation (OG vs LAG, $P = 0.094$).

CONCLUSION: We conclude that the liver function alteration after LAG may have been caused by direct liver manipulation or aberrant hepatic artery ligation rather than the CO₂ pneumoperitoneum.

Liver function alterations after laparoscopy-assisted gastrectomy for gastric cancer and its clinical significance. *World J Gastroenterol* 2011; 17(3): 372-378 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i3/372.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i3.372>

INTRODUCTION

While laparoscopic surgery has some limitations, such as a longer operating time and a more difficult surgical procedure than open surgery, it also has several advantages, such as less postoperative pain, an earlier recovery, and esthetic merits. A major difference between laparoscopic and open surgery is that CO₂ is used to create a pneumo-

peritoneum during laparoscopic surgery, which may result in respiratory and hemodynamic changes^[1]. According to many studies, a laparoscopic cholecystectomy, a standard surgical procedure for gallbladder disease, results in an alteration of postoperative liver function more frequently than open cholecystectomy, and the cause of such a liver function alteration is believed to be the pneumoperitoneum created by the CO₂^[1-5]. Based on previous studies, laparoscopy-assisted gastrectomy (LAG) is expected to result in liver function alterations resulting from the CO₂ pneumoperitoneum; this occurs because the CO₂ exposure time is much longer in LAG because of the difficulty of the surgical technique and a longer operating time compared to laparoscopic cholecystectomy.

We investigated whether liver function alterations take place in patients who undergo LAG for gastric cancer and whether other factors affect liver function besides a CO₂ pneumoperitoneum. We also investigated the effect of the liver function alterations on the clinical results. To do this, the postoperative liver functions of patients who underwent open gastrectomy (OG) and of patients who underwent LAG were compared. In addition, the postoperative liver functions of patients who underwent open colectomy (OC) and of patients who underwent laparoscopy-assisted colectomy (LAC) for colon cancer were compared.

MATERIALS AND METHODS

Patients

We collected data from 237 consecutive patients who received a radical gastrectomy for gastric cancer at Soonchunhyang University Bucheon Hospital between January 2006 and December 2007. Of these 237 patients, 22 were excluded: 6 had hepatic cirrhosis, 5 had undergone hepatic resection simultaneously with gastrectomy for benign hepatic diseases or hepatic metastasis, 10 had received endoscopic treatment for biliary tract stones before the surgery or intraoperatively had undergone biliary system surgery, and one patient had intraoperatively received a biliary system iatrogenic injury. These patients were excluded because the surgical techniques may have affected their liver function during surgery. However, patients whose liver function was normal, including those who had hepatitis or fatty liver before the operation, and patients who underwent a cholecystectomy simultaneously, were not excluded.

Patients who underwent a colectomy without direct liver manipulation during the operation were the control group for the gastrectomy patients because we thought that traction or manipulation of the liver during the operation might affect postoperative liver function. Of the 133 patients who underwent a radical colectomy for colon cancer during the same period, those included in the study were selected according to the same exclusion criteria.

The patients were divided into 4 groups based on diagnosis and surgical technique: LAG group, OG group, LAC group, and OC group.

Methods

The patients' clinicopathologic characteristics, hepatic disease history, surgical method, surgical outcome, and liver function before and after surgery were retrospectively examined using their medical records. Serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin (Bil), and alkaline phosphatase (ALP) were measured preoperatively and examined at postoperative day 1 (POD1), POD3, POD5, and POD7. The normal reference levels were AST 5-40 IU/L, ALT 0-40 IU/L, Bil 0.2-1.2 mg/dL, and ALP 35-115 IU/L. Patients who had hepatic enzyme levels higher than the normal reference level were defined as the "elevated" group, and patients with a normal reference level were defined as the 'normal' group.

Surgical methods

The operations were performed in the supine position for OG patients, in the reverse-Trendelenburg position for LAG patients, and in the Trendelenburg position for OC and LAC patients. For LAG and LAC, CO₂ was insufflated *via* a trocar to insert the laparoscope, and the pneumoperitoneal pressure was maintained at 12 mmHg or less. In patients undergoing LAG and OG, the range of the gastric resection or lymph node dissection depended on the tumor location or preoperative TNM stage; for gastric cancer invading the submucosal layer or deeper, a D2 lymph node dissection was performed according to the Japanese Gastric Cancer Guidelines. In the LAG and OG groups, to provide an operative field in the upper pancreatic border, the left lobe of the liver was lifted when the lesser curvature of the stomach was dissected. For the LAC and OC groups, the extent of colon resection was also determined based on tumor location and lesion stage before the surgery, and no difference was observed between the 2 groups.

Statistical analysis

All values are expressed as the mean \pm SD. The χ^2 -test, the independent *t*-test, and the paired *t*-test were conducted using SPSS software (version 15.0 for Windows; SPSS Inc., Chicago, IL, USA). *P* values < 0.05 were considered statistically significant.

RESULTS

Patient clinicopathologic characteristics

Two hundred and fifteen patients with gastric cancer participated in our study (124 patients in the OG group, 91 patients in the LAG group). The mean age of the patients was 58.6 years, with 164 males and 51 females. Of the patients with gastric cancer, 31 (14.4%) had underlying liver diseases: fatty liver in 15 and viral hepatitis in 16. A combined operation was performed in 46 cases (21.4%), most frequently a splenectomy, followed by a cholecystectomy, adrenalectomy, or distal pancreatectomy. Stage I was the most common TNM stage in both the OG and LAG groups (137 patients, 63.7%), but significantly more stage I patients were in the LAG group (92.3%) than in

the OG group ($P < 0.001$). A combined operation was performed more frequently in the OG group than in the LAG group ($P = 0.004$), and the operating time was significantly longer in the LAG group (203 min) than in the OG group (165 min, $P < 0.001$). No significant differences between the 2 groups were observed for age, presence or absence of underlying liver disease, type of anesthetic agent used, or postoperative complications.

Among the patients with colon cancer, 121 were included in the study. Their mean age was 60.9 years, and they consisted of 65 males and 56 females. No differences in gender, age, presence or absence of an underlying liver disease, combined operation rate, anesthetic agent, or postoperative complications were observed between the LAC (43 patients) and the OC groups (78 patients), whereas significant differences were found between the 2 groups for operating time and hospital stay after the operation, operating time being significantly longer in the LAC group and length of stay significantly longer in the OC group (Table 1).

Morbidity and mortality after the operation

Postoperative complications occurred in 24 (11.2%) patients who underwent a gastrectomy: wound infection in 7, anastomotic leakage in 5, postoperative bleeding in 5, intra-abdominal fluid collection in 5, and other complications in 2. Six cases of complications (5%) occurred in patients who underwent a colectomy: postoperative ileus in 3, anastomotic leak in one, and wound infection in one.

Two patients who underwent a gastrectomy (one each in the OG and LAG groups) and one patient who under-

went a colectomy (LAC group) died after the operation. Thus, the postoperative mortality rate was 0.9% and 0.8% in patients who underwent a gastrectomy and colectomy, respectively. The causes of death were postoperative pneumonia (2 patients in the gastrectomy group) and sepsis (one patient in the colectomy group); no patient died of postoperative hepatic failure.

Postoperative changes in liver function

The postoperative AST and ALT levels were significantly higher than the preoperative levels in both the OG and LAG groups until POD5 (Table 2).

The mean hepatic enzyme levels at POD1 in the LAG group were significantly higher than those in the OG group ($P = 0.047$ for AST and $P = 0.039$ for ALT). No changes in preoperative or postoperative Bil and ALP levels were observed in either group.

No significant changes in the pre- and postoperative AST, ALT, Bil, and ALP levels were observed among patients who underwent a colectomy, and the changes were not significantly different between the LAC and OC groups (Table 2).

Approximately 65% of the patients in the LAG group and 59.7% in the OG group showed increased levels of AST at POD1, and 25.3% in the LAG group and 27.4% in the OG group showed increased levels of AST at POD3 ($P > 0.05$). Similar to the results with AST, 69.2% of the patients in the LAG group and 58.1% in the OG group showed increased levels of ALT at POD1, and 39.6% in the LAG group and 33.9% in the OG group

showed increased levels at POD3 (*P* > 0.05, Figure 1).

Among the patients who underwent a gastrectomy, 13 showed more than a 5-fold increase in ALT levels from the normal level at POD1 (8 patients in the LAG group and 5 patients in the OG group). Of these 13 patients, 3 showed more than a 10-fold increase (2 patients in the LAG group and one patient in the OG group).

Factors that affected postoperative liver function after gastrectomy

Unlike LAG, no change in liver function was observed after LAC when using a CO₂ pneumoperitoneum. There-

fore, the characteristics of the patients who showed liver function alterations after LAG were examined to identify other factors that could cause changes in postoperative liver function. For this purpose, we investigated the ALT level at POD1, at which the change in postoperative liver function for those who underwent a gastrectomy was most prominent. The patients who underwent a gastrectomy were classified into 2 groups: a normal group that had a normal ALT range and an elevated group having higher ALT levels than the reference. We also examined their clinical features and surgical findings.

who underwent a gastrectomy were not significantly affected by gender, age, underlying liver disease, presence or absence of postoperative complications, type of anesthetic agent, or intraoperative transfusion. The body mass index (BMI) was significantly higher in the elevated group than in the normal group, and the operating time in the elevated group was significantly longer than in the normal group. Furthermore, 7.4% of the patients who experienced intraoperative hepatic injury showed increased ALT levels, which was a significantly higher proportion than in the patients who did not experience intraoperative hepatic injury ($P = 0.048$). Of the patients with normal ALT levels, 1.3% of patients had ligation of an aberrant left hepatic artery during the operation, whereas in the elevated group, 5.9% of patients had ligation of this artery, although this result had no statistical significance ($P = 0.052$). Thirty-five percent of the patients in the normal group underwent LAG, whereas 46.7% of the patients in the elevated group underwent LAG, but no significant difference was found ($P = 0.094$) (Table 3).

DISCUSSION

Pneumoperitoneum, which is created by CO₂ insufflation during a laparoscopic operation, results in postoperative transient liver function abnormalities. Halevy *et al.*^[6] first

reported that aminotransferase levels increased significantly after laparoscopic cholecystectomy. They suggested that the increase in aminotransferase was due to increased intra-abdominal pressure, pressure against the liver with the lifting of the gall bladder, damage to the liver parenchyma by electrocautery, deformity of the extrahepatic biliary duct, the possibility of introducing a small stone into the biliary duct, or damage to the left hepatic artery during surgery. Other studies have reported that a laparoscopic cholecystectomy was more likely to result in liver function abnormalities than an open cholecystectomy and suggested that the cause of the abnormalities was reduced blood flow into the hepatic portal vein as a result of the increased intra-abdominal pressure caused by the pneumoperitoneum; the degree of pneumoperitoneal pressure is related to the degree of liver function abnormality^[2,7].

Animal studies have also shown that a pneumoperitoneum directly damages rat liver tissue, that the degree of damage is related to pneumoperitoneal pressure, and that the persistence of the pressure at 15 mmHg or more for 60 min or longer may result in irreversible hepatic damage^[8]. Contrary to these reports, a study on 1034 patients who underwent laparoscopic cholecystectomy reported that only 3.9% of the patients had a mild elevation in hepatic enzyme levels after the operation, and that the number of liver function abnormality cases after laparoscopic cholecystectomy was much lower than in other studies^[9].

Very few studies have reported liver function abnormalities after LAG for gastric cancer. Etoh *et al.*^[10] and Kim *et al.*^[11] reported that liver function abnormalities occurred in patients who underwent LAG but not in those who had OG. They asserted that liver function abnormalities may occur after LAG due to the CO₂ pneumoperitoneum, although objective evidence for their assertion was unavailable.

Because LAG is more difficult to perform than OG, the operating time can be longer, and consequently, the exposure time of the intra-abdominal organs to the pneumoperitoneum may also be longer than in OG. Given this, a pneumoperitoneum was expected to cause liver function abnormalities. Thus, this study sought to determine whether postoperative liver function abnormalities would occur in patients who underwent LAG.

The change in the absolute hepatic enzyme levels was more marked in the LAG group than in the OG group. Moreover, consistent with the results of previous studies, this change was most prominent on POD1, but the level returned to normal on POD5. When the patients were divided into an elevated enzyme group and a normal group, the frequency of change in the absolute hepatic enzyme levels in the elevated group did not differ between the LAG and OG groups (Figure 1). Furthermore, when the patients who underwent a colectomy, in which the hepatic parenchyma and the vessels around the liver were not excessively manipulated, were divided into LAC and OC groups, no liver function abnormalities were found in either group. Thus, we presumed that the major cause of liver function abnormalities after LAG may not be the pneumoperitoneum. Similar to this result, Nguyen *et al.*^[12]

also reported no difference in the increase in hepatic enzyme levels between patients who underwent laparoscopic and open gastric bypass. They performed laparoscopic and open Roux-en-Y gastric bypass on obese patients and found that the hepatic enzyme level increase was highest in the first 24 h after the operation, and that liver function returned to normal 72 h after the operation. They also reported no significant difference in the hepatic enzyme level increase between those who underwent a laparoscopic vs an open operation, and they asserted that a prolonged pneumoperitoneum in patients who underwent the laparoscopic operation would not have greatly affected the change in the postoperative hepatic enzyme levels. The statistical significance of the effect of prolonged operating time on the increase in hepatic enzyme level after gastrectomy in the present study can be attributed to the long exposure time to the pneumoperitoneum. However, it can also be attributed to the long ischemic time of the liver due to extended liver traction.

Thus, we divided our patients into a group with normal liver function and a group with elevated liver function, based on the ALT level at POD1, at which the liver function abnormality was most prominent, to determine whether liver function after LAG is influenced by factors other than a pneumoperitoneum. The change in liver function was based on the ALT level because ALT exists mostly in the liver, unlike AST, and is the gold-standard clinical chemistry marker for liver injury^[13,14]. The classification of the elevated group was based on the normal ALT reference range of 0-40 IU/L, which is used at the authors' hospital. As a result, the surgical technique (OG and LAG) did not affect the increase in the ALT levels after the operation, but the BMI in the elevated group was significantly higher than in the normal group. Also, the operating time was significantly longer in the elevated group than in the normal group. When the hepatic parenchyma was damaged or when the aberrant left hepatic artery was ligated, the ALT level increased.

Many studies on liver function abnormalities after a laparoscopic operation have reported that the cause of postoperative liver function abnormality was hepatic ischemia caused by reduced portal flow due to the pneumoperitoneum^[8]. However, we did not find any liver function abnormalities after LAC, whereas liver function abnormalities after an open gastrectomy were found when the hepatic parenchyma was directly damaged or when the aberrant hepatic artery was ligated. Given these conditions, the causes of liver function abnormalities after LAG can be attributed to excessive liver traction, direct damage to the hepatic parenchyma, ligation of an aberrant hepatic artery during the operation, or reduced portal flow due to the pneumoperitoneum.

Patients who underwent a gastrectomy showed significantly increased hepatic enzyme levels on POD1, regardless of the surgical technique, which returned to normal on POD5. This transient liver function abnormality was not clinically meaningful because it did not cause hepatic failure or clinical symptoms. However, as patients with hepatic cirrhosis or decreased liver function were not included in this study, further research is required to de-

termine whether LAG is safe for patients with decreased liver function. The assumption was made that LAG could be performed safely in patients with decreased liver function by taking the greatest possible care with ligation of the aberrant hepatic artery and not damaging the hepatic parenchyma, or if the major cause of the liver function abnormality after LAG was damage to the hepatic parenchyma due to excessive liver traction.

COMMENTS

Background

A major difference between laparoscopic and open surgery is that carbon dioxide (CO₂) is used to create a pneumoperitoneum during laparoscopic surgery, which may result in respiratory and hemodynamic changes. According to many studies, a laparoscopic cholecystectomy, a standard surgical procedure for gallbladder disease, results in an alteration of postoperative liver function more frequently than open cholecystectomy, and the cause of such liver function alteration is believed to be the pneumoperitoneum created by CO₂. Based on previous studies, laparoscopy-assisted gastrectomy (LAG) is expected to result in liver function alterations due to the CO₂ pneumoperitoneum. The paper investigated whether liver function alterations take place in patients who undergo LAG for gastric cancer and whether other factors affect liver function besides a CO₂ pneumoperitoneum.

Innovations and breakthroughs

In the study, patients who underwent a colectomy without direct liver manipulation during the operation were the control group for the gastrectomy patients because the authors thought that traction or manipulation of the liver during the operation might affect postoperative liver function. The change in the absolute hepatic enzyme levels was more remarkable in the LAG group than in the open gastrectomy (OG) group. Moreover, consistent with the results of previous studies, this change was most prominent on postoperative day 1 (POD1), but the level returned to normal on POD5. When the patients were divided into an elevated group and a normal group, the frequency of change in the absolute hepatic enzyme levels in the elevated group did not differ between the LAG and OG groups. Furthermore, when the patients who underwent a colectomy, in which the hepatic parenchyma and the vessels around the liver were not excessively manipulated, were divided into laparoscopy-assisted colectomy (LAC) and open colectomy groups, no liver function abnormalities were found in either group. Thus, authors presumed that the major cause of liver function abnormalities after LAG may not be the pneumoperitoneum.

Applications

Many studies on liver function abnormalities after a laparoscopic operation have reported that the cause of postoperative liver function abnormality was hepatic ischemia caused by reduced portal flow due to the pneumoperitoneum. However, authors did not find any liver function abnormalities after LAC, whereas liver function abnormalities after an open gastrectomy were found when the hepatic parenchyma was directly damaged or when the aberrant hepatic artery was ligated. Given these conditions, the causes of liver function abnormalities after LAG can be attributed to excessive liver traction, direct damage to the hepatic parenchyma, ligation of an aberrant hepatic artery during the operation, or reduced portal flow due to the pneumoperitoneum. The assumption was made that LAG could be performed safely on patients with decreased liver function by taking the greatest possible care with the aberrant hepatic artery ligation and not damaging the hepatic parenchyma, or doing so if the major cause of the liver function abnormality after LAG was damage to the hepatic parenchyma due to excessive liver traction.

Peer review

This is a well designed and researched paper. The positive findings show more marked changes in liver function after a laparoscopy-assisted gastrectomy for gastric cancer than after an open gastrectomy, lasting for up to 5 d, these differences are related to body mass index (BMI) and longer operation time. The authors could have suggested that these could be explained by the heavier retraction of the liver which would be required in patients with a greater BMI and the greater duration of the retraction in the laparoscopy group.

Abstract

AIM: To study the computed tomography (CT) signs in facilitating early diagnosis of necrotic stercoral colitis (NSC).

METHODS: Ten patients with surgically and pathologically confirmed NSC were recruited from the Clinico-Pathologic-Radiologic conference at Chang Gung Memorial Hospital, Taoyuan, Taiwan. Their CT images and medical records were reviewed retrospectively to correlate CT findings with clinical presentation.

RESULTS: All these ten elderly patients with a mean age of 77.1 years presented with acute abdomen at our Emergency Room. Nine of them were with systemic med-

ical disease and 8 with chronic constipation. Seven were with leukocytosis, two with low-grade fever, two with peritoneal sign, and three with hypotensive shock. Only one patient was with radiographic detected abnormal gas. Except the crux of fecal impaction, the frequency of the CT signs of NSC were, proximal colon dilatation (20%), colon wall thickening (60%), dense mucosa (62.5%), mucosal sloughing (10%), perfusion defect (70%), pericolic stranding (80%), abnormal gas (50%) with pneumo-mesocolon (40%) in them, pericolic abscess (20%). The most sensitive signs in decreasing order were pericolic stranding, perfusion defect, dense mucosal, detecting about 80%, 70%, and 62.5% of the cases, respectively.

CONCLUSION: Awareness of NSC and familiarity with the CT diagnostic signs enable the differential diagnosis between NSC and benign stool impaction.

INTRODUCTION

Necrotic stercoral colitis is a necrotic process that occurs

in stercoral colitis (SC), caused by fecal impaction that results in pressure ulceration and regional necrosis. Perforation is rare, but has a mortality rate of 32%-57%^[1]. Early diagnosis with aggressive bowel cleansing and disimpaction may decrease the pressure and lessen the likelihood of ulceration of the colon^[2]. Fecal impaction frequently occurs in elderly patients, and those who are bed-ridden for a prolonged period of time.

Most patients present to the emergency room (ER) with an acute abdomen. Their physical examinations and laboratory data are often unreliable. Moreover, the peritoneal signs are often nonspecific and might be attributed to diverticulitis, which is more common in elderly patients^[3]. Computed tomography (CT) is readily available and is not operator-dependent; therefore, abdominal CT is often requested by emergency physicians to evaluate patients with acute abdominal conditions.

Very little has been published on NSC in the radiology literature^[3]. We reviewed the CT findings of 10 patients with NSC from our hospital, to call attention to this potentially fatal condition.

MATERIALS AND METHODS

Ethics

This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. This study was approved ethically by Chang Gung Memorial Hospital (98-0044B).

Patients

Between November 2002 and August 2009, ten patients with surgically and pathologically confirmed NSC were recruited from the Clinico-Pathologic-Radiologic conference at Chang Gung Memorial Hospital, Taoyuan, Taiwan. We reviewed their abdominal radiographs, CT images, and medical records retrospectively.

CT protocol

All of these patients underwent CT examinations of the abdomen and pelvis before surgical exploration, while they stayed in the ER. CT examinations were performed by four-detector CT (LightSpeed QX/i Scanner, General Electric Medical Systems, Milwaukee, WI, USA). Helical CT images were acquired using either 7- or 5-mm slice collimation, reconstruction interval of 5 mm, pitch of 1.5-2, 120 kV, and 200-240 mA. One hundred milliliters of intravenous (IV) contrast agent was used routinely.

CT interpretation

Several CT findings of fecal impaction in the colon, thickening of the colon wall, and pericolic stranding indicated SC, whereas the presence of extraluminal gas bubbles or an abscess suggested that perforation had occurred^[2].

The CT examinations were retrospectively reviewed by two independent board-certified abdominal radiologists who were blinded to the CT official reports and the surgical and pathologic findings. They viewed the CT images

on a picture archiving and communication system (PACS) independently and discussed the findings until consensus was reached. If consensus could not be reached, a third abdominal radiologist was consulted. All abdominal radiographs were reviewed for abnormal gas. They were also requested to determine the presence or absence of the CT features of NSC, including location of fecal impaction, proximal colon dilatation, colon wall thickening, dense mucosa, mucosal sloughing, perfusion defect, pericolic stranding, pericolic abscess, and abnormal gas with or without pneumo-mesocolon. Vascular ischemic colitis was excluded based on patency of the inferior mesenteric artery and vein.

Definition of CT signs

The individual CT signs were defined as follows - Fecal impaction: distended colon with much feces or packing of dehydrated fecaloma in the colon; Proximal colon dilatation: a distended left-sided colon with a cylindrical shape and cross-sectional diameter > 6 cm; Colon wall thickening: regional wall thickness > 3 mm in the obstruction site; Dense mucosa: increased mucosal lining density on pre-contrast CT; Mucosal sloughing: mucosa dislodged into the lumen; Perfusion defect: discontinuity of the enhancement of colon mucosa or apparently decreased enhancement as compared with adjacent small bowel loops; Pericolic stranding: increased streaks of pericolic fat; Pericolic abscess: pericolic loculated fluid or mottled substance; Abnormal gas: gas migrating into or beyond the colon wall as pneumoperitoneum or pneumoretroperitoneum, i.e. pneumo-intestinalis coli; gas entrapped in the mural wall; pneumo-mesocolon: gas confined inside the mesocolon; and portal vein gas: air leakage into the portomesenteric vessels.

RESULTS

Demography and clinical information

Six men and four women aged 39-88 years (mean, 77.1 years) were studied (Table 1). All of the patients presented to our ER with acute abdomen. Chronic constipation and systemic medical disease were the common clinical problems in these patients. Abdominal discomfort was not greatly improved after local removal of impacted feces by digital evacuation or fleet enema. On arrival at the ER, two patients (20%) presented with a low grade fever (< 38.5°C), two (20%) presented with peritoneal signs, and seven (70%) presented with leukocytosis with one other at borderline criteria of leukocytosis. Three patients (30%) arrived at the ER with hypotensive shock (systemic blood pressure < 90 mmHg). Surgical intervention was indicated for all of the patients. Seven of the patients died; thus, the mortality rate was 70%. Among these seven patients, three died within 1 wk, highlighting the rapidly progressive course of the disease.

CT signs

The imaging findings of NSC are listed in Table 2. CT

examination revealed fecal impaction at the sigmoid colon in nine patients (90%) and at the distal descending colon in one (10%). Proximal colon dilatation was found in two patients (20%). Colon wall thickening (Figure 1) occurred in six patients (60%), dense mucosa (Figure 2A) in five (62.5%), mucosal sloughing (Figure 3A) in one (10%), and

colon mucosal perfusion defect (Figure 2B) was found in seven (70%) patients. Pericolic stranding (Figure 2C) was identified in eight patients (80%), and pericolic abscess formation (Figure 3B) was observed in two (20%) patients. Abnormal gas was present in five patients (50%): pneumo-mesocolon in two (40%, Figure 4), and one pa-

Figure 1 A 70-year-old woman (patient 6) with necrotic stercoral colitis. The computed tomography scan revealed stool impaction and distension of the rectosigmoid colon with asymmetrical wall thickening at the posterior aspect (arrow).

Figure 2 An 80-year-old woman (patient 5) with perforation of the necrotic stercoral colitis at the sigmoid colon. A: An unenhanced computed tomography (CT) scan reveals dense mucosa (arrow) conforming to the colon wall; B: An enhanced abdominal CT scan reveals discontinuation of the colonic mucosa (arrow) suggesting perfusion defect; C: A small air bubble abutting the damaged colon (arrow) and increased pericolic infiltration (arrowhead) can be seen.

Figure 3 An 88-year-old woman (patient 7) with perforation of the necrotic stercoral colitis at the sigmoid colon. A: An enhanced abdominal computed tomography scan reveals mucosal flap (arrow) slough into the lumen of the colon indicating mucosal sloughing; B: Air pockets (arrow) abutting the colonic wall and pericolic loculated fluid indicative of abscess formation (arrowhead).

Figure 4 An 87-year-old man (patient 4) with perforated stercoral colitis at the proximal end of co-existing rectosigmoid colon cancer. An enhanced abdominal computed tomography scan at lung-window setting reveals air confined inside the mesocolon indicating pneumo-mesocolon (arrow).

tient (20%) with pneumoperitoneum was identified by radiograph.

Dense mucosa was evaluated with pre-contrast CT scanning in 8 of the patients who had undergone scanning of the lower abdomen. Dense mucosal lining conforming to the colon wall was differentiated from the fecalith which presented as clustered masses in the lumen with a calcified surface and gas in between.

Inter-observer agreement is shown in Table 2. Agreement was good to excellent for all signs except wall thick-

ening and perfusion defect. Disagreement occurred with respect to wall thickening in three patients, perfusion defect in four, dense mucosa in one, mucosal sloughing in one, pericolic stranding in one, and abnormal gas in one patient. Consensus was generally achieved following an open discussion and the opinion of a third radiologist when necessary.

DISCUSSION

Stercoral ulcer with perforation was first described by Berry in 1894, and to date, fewer than 150 cases have been reported^[4]. The incidence of perforated stercoral ulcer at autopsy ranges from 0.04% to 2.3%. Pre-mortem diagnosis is even less frequent, which suggests that the incidence of this condition is often underestimated^[3]. One study reported that stercoral perforation of the colon was found in 0.5% of all surgical colorectal procedures, 1.2% of all emergency colorectal procedures, and 3.2% of all colonic perforations^[5].

Fecal impaction and perforation occur most often in the sigmoid colon. The sigmoid colon is the narrowest region of the entire colon, and passage of stools with a more solid consistency can be difficult. In such cases, fecaloma exerts localized pressure on the walls of the sigmoid colon, the area with the most precarious vascular supply^[6], especially the vascular region known as Sudeck's point. Prolonged localized pressure and ischemia can give rise to pressure ulceration^[7,8].

Distention predisposes the colon to insufficient perfusion, leading to slight, moderate, or severe ischemic lesions^[9]. Ischemic colitis will occur when intraluminal pressure exceeds 35 cm H₂O for hours^[10]. Maurer *et al*^[5] have postulated that colonic dilatation and the presence of multiple fecalomas indicate additional stercoral ulceration and carry the risk of secondary perforation. This view was supported by Huang *et al*^[11] by visualization of stercoral ulceration during intraoperative colonoscopy.

Chronic constipation ($n = 8$) and systemic disease (90%, $n = 9$) were the common clinical problems of the patients in this study, some of them (50%, $n = 5$) presented with multiple necrotic foci involving long segmental bowel that spanned the territory of the superior and inferior mesenteric arteries. It is probable that long-term systemic disease weakens the colon, while stool impaction causes bowel dilatation and increases wall tension, which worsens perfusion insufficiency and leads eventually to necrosis and potentially to fatal perforation. Unfortunately, the early clinical signs such as fever (20%, $n = 2$), peritoneal signs (20%, $n = 2$), and leukocytosis (70%, $n = 7$) are insufficient to diagnose this severe condition in order to prompt appropriate intervention in these patients.

Obstructive colitis differs from colonic cancer with marginal ulceration at aspects of normal mucosa distal to cancer and, frequently, centimeters immediately proximal to the carcinoma are free of ulceration and inflammation^[12]. As an example of this, NSC was diagnosed in our case number 4.

Fecal impaction was present in all our patients and was

located mostly at the sigmoid colon (90%, $n = 9$), which was highly correlated with surgical findings and a result which agrees with other studies. Proximal dilatation was observed in two patients (20%), and was less frequent than we expected. It is possible that the colon could have ruptured prior to the CT scan, thus relieving the luminal pressure. This could also be due to the possible fulminant course which did not allow time for the colon to dilate. None of these two patients with proximal colon dilatation showed abnormal gas that would have indicated whether the colon had ruptured. Probably owing to absence of proximal colon dilatation in NSC, clinicians underestimate the stool impaction.

Colon wall thickening (60%, $n = 6$) is an indicator of stercoral colitis caused by edema or acute inflammation. Dense mucosa as a result of mucosal hemorrhage has been reported to be a sign of ischemic bowel^[13,14]. This was one of the most frequently observed signs of NSC and occurred in 62.5% (5 of 8) of our cases. Mucosal sloughing (10%, $n = 1$) and perfusion defect (70%, $n = 7$) indicated status of ischemia progressing to infarct of the colon. The radiologists' disagreement over wall thickening and perfusion defect may have been the result of subtle and localized changes. These findings indicate that the CT signs of NSC are not obvious, and that radiologists must be aware of the signs to make an early diagnosis. Pericolic fat stranding was the most frequent CT sign of NSC observed in our patients (8 of 10, 80%). Intraoperative findings indicated that pericolic fat stranding was the result of pericolic inflammation and edema. The pericolic reaction was most likely the cause of the intolerable abdominal pain experienced by these patients.

NSC with abnormal gas (50%, $n = 5$) often appears on CT scans as small gas bubbles in the proximity of the colon wall: pneumo-intestinalis coli or pneumo-mesocolon. This is usually undetected by radiography and differs from gastroduodenal perforation that usually presents massive pneumoperitoneum. Intraoperative findings indicate that the perforation can be temporarily plugged by a fecaloma. In our sample, a standing radiograph was not often obtained, partly because pneumoperitoneum was not suspected clinically, and the elderly patients were usually in a weakened state that impeded their assuming a standing posture. Pneumo-mesocolon was not always evident on the radiograph because it was obscured by the presence of a lot of fecal material in the abdomen. This explains why only one (20%) of five cases with abnormal gas was detected by radiography. Thus, abdominal CT, with meticulous searching for signs of abnormal gas, is required. Pericolic abscess formation was seen in two (20%) of our patients. When the NSC is perforated, the viscous nature of the fecal material causes it to further impede the peritoneum with soiling.

NSC differs from other colitis by absence of diarrhea clinically. It can be confirmed by intraoperative and histological findings^[5]. At surgery, stercoral ulcers and perforations are usually found on the anti-mesenteric side; ulcerations usually have sharp margins and measure 1-10 cm, and are occasionally multiple. Histological findings include

sharp demarcation without undermining at ulcer margins, and transmural necrosis at the perforated site. Treatment is usually resection of the affected bowel, colostomy, and Hartmann's procedure^[1,5].

Typically, only the more severe cases in this sample would have been discussed at the conference, and this resulted in a high mortality rate among our patients (70%; 7/10, which is higher than previously reported^[1]).

In the elderly and in nursing home patients, ascites associated with liver cirrhosis or malnutrition is often encountered. This could obscure the significance or specificity of pericolic fluid accumulation for colonic pathology. Thus, we did not investigate this factor for NSC.

This retrospective study consisted of a small population of patients with NSC; thus, the statistical significance and likelihood ratios of each CT sign for NSC could not be determined appropriately. Owing to the nature of the retrospective study, some important clinical data and imaging were unavailable. This study aimed to alert clinicians to the CT findings of NSC, a potentially fatal condition. A further study with a larger number of patients is needed to validate the accuracy of our CT findings.

In summary, elderly patients with a history of chronic constipation and systemic disease, presenting with fecal impaction and acute abdomen with indeterminate leukocytosis, are at risk of NSC. CT is justified to be suggested to investigate the possibility of NSC. Pericolic stranding, perfusion defect and dense mucosa were the most sensitive CT measures for NSC, detecting about 80%, 70%, and 62.5% of the cases, respectively. Awareness of NSC and familiarity with these CT signs enables us to make a differential diagnosis between this fatal condition and benign stool impaction.

COMMENTS

Background

In clinical practice, fecaloma-related necrotic stercoral colitis (NSC) is an infrequently and easily overlooked disease. It frequently occurs in patients who are elderly or have inactive status. High mortality is encountered when perforation takes place.

Research frontiers

In fact, most fecal impaction is usually relieved by non-invasive management, meaning that surgical and pathologic evidence for NSC has been unobtainable. In this era of liberal computed tomography (CT) use for patients with acute abdomen in emergency departments, few articles about CT of stercoral colitis have been published.

Innovations and breakthroughs

Over the last few years, the authors have collected ten patients with clinical,

surgical, pathologic and radiographic evidence of NSC. In practice, clinical clues alone are insufficient to exclude the disease. Characteristic CT presentations are useful to delineate this colon pathology, especially dense mucosa, pericolic stranding, perfusion defect, and mucosal sloughing of colon.

Peer review

The paper is an interesting one, but it needs major language refinement and some additional information to be provided. I then would suggest acceptance for publication, provided satisfactory revision requirements are met.

cases of double-duct-type SOD, which consisted of 7 (36.8%) patients who were cured endoscopically and 12 (63.2%) who were cured surgically. A total of 41 cases were diagnosed as biliary-pancreatic-reflux-type SOD. Twenty (48.8%) of them were treated endoscopically, 16 (39.0%) were treated by open abdominal surgery, and 5 (12.2%) were under observation.

CONCLUSION: The newly proposed SOD classification system introduced in this study better explains the clinical symptoms of SOD from the anatomical perspective and can guide clinical treatment of this disease.

Abstract

AIM: To propose a new classification system for sphincter of Oddi dysfunction (SOD) based on clinical data of patients.

METHODS: The clinical data of 305 SOD patients documented over the past decade at our center were analyzed retrospectively, and typical cases were reported.

RESULTS: The new classification with two more types (double-duct, biliary-pancreatic reflux) were set up on the basis of the Milwaukee criteria. There were 229 cases of biliary-type SOD, including 192 (83.8%) cases cured endoscopically, and 29 (12.7%) cured by open abdominal surgery, and the remaining 8 (3.5%) cases observed with unstable outcomes. Eight (50%) patients with pancreatic-type SOD were cured by endoscopic treatment, and the remaining 8 patients were cured after open abdominal surgery. There were 19

Management of patients with sphincter of Oddi dysfunction based on a new classification. *World J Gastroenterol* 2011; 17(3): 385-390 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i3/385.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i3.385>

INTRODUCTION

Sphincter of Oddi dysfunction (SOD) is characterized by a series of clinical pain symptoms caused by abnormalities in sphincter contractility^[1]. The sphincter of Oddi (SO), a fibromuscular sheath encircling the distal common bile duct (CBD), pancreatic duct and common channel, controls the flow of bile and pancreatic secretions into the duodenum and prevents reflux of duodenal contents into the pancreaticobiliary system^[2]. SO dyskinesia caused by injury or/and inflammation can result in a hypo- or

hypertonic sphincter with altered motility, causing an intermittent functional blockage of the sphincter. As it is often difficult to distinguish SO stenosis from dyskinesia, the term “sphincter of Oddi dysfunction” is used to cover both conditions^[3]. For SOD, the Milwaukee classification proposed by Hogan and Geenen has been widely accepted; it classifies SOD into two types: the biliary type and the pancreatic type^[4,6]. Biliary and pancreatic SOD are each sub-classified as type I, II and III on the basis of symptoms, laboratory tests and radiological imaging^[4,5]. This classification explains the clinical manifestations of SOD from the anatomical perspective and reveals the nature of SOD, thus providing a reliable anatomical basis for appropriate clinical treatment. In our long-term clinical practice, however, we have found this classification system somewhat flawed. For instance, the clinical manifestations in some patients with SOD are difficult to be satisfactorily defined using the Milwaukee criteria. Therefore, the existing system is insufficient in guiding the clinical treatment of all SOD patients. In this paper, we introduced a new classification of SOD based on the Milwaukee classification. In the new classification system, SOD is divided into four types according to anatomy, symptoms, endoscopic tests and radiological imaging. These types include not only those already established by the Milwaukee criteria (biliary and pancreatic types), but also two more new types (the double-duct and biliary-pancreatic reflux types) in an attempt to improve the clinical treatment of SOD.

MATERIALS AND METHODS

Patient data

A total of 1013 patients underwent endoscopic retrograde cholangiopancreatography (ERCP) from January 1999 to January 2009, and 305 (30%) patients who met the diagnostic criteria of SOD were included in this study. In the 305 SOD patients, there were 198 men and 107 women, aged from 36-79 years (mean age, 47.5 years) (Table 1). All the patients had to meet the following diagnostic criteria for SOD: (1) typical clinical symptoms, with or without abnormal liver function and amylase levels^[4,5]; and (2) baseline sphincter of Oddi manometry (SOM) pressure > 40 mmHg^[7], and/or paradoxical pressure response to cholecystokinin^[8], and/or delayed emptying of contrast medium in the common bile duct as indicated by ERCP^[9], and/or a diameter of common bile duct ≥ 10 mm without evidence of stones or tumors^[6]. Preliminary classification was performed based on the development of the disease, examinations and treatment, e.g. ERCP, magnetic resonance cholangiopancreatography (MRCP), endoscopic sphincterotomy (EST) and endoscopic pancreatic duct sphincterotomy (EPS). Some patients were ultimately classified according to the findings of surgical exploration. Intraoperative choledochography, choledochoscopy and pancreatoscopy were performed if necessary.

It may still take a long time to establish the diagnosis for double-duct type and biliary-pancreatic reflux type SOD. For SOD of the double-duct type, both the biliary and pancreatic ducts of the sphincter of Oddi are affected. So, the

≥ 10 mm	289 (94.75)
< 10 mm	16 (5.25)
Pancreatic duct dilation	76 (24.92)

biliary pain and pancreatic pain may occur simultaneously or alternately. For SOD of the biliary-pancreatic reflux type, the patients may have a congenital abnormality in the convergence of the biliary and pancreatic systems. When the ampullary anti-reflux valve is dysfunctional, small amounts of bile may repeatedly reflux into the pancreatic duct, which often induces pancreatitis. That is why sometimes an over long common duct of the biliary and pancreatic duct is found in auxiliary examination and operation.

Therapeutic methods

The therapeutic methods and results in patients with different types of SOD are shown in Table 2.

Typical cases

Case 1: A 43-year-old man first suffered from pancreatitis in November 2004. Three months later, his pancreatitis recurred, and B-mode ultrasonography suggested cholecystolithiasis. The patient suffered from recurrent pains in the upper abdomen six months after cholecystectomy performed in March 2005 due to clinically diagnosed biliary pancreatitis. Computed tomography (CT) suggested swelling of the pancreatic head and pancreatic duct distension, accompanied by stones. Moreover, the common bile duct had a diameter of 8 mm. With the duodenum preserved, the patient underwent resection of the swollen head of the pancreas, which was assumed to be compressing the bile duct, resulting in bile duct distension before the surgery. However, three months after surgery, the patient began to experience biliary colic with a frequency of 2-3 times per month. Laboratory tests showed normal blood amylase levels and aggravated liver dysfunction with alkaline phosphatase increasing from 579 to 1858 IU/L and glutamyl transpeptidase from 658 to 2006 IU/L, accompanied by enlargement of the diameter of the common bile duct

Table 2 Detailed classification, treatment and outcomes associated with sphincter of Oddi dysfunction

SOD: Sphincter of Oddi dysfunction; EST: Endoscopic sphincterotomy; EPS: Endoscopic pancreatic duct sphincterotomy; BPD: Biliopancreatic diversion.

from 8 to 14 mm. Endoscopic bile duct sphincterotomy was performed twice in three months but without satisfactory curative effect. Consequently, an open abdominal surgery was performed at our center for frequent biliary colic. The common bile duct was transected, and then a cholangiojejunostomy was performed. During the two-year follow-up, liver function returned to normal levels and no further abdominal pain was reported by the patient.

Case 2: A 41-year-old man was diagnosed as having acute pancreatitis in June 2001 due to pains in the upper abdomen and an increase in blood amylase levels. The patient was discharged one week later. In October 2001, the patient experienced abdominal pain again and was diagnosed as having pancreatitis from a swollen pancreas head according to CT examination. In addition, B-mode ultrasonography detected small stones in the gallbladder. Laparoscopic cholecystectomy was performed in February 2002. Pancreatitis recurred dozens of times during the period from Febru-

ary 2002 to August 2003. Accordingly, emergent EST was then carried out, with subsequent intraoperative findings including a swollen ampulla of Vater, duodenal hyperemia, and mucosal edema. No bile flow was observed within the ampulla of Vater after a 10-mm incision was cut. This suggested that EST had failed, and ERCP could not be performed. In November 2003, EST was performed again when duodenal hyperemia and edema subsided. ERCP was successful, which indicated a narrow and flexuous common duct of the bile and pancreatic ducts. After a 15-mm incision in the ampulla of Vater was executed, bile flow was observed; however, it was still difficult to insert a tube into the bile duct. Even though bile samples were collected occasionally from the hepatic portal area through a tube for amylase measurement, the amylase level was still as high as 7600 U/L, demonstrating that the previous EST had failed to prevent pancreatitis. During a period of one year after the second EST, pancreatitis recurred eight times in this patient, indicating the failure of the second EST. Biliary-pancreatic shunting was then performed based on evidence of biliary-pancreatic reflux. In January 2005, the patient received transection of the common bile duct and choledochointestinal anastomosis. During the operation, the bile duct pressure was measured to be 12 cmH₂O, and the bile amylase level was 690 U/L. In addition, pancreatoscopy revealed an 11-mm stenotic segment of the common duct after two ESTs, and the common duct was tortuous, which may lead to biliary-pancreatic reflux. During the two-year follow-up, pancreatitis did not recur. Moreover, a CT scan performed one year after the last surgery showed obvious shrinkage of the swollen pancreatic head, indicating an effective relief of the edema.

RESULTS

Based on our clinical observations, we added the double-duct type and the biliary-pancreatic reflux type of SOD to the Milwaukee classification, to achieve greater clarity in the SOD clinical symptoms and to guide the clinical treatment of SOD. The therapeutic methods and effects using this new classification are shown in Table 3.

Biliary type SOD

Among the 305 patients, 229 (75.1%) definitively demonstrated biliary-type SOD, and 6 of them were not eligible for EST due to a diverticulum near the ampulla of Vater; these patients were treated by open abdominal surgery. Of the 213 patients who underwent EST, 202 (94.8%) were successfully treated, but 10 (4.9%) of these patients had unsatisfactory therapeutic effects after EST, with biliary colic and bile duct distension. EST failed in 11 (5.2%) patients. Hence, a total of 21 patients had unsatisfactory therapeutic effects or EST failure. In addition to the 16 patients for whom open abdominal surgery was initially prescribed, only 29 patients actually underwent surgery (choledochointestinal anastomosis in 21 patients and sphincteroplasty in 8 patients) and had good therapeutic effects. The other 8 patients underwent conservative treatment, but showed no stable therapeutic effects.

Table 3 Clinical classification and features of sphincter of Oddi dysfunction

Features	Bile duct type (type I)	Pancreatic duct type (type II)	Double-duct type (type III)	Biliary-pancreatic reflux type (type IV)
Abdominal pain	Retrosternal pain	Epigastric pain	I + II	Same as type II
Radiating pain	The central point of the back	The left back or indefinite site	I + II	Same as type II
Timing of onset	After high-fat meals	After ordinary meals	I + II	At night or in the morning
Jaundice	±	-	±	-
Liver enzyme levels	±	-	+	±
Serum amylase levels	-	+	±	+
Bile duct distension	≥ 10 mm	< 10 mm	≥ 10 mm	≥ 10 mm
Pancreatic duct distension	-	++	+	+
Anterograde cholangiography				
Voiding time	> 10 min	Normal	> 10 min	Unexpected pancreatic duct visualization

Pancreatic type SOD

There were 16 (5.3%) cases of the pancreatic type of SOD, and 3 of them had multiple stones that were difficult to remove thoroughly because they were located deep in the pancreatic duct. Therefore, EPS was not indicated for these 3 patients. The other 13 cases were first treated by EPS, but the treatment failed in 3 cases (a success rate of 76.9%). Hence, a total of 6 cases were managed with pancreatico-jejunostomy subsequently. The therapeutic effect was satisfactory in these cases. The other 10 patients treated by EPS (5 patients with pancreatic duct stent placement) were followed up for more than two years. Satisfactory therapeutic effects were exhibited in 8 (73%) patients, and the other 2 patients were then treated by subsequent open abdominal surgery. These cases suggest that open abdominal surgery may be helpful for treating SOD regardless of whether pancreatic duct stones are involved.

Double-duct type SOD

There were 19 (6.2%) cases of double-duct type SOD, in which both the bile duct and the pancreatic duct of the sphincter of Oddi were affected. Among them, 11 patients were treated by EST, and 7 (63.6%) were cured. The remaining 8 cases were treated surgically. A total of 12 cases were treated by open abdominal surgery. Seven patients underwent choledocho-intestinal anastomosis plus pancreato-intestinal anastomosis, and one was treated with a resection of the pancreatic head with the duodenum preserved, followed by choledocho-intestinal anastomosis. Duodenopancreatectomy was performed on one patient. The other three received biliary sphincterotomies by EST and pancreato-intestinal anastomosis to treat distension of the pancreatic duct. Follow-up results revealed good curative effects in these cases.

Biliary-pancreatic reflux type SOD

Forty-one cases (13.4%) of SOD met the profile of the biliary-pancreatic reflux type, and EST was performed in 34, with a success rate of 58.8% (20/34). Surgical treatment was preferentially carried out for 2 cases, and then, a total 16 cases underwent laparotomic biliopancreatic diversion (BPD). During a follow-up period of 0.5-7 years, 14 patients showed satisfactory therapeutic effects, and in the other 2 cases, sclerotic changes were observed throughout

the pancreas. After surgery, abdominal pain occurred occasionally and was significantly mitigated in these 2 cases. Five cases without receiving any treatment are under observation, and their symptoms still often occurred.

DISCUSSION

Although the Milwaukee classification system has been widely accepted for the classification of patients with suspected SOD, it has some potential problems. For example, the description of typical biliary or pancreatic pain may be interpreted differently by different doctors, which may lead to inappropriate referrals for SOM. In addition, according to the Milwaukee criteria, a CBD diameter of at least 12 mm is required for the diagnosis of SOD. Most patients being investigated for SOD have had their gallbladder removed, and in the past, it was believed to be normal for a post-cholecystectomy CBD to be dilated by 2-3 mm^[10]. Moreover, there is a question of whether patients with both biliary and pancreatic pain should be classified into the biliary type or the pancreatic type. Freeman *et al*^[11] stated that for this group, all patients should undergo biliary sphincterotomy, and 40% should have pancreatic sphincterotomies. How to interpret these clinical data? The Milwaukee classification has some limitations. In our study, there were 60 cases that could not be accurately interpreted by the Milwaukee classification criteria. Our long-term observation of the clinical cases suggests that our new classification based on anatomy, symptoms, endoscopic tests and radiological imaging is superior to the Milwaukee criteria in guiding the treatment of SOD. According to the Milwaukee criteria, the two types of SOD (biliary and pancreatic) can be further classified into three subtypes each, making classification complex. The newly proposed classification of SOD and the clinical characteristics associated with each type are listed in Table 3.

The new classification system presented in this paper is simpler than the initial one, but continues to closely follow the Milwaukee classification criteria. For example, biliary-type SOD patients only have biliary pain, and pancreatic-type SOD patients only have pancreatic pain. The two types are no longer divided into subtypes. MRCP usually shows the distension of bile ducts for biliary SOD and dilation solely of the pancreatic duct for pancreatic-

type SOD. With respect to treatment, EST can often yield better results for patients suffering from biliary SOD, and EPS should be a good choice of treatment for patients with pancreatic SOD.

We have paid more attention to the clinical characteristics and significance of the other two types of SOD, i.e. the double-duct and biliary-pancreatic reflux types.

In double duct type of SOD, both the biliary and pancreatic ducts of the sphincter of Oddi are affected. Clinical cases of SOD meeting these criteria have previously been reported but have not been definitively classified^[12]. The characteristics of this SOD type include symptoms typical of both biliary- and pancreatic-type SOD that appear simultaneously or alternately, with mobile positions of abdominal pain and radiating pain. Meanwhile, laboratory tests indicate elevated levels of liver-related enzymes and amylase in the blood. These findings usually result in the diagnosis of chronic biliary pancreatitis, manifested as mild abnormal liver function due to edema of the pancreatic head. Imaging exams usually show distension of both the bile and pancreatic ducts and stones in the pancreatic duct. Notably, frequently recurrent pancreatitis and evident distension of the pancreatic duct could mislead surgeons to focus on pancreatitis, thus underestimating the severity of mild bile duct distension, causing the neglect of possible SOD diagnoses, and resulting in unsuccessful treatment. Therefore, it is necessary to outline the double-duct type of SOD so that patients with these symptoms can be effectively treated. Case 1 is a typical SOD of the double-duct type, with mild bile duct distension due to sphincter of Oddi stenosis, and not due to compression by the head of the pancreas. This was proved by the finding that the obstruction in the extremity of the bile duct was not relieved even when the head of the pancreas was resected in the first operation. In patients with the double-duct type SOD, the sphincter of common duct is short, but the inferior stenotic segment of the bile duct is relatively long. Hence, patients with this form of SOD can be treated by surgery rather than EPS.

The anatomical basis for biliary-pancreatic reflux type of SOD is probably as follows: Patients may have a congenital abnormality in the convergence of the biliary and pancreatic systems, i.e. an overlong duct (> 11 mm). Inflammation and stenosis mainly occur in the sphincter of the common duct, whereas the sphincters of the superior bile duct and the pancreatic duct remain relatively normal or only mildly affected. If fibrosis of the ampullary septum causes dysfunction in the anti-reflux valve, reflux between the bile and pancreatic ducts is likely to occur. Repeated reflux of small amounts of bile into the pancreatic duct will usually induce pancreatitis, including recurrent chronic biliary pancreatitis and even severe acute pancreatitis. Although the clinical manifestations of this SOD are quite similar to those of the pancreatic duct type, there are a few differences: (1) As the reciprocal reflux between the fluids in the bile and pancreatic ducts is structurally barrier-free, the pancreatic duct orifice has no evident stenosis or obstruction, and so distension of the pancreatic duct does not occur; (2) Because there was only mild biliary-pancreatic reflux in most cases, the pancreatic duct and

gland alveoli in the head of the pancreas near the biliary-pancreatic convergence were usually affected, inducing swelling of the pancreatic head, as indicated by imaging examination. Therefore, these cases are sometimes diagnosed as pancreatitis with a pancreatic head mass. Some authors have reported tumor-like features of chronic pancreatitis, and some of these cases may suffer from biliary-pancreatic reflux^[13,14]; (3) In this type of SOD, EST failed to incise the stenotic segment of the sphincter of Oddi due to the slender and tortuous common duct. EST was successful in only 56% of cases with this type of SOD at our center. However, the achievement ratio of incision on the normal ampulla of Vater was nearly 100%^[15,16]. Moreover, some patients can only be treated by open abdominal surgery due to failure to incise the stenotic common duct after several attempts by EST; and (4) The amylase levels in bile sampled from the biliary tract during ERCP in biliary-pancreatic-reflux-type SOD patients were about 2-10 times higher than normal.

Although distension does not always occur in the pancreatic duct and is usually slight in the biliary duct in the early stages of biliary-pancreatic reflux SOD, the symptoms of pancreatitis may be more serious than those in the simple pancreatic-type SOD. Because the common duct of the bile and pancreatic ducts is simply a potential duct due to the tension of the sphincter of Oddi, an image of an over long common duct was obtained from ERCP or MRCP in only a few cases. Case 2 mentioned above illustrates that the therapeutic effects of BPD were satisfactory for the biliary-pancreatic-reflux-type SOD patients who failed in EST. This demonstrates the significance of using the biliary-pancreatic reflux type classification for SOD.

In summary, the new classification of SOD proposed in this study demonstrates significant advantages for guiding the diagnosis and treatment of SOD patients in China, as compared with the conventional Milwaukee criteria. Nonetheless, further investigations on the applicability of this quaternary classification system to patients in other regions are needed.

COMMENTS

Background

Sphincter of Oddi dysfunction (SOD) is a pathological syndrome that is usually classified into the biliary type or the pancreatic type according to the Milwaukee criteria. However, this classification has some drawbacks in clinical practice, some of which result in flawed classification and failure to properly guide diagnosis and treatment.

Research frontiers

The conventional SOD classification system is insufficient in guiding the clinical treatment of all SOD patients. The authors conducted a retrospective analysis of 305 patients with SOD according to the clinical records in the past 10 years, and proposed a modified classification system based on the Milwaukee classification, which includes all SOD symptoms.

Innovations and breakthroughs

The authors proposed a new classification system for SOD according to anatomy, symptoms, endoscope tests and radiological imaging, i.e. SOD is divided into four types instead of two types: the biliary-type, the pancreatic-type, the double-duct type and the biliary-pancreatic reflux type. The new classification demonstrates significant advantages for guiding the diagnosis and treatment of SOD patients in China, as compared with the conventional Milwaukee criteria.

Applications

The new classification system has significant advantages for guiding the diagnosis and treatment of SOD patients, thus improving the clinical treatment of SOD.

Peer review

In order to solve some problems of the Milwaukee classification of SOD, the authors have proposed a new interesting classification. Compared with the Milwaukee classification, the new classification system presented in this paper is simpler than the Milwaukee classification, better explains clinical symptoms of the disease from the anatomical perspective, and should have some application values in guiding the diagnosis and treatment of SOD.

Abstract

AIM: To evaluate the effect of preoperative biliary drainage (PBD) on obstructive jaundice resulting from malignant tumors.

METHODS: According to the requirements of Cochrane systematic review, studies in the English language were retrieved from MEDLINE and Embase databases from 1995 to 2009 with the key word "preoperative biliary drainage". Two reviewers independently screened the eligible studies, evaluated their academic level and extracted the data from the eligible studies confirmed by cross-checking. Data about patients with and without PBD after resection of malignant tumors were processed for meta-analysis using the Stata 9.2 software, including postoperative mortality, incidence of postoperative pancreatic and bile leakage, abdominal abscess, delayed gastric emptying and incision infection.

RESULTS: Fourteen retrospective cohort studies involving 1826 patients with malignant obstructive jaundice accorded with our inclusion criteria, and were included in meta-analysis. Their baseline characteristics were comparable in all the studies. No significant difference was found in combined risk ratio (RR) of postoperative mortality and incidence of pancreatic and bile leakage, abdominal abscess, delayed gastric emptying between patients with and without PBD. However, the combined RR for the incidence of postoperative incision infection was improved better in patients with PBD than in those without PBD ($P < 0.05$).

CONCLUSION: PBD cannot significantly reduce the postoperative mortality and complications of malignant obstructive jaundice, and therefore should not be used as a preoperative routine procedure for malignant obstructive jaundice.

INTRODUCTION

Surgery for patients with malignant obstructive jaundice carries an increased risk of postoperative complications

and a high mortality rate^[1,2] and preoperative hyperbilirubinemia is considered an important risk factor for postoperative complications and death. Hyperbilirubinemia due to obstructive jaundice damages hepatic function, clearance of circulating endotoxins, coagulation system, immune function, and gastrointestinal barrier^[3-6]. To avoid the poor outcome, preoperative biliary drainage (PBD) has been used to reduce the postoperative morbidity and mortality of these patients. However, PBD has also many drawbacks, such as biliary stent-induced bacterial contamination and risk of cholangitis due to clogging. In addition, biliary stenting generates a severe inflammatory response in the bile duct which may increase the risk of bile leakage at the biliodigestive anastomosis. Since 1970s, several randomized and retrospective studies have compared the effect of PBD and surgery without PBD on malignant obstructive jaundice^[7,8]. However, it is difficult to find evidence that routine PBD improves the outcome of patients with malignant obstructive jaundice in clinical practice.

Despite the scarcity of clinical evidence, most patients with malignant obstructive jaundice undergo either percutaneous transhepatic or internal PBD in many centers. This meta-analysis was to evaluate the effect of PBD on malignant obstructive jaundice.

MATERIALS AND METHODS

Search strategy and selection criteria

Studies on obstructive jaundice in the English language were retrieved from MEDLINE and Embase databases from 1995 to 2009 with the key word “preoperative biliary drainage”. The primary selection criteria for meta-analysis included patients with malignant obstructive jaundice, those with or without PBD, and those with their postoperative mortality and incidence of complications assessed. The exclusion criteria were patients who underwent different surgical procedures, and those with other severe diseases unrelated to obstructive jaundice. The included studies were reviewed by two independent reviewers, with disagreements settled by group discussion.

Data extraction

Data were independently extracted by two investigators in a standard form. The concordance rate between the two investigators was 100%. Following information was extracted from all included publications including study group, year, number of included patients, type of drainage, postoperative mortality, incidence of postoperative pancreatic and bile leakage, abdominal abscess, delayed gastric emptying and incision infection

Analysis of methodological quality

Methodological quality was analyzed as previously described^[8].

Statistical methods

Stata 9.2 software was used in meta-analysis of the data. Effect measures of interest were relative risks for cohort

Table 1 Characteristics of 14 studies included in this study

Study	Yr	Type of drainage	Patients (n)

studies and corresponding 95% CI. Estimates of intervention effect on malignant obstructive jaundice were expressed as relative risks using a fixed effect model. χ^2 test or Fisher's exact test was used to calculate the probability values when appropriate. Pooled effect was estimated using a random-effect model. Publication bias was evaluated by funnel plots and Egger test.

RESULTS

Fourteen retrospective cohort studies that were relevant and eligible were retrieved according to the selection and exclusion criteria (Table 1). Of the 1826 patients with malignant obstructive jaundice included in the studies, 1028 were subjected to PBD and 798 were subjected to surgery but not to PBD. Furthermore, only internal PBD was used in 5 out of the 14 studies, and both internal and external PBD were described in the other 9 studies.

Overall mortality

No significant difference was observed in postoperative death rate reported in 9 studies between patients with or without PBD [risk ratio (RR) = 0.996, 95% CI: 0.669-1.484, Figure 1].

Incidence of postoperative pancreatic leakage

The incidence of postoperative pancreatic leakage was reported in 10 studies (Figure 2A). In our study, PBD intervention did not reduce the incidence of pancreatic leakage in patients without PBD (RR = 0.792, 95% CI: 0.478-1.311).

Incidence of postoperative bile leakage

The incidence of postoperative bile leakage was reported in 10 studies with no significant difference observed between experimental and control groups (RR = 0.935, 95% CI: 0.576-1.518, Figure 2B).

Incidence of postoperative incision infection

The incidence of postoperative incision infection was reported in 9 studies. A significant difference was observed

Figure 1 Overall mortality of patients with or without preoperative biliary drainage. Estimates of preoperative biliary drainage (PBD) effects of each study are presented on a log scale along with the 95% CI. The weight of each study is reflected by the size of square. The open diamond represents the global estimate of the PBD effect along with the 95% CI (random-effects model).

Figure 2 Incidence of postoperative pancreatic leakage (A), postoperative bile leakage (B), postoperative incision infection (C), postoperative abdominal abscess (D), and postoperative delayed gastric emptying (E). Estimates of preoperative biliary drainage (PBD) effect in each study are presented on a log scale along with the 95% CI. The weight of each study is reflected by the size of square. The open diamond represents the global estimate of the PBD effect along with the 95% CI (random-effects model).

between surgical patients with or without PBD (RR = 1.736, 95% CI: 1.229-2.450, $P < 0.05$, Figure 2C).

Incidence of postoperative abdominal abscess

The incidence of postoperative abdominal abscess in patients with or without PBD was reported in 9 studies. PBD could not decrease the postoperative abdominal abscess compared with surgery (RR = 0.957, 95% CI: 0.658-1.392, Figure 2D).

Incidence of postoperative delayed gastric emptying

The incidence of delayed postoperative gastric emptying was reported in 7 studies with no significant difference observed between patients with or without PBD (RR = 1.242, 95% CI: 0.849-1.819, Figure 2E).

DISCUSSION

Biliary obstruction has been identified to be an important risk factor for tumor which may result in alterations of glycogen metabolism, impaired hepatic and renal functions, decreased cell-mediated immunity, increased circulating endotoxins, and depressed synthesis of homeostasis factors^[23,24]. These factors can decrease the tolerance of patients to anesthesia and surgery, leading to increasing operative risks. For these reasons, in 1935, Whipple *et al*^[25] performed a staged surgery with a preliminary bypass to reduce jaundice and improve hepatic functions. In 1978, Nakayama *et al*^[26] found that the operative mortality is significantly reduced after PBD. Since then, more and more

investigators have accepted the concept that PBD can improve the hepatic functions of patients with malignant obstructive jaundice^[27-31].

With the great advances in surgical techniques and perioperative management, the postoperative complication rate has been dramatically declined in recent years. Whether PBD is still valuable in surgery for malignant obstructive jaundice is questioned by many experts. Several prospective randomized and retrospective studies compared the effect of PBD with surgery without PBD on malignant obstructive jaundice and showed that PBD cannot improve the postoperative outcome but can increase the overall complication rate^[32-35]. Although the controversy involves the indication of PBD for malignant obstructive jaundice, some centers still believe that PBD can improve the outcome for some time. To date, whether PBD should routinely be performed for malignant obstructive jaundice is still in debate. One of the reasons why the reported results are distinct is that the overwhelming majority of clinical trials were retrospective and some included heterogeneous groups of patients as well as a variety of different surgical procedures. Thus, unrecognized bias and differences in selection of patients may have affected the results. Another reason is that PBD failing to benefit patients with malignant obstructive jaundice may have a relatively short length of drainage, usually 2-3 wk. In fact, proliferation and fibrosis of bile duct epithelium may take 4-6 wk to recover, and avoid postoperative complications and impaired liver metabolism.

In the present study, the postoperative mortality, the

incidence of postoperative pancreatic and bile leakage, abdominal abscess, and delayed gastric emptying were not significantly different in patients with or without PBD, whereas the incidence of postoperative incision infection was significantly different in patients with or without PBD, which is consistent with other reports^[33,36,37]. Povoski *et al.*^[33] reviewed the effect of PBD and found that PBD has no beneficial effect on the postoperative outcome. In contrast, Trede *et al.*^[36] showed that the postoperative morbidity is significantly reduced in patients after internal PBD following pancreaticoduodenectomy. Lygidakis *et al.*^[37] also reported that the postoperative morbidity of obstructive jaundice is significantly decreased after internal PBD following pancreaticoduodenectomy. Due to the selective bias in choice of PBD, a well-selected subgroup of patients may benefit from PBD. Moreover, most patients with PBD, experiencing other serious diseases secondary to biliary obstruction, are in a relatively poorer condition than those undergoing surgery. Experimental and clinical evidence has shown that external PBD cannot improve the outcome of surgery, while internal PBD may have a beneficial effect because it can restore the nutritional and immune function^[7]. Since internal PBD can significantly reduce the number of postoperative laparotomies for bleeding, anastomotic leakage and abscess, many centers support the view that internal PBD reduces the morbidity rate of obstructive jaundice in patients undergoing surgery. However, Lai *et al.*^[38] did not support the routine use of internal PBD because of procedure-related complications, mainly cholangitis. In addition, biliary drainage for a proximal tumor with intrahepatic stenosis of the bile duct is also different from that for a distal obstruction. Therefore, various confounding factors affecting the prognosis should be taken into consideration in future clinical investigations.

In conclusion, there is no convincing evidence that supports the view that routine PBD improves postoperative outcome in patients with malignant obstructive jaundice. PBD has its own complications that partially cancel out its benefits. More randomized controlled trials are needed to identify patients who may benefit from PBD.

COMMENTS

Background

Preoperative hyperbilirubinemia in patients with malignant obstructive jaundice is considered an important risk factor for postoperative complications and death. Therefore, preoperative biliary drainage (PBD) has been used to reduce postoperative morbidity and mortality of such patients.

Research frontiers

Since 1970s, several randomized and retrospective studies have compared the effect of PBD with non-PBD on malignant obstructive jaundice. However, it is difficult to find convincing evidence that routine PBD can improve the outcome of patients with malignant obstructive jaundice in clinical practice.

Innovations and breakthroughs

To date, there is no convincing evidence that supports the view that routine PBD improves postoperative outcomes of patients with malignant obstructive jaundice. This is the first meta-analysis of the recent studies concerning the effect of PBD on malignant obstructive jaundice.

Applications

The present meta-analysis indicated that PBD could not significantly reduce the postoperative mortality and the complications of malignant obstructive jaundice. Therefore, PBD may not be regarded as a preoperative routine measure for malignant obstructive jaundice.

Peer review

A meta-analysis of the effect of PBD on malignant obstructive jaundice was performed by reviewing the publications between 1995 and 2009. The authors drew a conclusion that PBD may not be regarded as a preoperative routine measure for malignant obstructive jaundice. This is a very interesting topic for hepatologists and other digestive experts.

1.8 or 2.0 Gy per fraction. CRT planning was compared with IMRT.

RESULTS: The most common reported acute toxicities requiring medication (Radiation Therapy Oncology Group, Radiation Therapy Oncology Group Grade 2) were nausea (10/20 patients) and diarrhea (3/20). There were no treatment-related deaths. Compared with CRT planning, IMRT significantly reduced the volume of right kidney receiving > 20 Gy and the volume of liver receiving > 30 Gy. IMRT has a negligible impact on the volume of left kidney receiving > 20 Gy. The 95% of prescribed dose for a planning tumor volume using either 3D CRT or IMRT planning were 84.0% ± 6.7%, 82.9% ± 6.1%, respectively ($P > 0.05$).

CONCLUSION: IMRT achieves similar excellent target coverage as compared with CRT planning, while reducing the mean liver dose and volume above threshold dose. IMRT offers better sparing of the right kidney compared with CRT planning, with a significantly lower mean dose and volume above threshold dose.

Abstract

AIM: To assess the efficacy and toxicity of conformal radiotherapy (CRT) and compare with intensity-modulated radiotherapy (IMRT) in the treatment of gallbladder cancer.

METHODS: Between November 2003 and January 2010, 20 patients with gallbladder cancer were treated with CRT with or without chemotherapy after surgical resection. Preliminary survival data were collected and examined using both Kaplan-Meier and actuarial analysis. Demographic and treatment parameters were collected. All patients were planned to receive 46-56 Gy in

INTRODUCTION

Gallbladder cancer is the fifth most common malignancy of the gastrointestinal tract^[1]. In general, the prognosis of patients with gallbladder cancers is poor, with an overall 5-year survival rate of less than 10%^[2].

Gallbladder cancer was associated with a uniformly poor prognosis due to its highly aggressive behavior, only 10%-30% of the patients had resectable tumors at presentation^[3]. Better understanding of the biological behavior of the disease, its pattern of dissemination, better diagnostic tools, and more aggressive therapy has resulted in some improvement in survival in the last decade^[4]. However, most long-term survivors are patients with incidentally diagnosed carcinomas confined to the mucosa of the gallbladder.

Surgical therapy is the standard treatment for patients presenting with resectable disease. Unfortunately, a large number of patients develop recurrent diseases after undergoing curative resection. The long-term outcome of the patients with recurrent gallbladder cancer is very poor. And local-regional failure is common and is a major cause of mortality^[5]. Because of this, adjuvant therapy has been used to improve loco-regional control and survival rate. Several studies have reported improvement in survival for patients treated with adjuvant chemoradiation^[6,7].

Actually, the definite role of adjuvant therapy after curative resection is still uncertain. Studies to improve the loco-regional control rates with adjuvant radiation with/without chemotherapy or chemotherapy alone, have been conducted. Although gallbladder cancer is considered to be radiation resistant, radiation has been administered in the form of external beam radiotherapy, intra-operative radiation therapy and brachytherapy^[8-11]. However, the relative rarity of this malignant disease made it difficult to conduct large phase III studies to guide management in both the adjuvant and comprehensive treatment. This study reports a single-institution series that used adjuvant radiation therapy with or without chemotherapy after resection in patients with locally advanced gallbladder carcinoma. The aim of the study was to evaluate conformal radiotherapy (CRT) and intensity-modulated radiotherapy (IMRT) planning parameters in the treatment of this malignancy.

MATERIALS AND METHODS

Between November 2003 and January 2010, a total of 20 patients with pathologically diagnosed primary adenocarcinoma of gallbladder were treated in the Department of Radiation Oncology in our hospital. All patients were diagnosed with adenocarcinoma of gallbladder. All patients had complete resection, with negative microscopic margins. Demographic data were collected regarding patient age, gender, histological classification, tumor staging (Table 1). In addition to radiotherapy, the majority of patients received concurrent fluoropyrimidine-based and oxaliplatin-based chemotherapy. Concurrent and adjuvant chemotherapy regimens are shown in Table 2. Six patients received postoperative radiotherapy alone. No clear pattern of che-

mothy or standardized dosing regimen was evidenced from chart data available for review. All patients were simulated on a computed tomography-scanner (Siemens Definition AS 40) and were imaged using a slice of thickness 3.0 mm. All simulations were performed using a timed bolus of non-ionic intravenous contrast media to acquire images of early arterial/portal venous contrast phase, and a secondary venous contrast phase. Digital imaging and communications in medicine data were transferred to an inverse IMRT treatment planning station (Philips Pinnacle³ 7.6C). Gross target volumes and clinical target volumes (CTVs) according to ICRU 62 definitions^[12] were delineated on a slice-by-slice basis. External beam radiation therapy fields generally encompassed the tumor bed and regional lymph nodes (porta hepatis, celiac, pancreaticoduodenal) to a dose of 45 Gy in 1.8-2.0 Gy daily fractions. Reduced fields to tumor bed plus a 2-2.5 cm margin received an additional 5.0-10.0 Gy. A variety of multi-beam

Figure 1 Overall survival for all the patients.

techniques were used to treat the tumor bed to a median total prescription dose of 52 Gy (range, 46-56 Gy). Organs-at-risk (OAR) delineated included the spinal cord, kidneys, and healthy liver. A planning tumor volume (PTV) was created by volumetric expansion of the CTV by 10-15 mm. Dose volume histograms (DVHs) were utilized to evaluate the plans. Prescribed doses to the initial PTV ranged from 46 to 56 Gy in daily doses of 1.8-2.0 Gy. Relative constraints included left kidneys constrained to a D100 of < 20 Gy and D66 < 18 Gy; right kidneys were specified to achieve D100 < 30 Gy, with D66 < 20 Gy. The total mean liver dose was specified to < 22 Gy, and liver V20 kept under 33%. Treatment was delivered using a 10 MV linear accelerator (Siemens Primus M) with 200 MU/min delivery capability using a multi-leaf collimator. Survival data were collected and examined using the Kaplan-Meier method.

By a comparison of CRT and IMRT, all fields of the patients were coplanar. DVHs were obtained for the PTV, kidneys, liver and spinal cord. Acute toxicity was scored using the Radiation Therapy Oncology Group (RTOG) morbidity scoring criteria^[13]. Dosimetric endpoints for the target and critical structures were compared using the two tailed paired *t* test.

RESULTS

Survival analysis

The median follow-up for patients alive at analysis was 14.0 mo (range, 3.0-66.9 mo). Nine patients were alive. The median preliminary survival from diagnosis in the 20 patients was 19.2 mo (range, 4.2-66.9 mo, 95% confidence interval: 10.1-28.3). Kaplan-Meier analysis revealed an estimated one-year survival rate of 40.48% (Figure 1).

Toxicity analysis

Twenty patients completed their planned course of treatment without breaks and no reduction of planned chemotherapy. For gastrointestinal (GI) toxicity analysis, radiotherapy or chemotherapy with CRT was well tolerated without > grade 3 acute GI toxicity occurring during radiotherapy, and 11/20 and 4/20 patients reported grade 1 upper and

Figure 2 Isodose curves on an axial slice for a representative case. Intensity-modulated radiotherapy plan (upper picture) and conformal radiotherapy plan (lower picture).

lower acute RTOG GI toxicity scores. The most common reported acute toxicities requiring medication (RTOG Grade 2) were nausea (10/20 patients) and diarrhea (3/20). There were no treatment-related deaths.

Fourteen patients received chemotherapy (including concurrent chemotherapy), the major grade 3-4 adverse events were leukopenia (21%), neutropenia (29%) and anemia (14%). Compared with pre-treatment values, no abnormalities were detected in the laboratory test of kidney function for any of the 20 patients, either during treatment or at follow-up. Three patients had elevated liver enzymes about 6 mo after the completion of radiotherapy. No late toxicity was seen in this series.

Dosimetric comparison between 3D CRT and IMRT plans

To demonstrate the differences in dose distribution, Figure 2 shows isodose curves on an axial slice for one representative patient for IMRT and CRT. Figure 3 shows the DVH curves for the kidneys and liver at risk for one representative patient. Table 3 summarizes the mean doses to the PTV, kidneys and liver for CRT and IMRT plans. Compared with the CRT plan, IMRT significantly reduced the mean dose to the right kidney and liver, while the improvement in the dose to the left kidney was not significant. Both of CRT and IMRT limited the dose to spinal cord under 40 Gy. Table 4 summarizes the volume of critical structures receiving greater than the threshold dose^[14]. Compared with CRT planning, IMRT significantly reduced the volume of right kidney receiving > 20 Gy and the volume of liver receiving > 30 Gy. IMRT has a

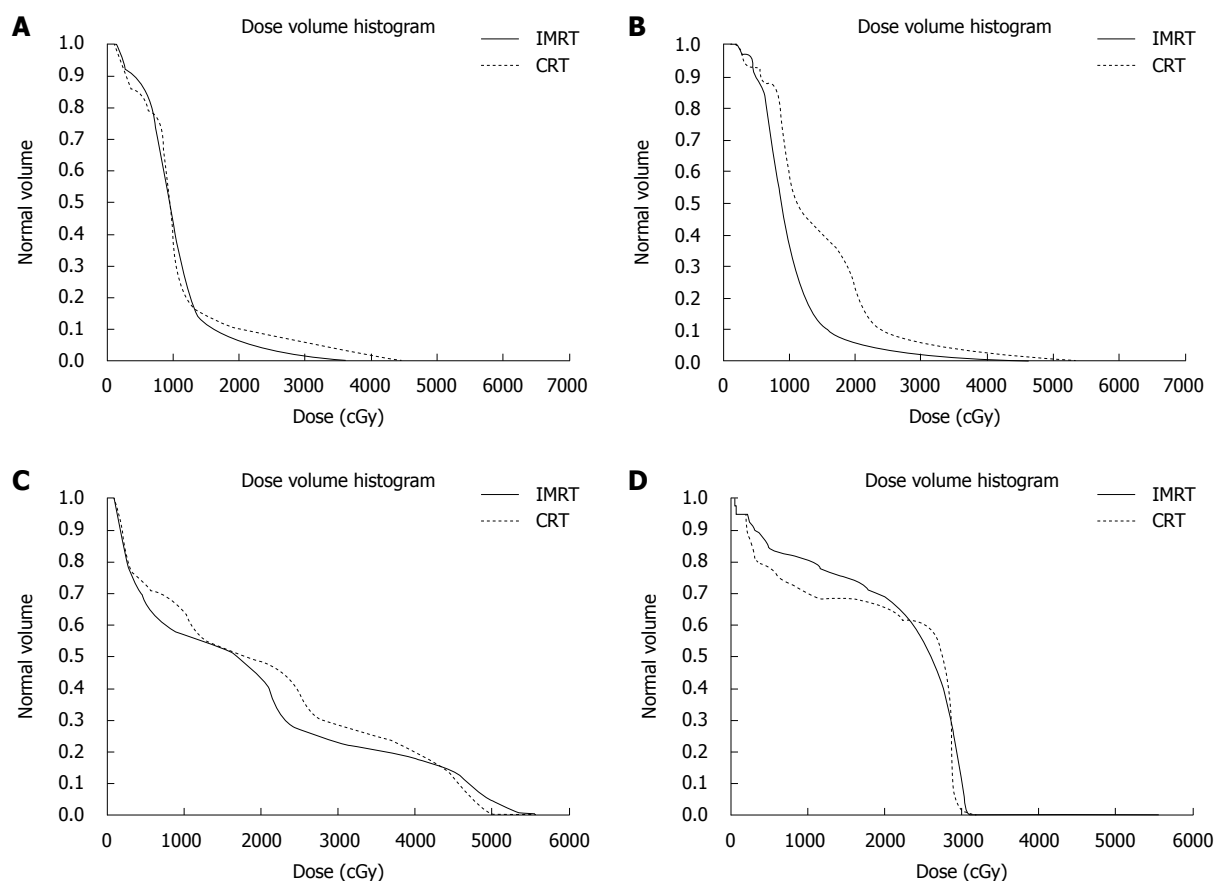

Figure 3 Dose volume histogram curves for the organs at risk in a representative case. Left kidney (A), right kidney (B), liver (C), and spinal cord (D). IMRT: Intensity-modulated radiation therapy; CRT: Conformal radiation therapy.

negligible impact on the volume of left kidney receiving > 20 Gy. The range of the 95% of prescribed dose for PTV using either 3DCRT or IMRT planning was 84.0% ± 6.7% and 82.9% ± 6.1%, respectively (*P* > 0.05).

DISCUSSION

Gallbladder cancer has a dismal prognosis and loco-regional recurrence has been described as the most frequent site of relapse, and death most commonly occurred due to complications and sequelae of loco-regional recurrence^[15]. Hepatic infiltration has been reported in 60%-70% and nodal involvement in 20%-40% in some series^[16,17]. The loco-regional pattern of recurrence after surgery provides

Table 4 Volume of structures/organs receiving greater than the threshold dose

Structure/organs	Dose (Gy)	Volume above threshold dose (%)		<i>P</i> value ¹
		CRT	IMRT	
PTV	95% of prescribed dose	84.0 ± 6.7	82.9 ± 6.1	NS
Organs at risk				
Right kidney	20.0	12.5 ± 11.7	5.4 ± 2.7	0.031
Left kidney	20.0	5.3 ± 6.0	3.7 ± 2.3	NS
Liver	30.0	34.5 ± 8.0	30.1 ± 6.3	0.0065

a rationale for the use of radiotherapy as a component of gallbladder cancer treatment. The radiosensitive nature of gallbladder cancer is evidenced by numerous clinical studies reporting tumor size reduction after radiotherapy for unresectable diseases^[18,19].

Our one-year survival rates and median preliminary survival time are similar to those reported in the limited radiotherapy literature and are generally better than those reported with surgery alone in patients with local advanced disease^[20,21].

IMRT and automated optimization have the abil-

ity to shape isodose curves, avoiding the dose to the OARs. The use of direct machine parameter optimization IMRT improves the PTV coverage compared with CRT for most patients, although dose escalation was only possible in a minority of patients. It is suspected that the dosimetric improvement with IMRT was less in these plans compared with CRT plans. However, these complex CRT plans are challenging to develop without automated optimization, and IMRT might have planning efficiency and time-saving advantages for these cases.

Our data demonstrated that IMRT offers better sparing of the right kidney compared with CRT planning, with a significantly lower mean dose and volume above threshold dose. IMRT achieves similar excellent target coverage as compared with CRT, while reducing the mean liver dose and volume above threshold dose. In summary, IMRT offers improved sparing of normal structures, however, it warrants further studies in the treatment of gallbladder carcinoma.

In conclusion, gallbladder carcinoma is an aggressive disease with a dismal prognosis. More effective adjuvant therapy is needed to improve overall survival. There was a clear association between adjuvant therapy use and improved survival in patients with loco-regional disease. The real benefit of adjuvant radiotherapy in gallbladder carcinoma remains unclear. A retrospective analysis^[21] was done about the surveillance, epidemiological, and end results survey by the American National Cancer Institute. The results showed that adjuvant radiotherapy is associated with improved survival in patients with locally advanced gallbladder cancer or gallbladder cancer with regional disease. Gallbladder cancer remains an aggressive disease that requires multimodality approach to individualize and optimize therapy. Prospective randomized trials of adjuvant therapy are needed in this disease. However, the low incidence of gallbladder cancer may make it difficult to successfully complete such trials, unless they are designed as inter-group studies within China or as international studies. In the future, methods of achieving earlier diagnoses may help improve the outcomes of the treatment. IMRT for dose escalation to improve tumor control and spare surrounding structure/organs from receiving radiation tolerance doses should be further studied.

COMMENTS

Background

Surgical therapy is the standard treatment for patients with resectable gallbladder cancer. Unfortunately, a large number of the patients develop recurrent disease despite curative resection. And local-regional failure is common and is a major cause of mortality. Because of this, adjuvant therapy has been used to improve loco-regional control and survival rate. Several studies have reported improvement for patients treated with adjuvant chemoradiation.

Research frontiers

Although gallbladder cancer is considered to be radiation resistant, radiation has been tried in the form of external beam radiotherapy, intra-operative radiation therapy and brachytherapy.

Innovations and breakthroughs

Intensity-modulated radiotherapy (IMRT) achieves similar excellent target coverage as compared with conformal radiotherapy (CRT) planning, while reducing

the mean liver dose and volume above threshold dose. IMRT offers better sparing of the right kidney compared with CRT planning, with a significantly lower mean dose and volume above threshold dose.

Applications

The mainstay of treatment has been surgery and the role of adjuvant therapy in the form of chemotherapy and/or radiation therapy remains to be defined. Some clinical studies suggest that adjuvant radiotherapy dosage was associated with a better local control of the tumor. IMRT may offer better sparing of the right kidney and liver compared with CRT planning, this makes it possible for dose escalation to improve tumor control and spare surrounding structure/organs.

Terminology

IMRT: A type of three-dimensional radiation therapy that uses computer-generated images to match radiation to the size and shape of a tumor, which is used to deliver a higher radiation dose to a tumor with less damage to the nearby healthy tissues.

Peer review

The role of adjuvant radiotherapy in gallbladder cancer is not definite. This paper deals with a methodological comparison of CRT and IMRT for gallbladder cancer. IMRT offered better sparing of right kidney and liver compared with CRT. This result can help clinicians understand the role and toxicity of radiotherapy in gallbladder cancer treatment.

Abstract

Pulmonary embolism occurs more frequently after hepatectomy than previously thought but is infrequently associated with peripheral deep vein thrombosis. In this paper, we report 2 cases of postoperative hepatic vein thrombosis after liver resection. Both patients had undergone major hepatectomy of a non-cirrhotic liver largely exposing the middle hepatic vein. Clots were incidentally found in the middle hepatic vein 4 and 17 d after surgery despite routine systemic thrombo-prophylaxis with low molecular weight heparin. Coagulation of the transition

INTRODUCTION

Patients undergoing liver surgery have long been considered to be at low risk of venous thromboembolism. Routine Doppler ultrasound following major hepatectomies identifies deep vein thrombosis in 2% of patients^[1], three to five times less than after general abdominal or colorectal procedures performed with adequate anticoagulation prophylaxis^[2-5]. However, pulmonary embolism has recently emerged as an increasingly frequent and potentially fatal complication following liver resections. Its incidence ranges between 1% and 3% in patients undergoing liver resections^[1,6] and has been reported to be as high as 10% in living-related donors undergoing a right hepatectomy^[7,8]. These figures are greater than the 0.3% incidence observed following general surgery and the 2%-3% incidence observed after high risk

procedures such as invasive neurosurgery, total hip arthroplasty, and radical cystectomy^[9]. Liver regeneration that follows major resections is indeed associated with an early and transient dysregulation of the haemostatic system resulting in a hypercoagulability state^[10].

This difference between a low incidence of deep vein thrombosis and a high incidence of pulmonary embolism is difficult to explain as more than 90% of pulmonary emboli are considered to arise from lower extremity and pelvic deep veins^[11]. Furthermore, less than 50% of patients developing a pulmonary embolism after liver resection have an associated deep vein thrombosis^[7].

We shed a new light on this discrepancy by reporting two patients who developed thrombi in their hepatic veins following hepatectomy. To our knowledge, this complication has not been previously reported which can be explained by the technical difficulty to visualise the hepatic veins on imaging studies in the early postoperative period.

CASE REPORT

Case 1

A 39-year-old woman underwent a right hepatectomy for a 13 cm large liver hemangioma responsible for incapacitating pain. Hepatic veins were patent and besides a body mass index of 32 kg/m² she had no known risk factors for thromboembolic disease^[12]. On the evening before surgery, tight-length graduated compression stockings were placed and she received a subcutaneous injection of 40 mg enoxaparin. Liver transection was performed using an ultrasonic dissector with two intermittent clamping of the hepatic pedicle of 11 and 15 min. Intrahepatic portal structures and hepatic veins were occluded with ligation, clips or bipolar coagulation as required. The right hepatic vein was closed extraparenchymally and the main trunk of the middle hepatic vein was retained with the left liver. Additional haemostasis of the transection surface was achieved with bipolar coagulation and the left liver was fixed to the diaphragm to prevent twisting of the hepatic veins under intraoperative ultrasound control^[13]. No transfusion was required, the patient was extubated 3 h after surgery and daily administration of 40 mg enoxaparin was reinitiated on the following morning.

The early postoperative course was uneventful with rapid normalization of liver function tests but on the fourth postoperative day, she developed shortness of breath and a temperature rise at 37.8°C at which time a computed tomography (CT) scan was performed. There was no obvious evidence of pulmonary embolism but three defects were found in the middle hepatic vein adjacent to the transection plan (Figure 1) that were confirmed to be 2-3 cm long clots by Doppler ultrasound. The inferior vena cava and termination of the middle hepatic vein had a normal flow pattern otherwise. Mild right pleural effusion, ascites and localised thrombosis of the right posterior tibial veins were also uncovered. Following administration of enoxaparin at 1.0 mg/kg twice daily, pulmonary symptoms disappeared within 48 h and control Doppler ultrasounds performed every other day

Figure 1 Postoperative computed tomography scan (day 4) in case 1. Defects are present in the middle hepatic vein close to the transection plan (arrowheads).

showed the progressive disappearance of two of the three clots and the reduction in size of the third at which time she was discharged (postoperative day 21). The postoperative course had otherwise been uneventful. A control CT scan performed 1 mo later showed the complete disappearance of the clots. Screening for inherited thrombophilia identified a heterozygote (20210AG) mutation of the prothrombin gene while other risk factors, including factor V Leiden mutation were absent.

Case 2

A 78-year-old man underwent simultaneous left hepatectomy extended to a part of segment 8 by laparotomy and laparoscopic sigmoidectomy for synchronous colorectal liver metastasis. He had no history of thromboembolic disease and surgery was preceded by 6 cycles of chemotherapy (FOLFOX regimen + cetuximab) that had induced a partial response according to RECIST criteria.

Figure 2 Postoperative computed tomography scan (day 17) in case 2. A biloma is present at the upper part of the transection plan and a defect is visible in the distal end of the middle hepatic vein extending in the inferior vena cava (arrowheads).

On the evening before surgery, tight-length graduated compression stockings were placed and he received a subcutaneous injection of 40 mg enoxaparin. Liver transection was performed as previously described, without vascular clamping. The middle hepatic vein was closed intraparenchymally while the left hepatic vein was closed extraparenchymally. No transfusion was required, the patient was extubated 3 h after surgery and daily administration of 40 mg enoxaparin was reinitiated on the following morning.

The early postoperative course was uneventful and the patient was discharged on postoperative day 11. He was re-admitted on postoperative day 17 for sepsis. CT scan showed bile collection close to the cut edge of the liver and a clot in the middle hepatic vein extending into the supra-hepatic vena cava (Figure 2). Percutaneous drainage of the collection was performed and anticoagulant therapy was administered, allowing complete regression of the thrombosis seven days later. Oral anticoagulation was then administered and the patient was discharged 10 d after admission (postoperative day 27). Screening for inherited thrombophilia was negative.

DISCUSSION

The present study reports two patients who developed early hepatic vein thrombosis following liver resection, a previously unrecognized complication. Both had several features in common: (1) they had undergone a major hepatectomy

within a non-cirrhotic liver; (2) the thrombosis was located within the hepatic vein adjacent to the transection plan; and (3) was discovered somewhat fortuitously.

We have previously shown that major resections of non-cirrhotic livers are associated with an early postoperative decrease in coagulation inhibitors protein C and antithrombin together with an increase in factor VIII and von Willebrand factor that induce a transient hypercoagulability state^[10]. Both patients underwent a major resection while already being at increased risk of thrombosis. One indeed retrospectively proved to be overweight and to have a heterozygote (20210AG) mutation of the prothrombin gene associated with a three- and two-fold increase in the risk of thrombosis, respectively^[14]. The other patient had an advanced malignancy that also increased the risk of thrombosis^[12,14] and is associated with increased procoagulant activity^[15].

The specific finding was, however, that thrombosis developed within the main trunk of a major hepatic vein adjacent to the transection plan. One patient (n°2) developed a biloma, an obvious local predisposing condition as local infection causes vein wall inflammation while general infection increases systemic procoagulant activity^[16]. This was not the case in the other (patient 1) and we believe that thrombosis may have been favoured by extensive coagulation of the raw surface of the liver. Bipolar coagulation, which is widely used to achieve hemostasis during parenchymal transection, may result in heat-induced endothelial injury when a major hepatic vein lies close to the transection plan which is the case during formal right and left hepatectomies. Portal triad clamping, which is frequently performed during major hepatectomies, may also favour through stasis these coagulation-induced thrombosis^[12].

The recognition of these thrombi in our patients was somewhat fortuitous which may explain why this complication might have previously been overlooked. CT imaging in the postoperative course of liver resections is generally indicated when a pulmonary embolism or an abdominal collection are suspected. Angio-CT scans are usually performed 15–20 s after the injection at which time hepatic veins are not visible. During more conventional CT scans, acquisition of images is similarly not always performed at the time hepatic veins are injected. Besides, the middle hepatic vein has a longitudinal direction and is therefore hardly visualized along a significant length by the transverse slices of CT scans.

Once present in major hepatic veins, these thrombi may easily migrate into the inferior vena cava as previously shown for tumour^[17] or hepatic fragments^[18]. Pulmonary embolism was not formally documented in our patients probably because anticoagulation therapy was initiated prior to clot migration.

In conclusion, thrombosis may occur in hepatic veins after liver resection as a result of intra- or postoperative local injury. This would explain why pulmonary emboli have been observed in the absence of peripheral deep vein thrombosis. This hazard should be taken into account when performing extensive coagulation of the raw surface of the liver when a major hepatic vein is exposed.

Abstract

We read with great interest the article by Vege *et al* published in issue 34 of *World J Gastroenterol* 2010. The article evaluates the ability of contrast-enhanced computerized tomography (CECT) to characterize the nature of peripancreatic collections found at surgery. The results of their study indicate that most of the peripancreatic collections seen on CECT in patients with severe acute pancreatitis who require operative intervention contain necrotic tissue and CECT has a limited role in differentiating various types of collections. However, there are some points that need to be addressed, including data about the stage of acute pancreatitis in which CECT was done and the time span between CECT examination and surgery.

TO THE EDITOR

We read with great interest the article by Vege *et al*^[1] published in issue 34 of *World J Gastroenterol* 2010. The article evaluates the ability of contrast-enhanced computerized tomography (CECT) to characterize the nature of peripancreatic collections found at surgery. For that purpose the authors excluded false positive and negative collections found on CT and presented their results in a comparative analysis. The results of their study indicate that most of the peripancreatic collections seen on CECT in patients with severe acute pancreatitis who require operative intervention contain necrotic tissue and CECT has a limited role in differentiating the different types of collections.

However, there are some points that need to be addressed. The authors neither specified in which stage of acute pancreatitis (pro-inflammatory or anti-inflammatory response) was CECT done nor they specified the time span between CECT examination and surgery. Since the clinical course of severe acute pancreatitis is very dynamic, and CECT and surgery were not performed concurrently, it may not be the matter of false negative and positive findings, but the collections could have rather be formed or disappeared in between CECT examination and surgery. Furthermore, the collections could have progressed from one stage to another, e.g. from necrotic to necrotic with pus or to liquefaction (as identified at surgery), which

could have also introduced significant bias into the analysis. We believe that this is a serious methodological limitation to this study which deserves attention, apart from having a significant number of unidentified collections with fluid but without necrosis on CECT.

By the way, the authors erroneously specified at the end of the 2nd paragraph in the Results section under the subheading *Peripancreatic collections* that 5 of 9 unidentified collections on CECT had associated necrosis and 4 had

only fluid without necrosis, whereas it is obvious from Figure 1 that 4 collections had associated necrosis and 5 had no associated necrosis.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organizations]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Fax: +86-10-85381893

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Nestin is a class VI intermediate filament protein that was originally described as a neuronal stem cell marker during central nervous system (CNS) development, and is currently widely used in that capacity. Nestin is also expressed in non-neuronal immature or progenitor cells in normal tissues. Under pathological conditions, nestin is expressed in repair processes in the CNS, muscle, liver, and infarcted myocardium. Furthermore, increased nestin expression has been reported in various tumor cells, including CNS tumors, gastrointestinal stromal tumors, pancreatic cancer, prostate cancer, breast cancer, malignant melanoma, dermatofibrosarcoma protuberances, and thyroid tumors. Nestin is reported to correlate with aggressive growth, metastasis, and poor prognosis in some tumors; however, the roles of nestin in cancer cells have not been well characterized. Furthermore, nestin is more specifically expressed in proliferating small-sized tumor vessels in glioblastoma and gastric, colorectal, and prostate cancers than are other tumor vessel markers. These findings indicate that nes-

tin may be a marker for newly synthesized tumor vessels and a therapeutic target for tumor angiogenesis. It has received a lot of attention recently as a cancer stem cell marker in various cancer cells including brain tumors, malignant rhabdoid tumors, and uterine, cervical, prostate, bladder, head and neck, ovarian, testicular, and pancreatic cancers. The purpose of this review is to clarify the roles of nestin in cancer cells and in tumor angiogenesis, and to examine the association between nestin and cancer stem cells. Nestin has the potential to serve as a molecular target for cancers with nestin-positive cancer cells and nestin-positive tumor vasculature.

INTRODUCTION

Nestin is an intermediate filament (IF) protein that was originally described in 1990 as a neuronal stem cell/progenitor cell marker during central nervous system (CNS) development^[1]. Cytoskeletal proteins mainly consist of microfilaments, IFs, and microtubules. The diameter of microfilaments (actin) is 5-7 nm and that of microtubules is 20-25 nm, while the diameter of IFs falls between the two at 10 nm, giving them their name. IFs are

classified into six subtypes^[2,3], and the IF protein members are expressed in specific cell types, for example, keratin in epithelial cells, vimentin in mesenchymal cells, desmin in muscular cells, neurofilament in neuronal cells, and glial fibrillar acidic protein in glial cells.

Nestin is expressed in dividing cells during the early stages of development in the CNS, peripheral nervous system, and myogenic and other tissues. With differentiation, nestin is downregulated and replaced by tissue-specific IF proteins, and therefore, is widely used as a neuronal stem cell marker. Nestin is also expressed in immature or progenitor cells in non-neuronal cells in normal tissues^[4-7]. High levels of nestin expression have been detected in oligodendroglial lineage cells, ependymocytes, Sertoli cells, enteric glia, hair follicle cells, podocytes of renal glomeruli, pancreatic stellate cells, pericytes, islets, optic nerve, and odontoblasts^[8-14]. Recent work has shown that nestin is also expressed in follicle stem cells and their immediate, differentiated progeny, and the hair follicle bulge area has been noted as an easily accessible source of actively growing pluripotent adult stem cells^[15]. In adult organisms, nestin-expressing cells are restricted to defined locations, where they may function as a cellular reserve that is capable of proliferation, differentiation, and migration after reactivation^[16].

In pathological conditions, nestin is expressed in repair processes in the CNS, muscle, liver^[17-20], and infarcted myocardium^[21]. Furthermore, increased nestin expression has been reported in various tumor cells, including CNS tumors, pancreatic cancer, gastrointestinal stromal tumors (GISTs), prostate cancer, breast cancer, malignant melanoma, dermatofibrosarcoma protuberans, and thyroid tumors^[22-28] (Table 1). Expression of nestin in several tumors has been reported to be closely correlated with poor prognosis. Recently, nestin has also received attention as a cancer stem cell marker in various tumor cells including brain tumors, uterine and cervical cancers, prostate cancer, bladder cancer, head and neck cancers, ovarian cancer, testicular cancer, pancreatic cancer, and malignant rhabdoid tumors^[29-36]. In the tumor tissues, proliferating vascular endothelial cells also highly express nestin, and nestin is therefore closely correlated with tumor angiogenesis^[37-40] (Table 2). Detailed analyses of expression patterns of nestin in various tumor tissues and tumor angiogenesis, including gastrointestinal cancer, will be helpful for examining the roles of nestin in mechanisms of tumor growth and invasion and for finding novel therapeutic targets.

STRUCTURE AND REGULATION OF NESTIN

Nestin is a large protein (> 1600 amino acids) with a highly conserved α -helical core domain of 300-330 amino acids flanked by N- and C-terminal domains and classified into type VI IFs^[1,3,41]. Nestin contains a short N terminus and an unusually long C terminus, which interacts with other IFs including vimentin, desmin, or internexin, form-

Table 1 Expression and roles of nestin in cancers

	Expression patterns	Roles
Glioblastoma ^[66-69]	Tumor cells and tumor vessels Glioma << glioblastoma	<i>In vitro</i> and <i>in vivo</i> growth G1/S arrest Migration, invasion
Pancreatic cancer ^[87,90]	30% of PDAC	Nerve invasion, migration Initiation of PanIN
GIST ^[25,96]	Tumor cells and interstitial cells of Cajal	
Prostate cancer ^[27]	Androgen-insensitive cancer cells 75% of lethal androgen-independent prostate cancer	Migration, invasion <i>in vitro</i> Lung metastasis
Breast cancer ^[26,101-103]	Basal breast cancer subtype Triple-negative breast cancer Lymphovascular embolus of inflammatory breast cancer	Shorter survival Independent prognostic factor
Malignant melanoma ^[24,106-108,112,113]	Tumor cells and endothelial cells Ulceration of primary tumors Infiltrating front of tumors Primary tumor << metastatic tumor Stage IV >> III/IV with no evidence of disease in blood	Advanced stage Metastasis Shorter survival

PanIN: Pancreatic intraepithelial neoplasia; GIST: Gastrointestinal stromal tumor; PDAC: Pancreatic ductal adenocarcinoma.

Table 2 Expression and roles of nestin in tumor angiogenesis

	Expression patterns	Roles
Gastric adenocarcinoma ^[37]	Tumor blood vessels	Shorter survival
Colorectal cancer ^[38]	Small-sized and proliferating tumor vessels	Shorter survival
Prostate cancer ^[39,40]	Proliferating vascular cells	Shorter survival
	Endothelial cells in metastatic bone	Recurrence
		Skeletal metastasis
Glioblastoma ^[131]	Proliferating endothelial cells	
Malignant melanoma ^[108]	Endothelial cells	Shorter survival

ing heterodimers and mixed polymers^[42-44], but in contrast to other IFs, nestin cannot form homopolymers^[2]. Nestin is known to contribute to the disassembly of vimentin during mitosis^[45]. It has been suggested that the long C-terminal portion of nestin protrudes from the filament body and may function as a linker or cross-bridge between IFs and microtubules^[2]. The assembly and disassembly of cytoskeletal IFs modulate a variety of signaling cascades, and several lines of evidence suggest that nestin participates in this regulation^[46]. Nestin may thus play a role in

connecting the three components of the cytoskeleton and coordinate changes in cell dynamics.

Nestin has a high molecular weight (about 240 kDa), which differs among organs because of modifications to the protein^[47]. It has multiple phosphorylation sites and glycosylated side chains, and the phosphorylated and glycosylated forms of nestin may affect intracellular localization or act as a means of functional regulation in specific cell types or brain regions^[48]. Nestin is known to be phosphorylated at Thr³¹⁶ by cdc2 kinase^[49] and/or cyclin-dependent kinase 5^[50], and modulates mitosis-associated cytoplasmic reorganization during mitosis. However, the roles of glycosylation have not been closely examined^[51].

The minimal promoter of the mouse nestin gene resides in the region -11 to +183 of the 5' non-coding and upstream flanking regions, and two adjacent Sp1-binding sites are necessary for promoter activity. Sp1 and Sp3 proteins are reported to regulate the expression of the mouse nestin gene^[52]. The nestin gene has four exons and three introns, and neural cell-specific expression is reported to be regulated by the second intron, whereas nestin expression in tumor endothelium is enhanced by the first intron^[53]. Nestin expression in muscle precursor cells is regulated by temporally and spatially restricted enhancer elements in the first intron^[54]. Furthermore, the epigenetic regulation of nestin transcripts has been reported; histone acetylation is sufficient to mediate the activation of nestin transcription, but DNA demethylation is not^[55]. Tissue- and cell-specific and spatiotemporal regulation of nestin is important for cell behavior during development or in pathological conditions. These observations also suggest that nestin is more than just a structural protein that serves as a progenitor stem cell marker.

NESTIN IN CNS TUMORS

Nestin has been implicated in the rapid proliferation of progenitor cells during neurogenesis^[56]. However, when precursor cells differentiate into neural or glial cell types, nestin expression is downregulated or disappears^[54,57]. Nestin mRNA is expressed at a high level in the cerebrum of the developing rat embryo on embryonic day 15, and the level decreases toward postnatal day 12, disappearing from postnatal day 18 to the adult stage^[1]. Cells that express nestin have been found at the ventricular border in mammalian brains, and these cells give rise to neurons and glia in avian models^[58,59]. Nestin expression has not been detected in normal astrocytes but is transiently detected in reactive astrocytes accompanying, for example, trauma, tumor growth, or neurodegenerative diseases in brain tissue^[19,60-62].

Nestin expression has been reported in tumor cells originating from the CNS, including astrocytoma, ependymoma, oligodendroglioma, glioblastoma, and primitive neuroectodermal tumors^[63-66]. Nestin has been detected in human gliomas, including low and high grade, but its expression has been observed more frequently in high-grade than in low-grade gliomas, such as pilocytic astrocy-

Figure 1 Tumor stem cells and nestin. Tumor stem cells have specific characteristics, including multi-lineage potential, self-renewal potential, refractoriness to therapy, and high invasiveness and metastatic potential. The origin of tumor stem cells has not been well clarified, but it is known that some tumor stem cells express nestin in their cytoplasm. Nestin in tumor stem cells thus is considered to be a novel therapeutic target.

tomas^[66,67]. The downregulation of nestin in glioblastomas induces cell cycle arrest at the G1/S phase^[68]. However, the roles of nestin in glial cell tumors have not been well clarified. Recent work has shown that nestin expression does not influence the *in vitro* proliferation of glioblastoma cell lines, while subclones characterized by high levels of nestin form larger tumors *in vivo* than those with low expression. Furthermore, blocking the expression of nestin in glioblastoma tumors via intratumoral injection of short hairpin RNA (shRNA) significantly slows tumor growth and volume^[69]. We have also found that expression of nestin correlates with cell growth, migration, and invasion in low- and high-grade gliomas. These findings demonstrate that nestin plays important roles in the development of glioblastomas and may potentially be a target for treatment of the disease.

Brain tumor stem cells (BTSCs), obtained by cell sorting of dissociated suspensions of tumor cells for the NSC marker CD133^[70,71], also express nestin but not differentiated neural lineage markers. These CD133⁺, nestin⁺ cells represent a minority fraction of the entire brain tumor cell population, exclusively generate clonal tumor spheres in suspension culture, and exhibit increased self-renewal capacity. These findings suggest that nestin serves as a BTSC marker. Furthermore, it has been reported that tumor stem cells play crucial roles in tumor proliferation, invasion, and metastasis; therefore, nestin may be closely associated with these tumor stem cell functions. The origin of tumor stem cells has been controversial, but nestin may be a novel therapeutic target to suppress them (Figure 1).

NESTIN IN PANCREATIC CANCER

During early embryonic development, neuronal and islet cells in the pancreas share many phenotypic properties, and developing islet cells express several neuronal-specific markers^[72-74]. In the adult pancreas, nestin-positive cells were initially described as a specific subpopulation of cells located in the endocrine islets, with a possible stem cell function^[75]. Nestin-expressing cells also reside in the pancreatic ducts, where they may function as possible progenitor cells^[76]. Nestin has been used as a selection marker for neuronal and pancreatic endocrine precursor cells^[77,78] dur-

ing differentiation assays using embryonic and adult stem cells. Additionally, the isolation of nestin-expressing cells from rat and human islets, and their *in vitro* differentiation into pancreatic endocrine and exocrine cells, has led to the suggestion that nestin-positive cells have a role as multipotent pancreatic stem cells^[76]. Moreover, nestin-positive cells do not necessarily serve as endocrine precursors during pancreas development in mice, rats and humans, or in a regenerating model of adult rat pancreas^[11,79-81].

Lineage-tracing experiments have indicated that exocrine cells are derived from nestin-expressing progenitor cells in the pancreas^[82-85]. In adult pancreas, localization of nestin has been reported in vascular endothelial cells and acinar cells at different levels but not in endocrine cells^[86-89]. In the regenerative process of a rat acute pancreatitis model, nestin expression was observed in proliferating capillary endothelial cells, stellate cells surrounding ductular structures, and submesothelial cells^[82].

Concerning nestin and pancreatic cancer, it has been demonstrated that activation of oncogenic K-ras in the nestin cell lineage is sufficient for initiation of premalignant pancreatic intraepithelial neoplasia in mice^[90]. We have reported that nestin immunoreactivity is present in the cancer cells in about 30% of pancreatic ductal adenocarcinoma (PDAC) cases, and nestin expression in pancreatic cancer cells correlates with nerve invasion and the presence of cancer cells at the tumor resection margins^[87]. We recently found that nestin expression also correlates with migration, invasion, and metastasis of pancreatic cancer cells.

Regarding pancreatic tumors other than PDAC, nestin expression has been reported in acinar cell carcinoma, pancreatoblastoma, solid-pseudopapillary neoplasm, and serous cystadenoma^[91]. However, nestin is rarely detected in intraductal papillary-mucinous neoplasms, mucinous cystic neoplasm, or undifferentiated carcinoma cases.

NESTIN IN GISTS

Mesenchymal tumors consisting of spindle-shaped cells develop in the gastrointestinal tract, and they were at first believed to originate from smooth muscle or neuronal cells. However, subsequent studies have shown that most of the tumors do not have the typical features of smooth muscle or neuronal cells; therefore, the most common mesenchymal tumors that differ from leiomyomas or schwannomas are designated as GISTs. Most GISTs express *c-kit* receptor tyrosine kinase (KIT) and CD34; both of which are expressed in hematopoietic stem cells^[92-95]. In some studies, nestin expression has been identified in most GIST cases examined but not in leiomyomas^[25,96]. However, a subsequent study from the same group has shown that nestin is also highly expressed in gastrointestinal schwannomas; thus, nestin may not be a definitive marker for GIST^[96]. Nestin expression has also been reported in granular cell tumors, considered to be benign neoplasms of Schwann cell origin in the gastrointestinal tract^[97].

In the normal gastrointestinal tract, intestinal cells of Cajal (ICCs), which are localized between the circular and longitudinal muscle layers, express KIT and CD34. ICCs are assumed to originate from mesenchymal progenitor cells that can also differentiate into smooth muscle cells^[98,99]. Expression of nestin in the ICCs and GIST supports the hypothesis that GIST is derived from ICCs.

NESTIN IN PROSTATE CANCER

Nestin is highly expressed in androgen-insensitive prostate cancer cell lines, but it has not been detected in androgen-dependent prostate cancer cells^[27]. Furthermore, nestin has been localized in 75% of lethal androgen-independent prostate cancer cases, but is undetectable in localized androgen-deprived tumors and in metastases without prior androgen deprivation. Work using shRNA against nestin has shown a marked decrease of migration and invasion of prostate cancer cells *in vitro*, and nestin knockdown in prostate cancer cells inhibits lung metastasis of the cells^[27]. Furthermore, it has been reported that nestin is a tumor stem cell marker of prostate cancer^[36,100]. The underlying mechanisms have not been well examined, but nestin may be a novel therapeutic target for preventing the metastatic and cancer stem cell potential of prostate cancer.

NESTIN IN BREAST CANCER

In normal human breast tissues, nestin is expressed in the cells within the basal/myoepithelial layers^[26,101,102] and may be used as a myoepithelial marker. In one of these cell types, nestin is co-expressed with Δ N-p63. This finding, coupled with the role of Δ N-p63 in preservation of self-renewal, suggests that nestin may be expressed in the regenerative compartment within the mammary gland. Furthermore, nestin and Δ N-p63 are coordinately expressed during pregnancy in the murine mammary gland^[26].

Among the breast cancer subtypes, nestin is highly expressed in basal breast cancer subtype (ER α ⁻/PR⁻/Her2) but not in the Her2 subtype (ER α ⁻/PR⁺/Her2⁺) or luminal epithelial phenotype (ER α ⁺/PR⁺)^[26]. The other group showed that triple-negative breast cancers, which do not express ER, PR, and Her2, have higher expression rates for nestin than other breast cancers^[103]. Furthermore, nestin expression has been associated with shorter survival and shown to be an independent prognostic factor of breast cancer^[103]. Another group has reported significantly high nestin expression in basal-like and triple-negative breast cancers in a cohort of 245 patients with invasive breast cancer treated with surgery followed by anthracycline-based chemotherapy^[104]. These findings indicate that nestin is a selective marker of the basal breast cancer subtype (triple negative), which displays aggressive growth and has a poor prognosis. Co-expression of nestin and melatonin receptor 1 (MT 1) in breast cancer cells has been reported in patients with higher stages (T II / III) and with a high risk of relapse. Co-expression of nestin and MT 1 may correlate with invasive breast cancer and ad-

vanced tumors^[102]. Lymphovascular emboli of inflammatory breast cancer, a particularly lethal form of breast cancer characterized by exaggerated lymphovascular invasion, express stem cell markers including nestin^[105]. These data indicate that nestin correlates with an aggressive growth phenotype and lymphatic invasion.

NESTIN IN MALIGNANT MELANOMA

Nestin is expressed in benign nevi and melanoma but not in basal cell carcinoma^[106]. Nestin expression is higher at the advanced stage in melanoma and in metastatic foci of melanoma cells^[24,107]. Nestin staining in stage I and II melanoma patients significantly predicts poor survival, with lower survival rates in cases with nestin positivity in tumoral and endothelial cells^[108]. Furthermore, the 5-year survival rate exceeded 80% in nestin-negative melanoma at all stages of tumor development^[109]. Nestin and SOX9 and SOX10 transcription factors are co-expressed in melanoma cells, and downregulation of SOX9 and SOX10 markedly decreases nestin levels^[110,111]. Furthermore, nestin has been significantly associated with the presence of ulceration in primary tumors of melanoma and with SOX9 in the more advanced state. These findings indicate that nestin and SOX9 may be negative prognostic markers in melanoma. Nestin protein has been shown to occur most abundantly at the infiltrating front of the tumors, suggesting that nestin plays important roles in melanoma cell migration and invasion^[106].

Nestin expression in the peripheral blood of melanoma patients has been examined using flow cytometry, and expression is higher in stage IV patients as compared with stage III/IV with no evidence of the disease^[112,113]. Nestin thus may be an additional marker of interest for circulating melanoma cells in the future.

Immunohistochemically, melanoma antigen-encoding-1 (MAGE-1), melanocyte-specific transcription factor, tyrosinase, and Melan-A have been reported as useful markers in the diagnosis of melanotic parts when HMB-45 is negative^[114]. However, nestin has been more specifically detected in HMB-45-negative melanoma cells in the dermal portions of melanotic and amelanotic nodular melanomas^[115]. Nestin thus also may be a useful diagnostic marker for HMB-45-negative melanoma.

NESTIN IN OTHER TUMORS

Few reports have addressed nestin expression in other types of tumor cells. Its expression has been reported in various kinds of thyroid tumors, and nestin mRNA has been detected in differentiated thyroid tumors but not in anaplastic carcinoma^[22]. Nestin mRNA is also expressed in normal thyroid tissues, therefore, the authors of the above study have suggested that nestin mRNA is not associated with the malignant characteristics of thyroid tumors. Dermatofibrosarcoma protuberans (DFSP) is a dermal and subcutaneous neoplasm of intermediate malignancy that is invasive and locally aggressive with frequent recurrence.

Histopathologically, the differential diagnosis between DFSP and dermatofibroma (DF) is important because DF is benign^[28]. In one study, nestin was found to be strongly expressed in DFSP, while all DFs examined were nestin negative. Based on these findings, nestin may serve as an additional marker for DFSP and for surgical margin evaluation of DFSP.

NESTIN IN TUMOR ANGIOGENESIS

Tumor angiogenesis is an important factor in the proliferation, metastasis, and drug sensitivity of human neoplasms. A possible explanation of this metastatic mechanism is that the increased number of tumor vessels increases the chances for tumor cells to enter the circulation. Newly formed tumor vessels or capillaries have leaky and weak basement membranes; thus, tumor cells can penetrate these more easily than they can mature vessels^[116]. Furthermore, increased tumor vessels supply abundant oxygen and nutrition to the tumor cells. Angiogenesis in malignant tumors, as measured by microvessel density (MVD), has been reported to correlate with clinicopathological factors or survival in breast, ovarian, esophageal, gastric, colorectal, and prostate cancers, malignant melanoma, and non-small-cell lung carcinoma^[117-124]. CD34, CD31, and factor-VIII-related antigen are commonly used as endothelial cell markers of tumor vessels, and MVD is determined based on staining of blood vessels with these markers^[125-127]. However, the markers identify not only newly formed small tumor blood vessels but also pre-existing large blood vessels^[128].

Nestin expression in endothelial cells accompanying the process of angiogenesis has been reported^[129]. In pathological conditions, nestin is strongly expressed in proliferating endothelial cells in acute pancreatitis^[82] and vascular malformations^[130]. Furthermore, nestin has been reported to be a marker of proliferating endothelial cells in brain tumor tissues^[131] (Table 2). In gastric adenocarcinoma, MVD determined by nestin correlates better with patient survival than MVD determined by CD34 when the size of the carcinoma exceeds 5 cm^[37]. We examined the effectiveness of nestin as an angiogenic marker in colorectal cancer^[38]. Diameters of nestin-positive and CD34-positive vessels were compared in subcutaneous colorectal cancer tumors formed in nude mice. Nestin was localized in the endothelial cells in small tumor blood vessels, whereas CD34 was localized in large blood vessels in nude mice. Furthermore, the diameter of nestin-positive vessels was smaller than that of CD34-positive vessels in human colorectal cancer. The ratio of proliferating cell nuclear antigen (PCNA)-positive to nestin-positive vascular endothelial cells was higher than that of PCNA-positive to CD34-positive cells. These findings indicate that nestin is expressed in small-sized and proliferating tumor vessels in colorectal cancer. Further, prognosis is worse in the highly nestin-positive MVD population of colorectal cancer patients. In pancreatic cancer tissues, CD31 is expressed in endothelial cells of most blood vessels, while nestin is

Figure 2 Expression of nestin and CD31 in pancreatic cancer tissues. Nestin is expressed in endothelial cells of small blood vessels (A, arrowheads) and cancer cells (asterisks), whereas it is not detected in large blood vessels (arrows). CD31 is expressed in endothelial cells of most blood vessels (B, arrowheads and arrows), but not in cancer cells (B, asterisks) in pancreatic tissues. Immunohistochemistry: bar, 100 μ m.

specifically expressed in those of small-sized blood vessels (Figure 2).

Recently, co-expression of nestin and Ki-67 has been shown to be a vascular proliferation marker in prostate cancer^[39], and vascular proliferation is of independent prognostic importance among prostate cancer. Furthermore, vascular proliferation is significantly increased in castration-resistant cases and metastatic lesions compared with localized cancers. Very recently, nestin expression has been reported in the endothelial cells of bone metastatic lesions of prostate cancer^[40]. These results indicate that nestin correlates with tumor angiogenesis in primary and metastatic lesions, and that nestin may be a novel molecular target for inhibition of tumor angiogenesis, as are vascular endothelial growth factor receptors (Figure 3).

CONCLUSION

Nestin is highly expressed in various kinds of cancer cells and proliferating tumor vasculature. The roles of nestin in cancer cells have not been clarified fully, although nestin correlates with growth, migration, invasion, and metastasis of some cancers. Nestin is also highly expressed in proliferating vascular endothelial cells in cancer tissues and metastatic lesions. These findings indicate that this protein may become a new molecular target for nestin-positive

Figure 3 Tumor angiogenesis and nestin. Tumor cells induce neovascular formation, known as tumor angiogenesis. Formation of the neovasculature leads to tumor aggressiveness through tumor cell proliferation, invasiveness, metastasis, and refractoriness to therapy. Nestin expression has been reported in tumor vessels, and nestin may be a new molecular target for tumor angiogenesis.

cancer cells and tumor vessels. Furthermore, nestin is highly expressed in tumor stem cells in various tissues, and research concerning its expression and roles in various tumors may provide us important information about the origin of cancer stem cells and differentiation of cancer stem cells into cancer cells.

Abstract

Pegylated interferon α (IFN α) in combination with ribavirin is currently recommended as a standard-of-care treatment for chronic hepatitis C virus (HCV) infection. This combination therapy has drastically improved the rate of sustained virological response, specifically in difficult-to-treat patients. Recently, individualized treatment, such as response-guided therapy, is being developed based on host-, HCV- and treatment-related factors. Furthermore, modified regimens with currently available medications, novel modified IFN α and ribavirin or combinations with specifically targeted antiviral therapy for HCV agents, are currently being investigated. The purpose of this review is to address some issues and epoch-making topics in the treatment of chronic HCV infection, and to discuss more optimal and highly individualized therapeutic strategies for HCV-infected patients.

Key words: Pegylated interferon α ; Ribavirin; Chronic hepatitis C virus infection; Difficult-to-treat patient; Individualized treatment; Response-guided therapy; Specifically targeted antiviral therapy for hepatitis C virus

INTRODUCTION

Pegylated interferon α (peginterferon α , peg-IFN α) in combination with weight-based doses of ribavirin (RBV) is currently recommended as the first-line “standard-of-care” treatment for chronic hepatitis C virus (HCV) infection^[1]. The pegylated formulation prolongs the half-life of conventional IFN α by covalently binding it to the polyethylene glycol (PEG) molecule, leading to improvement in the overall rate of sustained virological response (SVR) from < 20% to > 60%; 40%-60% of “difficult-to-treat” genotypes 1 and 4 patients with 48-wk treatment, and 70%-90% of “easy-to-treat” genotypes 2 and 3 patients with 24-wk treatment^[1-5].

A recent trend in the treatment strategy of chronic HCV infection is the development of individualized treatment regimens based on strong predictors of SVR to IFN-based treatment, such as HCV genotype^[2-4,6-10] and the initial virologic response to treatment^[9,11-19]. Meanwhile, alternative options, such as modified regimens with currently available medications, novel modified IFN α and RBV or combinations with specifically targeted antiviral therapy for HCV (STAT-C) agents, are currently being investigated for the growing number of patients for whom current “standard-of-care” treatment has failed. For the

foreseeable future, however, peg-IFN α and RBV appear to remain the backbone of “standard-of-care” treatment.

This review addresses and summarizes some issues and epoch-making topics in the treatment of chronic HCV infection, and discusses more optimal and highly individualized therapeutic strategies for patients infected with HCV.

FACTORS ASSOCIATED WITH SVR

SVR is defined as an undetectable qualitative HCV RNA level (by using a qualitative polymerase chain reaction assay) at 24 wk after the completion of treatment. Identification of factors predictive of SVR, including host-, virus- and treatment-related elements, provides relevant insights about the mechanisms of action of IFN α and RBV. So far, numerous factors have been identified as significant predictors of SVR or non-SVR. Strong predictors of the response to non-pegylated IFN α monotherapy, such as HCV genotype, pretreatment viral load and fibrosis stage, are also significantly associated with the outcome of peg-IFN α plus RBV combination therapy. Most importantly, by recognizing these factors, therapy can be tailored to individual needs, helping to make decisions regarding whether treatment should be initiated, continued or stopped. Individualized treatment regimens determined according to outcome predictors should increase the SVR rate and reduce unnecessary patient and social burdens, such as medical costs, side effects/adverse events associated with treatment, and treatment-related absenteeism.

Host-related factors

A number of pretreatment factors are known to reduce the SVR rate: older age, presence of cirrhosis or advanced fibrosis, African American race, overweight, obesity, diabetes, low alanine aminotransferase (ALT), abnormal baseline fasting glucose, low level of cholesterol, low hemoglobin, low platelet count, insulin resistance and hepatic steatosis^[2-4,20-29]. The contribution of gender to treatment outcome is controversial as it varies among studies^[26,29-32].

The response to treatment of patients with genotype 1 has been reported recently to be strongly associated with a single nucleotide polymorphism (SNP) near the interleukin-28B (*IL28B*) gene that resides on chromosome 19 and encodes IL28B or IFN-lambda-3^[32-34]. Patients with favorable genotypes at the SNPs (such as rs12979860^[33], rs12980275 and rs8099917^[32,34]) near the *IL28B* locus are more likely to achieve SVR than those with unfavorable genotypes. At present, the SNPs near the *IL28B* locus seem to be one of the strongest pretreatment predictors of SVR to peg-IFN α plus RBV or triple combination therapy including STAT-C agents, in addition to the HCV genotype. The population distribution of the favorable SNP genotype is significantly more prevalent in the Caucasian and Asian populations than in African Americans. Specifically, rs12979860 shows close correlations with the SVR rate and ethnicity: rs12979860 C-allele frequency is the highest in East Asians who show the highest rate of SVR among diverse ethnic groups^[33]. Therefore, racial dif-

ferences in treatment outcome may arise from divergence in host genomic genotype related to treatment response. Individualized therapeutic strategies should always consider ethnicity of individual patients as well as SNPs. However, it is highly unlikely that SNPs could be used alone to define different treatment strategies, since approximately 30%-40% of patients do not have the favorable genotype CC of rs12979860^[33].

HCV-related factors

HCV genotype, pretreatment viral load and initial virologic response are strong independent predictors of SVR to IFN monotherapy^[6-15,18,19,35]. These factors also have significant and independent impact on treatment outcome of conventional IFN α /peg-IFN α plus RBV combination therapy or triple combination therapy with telaprevir^[2-4,16,17,21,22,28,29,36-40]. Patients infected with “easy-to-treat” genotypes 2 and 3 respond much better than those with “difficult-to-treat” genotypes 1 and 4. Furthermore, those with low pretreatment viral load respond much better than those with high pretreatment viral load, although the cutoff value that discriminates between high and low viremia varies among studies. The earlier the serum HCV RNA becomes negative during the initial phase of treatment, the greater the likelihood of achieving SVR.

Although there are relatively few data regarding genotypes 4, 5, and 6, HCV genotypes can be ranked, in a decreasing order of susceptibility to IFN-based treatment, as follows: genotypes 2, 3, 4 and 1. Furthermore, genotype 1a rather than 1b and genotype 2a rather than 2b are likely to respond better to IFN-based therapy. Interestingly, resistant variants against telaprevir (an NS3/4a protease inhibitor) and viral breakthrough occur more frequently in genotypes 1a than in 1b for telaprevir alone or in combination with peg-IFN α (with or without RBV)^[40-42]. The different frequency results from nucleotide differences at amino acid position 155 of the nonstructural (NS3) protease region between genotypes 1a (aga, encodes R) and 1b (cga, also encodes R). The amino acid substitution of R with K at the position (R155K), which is most frequently related to telaprevir resistance, requires only one nucleotide substitution in genotype 1a and two substitutions in 1b. Similarly, the emergence of the resistant mutant R155K against boceprevir (an NS3 protease inhibitor) differs between genotype 1a and 1b^[43]. Thus, HCV sub-genotype as well as HCV genotype should be taken into consideration in triple combination therapy with peg-IFN α /RBV/STAT-C agent.

Two recent reports discuss the influence of wild and mutant types in the core or NS5 region of the HCV genome on treatment outcome of peg-IFN α plus RBV combination therapy in Japanese patients with genotype 1 and high pretreatment viral load^[31,44].

Treatment-related factors

The doses of both peg-IFN α and RBV are important and have significant impact on SVR^[2]. The likelihood of SVR increases as RBV dose (measured in mg/kg) increases^[2,4]: patients who receive peg-IFN α -2b plus a RBV dose of

10.6 mg/kg per day or more have a greater chance of achieving SVR than those receiving lower RBV doses^[2]. Furthermore, the moving average of SVR rates increases as RBV dose increases up to about 13 mg/kg, and is almost level between 13 and 15 mg/kg. Combination therapy with peg-IFN α -2a plus RBV for 48 wk is more effective in HCV genotype 1 patients if the ribavirin dose is 1000 or 1200 mg/d rather than 800 mg/d^[4]. In many cases, hemoglobin concentrations decrease drastically due to RBV-related hemolytic anemia (especially during the first 4 wk), and it may be necessary to reduce RBV dose and/or to initiate the use of erythropoietin. Any reduction in the RBV dose during the first 12-20 wk of therapy could have a larger negative influence on SVR rates than reductions in peg-IFN α dose^[21,45,46], although maintaining RBV exposure over the whole duration of therapy is crucial^[47,48]. Furthermore, a reduction in peg-IFN α dose during the first 12 wk could reduce the rate of early virologic response (EVR, defined as at least a 2-log decrease from the baseline levels or no detectable viremia) by 10%, but an additional reduction in RBV dose during this time was shown to decrease the EVR rate by another 37%^[45].

Adherence is important to achieve SVR^[49] and patients who take at least 80% of the prescribed total dose of the two drugs for at least 80% of the planned time are considered to be adherent (the “80/80/80” rule). For genotype 1 patients with unfavorable factors, more intensive therapy is recommended including a higher dosage of RBV and a longer duration of treatment or the use of STAT-C agents (such as telaprevir) as the initial therapy. Recent direct comparative trials, retrospective and meta-analysis studies demonstrated that treatment with peg-IFN α -2a is a significant and independent contributor to SVR in patients infected with genotype 1 or 3, compared to treatment with peg-IFN α -2b^[25,26,28,29], although the largest head-to-head trial (IDEAL study) failed to find a significant difference in SVR rates between the two peg-IFN α formulations^[27].

On-therapy response

HCV kinetics during the early phase of treatment are closely associated with SVR or non-SVR^[11-15,18,19]. Patients with rapid virological response (RVR), defined as undetectable HCV RNA levels at treatment week 4, have a better likelihood of achieving SVR, and this is a strong independent on-therapy predictor^[19,50-54]. The viral response is influenced by host-, virus- and treatment-related factors: young age, lean body, low baseline viral load and HCV genotype^[55]. Conversely, the probability of SVR is less than 5% in patients with a minimal fall in viral load of $< 1 \log_{10}$ from the baseline level at treatment week 4, even when peg-IFN α and RBV are combined with telaprevir^[40].

EVR is an important on-therapy indicator of the final treatment outcome: 65% of EVR patients have been reported to show SVR^[3]. Those with no detectable viremia at week 12 (complete EVR) had SVR compared with those who had only a 2-log decrease from the baseline level (75% *vs* 33%). In contrast, a lack of EVR was associ-

ated with no SVR in 97% of the patients^[3]. Such viral suppression during the initial phase is of crucial importance to resolve persistent viremia.

RESPONSE-GUIDED THERAPY

The extent of reduction in HCV RNA during the initial treatment phase is closely associated with the likelihood of achieving SVR^[11-19]. The more rapidly HCV RNA becomes negative during treatment, the higher the rate of SVR. This fact suggests that the rapidity of viral response could be used to modify the duration of treatment, and hence the design of response-guided therapy (RGT). RGT is a dynamic treatment algorithm that involves individualized treatment based on the virologic response. Based on the briskness of the viral response, the treatment duration of 48 wk could be shortened to 24 wk or extended to 72 wk in patients infected with genotype 1 or 4, whereas 24-wk duration could be reduced to 12-16 wk in “easier-to-treat” genotype 2 or 3 patients. The rationale for extending the duration of treatment is to increase the likelihood of achieving SVR and to reduce virological relapse after treatment^[56-58]. Conceivably, the shortened treatment would improve the overall tolerability and reduce exposure to unnecessary medication and economic burden. Likewise, a shorter therapy would avoid premature termination of treatment, while maintaining satisfactory SVR rates.

Genotype 1 or 4

The time points usually used to decide whether treatment should be stopped or continued are treatment weeks 4, 12 and 24, which constitute the basis for RGT^[11,19]. Among genotype 1 or 4 patients with RVR, the likelihood of SVR is approximately 80%-90% when treated for 48 wk^[19,27,51,59,60]. The existence of this patient subpopulation encouraged investigators to shorten the treatment duration to 24 wk without lowering the SVR rate. In patients with RVR treated for 24 wk, the SVR rate was 79%-89% for genotype 1 and 86%-87% for genotype 4^[50,52,55,60]. Specifically, these studies showed that abbreviated 24-wk regimens are best suited to genotype 1 or 4 patients with low baseline viremia who achieve RVR.

In contrast, patients who respond later have a lower likelihood of SVR and greater probability of virologic relapse when treated for 48 wk^[2,3,5,18,19,45,49]. Furthermore, the likelihood of achieving SVR is little or none in patients who do not show EVR or undetectable HCV RNA at week 24. Accordingly, a 12-wk stopping rule is widely accepted in patients who fail to achieve EVR^[1]. However, the negative predictive value for SVR in such patients could be reduced from over 95% to 85% by extending the treatment duration to 72 wk. Several studies investigated whether extending treatment to 72 wk increases the SVR rate in patients without RVR randomized to 48- or 72-wk regimens (Table 1)^[56-58,61]. In genotype 1 patients without RVR (including those with EVR who become HCV RNA-negative for the first time at treatment week 24, so called slow viral response), prolongation of treatment from 48 to 72 wk increases the likelihood of achieving

SVR and reduces the probability of relapse. The rates of virologic response at the end of treatment and adverse events are similar between 48- and 72-wk regimens, although the rates of withdrawal from treatment and subsequent follow-up are higher in the latter than in the former.

However, some issues should be noted and carefully addressed to interpret the results of randomized controlled trials (RCTs), because they have differed in treatment regimens, criteria and time points for randomization, and study population. Firstly, to resolve these differences, investigators should identify patients who will benefit from 72-wk treatment, and the best time points and the response criteria to be used to prolong the duration of treatment. Secondly, it may be better to distinguish between “complete” (undetectable HCV RNA) and “partial” (> 2-log HCV RNA drop from baseline but detectable viremia) EVRs. Currently, we comply with the following recommendation for the extended 72-wk treatment in clinical practice: when patients do not achieve complete EVR but have slow viral response, they are advised to prolong the treatment to 72 wk. In the near future, it should be clarified whether extension of treatment to longer than 72 wk further would increase the SVR rate. Thirdly, it is not always clear whether patients with genotype 1 and 4 are treated in an identical manner in RGT, because the number of studied genotype 4 patients has been very small.

Genotype 2 or 3

Patients with genotype 2 or 3 are more susceptible to peg-IFN α plus RBV treatment than those with genotype 1 or 4, and the current recommendation advocates a 24-wk treatment course, because more than 80% of the former group will attain SVR^[4,22,37,38,45,62]. Several small studies showed that the treatment duration could be shortened from 24 to between 12 and 16 wk without adversely affecting outcome in patients with RVR at week 4^[36-38,62-64]. However, the results of large trials clearly indicated that shortening the treatment duration to 16, 14, or 12 wk significantly lessened the SVR rates, because of a higher rate of virological relapse^[39,62,65]. The results of these studies suggest that patients with RVR have high probability of achieving SVR regardless of treatment duration, but that the risk of relapse increases with abbreviated treatment. Still, the pros

and cons of the abbreviated treatment do not allow the making of a firm conclusion at present. Conversely, there is little information on the most suitable duration of treatment for patients with genotype 2 or 3 who do not achieve RVR. In this regard, there is a need to verify whether treatment week 4 is appropriate for prediction of outcome in genotype 2 or 3 patients, because the susceptibility to IFN-based therapy at the recommended duration of treatment apparently differs between genotypes 1/4 and 2/3.

Interestingly, there is ample evidence that peg-IFN α plus RBV treatment is more beneficial in patients infected with genotype 2 than those with genotype 3^[22,29,37,39,63,65]. This suggests that the two genotypes are not a homogeneous group, and that treatment regimens should perhaps be tailored or individualized for each genotype, with a special emphasis on the duration of treatment. Strictly speaking, the susceptibility to IFN-based treatment somewhat differs between sub-genotypes (e.g. genotype 1a *vs* 1b or genotype 2a *vs* 2b). For instance, treatment with peg-IFN α alone for 4 and 12 wk produced SVR rates of 91% and 100%, respectively, in genotype 2a patients with low viral load who became HCV RNA-negative at treatment week 1^[66]. Such subgrouping of patients with some strong predictors could further shorten the treatment duration with preservation of a high SVR rate.

Virologic response at critical time points, viral load at baseline, and HCV kinetics during the initial treatment phase provide useful information for tailoring or individualizing treatment to a given individual, leading to substantial reductions in both patient and society burdens without adversely affecting treatment outcomes.

DIFFERENCES BETWEEN PEG-IFN α -2a AND α -2b

Pegylation of therapeutic proteins modifies immunologic, pharmacokinetic and pharmacodynamic properties. Pegylation technology has been applied to improve these properties of conventional IFN α , to even out large fluctuating serum concentrations, and to resolve the inconvenient dosing regimens associated with conventional IFN α . The structure and size of the PEG moiety and covalent binding modes characterize the properties of the

modified biomolecule. Peg-IFN α -2a has a large, branched 40-kDa monomethoxy PEG, comprising two linked 20-kDa chains, attached to the lysine residues of IFN α -2a *via* amide bonds that are not susceptible to hydrolysis, and consists of 4 major positional isomers^[67]. In contrast, peg-IFN α -2b is pegylated with a small, linear 12-kDa monomethoxy PEG moiety and involves 13 positional isomers, with the main isomer linked to His-34 of IFN α -2b *via* a urethane bond that is unstable and susceptible to hydrolysis^[68]. These differences between the two peg-IFN formulations have an impact on the pharmacokinetic/pharmacodynamic properties.

Pharmacokinetic properties

The absorption half-life for peg-IFN α is longer than for unmodified IFN α (50 h and 4.6 h for 2a and 2b, respectively)^[69-71]. The absolute bioavailability of peg-IFN α -2a is at least 60%. The time to maximum concentration (T_{max}) is 78-80 h after a single dose and 45 h after multiple doses of peg-IFN α -2a, while T_{max} times are 15-44 h and 22-29 h, respectively, in dosing of peg-IFN α -2b. The serum concentration after a single dose of peg-IFN α -2a is sustained up to 168 h (elimination half-life, 65 h), and up to 48-72 h (elimination half-life, 40 h) for peg-IFN α -2b. At steady phase, which is attained 5-8 wk after initiation of treatment, the peak-to-trough ratio of serum concentrations of peg-IFN α -2a and -2b is 1.5-2.0 and > 10, respectively, indicating that serum concentrations of peg-IFN α -2a are sustained during the 1-wk dosage interval. Since variations in the peak-to-trough ratios for peg-IFN α -2b are greater than for peg-IFN α -2a, viremia levels tend to fluctuate more with peg-IFN α -2b than peg-IFN α -2a (at least within the initial 4 wk of treatment). The volume of distribution is dependent on the body composition because of the wide distribution of peg-IFN α -2b throughout body fluids and tissues, whereas peg-IFN α -2a exhibits restricted

distribution with the highest concentrations in the liver. Thus, peg-IFN α -2b requires weight-based dosing, while peg-IFN α -2a is used at a fixed dose.

Pharmacodynamic properties

Comparative studies of the initial viral kinetics after treatment have shown either a greater HCV RNA decline in patients treated with peg-IFN α -2a than those treated with peg-IFN α -2b^[71] or vice versa^[72], or no difference^[73]. Pharmacodynamic profiling studies of the two formulations also showed conflicting results. Single dosing induced a similar degree or pattern of activity of 2'-5'-oligoadenylate synthetase and serum protein levels of neopterin and β 2-microglobulin, indicating no difference between both types of peg-IFNs (plus RBV)^[74]. In contrast, another study showed that peg-IFN α -2b up-regulated IFN response genes significantly more than peg-IFN α -2a during the first 72 h after single dosing of each peg-IFN α , both administered without RBV^[72]. The enzymatic activity and serum protein levels were assayed in the former study, while RNA transcription was measured in the latter study. Furthermore, the methods and duration applied to evaluate various indicators differed between the two studies. Peg-IFN α was administered in combination with RBV during the evaluation period in the former, but not in the latter. Collectively, it is difficult to draw definite conclusions by simply comparing the results of relatively small studies, which have varied in several respects including the aforementioned differences.

Head-to-head comparison

Which of the peg-IFNs is more effective in combination therapy with RBV for chronic hepatitis C? So far, several head-to-head studies have compared peg-IFN α -2a *vs* -2b in combination with RBV (Table 2).

Two investigator-initiated, independent, single-center,

randomized, controlled, head-to-head trials compared peg-IFN α -2a *vs* -2b in combination with RBV for 48 wk (genotype 1 or 4) or 24 wk (genotype 2 or 3). Peg-IFN α -2a plus RBV produced a significantly higher SVR rate than peg-IFN α -2b plus RBV in treatment-naïve patients^[28,29]. In a prospective observational cohort study (PROBE, sponsored by Roche), the rate of SVR was higher in genotype 1 patients treated with peg-IFN α -2a than with peg-IFN α -2b (36% *vs* 29%, $P = 0.02$)^[26]. In a retrospective observational cohort study (PRACTICE), matched pair analysis also showed a significant difference in the SVR rate between peg-IFN α -2a and -2b treatments (59.3% *vs* 53.0%, $P = 0.008$)^[75]. An observational retrospective cohort study at the Veteran Hospitals in the United States also reported that treatment with peg-IFN α -2a was associated with a higher likelihood of SVR than treatment with peg-IFN α -2b (25% *vs* 18%, $P < 0.001$)^[25]. These studies have highlighted the superiority of peg-IFN α -2a over peg-IFN α -2b in the critical end-point of efficacy.

In contrast, the largest multicenter, randomized, head-to-head trial (IDEAL study, sponsored by Schering-Plough) showed no statistical difference in SVR rates among treatment arms with low-dose (1.0 μ g/kg per week) or standard-dose (1.5 μ g/kg per week) peg-IFN α -2b or peg-IFN α -2a (180 μ g/wk), in combination with various RBV regimens (38.0%, 39.8% *vs* 40.9%, respectively)^[27]. However, there were some differences between the IDEAL and other studies that could be described as critical limitations: (1) RBV regimens differed in initial doses and dose reduction rules between the treatment arms or studies; (2) the IDEAL study compared treatment regimens but did not directly evaluate the difference between the two peg-IFNs; (3) the dosing rules seem inappropriate by current standards in some studies; and (4) the IDEAL study included higher proportions of overweight, obese, and black/Latino patients. Using the same dosing and dose reduction rules of RBV across all the treatment arms and studies might have provided a fairer comparison of the different performance of the two peg-IFNs without a confounding effect of various RBV regimens. In the two studies where RBV dosing was identical between the two arms (one RCT and one cohort-matched pair analysis)^[29,75], the difference in favor of peg-IFN α -2a was maintained. Interestingly, the safety and adverse-event profiles were similar among the treatment arms in the above studies, irrespective of the RBV regimen.

A recent Cochrane systematic review of randomized trials that compared both peg-IFNs identified 12 studies (5008 participants)^[76]. Meta-analysis using intention-to-treat analysis for SVR included 8 trials (4335 participants), and yielded an estimated effect in favor of peg-IFN α -2a [47% *vs* 41% with peg-IFN α -2b; risk ratio = 1.11; 95% confidence interval (CI): 1.04-1.19, $P = 0.004$]. Subgroup analyses with regard to HCV genotype yielded similar results for all subgroups. The meta-analysis of adverse effects leading to discontinuation of treatment included 11 trials and showed no significant differences between the two peg-IFNs. However, the study did not reach a definitive conclusion as to which of the two peg-IFN formulations in combination with RBV is superior across popula-

tions based on more appropriate RBV dosing.

Taken together, all these studies involve several relevant methodological flaws (such as mixed genotypes, inclusion of prior non-responders and co-infected patients, small samples, insufficient power, and different RBV doses and dose reduction rules) that preclude, at least for the time being, any firm conclusions about differences in efficacy between the two peg-IFN α formulations.

TREATMENT OF DIFFICULT-TO-TREAT PATIENTS

Advances in IFN-based treatment for chronic hepatitis C, such as the development of peg-IFN α and RBV and treatment modifications, have improved the SVR rates in patients with difficult-to-treat characteristics, such as genotype 1/4, high baseline viral load, previous non-response, overweight, and the presence of cirrhosis. However, the outcomes of treatments in such patients are still inadequate. Further treatment development for this difficult-to-treat population is necessary.

Re-treatment of non-responders

For the increasing number of non-responders to IFN-based treatment or patients with multiple difficult-to-treat features, retreatment with current standard combination^[21,77] or alternative options, such as maintenance therapy with peg-IFN^[78-81] or the use of higher doses^[82-84] and/or extended duration of treatment^[85], have been explored vigorously. Most retreatment options for non-responders have provided a limited chance of SVR and in fact have been associated with increased side effects. In contrast, treatment-naïve patients with several difficult-to-treat predictors of poor response are reported to gain from aggressive modification of the treatment regimens and show higher SVR rates.

The SVR rate with retreatment consisting of standard peg-IFN α -2b plus RBV regimen was 12% in non-responders to prior treatment with conventional IFN α /RBV or peg-IFN α /RBV who had detectable HCV RNA at retreatment week 12^[77]. The SVR rate with standard peg-IFN α -2a plus RBV regimen was 18% in non-responders (with advanced fibrosis/cirrhosis) to prior conventional IFN-based treatment who had undetectable HCV RNA at retreatment week 20^[21]. A randomized retreatment study for non-responders to prior peg-IFN α -2b plus RBV compared 48-wk *vs* 72-wk treatment duration using higher induction dose (360 μ g weekly for 12 wk) or standard dose peg-IFN α -2a (180 μ g weekly) plus RBV^[85]. Although the extended treatment duration rather than higher induction dose significantly increased SVR rates (16% for 72 wk *vs* 8% for 48 wk, $P < 0.001$), the SVR rate was unsatisfactorily low: 16% for the 72-wk/higher induction dose group, 14% for the 72-wk/standard dose group, 7% for the 48-wk/higher induction dose group, and 9% for the 48-wk/standard group. However, the study showed that SVR rates were higher in patients with undetectable HCV RNA at re-treatment week 12 (49%) compared to those with detectable HCV RNA at re-

treatment week 12 (4%). Despite differences in the study population and design among these retreatment trials, most of them have produced modest SVR rates ranging from 7% to 18%. A recent meta-analysis indicated that the pooled estimate of SVR rate was 16.3% with a 95% CI of 8.3%-29.6%, although there was a significant heterogeneity among the studies ($P < 0.0001$)^[86].

Difficult-to-treat naïve patients

In contrast, treatment-naïve patients, even with multiple unfavorable factors, may show a favorable treatment outcome with aggressive treatment regimens. A pilot study of peg-IFN α -2b administered twice weekly in combination with RBV showed a significantly higher SVR rate among treatment-naïve patients with genotype 1/4 and high baseline viral load (55% *vs* 17% with the standard regimen)^[83]. In another study, a very high dose of RBV based on an individualized schedule yielded a very high SVR rate with the combination of peg-IFN α -2a for treatment-naïve patients with genotype 1 and high baseline viral load, although this was a very small pilot study^[82]. A pilot, double-blind, RCT for treatment-naïve patients with multiple predictors of poor treatment response (genotype 1, high baseline viral loads of $> 800\,000$ IU/mL, and body weight > 85 kg) showed that high fixed doses of peg-IFN α -2a (270 μ g/wk) and RBV (1600 mg/d) increased SVR rates compared with lower, conventional doses of both agents (180 μ g/wk and 1200 mg/d, respectively)^[54]. Week 48 end-of-treatment virologic response and SVR rates were 55% *vs* 46% and 47% *vs* 28%, respectively, suggesting that a more aggressive treatment approach could improve the virologic response and suppress relapse, although increasing the dose of RBV alone did not reduce relapse or substantially improve the SVR rates. However, the initial 12-wk induction with high dose of peg-IFN α -2b (3.0 μ g/kg per day) failed to produce a positively favorable treatment outcome in treatment-naïve genotype 1 patients, compared to standard regimen^[84].

Taken together, non-responders to a prior 48-wk course of standard peg-IFN α plus RBV combination who have no virologic response at retreatment week 12 are the most difficult-to-treat population. Such non-responders may have a cluster of difficult-to-treat characteristics or yet undiscovered resistant factors. The overall modest efficacy in non-responders argues against an indiscriminate retreatment with peg-IFN α and RBV. Restricting retreatment to patients with favorable factors or less unfavorable conditions, using a 12-wk treatment stopping rule, would optimize the potential benefit with little likelihood of missing a curative response. For instance, relapsers with earlier virologic response to the prior treatment, and patients infected with genotype 2 or 3, would be possible candidates for successful retreatment. For treatment-naïve patients even with multiple predictors of poor treatment response, aggressive treatment regimens using currently available medications could significantly improve the likelihood of achieving SVR.

STAT-C AGENTS

A large number of STAT-C agents have been developed and are currently being tested in phase 1-3 trials^[87,88]. Adding STAT-C agents to peg-IFN α plus RBV should provide new treatment options for chronic hepatitis C. Recently, the Protease Inhibition for Viral Evaluation (PROVE, evaluating telaprevir) and Serine Protease Inhibitor Therapy (SPRINT, evaluating boceprevir) clinical trials have suggested that protease inhibitors combined with peg-IFN α plus RBV could produce SVR rates of 70%-75% in treatment-naïve genotype 1 patients^[40,89,90]. Telaprevir and boceprevir, orally bioavailable inhibitors of the HCV NS3 protease, are two of several investigational agents that specifically and directly target HCV with increased likelihood of SVR. In the PROVE studies, discontinuation of treatment because of adverse events was more frequent in telaprevir-based groups, with rash the most common reason for discontinuation. The frequencies of pruritus, rash and anemia were increased in telaprevir-based groups^[40,89,91]. In the SPRINT-1 study, the most common adverse events leading to discontinuation in boceprevir regimens were fatigue, nausea, depression, neutropenia and anemia. Incidence of rash-related adverse events was similar in boceprevir regimens and control^[90].

More recently, the results of the PROVE-3 study showed that retreatment with telaprevir in combination with peg-IFN α -2a plus RBV was more effective than retreatment with peg-IFN α -2a plus RBV alone in patients who failed to show SVR to the initial full course of peg-IFN α plus RBV^[91]. The SVR rates of the three telaprevir-treated groups: 51% in the T12PR24 group [telaprevir (1125-mg loading dose, then 750 mg every 8 h) for 12 wk and peg-IFN α -2a (180 μ g weekly) and weight-based RBV (1000 or 1200 mg/d) for 24 wk], 53% in the T24PR48 group (telaprevir for 24 wk and peg-IFN α -2a and RBV for 48 wk), and 24% in the T24P24 group (telaprevir and peg-IFN α -2a for 24 wk), were significantly higher than that of the PR48 (control) group (peg-IFN α -2a and RBV for 48 wk; 14%; $P < 0.001$, $P < 0.001$ and $P = 0.02$, respectively). Patients with a previous relapse in the T12PR24 and T24PR48 groups had SVR rates of 69% and 76%, respectively. Of note, those with a previous non-response had SVR rates of 39% and 38%, respectively, which are the highest reported to date and more than four times the SVR in the control group (9%). The higher discontinuation rates and the lower relapse rates in the T24PR48 group compared with the T12PR24 group suggest that an optimal retreatment regimen may consist of a shorter period of treatment with telaprevir combined with a longer period of treatment with peg-IFN α and RBV.

In the SPRINT-1 study, boceprevir in combination with peg-IFN α -2a (P) plus RBV (R) was more effective than P/R for 48 wk (control)^[90]. The SVR rates of four boceprevir-treated regimens: 56% or 75% after 4 wk of P/R lead-in followed by P/R/boceprevir for 24 or 44 wk, and 55% or 67% after P/R/boceprevir for 28 or 48 wk, were significantly higher than that of the control (38%; P

= 0.0048, < 0.0001, = 0.0082 and < 0.0001, respectively). 48-wk boceprevir regimens had very low relapse rates. However, P/low-dose R/boceprevir for 48 wk was associated with increased viral breakthrough (27%), relapse (23%) and lower efficacy (36%).

The addition of STAT-C agents, such as telaprevir, to current standard treatment adds promising antiviral activity and is one of the most powerful retreatment strategies, especially for the non-responder population.

LONG-TERM EFFECT OF IFN TREATMENT ON THE PROGRESSION OF LIVER DISEASES

Retrospective cohort studies and preliminary randomized controlled trials

There are few satisfactory medical treatments for patients who do not achieve SVR in response to IFN-based treatment. In such patients, the liver disease could progress to cirrhosis, hepatocellular carcinoma (HCC) and liver failure, culminating in liver disease-related death. Earlier retrospective cohort studies suggested that conventional IFN treatment reduces the risk of HCC even in patients who are treated with a single course as brief as 6 mo and who show transient biochemical response but fail to eradicate HCV^[92-95]. In these non-randomized analyses, the short- or long-term efficacy of conventional IFN or impact of the treatment outcome on the clinical end point were evaluated based on serum ALT levels, but not the degree of viral response because serum HCV RNA levels were not monitored. These studies included patients with various liver disease stages (degree of fibrosis) and perhaps those with SVR at a certain rate. The SVR induced by conventional IFN treatment apparently provides a long-term benefit by reducing liver-related death^[96]. As shown by other retrospective cohort studies, it is conceivable that achievement of SVR following IFN-based treatment would reduce the risk of adverse clinical outcomes (liver-related complications, HCC and liver-related mortality) even in patients with cirrhosis or advanced fibrosis, compared to non-SVR^[97-99]. Furthermore, a small, prospective RCT suggested that even a single, brief (24-wk) course of conventional IFN treatment for patients with compensated cirrhosis (grade A on the Child-Pugh scoring system) could slow liver disease progression and reduce the cumulative incidence of HCC and mortality in the very long-term clinical course^[100]. Another RCT of extended conventional IFN treatment to 30 mo showed suppression of HCV RNA levels and reduction in serum ALT levels and histologic findings (necroinflammation and fibrosis) in non-responders to 6-mo conventional IFN treatment but with a histologic response^[101]. In that preliminary study, the majority of patients did not have advanced fibrosis or cirrhosis, and the impact of maintenance treatment on morbidity and mortality was not assessed. These favorable results encouraged clinicians to prevent progressive liver disease, including development of HCC and progression to cirrhosis and liver failure, with IFN-based maintenance

treatment even in patients with advanced fibrosis or cirrhosis. However, most of the following prospective RCTs did not recommend long-term maintenance treatment for such patients.

Randomized controlled trials for advanced fibrosis and cirrhosis

A large, prospective RCT [the Hepatitis C Antiviral Long-term Treatment against Cirrhosis (HALT-C) trial] also showed that maintenance treatment of peg-IFN α -2a at a dosage of 90 μ g weekly for 3.5 years correlated significantly with decreases in serum HCV RNA levels, serum ALT levels and histologic necroinflammatory scores, compared to no treatment ($P < 0.001$), in patients with advanced fibrosis who had not achieved SVR to a standard regimen of peg-IFN α -2a plus RBV^[80]. Nevertheless, the maintenance treatment failed to reduce the rate of disease progression, as indicated by death, HCC, hepatic decompensation, or increase in the fibrosis score, in those with or without cirrhosis: 34.1% in the treatment group *vs* 33.8% in the control group ($P = 0.90$). Among patients with bridging fibrosis at baseline, cirrhosis developed by year 3.5 at rates similar in the two groups (28.2% *vs* 31.9%, respectively). Conversely, the rate of at least one serious adverse event was higher in the treatment group (38.6%) than in the control group (31.8%, $P = 0.07$).

In a substudy of the HALT-C trial, profound viral suppression by $\geq 4 \log_{10}$ with standard-dose peg-IFN plus RBV during the 24-wk lead-in phase was significantly related to fewer clinically critical events ($P = 0.003$) over the ensuing 3.5 years, regardless of whether randomized to maintenance therapy or no treatment^[81]. Unexpectedly, persistent viral suppression by $\geq 4 \log_{10}$ with maintenance therapy did not lead to a further reduction in clinical events. Thus, there is no rationale for peg-IFN α maintenance therapy in patients without viral suppression to undetectable levels during the treatment. Strangely, profound viral suppression even for a relatively brief period during the lead-in phase may be associated with clinical benefits.

In a small RCT, patients with biopsy-proven compensated cirrhosis who had at least one risk factor of complications were randomized to either conventional IFN α -2a (3 MU three times weekly) or no treatment for 24 mo^[102]. In the Colchicine Versus Peginteron Long-term Therapy (COPILOT) trial, patients with advanced fibrosis or cirrhosis who were non-responders to either conventional IFN or peg-IFN α with or without RBV were randomized to receive either peg-IFN α -2b at a dose of 0.5 μ g/kg per week or colchicine for 4 years^[78]. In the study design of the Evaluation of Peginteron in Control of Hepatitis C Cirrhosis (EPIC3) trial, non-responders to a lead-in treatment phase of peg-IFN α -2b plus RBV were randomized to receive either peg-IFN α -2b at a dose of 0.5 μ g/kg per week or no treatment for up to 3 years^[79]. Despite differences in the study design, the results of these trials were similar to those observed in the HALT-C trial; maintenance therapy with conventional IFN or peg-IFN α has little or no impact on prevention of progressive liver disease or complication-free survival in patients with advanced fibrosis

or cirrhosis. In the COPILOT and EPIC3 trials, however, maintenance therapy reduced complications almost exclusively in patients with portal hypertension.

The results of these prospective RCTs contradict those of the majority of retrospective, non-randomized cohort studies and earlier preliminary prospective RCTs. There were some differences among studies: the end points of disease events, inclusion criteria for the study, patients' background involving wide-ranging fibrosis stage or advanced fibrosis/cirrhosis, race, and life-style (high calorie, cigarette smoking, or alcohol intake), and evaluation on the basis of the degree of viral suppression or decline in serum ALT. It is not clear why control patients in previous retrospective studies did not receive IFN-based treatment for long-term periods. These uncertainties may tip the balance in favor of the IFN-treated patient group. At the least, maintenance treatment with low-dose peg-IFN α or conventional IFN for 2-3.5 years does not appear to prevent disease progression in patients with advanced fibrosis/cirrhosis and persistent viremia, and thus provides no overall benefit to such patients. If maintenance therapy leads to profound viral suppression, it can potentially prevent progressive disease and liver-related complications.

NEW INTERFERON AND ALTERNATIVE FORMS OF RIBAVIRIN

The clinical trials of STAT-C agents, PROVE and SPRINT^[40,89,90], suggest that peg-IFN α -2a or -2b and standard-dose RBV are required as indispensable components even in new combination regimens with the first-generation protease inhibitors, because treatment arms without ribavirin in the PROVE2 trial and with low-dose RBV in the SPRINT-1 trial showed increased viral breakthrough, higher relapse, and lower SVR. However, the addition of telaprevir or boceprevir resulted in higher rates of treatment discontinuation because of adverse events (rash, pruritus, and anemia), compared with the control arm. Furthermore, pre-existing resistant variants and naturally occurring resistance-related mutations against STAT-C agents would disturb the efficacy of "add-on" triple combination therapy^[41,103]. To overcome these disadvantages resulting from the addition of STAT-C agents, alternative approaches to new treatment strategies are needed to increase the SVR rates and reduce adverse events by altering formulations of IFN and RBV.

Albinterferon

Recombinant human albumin-interferon α -2b (albinterferon, alb-IFN), a novel formulation of IFN α , is an 85.7-kDa protein consisting of IFN α -2b genetically fused to human albumin. In an *in vitro* study using liver cell-based and non-liver cell-based HCV replicon cell lines, alb-IFN preserved the antiviral properties of IFN α with significant suppression of HCV RNA at clinically relevant serum concentrations^[104]. In a study of monkeys, alb-IFN had a prolonged elimination half-life, and consequently provided greater exposure relative to IFN α ^[105]. In dose-

-ranging phase 1/2 studies involving IFN-experienced and naïve patients, alb-IFN administration of up to 1200 μ g at 14-d intervals demonstrated a favorable safety profile, the half-life was extended to approximate 144 h, and antiviral activity increased in a dose-dependent manner^[106,107]. Alb-IFN was detectable throughout the entire dosing interval, corresponding to viral dynamic changes observed at doses of 900-1200 μ g.

A phase 2b trial randomized naïve genotype 1 patients to four treatment arms: peg-IFN α -2a (180 μ g once weekly), alb-IFN [900 or 1200 μ g once every two weeks (q2wk), or 1200 μ g once every four weeks (q4wk)] plus weight-based RBV (1000 or 1200 mg/d) for 48 wk^[108]. The SVR rates in the 900- μ g q2wk- and 1200- μ g q2wk-alb-IFN groups (59% and 56%, respectively) were comparable to that in the peg-IFN α -2a group (58%), while SVR rate in the 1200- μ g q4wk-alb-IFN group was lower (51%, $P = 0.28$). The discontinuation rates due to adverse events were comparable among the 900- μ g q2wk- and 1200- μ g q4wk-alb-IFN and peg-IFN α -2a groups (9%, 12%, and 6%, respectively), and higher for 1200- μ g q2wk-alb-IFN (18%, $P = 0.04$). Another trial compared five alb-IFN-based regimens for non-responders to prior IFN-based treatment: 1200- μ g q4wk and 900-, 1200-, 1500-, and 1800- μ g q2wk plus RBV for 48 wk^[109]. Although the overall SVR rate was only 11% for previous genotype 1 non-responders to peg-IFN α plus RBV, the trial suggested the potential advantage of higher doses of alb-IFN (1800 μ g q2wk) and its promising antiviral activity. Taken together, alb-IFN is likely to have overall efficacy and safety profiles comparable to those of peg-IFN α -2a, with the convenience of a 2-wk to 4-wk interval dosing schedule. Interestingly, alb-IFN improves patients' psychological condition and reduces missed workdays, and could further reduce the immunogenicity of IFN, compared to peg-IFN α .

Taribavirin (Viramidine)

Hemolytic anemia induced by RBV can cause fatigue, affect quality of life, and consequently result in dose reductions, which could lower the chance of SVR^[2,3,45,49,110,111]. Erythropoietin preparations used to alleviate anemia and maintain RBV dose substantially increase medical expenses and may induce adverse effects^[46,112]. Some protease and polymerase inhibitors exacerbate anemia observed with peg-IFN α plus RBV combination treatment^[40,89]. Such cases strongly emphasize the need for an RBV analogue to alleviate hemolytic anemia.

Taribavirin (TBV, previously known as viramidine) is a prodrug of RBV being developed for combination treatment with peg-IFN α , in expectation of a lower incidence of anemia. The agent is a guanosine analogue that is primarily taken up by the liver and is rapidly converted to RBV by adenosine deaminase^[113-116]. TBV-derived RBV is concentrated in the liver at three-fold the rate of native RBV^[116]. Furthermore, TBV containing a positively charged 3-carboxamide group accumulates poorly in red blood cells (RBCs) and reduces RBV concentration in RBCs by half^[114-116].

A phase 2 dose-ranging comparison of TBV *vs* RBV combined with peg-IFN α -2a (180 μ g/wk) evaluated TBV doses of 800, 1200 and 1600 mg/d and RBV at a weight-based dose of 1000 or 1200 mg/d^[117]. The SVR rates were lower in the TBV groups than in the RBV group (23%, 37%, 29% *vs* 44%), although anemia was significantly less in the TBV groups. The phase 3, double-blind, ViraMidine's Safety and Efficacy versus Ribavirin 1 (ViSER1) study for naïve patients compared the safety and efficacy of flat-dose TBV (1200 mg/d) *vs* weight-based RBV (1000 or 1200 mg/d) in combination with peg-IFN α -2b (1.5 μ g/kg per week)^[118]. The SVR rates were 38% and 52%, respectively. The VR rate at every time point during the study was lower, and the relapse rate was higher in the TBV group. Thus, flat-dose TBV failed to show non-inferiority efficacy compared to weight-based RBV, suggesting that the dosage of TBV (1200 mg/d) is suboptimal or insufficient at least for a proportion of patients. However, the incidence of hemoglobin (Hb) events (Hb < 10 g/dL or a decrease of \geq 2.5 g/dL from baseline) was significantly lower with TBV (55%) than with RBV (84%, $P < 0.001$). More patients were encountered in the TBV arm with diarrhea (30%) compared to the RBV arm (20%). The incidence of moderate or severe diarrhea in the former group was double that in the latter (10% *vs* 5%, respectively).

The ViSER2 study showed similar results of efficacy and safety^[119]. It was performed with the same study design, except for the usage of peg-IFN α -2a (180 μ g once weekly, instead of peg-IFN α -2b). The SVR rate was 40% in the flat-dose TBV group and 55% in the weight-based RBV group. TBV was significantly superior to RBV in Hb event rates (54% *vs* 80%, $P < 0.001$). The rates of adverse events were similar between the groups except for diarrhea (TBV 30%; RBV 16%, $P < 0.0001$).

Similar to RBV, TBV appears to improve the SVR rate with higher TBV exposure based on body weight (mg/kg), and a dosage of > 18 mg/kg may be needed to produce SVR rates comparable to those of weight-based RBV^[118,119]. Therefore, further studies of TBV administered on a weight-based dosing schedule are required to determine the optimal dosage that would yield superior efficacy to, or at least comparable to, RBV, with preservation of the safety profile.

CONCLUSION

In summary, more optimal and highly individualized therapeutic strategies for HCV-infected individual patients are currently being investigated and developed, such as response-guided therapy, modified regimens with currently available medications, novel modified IFN α and RBV or combinations with STAT-C agents. In the foreseeable future, these ceaseless efforts will relieve a large number of HCV-infected patients all over the world.

ease (CD) is an important clinical challenge of considerable therapeutic significance. The problem is of greatest magnitude in countries where tuberculosis continues to be highly prevalent, and where the incidence of CD is increasing. The final clinical diagnosis is based on a combination of the clinical history with endoscopic studies, culture and polymerase chain reaction for *Mycobacterium tuberculosis*, biopsy pathology, radiological investigations and response to therapy. In a subset of patients, surgery is required and intraoperative findings with pathological study of the resected bowel provide a definitive diagnosis. Awareness of the parameters useful in distinguishing these two disorders in each of the different diagnostic modalities is crucial to accurate decision making. Newer techniques, such as capsule endoscopy, small bowel enteroscopy and immunological assays for *Mycobacterium tuberculosis*, have a role to play in the differentiation of intestinal tuberculosis and CD. This review presents currently available evidence regarding the usefulness and limitations of all these different modalities available for the evaluation of these two disorders.

Abstract

Differentiating intestinal tuberculosis from Crohn's dis-

INTRODUCTION

Tuberculosis (TB) of the gastrointestinal tract and Crohn's disease (CD) are chronic granulomatous disorders with similarities in their clinical presentation and pathology. The rising incidence of CD in countries like India where TB continues to be endemic has made the differentiation of these two disorders a diagnostic challenge^[1-4]. Misdiagnosis leads to delays in initiating effective therapy with increased morbidity and mortality, hence the importance of making an accurate diagnosis at the earliest possible stage. Despite the similarities of these two disorders a number of studies have identified specific differences in their clinical, endoscopic, radiological and pathologic findings. Other laboratory tests such as culture and molecular testing for *Mycobacterium tuberculosis* (MTB) have also been described to be useful in distinguishing them, as has been their response to therapy^[5,6]. In this review we present current evidence from the literature regarding conventional and new modalities that could be helpful in discriminating intestinal TB from CD.

CLINICAL FEATURES

Clinical features in both diseases include (1) constitutional symptoms such as fever, anorexia and weight loss; (2) symptoms due to mucosal ulceration such as diarrhea, hematochezia and malabsorption; (3) symptoms due to transmural involvement such as abdominal pain, and distention and vomiting due to luminal obstruction; a palpable lump; intestinal perforation and perianal and intestinal fistulization; (4) extra-intestinal manifestations such as arthritis and sclerosing cholangitis in the case of CD and involvement of other organs such as joints, lungs, peritoneum and lymph nodes in the case of TB; and (5) a family history of inflammatory bowel disease (IBD) in the case of CD or a history of family contacts in the case of TB^[7,8].

In patients with CD the duration of illness is generally more than 12 mo while it is shorter, lasting around 6 to 7 mo, in intestinal TB^[7]. Diarrhea and hematochezia are more commonly seen in CD while fever, ascites and co-existing TB at other sites are seen in gastrointestinal TB. Perianal disease, malabsorption and recurrence of disease after surgery are in favor of CD. A family history of IBD may be seen in 10% of patients with CD. Extra-intestinal involvement due to tuberculosis is seen in a third of patients with intestinal TB^[7,9]. A high index of clinical suspicion is required, however, to differentiate between the two conditions clinically.

SEROLOGY

Abnormalities in routine blood tests such as total and differential leukocyte count, raised ESR, C-reactive protein and low hemoglobin are seen in the active phase of both intestinal TB and CD^[5,7]. Platelet counts may be raised in the active phase of CD due to reversible hyposplenism and may increase the suspicion of CD over intestinal TB. One study on a small number of patients with intestinal

TB showed that only one of 14 (7%) patients had a positive result to enzyme-linked immunosorbent assay (ELISA) against anti-*Saccharomyces cerevisiae* antibody (ASCA) in serum in contrast to 49% with CD^[10], therefore, the authors recommended use of this test for differentiation between CD and intestinal TB. However, two studies from India involving a larger number of patients showed that ASCA was not useful in differentiating between CD and TB^[11,12]. Almost half of the patients with intestinal TB in both studies were ASCA-positive, which was comparable to the frequency in patients with CD. ASCA is a non-specific antibody resulting from macromolecular transport of food antigens (including antigens contained in baker's yeast), partly resulting from an increase in intestinal permeability. Since patients with intestinal TB have chronic inflammatory lesions of the small intestine, similar to patients with CD with increased small intestinal permeability, frequent positive results with the ASCA test in the former condition is quite expected^[11].

CULTURES

The most reliable method to differentiate between intestinal TB and CD is demonstration of acid-fast bacilli (AFB) either in smears or by culture. However, smear and culture to demonstrate MTB have low sensitivity. Furthermore, *Mycobacteria* take a very long time (4-6 wk) to grow in culture. Identification of AFB on intestinal biopsies has been reported with variable frequency (25%-36%)^[5,7,13]. MTB was cultured from mucosal biopsies only in one third of patients with colonic TB^[14]. The use of fluorescent stain for the diagnosis of intestinal TB increases sensitivity but lacks specificity and results are still poor due to the paucibacillary nature of the disease^[7]. The time to recovery of *Mycobacteria* from culture has been shortened to 2-3 wk by the use of automated culture systems such as BACTEC, *Mycobacteria* growth indicator tube (MGIT), MB/BacT mycobacterial detection system and the ESP culture system II^[15]. The sensitivity of the BACTEC system was found to be poor, however, for the diagnosis of intestinal TB^[7,8]. In the MGIT system, a fluorescent compound is embedded in silicone at the bottom of the tube. This compound is sensitive to dissolved oxygen in broth. As the actively growing bacteria consume the dissolved oxygen, the fluorescence is unmasked and can be observed in the tube under long wave UV light^[16]. MB/BacT is a colorimetric, non-radiometric method of detection of mycobacterial growth, which uses Middlebrook 7H9 media in an atmosphere of CO₂, H₂ and O₂ under vacuum. In ESP culture system II, each culture bottle is continuously monitored for any change in gas pressure due to metabolic activity of the microorganism^[16]. These systems, however, need to be evaluated for the diagnosis of intestinal TB.

POLYMERASE CHAIN REACTION FOR MTB

The TB polymerase chain reaction (PCR) assay is based on

augmenting oligonucleotides found in MTB chromosomes that are highly specific for the organism. TB PCR analysis of endoscopic biopsy specimens or surgical specimens can be done quickly and results can be obtained within 48 h^[17]. This test is very specific for TB but occasionally may be positive in patients with CD^[18,19]. Sensitivity of this test is modest and there is no correlation between PCR positivity and histological lesions such as caseation or granulomas^[17,18]. *In situ* TB PCR and analysis of fecal samples of patients with gastrointestinal TB have been shown to be useful in small studies^[14,20], but need validation in larger numbers of patients. The *in situ* TB PCR technique needs to be improved for better sensitivity. As currently used, TB PCR on biopsy samples has a high positive predictive value but a very low negative predictive value.

QUANTIFERON-TB GOLD

Quantiferon-TB Gold (QFT-G, Cellestis Limited, Carnegie, Victoria, Australia) is an *in vitro* ELISA which detects the release of interferon-gamma after stimulation by MTB antigen. The test, approved by the Food and Drug Administration (FDA) as an aid in diagnosing MTB infection, including both latent TB infection and TB disease, is performed by incubating fresh heparinized whole blood from sensitized persons with mixtures of synthetic peptides representing proteins present in *M. tuberculosis*: early secretory antigenic target-6 (ESAT-6) and culture filtrate protein-10 (CFP-10). The synthetic peptides used in QFT-G are absent from all BCG strains and most nontuberculosis mycobacteria except *M. kansasii*, *M. szulgai* and *M. marinum*.

Advantages and limitations

The advantages of QFT-G include lack of cross-reaction with BCG and most nontuberculous mycobacteria, avoidance of reader bias and the need for only a single patient visit. It may also be useful in monitoring the clinical response to anti-TB therapy.

The limitations include the need for incubation within 12 h of blood collection and its inability to differentiate infection with TB from latent TB infection. Though the sensitivity of QFT-G for detecting MTB infection in individuals with untreated culture-confirmed TB is approximately 80% in published studies, its sensitivity for latent TB infection seems to be less than that of the tuberculin skin test. The ability of the test to predict the risk of progression to subsequent TB disease in latent TB has not been determined. The test should be interpreted with caution as a patient with a negative test may still have latent TB infection or active TB disease. In a study of HIV sero-negative pulmonary TB patients from Chennai, QFT-G and the tuberculin skin test yielded diagnostic sensitivities of 90.6% (95% CI: 86.3%-94.9%) and 68.9% (95% CI: 60.6%-77.2%), and specificities of 55% (95% CI: 35.2%-54.8%) and 75.5% (95% CI: 66.8%-84.2%), respectively. The higher sensitivity noted in this study may be due to the exclusion of HIV patients^[21].

Role of QFT-G in intestinal tuberculosis

The role of QFT-G in intestinal tuberculosis is not clear. The test may have a possible role in follow up of patients on antituberculous therapy (ATT), in the diagnostic dilemma of CD *vs* TB and may be undertaken prior to starting biologicals in CD patients.

ENDOSCOPY

Gastrointestinal endoscopy - ileo-colonoscopy, device-assisted enteroscopy and gastro-duodenoscopy - plays a crucial role in the differentiation of intestinal TB from CD^[6,22]. Endoscopy permits direct visualization and biopsy of lesions for histological and other studies from virtually the entire alimentary tract^[23,24].

The ileo-cecal region is the most common site affected in either condition, and colonoscopy with retrograde intubation of the ileum is the initial procedure of choice. In patients with suspected or proven CD, ileo-colonoscopy provided similar sensitivity (67% *vs* 83%) but significantly higher specificity (100% *vs* 53%) compared to video capsule endoscopy^[25]. The incremental diagnostic yield of ileoscopy, low at 3.7%, may yet be important in a given patient^[26]. The diagnostic yield of histology increases with increasing number of biopsies from up to four segments in the colon^[1]. Endoscopic biopsies from segments upstream after dilating a stricture, and also from the normal looking ileum, increase the yield in patients with suspected TB^[27,28].

When the colon is spared, gastro-duodenoscopy and enteroscopy may be appropriate^[6,22,24]. Balloon-assisted and spiral enteroscopy are preferred modalities for evaluating the small bowel today because of biopsy and therapeutic capability^[23]. Biopsying small bowel lesions is important because the causes of ulcerating lesions cannot be differentiated based on endoscopic appearances alone^[23]. Biopsies from normal appearing colonic or gastro-duodenal mucosa may provide diagnostic clues in suspected CD^[1,29].

Characteristic endoscopic features have been described in intestinal TB and CD^[6,22,24]. Transversely placed ulcers, nodularity and hypertrophic lesions resembling masses are characteristic of TB. Aphthoid or longitudinal, deep, fissuring ulcers and a cobblestone appearance are said to be more typical of CD. Very few studies have directly compared these or evaluated their diagnostic value and inter-observer agreement.

In a small comparative study, ano-rectal lesions, longitudinal ulcers, aphthous ulcers, and a cobblestone appearance were significantly more common in CD, and involvement of fewer than four segments, a patulous ileocecal valve, transverse ulcers, and pseudopolyps were more frequent in intestinal TB. Assuming that a diagnosis of one or the other disease could be made based on which parameters were more common in a given patient, the endoscopic diagnosis would have been proved correct in 77 of 88 (87.5%) patients^[30]. These findings need to be validated before recommendation for routine use.

In a more recent prospective study, skip lesions in

the colon were significantly more frequent in patients with CD compared to patients with intestinal TB (66% *vs* 17%)^[31], as were aphthous ulceration (54% *vs* 13%), linear ulceration (30% *vs* 7%) and superficial ulceration (51% *vs* 17%). Cobblestoning of the colonic mucosa was seen only in CD (17% *vs* 0%). Nodularity of the colonic mucosa was significantly more common in patients with TB than in those with CD (49% *vs* 24.5%).

Capsule endoscopy

Capsule endoscopy has been established as a safe and non-invasive modality for the diagnosis of CD^[32,33]. A meta analysis comparing capsule endoscopy with other imaging modalities of the small bowel for inflammatory bowel disease established that capsule endoscopy has an incremental diagnostic yield of 25%-40% over other modalities^[34]. Capsule endoscopy has the unique ability to visualize small ulcers and early inflammatory lesions. Fidler *et al*^[35] defined a positive capsule result for CD as presence of four or more ulcers, erosions, or a region with clear exudate and mucosal hyperemia and edema. A scoring index developed to quantify mucosal changes detected by capsule endoscopy in any inflammatory processes of the small bowel is based on three variables: villous appearance, ulceration and stenosis. Each variable is assessed by size and extent of change. The index does not diagnose or measure a disease and does not have the discriminatory ability to differentiate between illnesses, but only measures mucosal changes. The International Conference on Capsule Endoscopy consensus statement declared that capsule endoscopy may play an important role in the diagnosis and monitoring of patients with known or suspected CD^[36]; playing a unique role in assessing mucosal healing after medical therapy, helping to assess early postoperative recurrence and guiding therapy. The consensus statement concluded that capsule endoscopy may identify sub-clinical markers in asymptomatic family members and contribute to the understanding of the natural history of IBD.

There are limited data regarding capsule endoscopy in intestinal TB. This can be attributed to non-affordability of capsule endoscopy in TB endemic countries and the inability of capsule endoscopy to take biopsies. A few case reports have described capsule endoscopic features of intestinal TB as multiple scattered short, oblique or transverse mucosal ulcers with a necrotic base in the jejunum and ileum^[37]. Cello *et al*^[38] also found that ulcers of the small bowel in intestinal TB were characteristically shallow with extensive irregular "geographic" borders, were usually not larger than 1-2 cm and were transverse rather than longitudinal. However, it is difficult to differentiate CD from TB based on capsule endoscopic features alone.

Small bowel enteroscopy

Double balloon and single balloon enteroscopy have the unique ability to visualize most of the small intestine by combined antegrade and retrograde approaches with biopsy capability and the possibility of therapeutic interven-

tions^[39,40]. However, they are more invasive than capsule endoscopy and need to be performed under sedation. A meta analysis compared capsule endoscopy and double balloon enteroscopy in patients with suspected inflammatory lesions and found no statistically significant difference in their diagnostic yield^[41]. A few case reports have described the double balloon enteroscopic findings in intestinal TB. Nakamura *et al*^[42] described multiple focal shallow irregular ulcers with necrotic bases of about 5 mm in the mid and distal ileum by double balloon enteroscopy through the retrograde route. In a series of 106 cases of single balloon enteroscopy, Ramchandani *et al*^[43] diagnosed 13 cases of CD and 3 cases of intestinal TB, which were confirmed by mucosal biopsies. There were focal longitudinal and aphthous ulcers in the jejunum and ileum in CD, whereas ulcers in TB were oblique or transverse with a necrotic base. Focal ulcerated strictures were noted in the distal jejunum and ileum in four cases of CD.

RADIOLOGY

Imaging plays an important role in diagnosing and differentiating intestinal TB from CD^[44-46]. Barium examination is the mainstay for the evaluation of the intestinal tract. Computed tomography (CT) is complementary to barium examination for the evaluation of extra-intestinal pathologies. CT enteroclysis is a hybrid technique that combines the advantages of both barium examination and CT.

In the vast majority of cases, differentiation of intestinal TB from CD is possible when radiological findings are correlated with clinical features, histopathological findings and response to treatment^[47-49].

Various points of distinction are summarized as follows.

Distribution of disease

The ileo-cecal region is the most common site involved in intestinal TB (Figure 1)^[49,50]. Isolated involvement of the ileo-cecal region is not seen in CD which typically involves the ileum with conspicuous sparing of the ileocecal valve. The cecum may rarely be involved in direct contiguity with the ileum or colonic disease.

Colorectal involvement with small bowel disease is more often seen in CD than in TB whereas the ascending colon may be involved in direct contiguity with the ileocecal region in TB. Isolated colorectal involvement in TB is rare as compared to CD.

Barium findings (small bowel)

Strictures are the most common finding in intestinal TB and are typically short, concentric and smooth in outline with significant prestenotic dilatation (Figure 1A). In CD, strictures are usually long (the result of fibrosis, irritability and inflammation), eccentric with sacculations at the anti-mesenteric border and without significant prestenotic dilatation (Figure 1B). Aphthous ulcers and an ulceronodular pattern are almost pathognomonic in the appropriate clinical settings (Figure 1C). Tubercular

Figure 1 Findings on barium study of the small intestine. A: Barium study in three different patients with tuberculosis (TB) demonstrating shrunken, conical and retracted cecum (arrows); B: Multiple strictures (arrows) in ileal loops of a patient with TB. Note the short, concentric and smooth outline of the strictures; C: Multiple eccentric strictures seen in the ileum of a patient with Crohn's disease (CD). Note the normal ileo-cecal junction; D: Barium study showing an ulceronodular pattern involving a long segment of the ileum in a patient with CD. Note sparing of the ileo-cecal junction (arrow).

Figure 2 Findings on barium study of the colon in tuberculosis and Crohn's disease. A: Barium enema showing tubercular strictures (arrows) of the colon; B: Barium enema demonstrating skip lesions affecting descending and transverse colon as ulcers with areas of narrowing in a patient with Crohn's disease (CD); C: Deep ulcers with double tracking of sigmoid colon in a patient with CD (arrows).

ulcers are less common, longitudinally oriented and tend to be round to oval in configuration. Perforation and fistulae are more often encountered with CD, while enteroliths are more common in intestinal TB. Malignancy is a complication seen only with CD.

Barium findings (large bowel)

In TB, solitary or multiple strictures which are smooth and concentric are the most common finding (Figure 2A) while aphthous ulcers, segmental colitis and cobblestoning are the predominant findings in CD (Figure 2B and C).

Computed tomography

In CD, mural thickening with stratification is seen with active inflammation (Figure 3A) (Table 1). In addition, vascular engorgement of the mesentery (comb sign) and mesenteric fibrofatty proliferation are seen (Figure 3B and C). Mural thickening with contiguous ileo-cecal involvement is more often the presentation of intestinal TB (Figure 3D). Hypodense lymph nodes with peripheral enhancement in the mesentery and retro-peritoneum are characteristic of TB (Figure 3E), while in CD hypodense lymph nodes are seen.

Figure 3 Findings on computed tomography. A: Computed tomography (CT) enteroclysis with negative oral contrast showing mural thickening of ileum with skip areas and sparing of cecum in a patient with Crohn's disease (CD); B: Contrast-enhanced CT scan (CECT) showing asymmetrical mural thickening in ileal loop with deep ulcerations. Note fibro-fatty proliferation of mesentery; C: CECT in another patient with CD showing mesenteric vascular engorgement (Comb sign) with fibro-fatty proliferation of the mesentery; D: CT enteroclysis with negative oral contrast showing contiguous mural thickening of the terminal ileum and cecum in a patient with tuberculosis (TB); E: CECT in a patient with TB showing mural thickening of the terminal ileum and cecum (thick arrow) with multiple enlarged mesenteric lymph nodes showing central hypoattenuating and peripherally enhancing rims (thin arrow).

Table 1 Computed tomographic features of intestinal tuberculosis and Crohn's disease

Tuberculosis	Crohn's disease
Mural thickening without stratification	Mural thickening with stratification in active inflammation
Strictures concentric	Strictures eccentric
Fibrofatty proliferation of mesentery very rare	Fibrofatty proliferation of mesentery
Mesenteric inflammation but no vascular engorgement	Hypervascular mesentery (comb sign)
Hypodense lymph nodes with peripheral enhancement	Mild lymphadenopathy
High density ascites	Abscesses

PATHOLOGY

Surgical resections

Macroscopically, TB classically causes ulceration, short strictures, marked thickening of the bowel wall due to inflammation, fibrosis and adhesions, or a combination of these. The ulcers are transverse, often circumferential, with ill-defined, sloping or overhanging edges. The surrounding mucosa may show flattening of folds, ulcers, erosions and pseudopolyps. The cut section of the intestinal wall shows scarring and necrosis, often with loss of distinction of the different layers. The serosal surface may show 2-5 mm-sized nodules and adhesions. The regional lymph nodes are invariably enlarged and may show caseation^[51].

The histological hallmarks of TB are confluent, caseat-

ing granulomas containing acid fast bacilli and surrounded by a lymphoid cuff. These are found in all layers of the intestinal wall and in regional lymph nodes, but sometimes only in the latter^[51]. Early granulomas are usually found within lymphoid tissue^[52]. There may be extensive pyloric metaplasia. Occasional superficial fissuring ulcers that extend into the submucosa may be seen. Healing occurs by fibrosis, and epithelial regeneration begins at the edge of ulcers. Healing granulomas are surrounded by a rim of fibrous tissue in lymph nodes, but not in the intestinal wall^[51].

Macroscopically, CD also shows bowel wall thickening, skip lesions and strictures, but the latter are longer than in TB. Fat wrapping is common, as are adhesions, fistulae, sinuses and extra-intestinal abscesses^[53]. Mucosal aphthous ulcers are seen at an early stage, and coalesce to form larger stellate ulcers. Deep, longitudinal, fissuring ulcers are characteristic of CD, as well as smaller longitudinal ulcers separating edematous or uninvolved mucosa to create a cobblestone appearance^[54].

Microscopically, common features are aphthous ulcers over lymphoid follicles, fissuring ulcers that extend into the muscularis propria or deeper, distortion of the mucosal architecture, pyloric metaplasia, cryptitis and crypt abscess formation with moderate to severe chronic inflammation. These changes are often segmental or patchy and extend transmurally. Prominent lymphoid follicles in the submucosa and serosa are another characteristic feature of CD. Granulomas, characteristically small, are seen

Figure 4 Histological features. A: Confluent granulomas in inflammatory granulation tissue from ulcerated colonic mucosa of a patient with tuberculosis (TB) [Hematoxylin and eosin (HE), 100 ×]; B: Large granuloma in the ulcerated mucosa of a patient with TB (HE, 100 ×); C: Microgranuloma composed of a small aggregate of macrophages in a lymphoid follicle from the mucosa of a patient with Crohn's disease (CD) (HE, 400 ×); D: Small pericryptal granuloma in the colonic mucosa of a patient with CD (HE, 100 ×).

in 50%-60% of resection specimens and may be found in the regional lymph nodes in about 25% of cases^[54].

Mucosal biopsies

With the increasing use of endoscopic procedures to visualize the intestinal lumen and obtain targeted biopsies from diseased areas, the histological differentiation of intestinal TB and CD is most commonly made on mucosal biopsies. One of the limitations of mucosal biopsies is that granulomas, the primary differentiating feature of TB from CD, are found in only 50%-80% of intestinal mucosal biopsies from patients with clinically confirmed TB^[51,55,56] and in 15%-65% of mucosal biopsies from patients with CD^[57]. Caseation and AFB, the diagnostic features of TB, are found in only 18%-33% of cases^[56,58] and in as low as 5% of cases^[58], respectively. Other features suggestive of TB include confluent granulomas (Figure 4A), a lymphoid cuff around granulomas, granulomas larger than 400 µm in diameter (Figure 4B), 5 or more granulomas in biopsies from one segment, granulomas located in the submucosa or in granulation tissue, often as palisaded epithelioid histiocytes, and disproportionate submucosal inflammation^[1,3]. Features that favor a diagnosis of CD on mucosal biopsies include infrequent (< 5), small (< 200 µm in size) granulomas that are poorly organized and discrete or isolated. Granulomas are located more commonly in the mucosa than in other sites in CD. Microgranulomas, or aggregates of histiocytes (Figure 4C), and

crypt-centered inflammation such as pericryptal granulomas (Figure 4D) and focally enhanced colitis are also features of CD^[1,3,59].

SURGERY

In India, due to a high prevalence of TB, the diagnosis of CD is often delayed. In one report nearly a quarter of patients with CD were being treated as tuberculosis^[60]. In a study published from India of 28 patients undergoing surgery for CD, elective surgery was performed in 23 and emergency intervention was required in 5. The commonest indication was subacute intestinal obstruction (53%), followed by enteroenteric and enterocutaneous fistulae (10.7%), chronic gastrointestinal blood loss (7%) and protein losing enteropathy (7%). The emergency indications included perforation and peritonitis (14%) and massive GI bleed (4%). Two patients required surgery for gastric outlet obstruction (4%). Eleven patients had combinations of pathology, such as stricture with fistula or perforations. Table 2 shows the clinical and operative findings of 68 patients who underwent surgery for CD and 41 patients for TB in a tertiary referral centre in South India. Indications for surgery in TB were diagnosis and relief of intestinal obstruction. In this study as in previous studies^[7], fever, altered bowel habits, clinical presentation as recurrent intestinal obstruction, diffuse small bowel involvement with multiple strictures and deep linear ulcers/cobblestone

Table 2 Clinical parameters and operative findings of 68 surgical patients with Crohn's and 41 patients with intestinal tuberculosis *n* (%)

Parameter	Crohn's disease (<i>n</i> = 68)	Intestinal Tuberculosis (<i>n</i> = 41)	<i>P</i> value ¹
Clinical parameters			
Male:female	38:30	28:13	NS
Mean age (yr)	31.2 (16-52)	36.8 (23-64)	NS
Fever	17 (25)	28 (68)	< 0.010
Pain	50 (73)	26 (63)	NS
Altered bowel habits	46 (67)	14 (34)	< 0.001
Fistula in ano	7 (12)	1 (2.4)	NS
Anemia	34 (50)	28 (68)	NS
Edema	22 (32)	14 (34)	NS
Growth retardation	14 (20)	4 (9.7)	NS
Treated as tuberculosis	18 (26)	8 (19)	NS
Pulmonary involvement	6 (8.2)	14 (34)	< 0.010
Abdominal distension	18 (26)	19 (46)	< 0.050
Abdominal lump	7 (12)	8 (19)	NS
Recurrent intestinal obstruction	40 (59)	14 (34)	< 0.020
Operative findings			
Peritoneal nodules	15 (22)	32 (78)	< 0.001
Ascites	19 (27)	28 (68)	< 0.001
Nodules over bowel/mesentery	14 (20)	14 (34)	NS
Site of involvement:			
Diffuse small bowel	22 (32)	6 (14.6)	< 0.050
Jejunum	14 (20)	6 (14.6)	NS
Ileum	44 (64)	32 (78)	NS
Colon	6 (8.8)	2 (4.8)	NS
Small bowel and colon	18 (26)	3 (7.3)	< 0.020
Multiple strictures	44 (64)	4 (9.7)	< 0.001
Skip lesions	17 (25)	4 (9.7)	NS
Internal fistula	14 (20)	1 (2.4)	< 0.01
Mesenteric fat creeping	44 (64)	28 (51)	NS
Shortened mesentery	18 (26)	14 (34)	NS
Aphthoid ulcers	32 (47)	15 (36)	NS
Deep linear ulcers	40 (59)	8 (19)	< 0.001
Cobblestone appearance	44 (64)	7 (17)	< 0.001
Stricture	40 (59)	18 (44)	NS

¹*P* value: by χ^2 . NS: Not significant.

appearance of bowel were significantly more common in CD than in TB. Conversely, pulmonary involvement, abdominal distension, ascites, peritoneal nodules and terminal ileal/ileocolic involvement without multiple strictures were significantly more common in TB.

ROLE OF THERAPY AND FOLLOW UP

Even when the best available diagnostic modalities are utilized, the differentiation of TB from CD remains a problem in 10%-15% of patients in India. Four decades ago, it was usual for these patients to have received anti-tuberculous treatment (ATT) for two years and the individuals who did not respond to such treatment were then diagnosed as having CD. However, advances in diagnosis and increasing experience have allowed Indian gastroenterologists to make a diagnosis of CD in the first instance. Today, nearly half of our patients with CD continue to have received ATT prior to the establishment of the diagnosis of CD. Clearly, a good response to ATT, confirmed

by endoscopic and histological clearance of disease, establishes and confirms the diagnosis of TB. Conversely, a poor response to ATT could indicate that the diagnosis is really CD, but could also represent non-responsive TB or drug-resistant TB. An understanding of the intestinal response to therapy of TB and of CD is therefore basic to the use of therapy in differentiating these two diseases.

Use of the directly observed treatment, short course (DOTS) strategy for 6 mo has become standard in the treatment of TB in India. In patients with newly diagnosed pulmonary TB, the "cure" rate after DOTS ranges from 75%-92%^[61,62]. Treatment success in extrapulmonary TB was 91% in one study, but this study did not further categorize extrapulmonary TB^[62]. In a study from Kerala of 47 patients treated with either DOTS or daily chemotherapy, complete mucosal healing was noted at colonoscopy in 35 at 2 mo and in all 47 at 6 mo^[63]. However, biopsies were not taken from these patients during follow up nor was there any long term follow up of the treated individuals. Similar observations have been made of mucosal healing soon after commencement of ATT in colonic TB, but the lack of long term follow up - to ensure that disease does not recur - is a drawback of these studies^[64]. In our anecdotal experience, it is common for a proportion of patients to have recurrent disease one to five years after cessation of ATT. At this point it is often difficult to decide whether the patient has recurrence of TB or whether the patient is actually suffering from CD. Drug resistance is increasingly common in strains of MTB and may contribute to recurrent or persistent disease in patients correctly diagnosed as having TB but not showing clinical, endoscopic or histological response to treatment with first line chemotherapy for TB. Multi-drug resistance (MDR) has been observed in 2.4% to 13.2% of strains of MTB isolated from newly diagnosed pulmonary TB patients and in 17.4% to 25.5% of previously treated patients^[65,66]. Extensive drug resistance (XDR) is found almost exclusively in previously treated patients and accounts for about 6% of MDR TB^[67]. Statistics regarding prevalence of MDR and XDR strains in intestinal TB are not available from India; however, in one series of 30 patients with colonic TB in Taiwan, 4 (13%) had MDR TB^[68].

Studies carried out in the last three decades clearly demonstrate that CD does not respond to conventional ATT including isoniazid, rifampicin and ethambutol^[69,70]. Prolonged treatment for *Mycobacterium avium* subsp. *paratuberculosis* with clarithromycin, rifabutin and clofazimine did lead to improvements in disease activity in patients with CD, but such improvement was not sustained^[71].

In summary, the response to an adequate course of ATT should differentiate patients with TB from CD in instances when this becomes necessary. Such response should be assessed by clinical and biochemical parameters, but also by evidence of mucosal healing at endoscopy and on segmental mucosal biopsies. A proportion of patients with intestinal TB (amounting in our experience to about 10%) will not show the desired response and may then be incorrectly diagnosed as having CD. Longer term follow up in these patients will eventually reveal the correct diagnosis.

CONCLUSION

In conclusion, differentiating intestinal TB from CD in countries like India, where both diseases are prevalent, is an important clinical problem. A combination of a good clinical history with colonoscopy, biopsies, cultures, and barium or simple CT studies can be utilized to make a diagnosis in the majority of cases. This article has highlighted important parameters that differentiate intestinal TB from CD in each of these diagnostic modalities. The role of newer techniques, such as capsule endoscopy, single and double balloon enteroscopy, CT enteroclysis, PCR and immunological assays for MTB, has also been highlighted. An adequate course of antituberculous therapy and longer term follow up may become necessary to differentiate patients with TB from CD in some instances. An understanding of the intestinal response to treatment of TB and of CD is, however, fundamental to the use of therapy in differentiating these two diseases.

Abstract

The possible relationship between diabetes mellitus (DM) and colorectal cancer (CRC), concerning pathophysiological and molecular mechanisms is highlighted in this review. The most recent and complete articles and developments in this particular field were thoroughly reviewed. Common risk factors, such as obesity, sedentary lifestyle, and Western diet between DM and CRC, led to the theory that DM might be a causal agent for CRC development. Various studies have connected type 2 DM and CRC, either proximal or distal, in both sexes. Additionally, chronic insulin treatment has been linked with increased colorectal tumor risk among type 2 diabetic patients. Interestingly, elevated hemoglobin A1c has been proven to be an independent predictor of aggressive clinical behavior in CRC patients. These mechanisms include the insulin-like growth factor-hyperinsulinemia theory and the participation of oncogenic intracellular signaling pathways. Furthermore, it has been proposed that Cox-2 inhibitors might have a role in decreasing the incidence of CRC. Finally, the use of statins to reduce the risk for colon cancer in patients with diabetes has

remained controversial. Diabetic patients over 50 should receive counseling regarding their elevated risk for CRC, and screening colonoscopy should be recommended before initiating insulin therapy. However, there are no current guidelines, and this strategy is not yet applicable to some countries, as the corresponding risk would not allow screening colonoscopy to be adopted. There is strong evidence to indicate that DM is a causal agent for CRC development. This conclusion provides new impetus for re-evaluating CRC screening worldwide.

INTRODUCTION

Colorectal cancer (CRC) is the third leading cause of cancer-related death in the Western world with 655 000 deaths per year^[1]. In addition, the incidence of diabetes mellitus (DM) is increasing rapidly. In 2000, at least 171 million patients suffered from diabetes worldwide, and it is estimated that by the year 2030, the number will almost double^[2]. Serious long-term complications of DM include cardiovascular, retinal, and nerve disease, along with chronic renal failure and high tendency for infections. Common etiologic factors including obesity, sedentary

lifestyle, and Western diet between these two widespread diseases, led to the hypothesis that there might be a connection between diabetes and CRC, rendering diabetes a causal agent for CRC.

Diabetes has been linked with ovarian^[3], pancreatic^[4,5], liver^[5], renal^[6], breast cancer^[4], melanomas^[6], and cancers of the urinary tract^[6], stomach^[7], cervix^[7], and endometrium^[7]. Patients with type 1 and type 2 diabetes might be at an increased risk for cancer, but there is more evidence available for patients with type 2 diabetes^[6]. As far as CRC is concerned, type 2 DM has also been linked with the aforementioned cancer.

RELATIONSHIP BETWEEN DIABETES MELLITUS AND COLORECTAL CANCER

Various studies have connected diabetes with men or women suffering from CRC, with proximal or distal CRC, or with both sexes and colorectal subsites. Part of these discrepancies might be attributed to different sample sizes, follow-up duration, inclusion/exclusion criteria of the studied population, classification systems, disease heterogeneity, or interplay between biological and environmental factors. A large retrospective study conducted in 2006 reported that there is a significantly elevated risk for proximal CRC in type 2 diabetic men, but no significant increase in risk for diabetic women^[8]. Cigarette smoking has been reported to positively modify diabetes-associated CRC risk^[8]. Moreover, CRC has been connected with type 2 diabetic men^[8-10], diabetic women^[11], or both sexes^[12]. Interestingly, type 2 diabetes predisposes patients to an increased risk for proximal^[8] or distal CRC^[9], or both proximal and distal, colonic and rectal cancers^[12]. Thus, the relationship between type 2 diabetes and CRC has been proposed and reported in several studies.

Chronic insulin therapy has been associated with an increased colorectal tumor risk among type 2 diabetic patients^[13,14]. Specifically, a three-fold risk increase for patients with insulin-dependent type 2 DM in comparison to the general population has been observed^[15]. On the other hand, there is limited information on the short and long term outcome for diabetic patients diagnosed with CRC. An association between the control of type 2 DM, as determined by the levels of hemoglobin A1c (HbA1c), has been examined. Elevated HbA1c has been proven to be an independent predictor of aggressive clinical behavior in patients with CRC. Siddiqui *et al.*^[16] reported that patients with poorly controlled type 2 DM have more right sided and advanced colorectal cancers, a younger age of presentation, greater use of exogenous insulin, and a poorer 5-year survival. Interestingly, neoadjuvant chemotherapy in rectal cancer is less effective in diabetic patients than in non-diabetics^[17]. Nevertheless, according to a Norwegian study, diabetes does not seem to affect the short-term survival or the overall cancer-specific survival in patients with CRC. Indeed, the shorter overall survival in diabetic patients suffering from colorectal cancer in comparison to non-diabetics is attributed to cardiac diseases and higher age^[18].

PATHOPHYSIOLOGICAL AND MOLECULAR MECHANISMS

Several pathophysiological mechanisms have been proposed to explain the possible relation between DM and CRC. The insulin-like growth factor (IGF-1)-hyperinsulinemia theory implies that elevated insulin and free IGF-1 levels support the proliferation of colon cells, thereby leading to a survival benefit, resulting in CRC^[19]. In patients with type 2 DM, elevated insulin levels are present in an effort to overcome peripheral insulin resistance by increased insulin production. Moreover, hyperinsulinemia is further augmented by exogenous application of insulin. The aforementioned molecular model suggests that hyperinsulinemia, IGF-1, and the relative binding proteins play important roles in metabolism, cell growth, proliferation, and the regulation of apoptotic process in colon cells^[6]. Thus, normal colon cells acquire neoplastic characteristics, displaying cancerous transformation.

The aforementioned theory supports the view that not only does insulin stimulate the growth of colon cells *in vitro*^[20], but its proliferative effect is also mediated by insulin cognate and IGF-1 receptors^[21]. It has been demonstrated that the epithelium of colon carcinoma cell lines shows an increased insulin receptor density in comparison to normal colon epithelium. Furthermore, insulin leads to increased bioavailability of IGF-1^[19]. Insulin and IGF-1 signaling pathways either enhance proliferation, or inhibit apoptosis of colon epithelial cells, leading to carcinogenesis.

Oncogenic intracellular pathways mainly involving kinase neoplastic proteins [mitogen activated protein kinases, extracellular signal regulated kinase, phosphatidylinositol-3-kinase, protein kinase B and mammalian target of rapamycin (mTOR)] are activated^[19] (Figure 1). However, there have been conflicting results concerning the link between IGF-1 and CRC, as there are studies both supporting and disputing this link^[6]. In addition, the actions of insulin and IGF-1 are mediated by the activation of Ras, which may lead to increased sensitivity of colon cells to growth factors and accelerated progression from adenoma to carcinoma^[19]. The time from adenoma formation to development of CRC is believed to be between 10 and 15 years^[6].

Interestingly, insulin stimulates cell proliferation and c-Myc expression in various colon cancer cell lines, in the intestinal non-cancer cell line IEC-6, and in fetal rat intestinal cell cultures (Figure 1). The effects of insulin involve activation of the mTOR signaling pathway in combination with nuclear translocation of β -catenin, an effector of Wnt signaling (Figure 1). Hence, both Wnt and mTOR pathways participate in insulin-stimulated oncogene expression in intestinal cells^[22,23]. Furthermore, it has been reported that insulin stimulates the phosphorylation and activation of p-21-activated protein kinase-1 (PAK-1) in an *in vivo* hyperinsulinemic mouse model, indicating that PAK-1 serves as an important link between insulin and Wnt signaling pathways, promoting intestinal carcinogenesis^[24]. Finally,

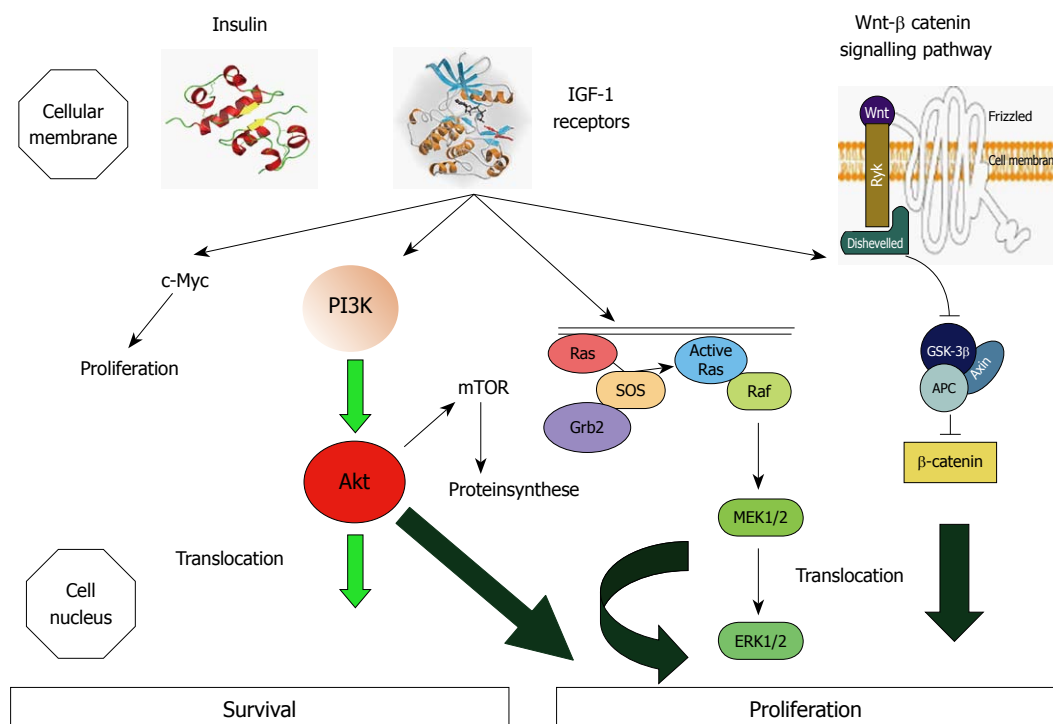

Figure 1 Schematic review of the molecular mechanisms linking diabetes mellitus and colorectal cancer. Insulin and insulin-like growth factor (IGF-1) signaling pathways are shown, along with their effect on apoptosis, proliferation, and protein synthesis. The activated mitogen activated protein kinases (MAPK) pathway is associated with proliferation and the phosphatidylinositol-3-kinase (PI3K)/protein kinase B (Akt) pathway mainly leads to survival (inhibition of apoptosis). Moreover, protein synthesis is induced via the Akt pathway. The complexity of the system and the cross-talk between the individual pathways are presented. MEK: Mitogen extracellular kinases; ERK: Extracellular signal-regulated kinases; mTOR: Mammalian target of rapamycin; Ras: "Rapid accelerating sarcoma" serine/threonine-kinase; Raf: "Rapid accelerating fibrosarcoma" serine/threonine-kinase; Ryk: Related to tyrosine kinases; SOS: Silencing of survival signals; Grb2: Growth factor receptor binding protein 2; APC: Activated protein C; GSK-3 β : Glycogen synthetase kinase-3 β ; Axin: Activated extracellular index.

the peroxisome proliferators-activated receptor- γ is associated with CRC, including insulin and inflammation related mechanisms, given its association with insulin, diabetes, obesity, and inflammation^[25] (Figure 1).

Another possible molecular mechanism linking diabetes and CRC involves the hormone glucagon-like peptide-1 (GLP-1), secreted by the intestinal endocrine L cells, along with the participation of Wnt signaling pathway and the oncogenes c-Myc and cyclin D1. Specifically, in type 2 diabetic patients, GLP-1 secretion is reduced, due to insulin resistance. Reduction of GLP-1 secretion causes compensatory activation of the Wnt pathway in combination with increased expression of proto-oncogenes, such as c-Myc, resulting in intestinal cell proliferation and, plausibly, CRC development^[26]. Nevertheless, cross talk exists between individual oncogenic pathways, which regulate either apoptosis or survival of colon cells. Thus, the theory defined remains controversial, with several aspects requiring thorough investigation, further complicating the relationship between DM and CRC.

Slower bowel transit time is another appealing concept connecting diabetes and CRC. Patients with diabetes are more prone to suffer constipation (bowel movements less than once a day) and slower colonic transit times, possibly because of diabetic neuropathy affecting the intestine. Certain fecal contents are cancer promoting, such as bile acids, ammonium acetate, and fecapentaene-12^[6]. Nevertheless, there is no epidemiological

evidence that constipation is associated with CRC.

Risk factors such as sedentary lifestyle, obesity, Western diet, and the metabolic syndrome are common in both type 2 DM and CRC^[27]. Obesity has a role in increased CRC risk of the diabetic population, because of a variety of factors including insulin resistance, increased inflammatory markers [interleukin (IL)-1, IL-6, tumor necrosis factor- α], and high levels of androgens and estrogens^[6,27].

PROPHYLAXIS FOR COLORECTAL CANCER

Given the increased CRC risk in patients with type 2 DM, it would be reasonable to postulate that these patients might benefit from any potential prophylaxis against CRC. The use of potential chemoprotective agents, such as aspirin, non-aspirin nonsteroidal anti-inflammatory drugs (NSAIDs), and cyclooxygenase 2 (Cox-2) inhibitors, have been considered and investigated. The basis for applying these agents is that they inhibit the production of prostaglandins, which are inflammatory mediators participating in the formation and proliferation of cancers^[28].

Data from two large randomized trials (the British Doctors Aspirin Trial and the UK-TIA Aspirin Trial) show that the use of high-dose aspirin (1200-300 mg/dL) for a minimum period of five years reduces the incidence of CRC^[6]. However, applying both high-dose aspirin and

NSAIDs over the long term is associated with gastrointestinal complications. Therefore, benefits and risks have to be considered on an individual basis. It would also be helpful to establish if smaller doses of aspirin could be effective for chemoprevention.

The association between Cox-2 expression, adenomatous polyps, and CRC has generated much interest. Specific Cox-2 inhibition might have a role, because colorectal adenomas and cancers show a higher than normal Cox-2 expression, which has been associated with worse survival^[6,28]. Thus, Cox-2 inhibitors have been shown to decrease the incidence of CRC. The effects of Cox-2 inhibitors are regulated by inhibition of prostaglandin synthesis. Cox-2 and prostaglandins mediate resistance to apoptosis, modulate tumor angiogenesis, and increase metastatic potential in the intestine. These effects are controlled through prostaglandin E2 and the epidermal growth factor receptor. Although there is some evidence that Cox-2 inhibitors might reduce the incidence of CRC, the cardiovascular risk (acute myocardial infarction) outweighs the potential benefit^[6,28].

An interesting theory has been proposed recently, implicating homocysteine as the missing link between type 2 DM and CRC^[29]. Recent findings indicate that a high homocysteine level is a risk factor for developing DM. In addition, hyperhomocysteinemia is associated with aberrant methylation of DNA, which might lead to inactivation of tumor suppressor genes and CRC growth^[29].

Moreover, the use of statins has been associated with a small reduction in the risk for colon cancer in diabetic patients. However, the causal link is not clear^[30]. There are also studies, which do not connect statins with a reduced risk of CRC in large cohorts of patients, indicating that long-term regular use of statins does not protect against CRC^[31-34]. Nevertheless, the application of statins has been linked with a relative reduction in the CRC risk^[35], along with a reduced risk for stage IV CRC^[31]. Interestingly, simvastatin therapy results in inhibition of the release of IL-8 and IL-6 from colorectal cell lines. Hence, CRC risk is reduced because of decreased synthesis and release of the aforementioned proinflammatory cytokines by the tumor cells^[36]. Thus, the conflicting results necessitate further investigation to elucidate this controversial topic.

PREVENTING COLORECTAL CANCER

A large number of epidemiological studies have demonstrated that the risk for CRC is increased in patients with type 2 DM. A recent meta-analysis showed that patients with type 2 DM have a 30% increased risk for CRC versus the general population and that this risk is doubled in diabetic patients treated with insulin. The increased risk correlates with the duration of insulin therapy and might be due to increased levels of insulin and free IGF-1. The increased risk in patients with type 2 DM treated with insulin is comparable to a positive family history.

A better way to prevent CRC in patients with type 2 DM is screening. Over the past decade, tests generally offered in screening guidelines include colonoscopy every 10

years, fecal occult blood testing (FOBT) annually, double contrast barium enema every five years, or flexible sigmoidoscopy every 5-10 years. Current guidelines in most Western countries recommend colonoscopy every 10 years, beginning at the age of 50 years for people with average risk, or alternatively screening with FOBT every year combined with flexible sigmoidoscopy every five years.

Most patients with type 2 DM will be over 50 at diagnosis and are eligible for screening according to screening guidelines. Diabetic patients over 50 should receive counseling regarding their elevated risk for CRC and screening colonoscopy should be recommended before initiating insulin therapy. In younger diabetic patients, the decision should be made individually and be based on the presence of other risk factors, such as smoking or previous insulin therapy. Bearing in mind that the action of insulin and IGF-1 is partly mediated by the activation of Ras, which might lead to accelerated progression from adenoma to carcinoma, screening intervals concerning the population with a positive family history should not exceed five years, especially in patients under insulin treatment. However, there are no current guidelines for this group of patients, and these recommendations only reflect the opinion of some experts. Hence, this strategy may not be applicable to some countries, as the corresponding risk would not allow screening colonoscopy to be adopted. Unfortunately, patients are often reluctant to undergo screening for CRC, and a high percentage of colorectal cancers could have been prevented; the disease is often diagnosed at advanced stages. Thus, the duty of the medical community is to inform the patients concisely, accurately, and clearly, convincing them to be checked regularly.

In conclusion, more clinical trials are required to elucidate not only the relationship between type 2 DM and CRC, but also CRC outcome in diabetic patients. Furthermore, the precise molecular mechanisms should be determined, which will lead to targeted therapy for CRC in diabetic patients.

Abstract

AIM: To investigate plasma ghrelin, gastrin and growth hormone secretagogue receptor (GHS-R) expression in advanced gastric cancer (GC) before and after resection.

METHODS: Seventy subjects in whom endoscopy of the upper gastrointestinal tract was performed in the Department of General Surgery at Cracow University during the past decade: (1) 25 patients with GC associated with *Helicobacter pylori* (*H. pylori*) infection; (2)

10 patients with GC 4-5 years after (total or subtotal) gastrectomy; (3) 25 healthy *H. pylori*-negative controls, matched by age and BMI to the above two groups; and (4) 10 GC patients 4-5 years after total gastrectomy. Ghrelin and gastrin plasma concentrations were measured by specific radioimmunoassay under fasting conditions and postprandially at 60 and 90 min after ingestion of a mixed meal. GHS-R expression was examined in biopsy samples from intact healthy mucosa and GC tissue using semi-quantitative reverse transcription-polymerase chain reaction.

RESULTS: In healthy controls, fasting plasma ghrelin levels were significantly elevated and declined markedly at 60 and 90 min after a mixed meal. The concomitant enhanced ghrelin, GHS-R and gastrin expression in GC tissue over that recorded in intact mucosa, and the marked rise in plasma gastrin in these subjects under fasting conditions indicate the role of these hormonal factors in GC formation. Fasting plasma levels and postprandial response of ghrelin and gastrin appear to be inversely correlated in healthy subjects. Feeding in the controls resulted in a significant fall in plasma ghrelin with a subsequent rise in plasma gastrin, but in *H. pylori*-positive GC patients submitted to total or distal gastrectomy, feeding failed to affect significantly the fall in plasma ghrelin that was recorded in these patients before surgery. Fasting ghrelin concentrations were significantly lower in patients 4-5 years after total gastrectomy compared to those in healthy controls and to these in GC patients before surgery.

CONCLUSION: Elevated plasma gastrin and suppression of fasting ghrelin in patients with GC suggest the existence of a close relationship between these two hormones in gastric carcinogenesis.

INTRODUCTION

Ghrelin, a natural ligand for growth hormone secretagogue receptor (GHS-R), was originally identified in rat gastric mucosa and shown to be expressed by the endocrine ghrelin (Gr)-cells of this mucosa^[1,2]. These Gr-cells, represent about 20% of the total population of endocrine cells in human gastric mucosa, and are located in the lower parts of the oxyntic glands in the fundus and body of the stomach. Gastric acid secretion is stimulated physiologically by gastrin and histamine as well as by ghrelin itself^[2-6] (Figure 1).

Ghrelin is a stimulant of GH secretion, which acts *via* release of GHS-R in the stomach, but characteristically, it is also the only circulatory gastrointestinal hormone that is known to be secreted by the empty (fasting) stomach, to enhance food intake and maintain energy homeostasis following its central or peripheral administration^[6]. Ghrelin is currently considered as the most powerful endogenous orexigenic (appetite-stimulating) hormone, which results in a positive energy balance^[4,6,7]. Its action on gastric mucosa might contribute to carcinogenesis, but the role of ghrelin/GHS-R in gastric cancer (GC) pathogenesis^[8] awaits explanation, and possible use of ghrelin in severe gastric-originated cachexia remains unknown.

The reduction in the ghrelin levels after gastrectomy by > 60% supports the notion that the gastric mucosa is the main site of ghrelin production^[3,4,9]. Gastric cancer modifies the expression of ghrelin in gastric mucosa and this could be attributed, at least in part, to severe atrophic gastritis^[10,11], which usually precedes and might lead to gastric carcinogenesis. Mottershead *et al*^[12] have observed a lack of expression of mRNA for ghrelin in GC cells by immunohistochemical and reverse transcription-polymerase chain reaction methods. According to our recent experience, the expression of mRNA for ghrelin in pronounced atrophic gastritis is relatively low, so major changes in plasma ghrelin cannot originate from the *Helicobacter pylori* (*H. pylori*)-related atrophic gastritis tissue^[12].

The aim of the present study was to analyze the plasma concentrations of the ghrelin-GHS-R complex in patients with advanced GC before and after total or distal gastrectomy. In addition, we analyzed plasma ghrelin concentrations and mucosal gene expression of ghrelin and its receptor, GHS-R, in intact mucosa and in *H. pylori*-infected GC tissue. Moreover, the analysis of fasting and postprandial plasma ghrelin levels *vs* plasma gastrin con-

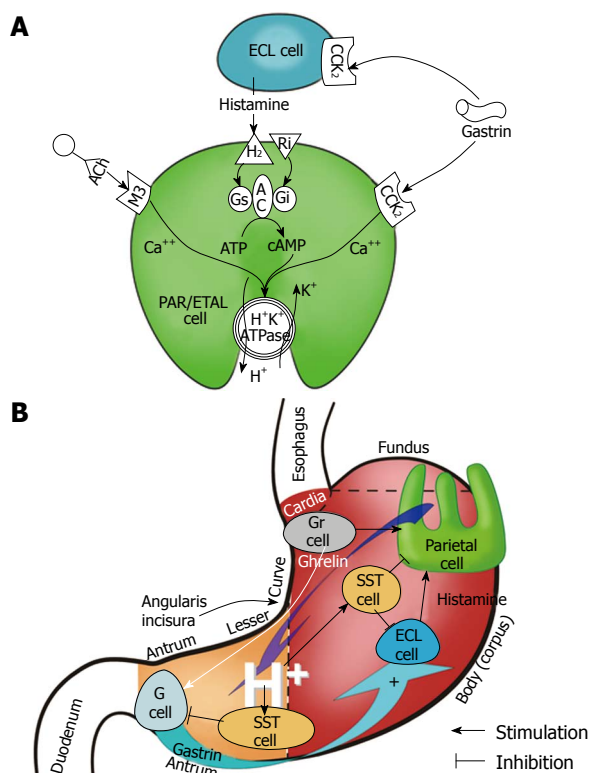

Figure 1 Gastric secretory mechanism at the parietal cell (oxyntic) level (A) and at the level of the whole stomach (B).

centrations in patients at 4-5 years after total and distal gastrectomy was assessed to elucidate the possible compensatory extragastric production of these hormones.

MATERIALS AND METHODS

The study included 70 patients, aged 18 and over who, from January 2006 to May 2008, underwent upper gastrointestinal tract endoscopy in a specialized unit of the Department of Surgery, Jagiellonian University Medical College, Cracow.

Exclusion criteria included any of the following: age < 18 years; no consent to participate in the study; a history of diabetes, thyroid disease and neuroendocrine tumors, use of glucocorticoids, progesterone or testosterone, renal and/or liver failure; prior chemotherapy (not applicable to a group of patients 4-5 years after gastrectomy); drugs and/or alcohol addiction; and body mass index (BMI) > 30 kg/m². Patients included in the research program based on the above criteria were assigned to one of the following groups: (1) 25 patients with GC associated with *H. pylori* infection; (2) 10 patients with GC 4-5 years after (total or subtotal) gastrectomy; (3) 25 healthy *H. pylori*-negative controls, matched by age and BMI to the above two groups; and (4) 10 GC patients 4-5 years after total gastrectomy. The basis of this categorization was the initial diagnosis upon admission to our gastrointestinal unit (Table 1). The study was approved and supervised by the Institutional Research Ethical Committee and informed consent was obtained from each participant in this study.

GC: Gastric cancer; *H. pylori*: *Helicobacter pylori*; BMI: Body mass index.

All subjects underwent gastroscopy with mucosal biopsy. The study was performed after at least 12 h of fasting. Topical lidocaine (Lignocaine aerosol 10%, Glaxo-Wellcome, UK) was used for local throat anesthesia if there was no history of allergy to it. All gastroscopies were performed by the same highly experienced endoscopists. During each endoscopy procedure, visual assessment was made of the mucosa of the esophagus and gastric cardia, fundus, corpus, pylorus and antrum, and the first portion of the duodenum and fundus of the stomach in inverted gastroscopy. In post-gastrectomy patients, during initial endoscopy, esophago-jejunal anastomosis was evaluated and tissue samples were taken for histological examination.

In patients with GC and in the control group, the rapid urease test was performed at the time of endoscopy. The biopsy samples from the antral mucosa (or in cases of cancer involvement of the distal stomach from any part of the gastric mucosa) were placed on the yellow colored gel that contained urea. The change in color of the indicator contained in the gel from yellow to pink demonstrated the presence of urease in the specimen. In accordance with the attached instructions (Urease Test "GUTplus", Lencomm Trade International, UK), the results were read at 30 min and 3 h after collection to decide whether or not the mucosa was infected by *H. pylori*.

In controls during endoscopy, samples from the gastric fundus mucosa, body and antrum were obtained for histopathological examination. In patients with GC, biopsy specimens were also taken from the tumor itself. The morphological form of the cancer was assessed according to the Bormann classification system. Patients with GC underwent surgery; in 10 cases, it was total gastrectomy, and in eight, it was subtotal (distal) gastrectomy.

Venous blood was collected from all patients with an empty stomach (i.e. at least 12 h without eating solid or liquid meals), at 08:00 h, and postprandially at 60 and 90 min after a mixed carbohydrate/protein/fat meal plus 250 mL milk of about 600 Kcal (given at 10:00 h). In the patients with GC, the above-mentioned protocol was repeated twice, that is, before treatment and 10 d after surgery, when the patients started to eat.

Venous blood samples were collected into tubes that contained a 10% aqueous solution of disodium EDTA to prevent clotting (0.05 mL 10% EDTA in 5 mL of blood). The centrifugation was performed within 10 min from of

blood collection. The blood was centrifuged for 10 min at 3000 r/min (MPW-340 centrifuge; Precision Mechanics, Warsaw, Poland). Plasma obtained after separation was divided into three portions and frozen (at about -80°C) until quantification analysis of ghrelin, GHS-R and gastrin by radioimmunoassay.

Laboratory tests were performed in the specialized Hormonal Research Laboratory of Isotopic Diagnostics at the Department of Physiology, Jagiellonian University Medical College.

The concentration of ghrelin in the test plasma samples was determined using S-2227RIKU4864 radioimmunoassay kits (Peninsula Laboratories, San Carlos, CA, USA). All measurements were performed in duplicate. Standard curves were prepared by appropriate dilution of 12.8 µL lyophilized peptide. Initial incubation of 100 µL plasma samples and subsequent dilutions of ghrelin standards (1, 2, 4, 8, 16, 32, 64, and 128 pg) was carried out for 24 h at 4°C, after addition of 100 µL highly specific rabbit antibodies for human ghrelin. Later, 100 µL of tracer (¹²⁵I-ghrelin, 10000-15000 cpm) was added to each sample and incubation was continued for another 24 h at 4°C. Immunoprecipitation by addition of second antibody (goat anti-rabbit IgG) and centrifugation after 90 min incubation at 25°C was performed for the final separation of the free and bound fractions. The concentration of ghrelin in plasma samples was calculated based on the calibration curve that was obtained by "Spline" method, based on measurements of radioactivity (gamma counter) for consecutive concentrations of the standards. Assay sensitivity was 3.0 pg/mL, and the specificity of the antibodies for the labeled human ghrelin was 100%. In accordance with the attached attestation (Peninsula Laboratories, USA) antibodies do not fall (0%) in cross-reaction with motilin, growth hormone releasing factor, orexin, secretin, VIP and galanin.

Assessments of gastrin levels were performed using a commercial kit (GAS-PR RIA; CIS Bio-International, France) following the manufacturer's recommendations as described before^[5,6,13]. The plasma samples (100 µL) were incubated in duplicate at 25°C for 3 h with 100 µL of tracer (¹²⁵I-gastrin) and 300 µL of anti G-17 antibody. The antibody equally recognized and had affinity to the gastrins G-17 and G-34. Points of the standard curve at concentrations of 11.2, 28.4, 68.4, 255.8, 651.2 pmol/L were prepared from lyophilized synthetic G-17 and incubated as above. Separation of the free from bound fraction was obtained by immunoprecipitation. Final radioactivity in the samples was assayed, and standard curve points were measured in a gamma counter (1574 Clinigamma, Wallac-LKB, Sweden), using the computer program Spline in order to calculate the concentration of gastrin.

Histopathological examination of gastric endoscopic biopsies was performed at the Department of Pathomorphology, Jagiellonian University Medical College. Specimens were fixed in 10% buffered formalin and used for paraffin preparations stained with hematoxylin and eosin, alcian blue and periodic acid-Schiff stain at pH 2.5, and the standard Giemsa method. Fixed specimens

Table 2 Plasma ghrelin concentrations (median and range) recorded under fasting conditions and postprandially (at 60 and 90 min after a meal) in gastric cancer patients before surgery, 4-5 yr after gastrectomy, and healthy controls (95% CI) (pg/mL)

were immersed in a series of alcohols and xylenes with increasing concentrations, and then embedded in a paraffin block. The paraffin blocks were cut into sections of 3 μ m, deparaffinized in a series of xylenes and alcohols with decreasing concentration, and stained by pathological methods. The Sydney classification system was used for the assessment of inflammation and atrophy, and Lauren's classification system for the evaluation of the type of gastric cancer.

Comparison of average hormone concentrations was performed using the general linear model, and more specifically, analysis of covariance. If a factor was statistically significant (at $\alpha = 0.05$), the post-hoc Tukey test (according to unequidistributed groups variant) was used to compare all possible pairs of means resulting from categorization according to factor.

RESULTS

In fasting and 60 and 90 min postprandial plasma samples from healthy controls, ghrelin levels decreased significantly at 60 and 90 min after food intake (Table 2, Figure 2). In contrast, plasma gastrin, which showed the lowest values under fasting conditions, almost doubled at 60 and 90 min after ingestion of a mixed meal (Table 3, Figure 2), so an inverse relationship was seen between fasting and postprandial ghrelin and gastrin concentrations in healthy subjects. Neither group of GC patients, just before surgery or 4-5 years after gastrectomy, showed this clear inverse relationship between fasting and postprandial plasma ghrelin and gastrin (Table 2).

Plasma ghrelin originates mainly from the Gr/endocrine/neurocrine cells that are present mainly in the gastric mucosa, and predominantly in the lining of the

Figure 2 Plasma ghrelin and gastrin concentrations in healthy subjects under fasting and postprandial conditions at 60 and 90 min after a meal. Median values (with range). "a" and "c" indicates significant ($P < 0.05$) change compared to fasting ghrelin or gastrin plasma concentrations.

proximal portion of the stomach. Therefore, we first analyzed the fasting and postprandial plasma ghrelin levels in patients with GC located in the proximal (fundus and corpus) or distal (antrum) stomach. Mean plasma levels of ghrelin (fasting, 60 and 90 min postprandially) in cancer patients before surgery in each of subsequent measurements (fasting, 60 and 90 min after a meal) were significantly lower in those with tumor located in the proximal stomach (fundus or corpus) compared with that in the distal stomach (antrum). As shown in Figure 3 and Table 2, in GC of the proximal stomach, the plasma ghrelin levels were as follows: mean fasting concentration was 193 pg/mL (95% CI: 150-220 pg/mL), and postprandial ghrelin level at 60 min was 161 pg/mL (95% CI: 125-

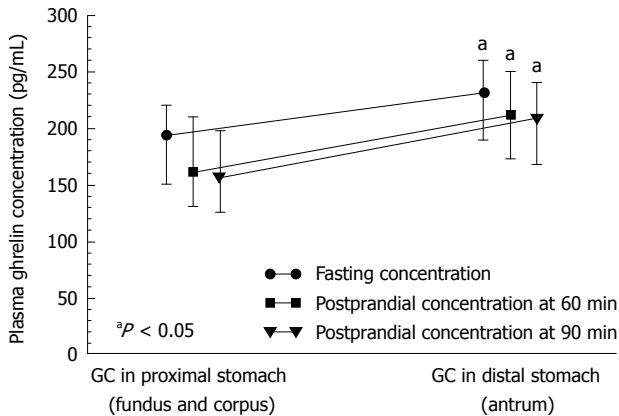

Figure 3 Median values (and range) of fasting and postprandial plasma ghrelin concentrations recorded in patients with gastric cancer localized in the proximal versus distal stomach. "a" indicates significant (^a $P < 0.05$) increase above the ghrelin levels in gastric cancer (GC) localized in proximal stomach.

220 pg/mL), and at 90 min, it was 160 pg/mL (95% CI: 153-248 pg/mL). There was no significant difference between fasting and postprandial ghrelin levels recorded in patients with proximal GC, whereas plasma ghrelin levels in patients with distal GC showed a small but significant increase. However, no difference was found between fasting and postprandial ghrelin levels in patients with GC localized in the proximal or distal portion of the stomach ($P = 0.3394$). As shown in Figure 3, in patients with distal GC, the corresponding plasma ghrelin values in subsequent samples were as follows: fasting, 230 pg/mL (95% CI: 182-252 pg/mL); 60 min postprandially, 201 pg/mL (95% CI: 165-235 pg/mL); and 90 min postprandially, 201 pg/mL (95% CI: 162-225 pg/mL).

The mRNA expressions for all three hormones, ghrelin, GHS-R and gastrin, in intact antrum and the gastric corpus and fundic mucosa are shown in Figure 4. Expression of gastrin and GHS-R mRNA was high in the GC tissue, whereas that of ghrelin was low. Expression of GHS-R and gastrin reached a high level in the intact antral mucosa and GC tissue, whereas ghrelin expression was low in GC but high in intact corpus and fundus mucosa (Figure 4).

Statistically significant differences in plasma levels of ghrelin under fasting conditions and after meal (at 60 and 90 min postprandially) were found in patients following total gastrectomy [in patients with proximal GC (fundus and body)] compared with those after distal gastrectomy (in patients with distal GC), both under fasting conditions and postprandially (Figure 5). Plasma ghrelin levels were significantly lower in the patients with total gastrectomy compared to those recorded after distal gastrectomy.

The plasma ghrelin levels in patients after total gastrectomy were as follows: fasting, 134 pg/mL (95% CI: 104-174 pg/mL); 60 min postprandial, 134 pg/mL (95% CI: 100.2-178 pg/mL); and 90 min postprandial, 136 pg/mL (95% CI: 100.6-161 pg/mL). In patients after subtotal (distal) gastrectomy, fasting ghrelin was a mean 241 pg/mL (95% CI: 205-300 pg/mL); at 60 min postprandially, it was

215 pg/mL (95% CI: 180-260 pg/mL) (subtotal gastrectomy); and at 90 min postprandial, it was 218 pg/mL (95% CI: 175-270 pg/mL). Plasma ghrelin concentrations under fasting conditions and postprandially at 60 and 90 min in patients following total gastrectomy were significantly lower ($P = 0.0183$) than those after subtotal gastrectomy (Figure 5).

Plasma gastrin recorded preoperatively under fasting conditions and postprandially (Figure 6) was significantly higher ($P < 0.05$) than that assessed after distal gastrectomy in patients operated upon for distal GC compared to those who underwent total gastrectomy. Unlike healthy controls, the GC patients who underwent surgery showed no significant difference between fasting and postprandial gastrin levels (at 60 and 90 min) after total or distal gastrectomy ($P = 0.4893$). It should be mentioned that both fasting and postprandial plasma gastrin levels tended to reach relatively lower values in patients with GC located in the proximal (fundic) portion of the stomach when compared to those recorded in patients with GC located beyond the fundus (Figure 7), but the difference between these levels was not statistically significant.

Plasma gastrin level showed a strong and statistically significant difference between fasting and postprandial conditions in the control subjects (Table 3, Figure 6). The lowest plasma gastrin occurred under fasting conditions, and the highest concentrations were observed at 60 and 90 min after food intake. Basal gastrin level in healthy controls was a mean 18.3 (95% CI: 8.4-39.5) pmol/L and it was almost doubled after 60 and 90 min upon food intake, reaching respectively, 39 pmol/L (95% CI: 19.1-79 pmol/L, $P = 0.0027$) and 40 pmol/L (95% CI: 20-79 pmol/L, $P = 0.0036$) (Table 3). In GC patients, fasting median plasma gastrin was 29 pmol/L (95% CI: 20-43 pmol/L), which was significantly higher than that observed in healthy controls. However, after food intake, mean plasma gastrin showed a relatively small, though significant increase at 60 min (38 pmol/L; 95% CI: 24.5-54.2 pmol/L) and at 90 min after food intake (37 pmol/L; 95% CI: 26.4-53 pmol/L). These elevations in plasma gastrin after feeding in GC patients were statistically significant only before surgery (Figure 6). At 4-5 years after gastrectomy (combined total and distal gastrectomy), there was no significant change in plasma gastrin after food intake, but median fasting gastrin levels (25.4 pmol/L; 95% CI: 14-45.5 pmol/L) were still significantly higher than those in healthy controls (Table 3).

After distal gastrectomy, fasting plasma gastrin fell significantly from about 25 pmol/L (95% CI: 21-32 pmol/L) before surgery to 15.7 pmol/L (95% CI: 11-21.1 pmol/L) after gastrectomy, and the differences between these concentrations were statistically significant (Figure 8). The decrease of median gastrin concentration after total gastrectomy was relatively stronger than that observed after subtotal gastrectomy (Figure 8).

The decrease in fasting and postprandial plasma gastrin was observed in both gastrectomy groups though postprandial gastrin level was relatively more reduced after

Figure 4 mRNA expression in mucosal and cancer tissue for ghrelin, growth hormone secretagogue receptor and gastrin. total than distal gastrectomy after which small but significant increase in plasma gastrin was observed postprandially in the last 90 min postprandial sample (Figure 9).

DISCUSSION

The aim of this study was to determine the relationship between plasma ghrelin and gastrin levels under fasting and postprandial conditions in healthy subjects and patients with GC who underwent total and distal gastrectomy. In addition, we analyzed gastric mRNA expression for ghrelin, GHS-R and gastrin in intact gastric mucosa and cancer tissue. It was found that in healthy controls, an inverse relationship existed; such that, when under fasting conditions plasma ghrelin increased, plasma gastrin decreased, and postprandially, when plasma ghrelin was

markedly attenuated, plasma gastrin was significantly increased compared to preprandial levels. The reason for this inverse relationship in healthy subjects is not known, but it is likely that, in the fasting stomach, the high level of ghrelin release, that activates gastric motility and stimulates appetite, causes excessive release of gastrin immediately after the entrance of a food bolus into the stomach. The stimulatory synergistic action of ghrelin on gastrin and gastric acid secretion has been observed previously, but mostly in experimental animals^[14], and this effect has been attributed to hormonal stimulation of vagal nerves and histamine release from the gastric enterochromaffin-like cells. Our results suggest that increased ghrelin release in the fasting (empty) stomach promotes gastrin secretion immediately after food intake. Our recent but unpublished data with parenteral administration of synthetic ghrelin

analog^[12] showed that it potently enhances plasma gastrin level, thus providing direct evidence that ghrelin is capable of stimulating gastrin release in humans, but it remains to be elucidated why plasma ghrelin falls immediately after

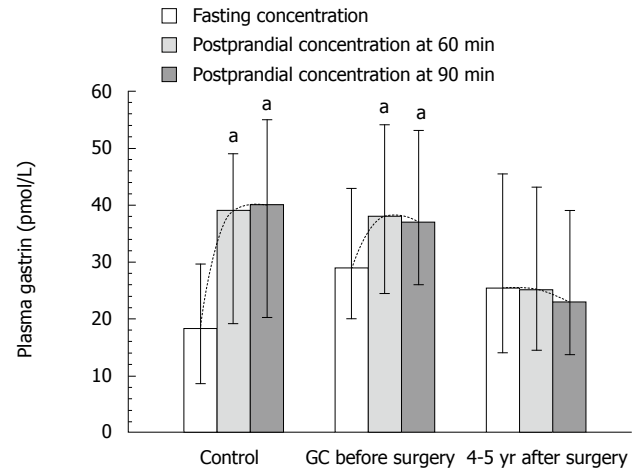

Figure 8 Plasma gastrin levels under fasting and postprandial conditions (at 60 and 90 min after a meal) in healthy controls, gastric cancer patients and patients after 4-5 yr of gastrectomy patients due to gastric cancer. food intake. It is possible that gastric acid stimulated by the combined action of ghrelin and gastrin^[13-15] activates local gastric somatostatin release that might cause paracrine inhibition of secretory activity of Gr-cells, which decreases plasma ghrelin level, but this requires further experimental and clinical data.

The major purpose of the present study was to explain the role of ghrelin in gastric carcinogenesis associated with *H. pylori* infection^[16-18], the spread of GC to the proximal or distal portion the stomach, and impairment of the ghrelin-gastrin relationship. The location and extent of tumor infiltration combined with widespread multifocal atrophic gastritis (caused by *H. pylori* infection) was found to affect ghrelin and gastrin release, and subsequently, to impair the intricate relationship between these two hormones. Indeed, we found that GC patients secrete significantly less ghrelin under fasting conditions, with little tendency

of this hormone to decline postprandially, whereas gastrin release greatly increases. The reduction in fasting plasma ghrelin in GC appears to depend upon: (1) the extent and proliferation of cancer in the stomach; and (2) *H. pylori*-induced atrophic gastritis. As expected from our previous studies, plasma gastrin is enhanced in GC; probably due to its expression and release by cancer cells themselves^[17,18]. In fundic GC, the fasting and postprandial ghrelin levels were lower than those in with GC in distal stomach (Figures 3 and 5).

The most marked alteration in ghrelin/gastrin ratio was found in patients who underwent total, and to a lesser extent distal gastrectomy. The inverse relationship between ghrelin and gastrin disappeared and both hormones became markedly altered by total gastrectomy. This agrees with the results of our most recent study^[13], which has shown that GC associated with *H. pylori* infection results in a marked decrease in ghrelin in plasma and cancer tissue. In the present study, we found that plasma levels of ghrelin were lower in patients with GC and in those with previous GC who underwent surgery 4-5 years previously, compared with the control group. Huang *et al*^[19] have shown no correlation between preoperative levels of ghrelin and the proximal or distal location of GC. Similarly, Jeon *et al*^[9] have not found any marked difference in preoperative serum ghrelin concentrations in patients with GC scheduled for gastric resection (total, subtotal and proximal). However, their analysis of ghrelin levels before and after surgery (on day 10) showed a significant difference in plasma ghrelin between patients who underwent total and distal gastrectomy. In the group with total gastrectomy, similar to our study, the decrease in ghrelin after surgery was significantly greater, and reached a maximum of about 70% of the preoperative concentration. This confirms the important role of the stomach, particularly its proximal portion, as the main source of ghrelin secretion^[3,8,9].

In our study, the mean ghrelin concentrations tended to increase slightly but significantly after distal but not total gastrectomy. The mean concentrations of plasma ghrelin among GC patients depended on the type of resection, particularly on its extent, and most importantly, upon preservation of the part of the stomach responsible for the production of most ghrelin, that is, the fundus and corpus. In the total resection group, on postoperative day 10, taking into account the plasma ghrelin concentration, it can be concluded that, in some patients, other tissues begin to take over slow production of ghrelin. However, after distal resection, when the fundus of the stomach was preserved, the levels of ghrelin actually increased compared to preoperative values^[20].

The plasma level of ghrelin after surgery in the subsequent samples (fasting and postprandial) showed a significant difference between patients who underwent total and subtotal resection. Plasma ghrelin levels at 60 and 90 min postprandially were significantly higher in patients who underwent distal gastric resection, compared to the group treated by total resection. Furthermore, physiological regulation of ghrelin secretion and its plasma level were, however, at least in part preserved; being highest in the fasting

state, lowest in the hour after a meal, and intermediate at 90 min after a meal (Figures 3 and 5). Jeon *et al*^[9] have also analyzed plasma levels of ghrelin in patients who underwent various types of gastric resection. However, unlike in our study, patients with early GC or GC infiltrating < 2 cm were examined within the first 7 d after surgery. In patients after resection of the proximal stomach, postoperative ghrelin increased more slowly than in patients after fundus-preserving resection. They concluded that compensatory ghrelin production occurs in the preserved part of the stomach. According to their experience, preservation of the fundus is more important than the distal stomach for ghrelin production after gastrectomy. After complete resection of the stomach, ghrelin levels in serum fell to about 30% of those before surgery. They did not observe compensatory production of ghrelin by other tissues until day 7 after surgery^[9]. Also, Takachi *et al*^[21] have demonstrated a significant decrease in the concentration of ghrelin after total gastrectomy, which was up to 12% of preoperative levels (measured on days 3 and 7 after surgery). Very low levels of ghrelin were observed in this group in the long-term follow-up after surgery (mean: 41 mo). By contrast, in patients treated by distal gastrectomy, on postoperative day 3, the hormone levels decreased to 39%, and on day 7, increased back to 56% of preoperative levels. Different results have been presented by Kim *et al*^[22], who found that after distal gastric resection for GC, the number of ghrelin-producing cells failed to increase, which correlated well with low plasma ghrelin levels.

In our study, the concentration of plasma ghrelin in patients who had undergone total gastrectomy 4-5 years previously was significantly lower than that after distal gastrectomy, and lower again when compared to the control group. The fasting levels of ghrelin were also lower compared to those in GC patients before surgery. Plasma ghrelin level in this group of GC patients was at 26%-66% of the reference value in the healthy controls. Thus, in our study group, only partial compensation of ghrelin production by other tissues was observed after removal of the stomach. Hosoda *et al*^[23] have shown that, after complete gastric resection, serum ghrelin concentration tends to normalize gradually as a result of production by other tissues. Plasma ghrelin level in their three patients fell at 30 min after gastrectomy to 50% of the preoperative concentration. At 240 d after gastric resection, plasma ghrelin reached about two-thirds of the preoperative value in two patients and 100% in the other. However, Ariyasu *et al*^[31] have found that plasma ghrelin in patients at 1-8 years after total gastrectomy was comparable with the control group, with a concentration that was about 35% of the preoperative level. Also, the above-mentioned study of Takachi *et al*^[21] has demonstrated very low levels of ghrelin during long-term follow-up after total gastrectomy.

In our study, we analyzed gastrin as well. Basal plasma gastrin was found to be markedly elevated in our patients with GC and coexisting *H. pylori* infection, as compared to the control group. Patients with GC tended to have higher levels of gastrin (Figures 6-9), which can result from *H. pylori* infection with accompanying atrophy of the mucous

membrane, and increased production of the hormone by the tumor cells themselves^[17,18]. We noted, however, significant differences in plasma levels of gastrin before and after surgery only in patients who underwent total gastrectomy.

In summary, a significant decrease to about 70% of preoperative levels of ghrelin was observed in our patients after total gastrectomy, which confirms an important role of the stomach as the principal place of ghrelin expression. After distal resection of the stomach, a compensatory increase in the production of ghrelin in relation to the level before surgery was observed. At 4-5 years after gastrectomy, full compensatory production of ghrelin by other tissues was not demonstrated. Higher basal plasma gastrin levels in patients with GC accompanied by *H. pylori* infection, compared to the control group, were probably associated with increased production of the hormone by the tumor cells themselves.

COMMENTS

Background

The major purpose of the present study was to explain the role of ghrelin and gastrin in gastric carcinogenesis associated with *Helicobacter pylori* (*H. pylori*) infection, the spread of gastric cancer (GC) into the proximal or distal stomach, and the profound impairment of the ghrelin-gastrin relationship.

Research frontiers

The location and extent of tumor infiltration combined with widespread multifocal atrophic gastritis (caused in this study by *H. pylori* infection) was found to affect ghrelin and gastrin release, and subsequently, to impair the intricate relationship between these two hormones. The authors found that GC patients express significantly less ghrelin under fasting conditions, with little tendency of this hormone to decline postprandially, whereas gastrin release remained strongly increased. The reduction in fasting plasma ghrelin in GC appears to depend upon: (1) extent and proliferation of the cancer in the stomach; and (2) *H. pylori*-induced atrophic gastritis. As expected from our previous studies, plasma gastrin was markedly enhanced in GC, probably due to its expression and release by cancer cells themselves. In fundic cancer, the fasting and postprandial ghrelin levels were lower than those in healthy controls; probably due to impairment by cancer and accompanying gastritis of the Gr-cells that are present mainly in the mucosal lining of the proximal stomach. In this study, the authors analyzed the plasma concentrations of ghrelin and gastrin in patients with advanced GC before and after total or subtotal gastrectomy. In addition, plasma concentrations of gastrin, ghrelin and gene expression of these hormonal peptides and growth hormone secretagogue receptor (GHS-R), were evaluated in intact mucosa and GC tissue associated with *H. pylori* infection.

Innovations and breakthroughs

A significant decrease to about 70% of preoperative levels of ghrelin observed in our patients after total gastrectomy confirms a crucial role of the stomach, particularly its proximal portion, as the principal place of ghrelin expression and release. After distal resection of the stomach, a compensatory increase in the production of ghrelin was clearly demonstrated. At 4-5 years after total gastrectomy, full compensatory takeover of ghrelin production by other tissues did not occur possibly due to the absence of the proximal stomach, which is the major source of ghrelin production. Higher basal plasma gastrin levels in patients with GC accompanied by *H. pylori* infection, compared to the control group, were

probably associated with increased production of the hormone by the tumor cells themselves.

Applications

Further study is required: (1) long-term observation of patients after resection of the stomach; (2) measurement of plasma ghrelin to establish whether compensation of hormone production by other tissues can be expected; and (3) consideration of the possible need for substitution of exogenous ghrelin or its active analogs in these patients.

Terminology

Ghrelin is a natural ligand for GHS-R. It was originally identified in rat gastric mucosa and shown to be expressed by endocrine Gr-cells. These ghrelin (Gr)-producing cells, represent about 20% of the total population of endocrine cells in the gastric mucosa. They are located in the lower parts of the oxyntic glands, and are present mostly in the proximal portion of the stomach (fundus and corpus). They are also the major source of hydrochloric acid, intrinsic factor, numerous growth factors, and pepsinogens, and therefore, they are important for digestive processes stimulated by the vagal nerves, gastrin/histamine, as well as by ghrelin itself. Ghrelin is a 28-amino acid peptide that acts as a stimulant for GH secretion by interacting with the receptor GHS-R. Characteristically, it is also the only circulatory gastrointestinal hormone that is known to be secreted by the empty (fasting) stomach to enhance food intake and maintain energy homeostasis following its central or peripheral administration. Ghrelin is currently considered to be the most powerful endogenous orexigenic (appetite stimulating) hormone, which results in a positive energy balance and subsequently in weight gain.

Peer review

This paper reports the results of studies on the relationship of ghrelin to gastrin in GC before and after gastrectomy. Using blood and biopsy specimens obtained from 70 patients who underwent endoscopy of the upper gastrointestinal tract, the authors demonstrated that, in healthy controls, plasma ghrelin reaches higher values under fasting conditions and falls postprandially, while gastrin level is low during fasting and shows a marked increase following food ingestion. Moreover, the decrease in fasting levels of ghrelin was observed in GC patients after total gastrectomy, but the level of plasma gastrin showed an increase. It is concluded, that the elevated plasma gastrin and suppression in fasting ghrelin in patients with GC suggests an intimate relationship between these two hormones in gastric carcinogenesis.

Abstract

AIM: To assess the anti-inflammatory effect of the probiotic *Bifidobacterium lactis* (*B. lactis*) in an adoptive transfer model of colitis.

METHODS: Donor and recipient mice received either *B. lactis* or bacterial culture medium as control (deMan Rogosa Sharpe) in drinking water for one week prior to transfer of a mix of naive and regulatory T cells until sacrifice.

RESULTS: All recipient mice developed signs of colonic inflammation, but a significant reduction of weight loss was observed in *B. lactis*-fed recipient mice compared to control mice. Moreover, a trend toward a diminution of mucosal thickness and attenuated epithelial damage was revealed. Colonic expression of pro-inflammatory and T cell markers was significantly reduced in *B. lactis*-fed recipient mice compared to controls. Concomitantly,

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC), referred to as inflammatory bowel diseases (IBDs), are chronic relapsing and remitting inflammatory diseases of the gastrointestinal tract. IBD affects people in the prime of their lives, with first diagnosis usually between the ages of 15 and 25 years, and due to the chronic nature of IBD, patients usually require lifelong treatment. More than one million people in the United States and more than four million people worldwide suffer from IBD. According to the current increase in affected people, IBD medical costs will reach approximately 2 billion euros by the end of 2010. The high cost and limited response to current thera-

pies prompt research and development of new treatment options.

IBD is thought to result from an inappropriate, overwhelming and ongoing activation of the mucosal immune system in genetically susceptible individuals driven by antigens originating from the microbiota of the gastrointestinal tract^[1]. Some of the immune-related characteristics of IBD include over-activity of effector lymphocytes, induction of pro-inflammatory cytokines, and failure of regulatory T cells (Tregs) to control inflammation^[2,3].

The crucial role of the intestinal microbiota in the induction and progress of disease has been validated in patients and in animal models of intestinal inflammation resembling IBD^[4,5]. Indeed, it was demonstrated that intestinal inflammation could not be induced under germ-free conditions^[6] and that antibiotic treatment attenuated the disease severity^[7]. Interestingly, the equilibrium of the intestinal microbiota appears to be perturbed in IBD as decreased levels of *Bifidobacterium* and *Lactobacillus* strains have been described in fecal samples, whereas raised counts of *Enterococcus* and *Bacteroides* species are found in inflamed mucosa of patients^[8]. Thus, as probiotics are known to have a strong homeostatic impact on the intestinal flora^[9], it is valuable to consider probiotics as alternative therapies for IBD. Hence, although conflicting reports exist, a number of studies report the benefits of probiotic therapy in the alleviation of IBD^[10-13]. For example, VSL#3, a mixture of four lactobacilli, three bifidobacteria and a streptococcus species, proved to be effective in inducing and maintaining remission in UC patients or in preventing pouchitis^[14-17].

While most clinical studies have relied on mixes of probiotic strains or on synbiotics to act on IBD, a few preclinical or *ex-vivo* studies have begun to reveal that the use of single probiotic strains, mainly consisting of *Lactobacillus* strains, can also be efficient in dampening inflammation^[18-21].

The present study reports on the beneficial effects of the use of a single *Bifidobacterium* strain, *Bifidobacterium lactis* (*B. lactis*), on intestinal inflammation in a murine model of T cell-mediated colitis. This well established Th1-type cytokine-mediated hyper-response model relies on the adoptive transfer of CD4⁺CD45RB^{high} naive T cells in immunodeficient mice^[22], such as RAG2^{-/-} mice which lack adaptive immunity^[23]. This cell transfer initiates colitis pathology akin to that of humans^[24], which develops as a result of the absence of suppressive regulatory cells in the recipient mice. Indeed, co-transfer of mature CD4⁺CD45RB^{low} T cells, a source of Tregs, reduces or even prevents colitis^[25]. In the present work, naive T cells were adoptively transferred together with a low proportion of Tregs. This particular setting, still permitting the induction of inflammation in recipient mice, provided an interesting tool allowing the simultaneous analysis of the impact of prophylactic *B. lactis* administration on both T cell partners involved in the induction (naive T cells) or regulation (Tregs) of IBD pathology.

MATERIALS AND METHODS

Animals

C57BL/6J mice (8- to 12-wk-old) were purchased from Harlan (Oxon, UK). Immunodeficient RAG2^{-/-} mice (8- to 12-wk-old)^[26] were used from a colony of RAG2^{-/-} mice maintained at the Institute for Labortierkunde, University of Zurich, Switzerland. The RAG2^{-/-} mouse colony was derived from a colony from Bern (Switzerland) by embryo transfer under gnotobiotic conditions and recolonized with an Altered Schaedler Flora^[27].

Preparation of *B. lactis* and experimental design

A freshly prepared solution containing *Bifidobacteria lactis* (*B. animalis* subsp. *lactis* NCC 2818) from the Nestlé Culture Collection (Nestlé Research Center, Lausanne, Switzerland) was used for this study. This strain was chosen according to *in vitro* anti-inflammatory properties (data not shown). Bacteria were grown for two passages under strictly anaerobic conditions in deMan Rogosa Sharpe (MRS) broth containing 0.05% cysteine (BD, Switzerland). After quantification of bacteria by serial dilution as described for fecal microbiota, 10% glycerol was added to the bacteria stock; aliquots were made and stored at -80°C until use. Frozen bacteria were added to drinking water each day of the study at 1×10^9 colony-forming units (CFU)/mL leading to a dose approximating 3×10^9 CFU/d per mouse. Donor and recipient mice were supplemented with either probiotic or MRS control solution (both containing 10% glycerol) according the study design (Figure 1). Note that as the settings of the present adoptive transfer model permit a focus on Tregs, probiotics were also given to donor mice in order to potentially stimulate these cells as soon as possible. Each group of recipient mice consisted of 5 mice.

Induction of colitis in RAG2^{-/-} mice by adoptive transfer

CD4⁺ T cells from mesenteric lymph nodes (MLNs) were isolated from C57BL/6 donor mice by negative depletion using MACS technology (Miltenyi Biotec, Germany). The negative fraction, enriched for CD4⁺ T cells, was stained using Fluorescein isothiocyanate-conjugated CD45RB antibody (mAb) (eBioscience, San Diego, USA) and Phycoerythrin-conjugated CD4 mAb (eBioscience, San Diego, USA). Subsequently, CD4⁺ T cells were sorted according to the expression of CD45RB on a FACS Aria (BD; Allschwil, Switzerland). Sorted CD4⁺CD45RB^{high} and CD4⁺CD45RB^{low} T cells were washed, resuspended at 1×10^6 cells/mL in sterile phosphate buffered saline and injected i.p. at the ratio of 9:1 respectively (2×10^5 total cells) into each of the 8- to 12-wk-old syngeneic RAG2^{-/-} recipient mice. This 9:1 ratio was chosen because it still allowed development of colitis despite the co-injection of regulatory cells. Body weight of recipient mice was measured every three days from day 0 to day 21, and then every other day until sacrifice (day 27). Body weights were recorded as percentage of initial body weight.

Figure 1 Experimental set up. Feeding of *Bifidobacterium lactis* (*B. lactis*)-fed donors and recipients mice were started on day -7 (D-7) until D0 for donor mice and until D27 for recipients. At D0, donor mice were sacrificed and cell transfer was performed in RAG⁺ recipient mice..

Sample collection

Fresh fecal samples (approximately 0.05 g) were collected at three time-points during the study: before initiation of *B. lactis* supplementation (day -7), at the day of T cell transfer (day 0), and at the end of the study (day 27). They were collected into 0.5 mL Ringer's solution, immediately homogenized and snap-frozen, then stored at -80°C until analysis. Blood samples were collected at the same time points as fecal samples and frozen at -80°C until needed. At the end of the experimental period, mice were sacrificed and colon was divided into three parts. The proximal and the distal parts were snap-frozen in liquid nitrogen for protein and mRNA expression analysis, respectively. A smaller sample of the middle colon was used for histopathological analysis.

Fecal microbiota

Fecal extracts were diluted in pre-reduced Ringer's solution (0.5% cysteine) to perform serial dilutions (10^{-2} to 10^{-6}) and then plated. Portions (100 μ L) of appropriate dilutions were plated onto selective or semi/selective media. *Bifidobacteria* were counted on tomato juice agar medium. Plates for the enumeration of *Bifidobacteria* colonies were incubated at 37°C in anaerobic conditions, in a jar containing Anaerocult A tablets (Merck, Germany), for 48 h. After incubation, each plate was examined for bacterial colonies. The detection-limit for the assessed bacteria dilutions was 10^3 . Bacterial counts were expressed as means log₁₀ CFU/g feces \pm SE. Detection of *B. lactis* was performed by polymerase chain reaction (PCR) using *B. lactis*-specific primers.

Histological assessment

Paraffin-embedded colonic tissue sections were scored as previously described^[28], with minor modifications. Briefly, specimens of the transverse colon of each animal were collected and fixed immediately in 4% buffered paraformaldehyde for 16-24 h for subsequent preparation of paraffin-embedded tissue blocks. Tissue sections were stained with hematoxylin/eosin for subsequent histopathological assessment. Each tissue section was independently evaluated by at least two trained pathologists according to a standard evaluation sheet in a blinded fashion. Histological assessment was performed using the scoring criteria displayed in Table 1. The range of histopathological scores was from 1 (no alteration) to 16 (most severe signs of colitis).

Table 1 Summary of assessed criteria to determine histological scoring

Criteria	Scoring
Infiltration of the colonic lamina propria	0-3
Loss of goblet cells	0-3
Crypt abscesses	0-3
Epithelial erosion	0-2
Hyperemia	0-2
Thickness of the colonic mucosa	1-3

Protein expression

Protein extraction and quantification: Colons were homogenized in RIPA (Radio Immuno-Precipitation Assay) buffer containing 50 mmol/L Tris base 50, 150 mmol/L NaCl, 2 mmol/L EDTA (Ethylene Diamine Tetraacetic Acid), 2 mmol/L EGTA (Ethylene Glycol Tetraacetic Acid), 0.5% sodium deoxycholate, 1% Nonidet P-40, 0.1% SDS (Sodium Dodecyl Sulfate), 50 mmol/L NaF, 200 μ mol/L Na₃VO₄, 0.1% β -mercaptoethanol, 500 μ mol/L AEBSF [4-(2-AminoEthyl) BenzeneSulfonyl Fluoride hydrochloride], 20 μ mol/L bestatin, 7 μ mol/L E-64, 11 μ mol/L leupeptin, 7.5 μ mol/L pepstatin A, and 0.4 μ mol/L aprotinin. The pH was adjusted to 7.2. The homogenate was then centrifuged at 10000 g for 10 min at 4°C to remove debris. Protein determination was carried out using a modified Lowry method, as described by the manufacturer (Bio-Rad, USA).

Enzyme-linked immunosorbent assay measurements:

Interleukin (IL)-6 and tumor necrosis factor (TNF)- α levels were measured in the colon protein extracts by enzyme-linked immunosorbent assay (ELISA) following the manufacturer's instructions (R&D Systems, England). To avoid interference of the protein lysis buffer with the ELISA reaction, four independent dilutions were performed. All samples were measured in technical duplicates and the concentration calculations were derived from appropriate standard curves.

Electrophoresis and Western blotting: 50 μ g of protein were separated by electrophoresis on a MOPS [3-(N-Morpholino)PropaneSulfonic acid] SDS running 4%-12% bis-tris gel (Invitrogen, USA). Proteins were then transferred to a nitrocellulose (NC) membrane by electroblotting

(30 V for 60 min). Western blot analysis was performed with antibodies against murine cyclooxygenase 2 (COX-2) (Cayman Chemicals, USA), p38 and phospho p38 (Cell Signaling Technology, USA), signal transducer and activator of transcription 3 (STAT-3) and phospho STAT-3 (Cell Signaling Technology, USA) and β -actin (Sigma, St. Louis, MO, USA). Secondary antibodies were from Molecular Probes (USA) or Jackson ImmunoResearch Laboratories (USA). Relative quantitation of bands was determined using the Scion Image Densitometry System (Scion Corp., USA), with all quantities normalized to expression levels of β -actin.

Immunohistochemistry for Ki-67 on formalin-fixed tissue sections: After dewaxing, tissue sections were pretreated in 10 mmol/L citrate buffer, pH 6.0, for 7 min at 1 bar/121°C. Pretreated tissue sections were subsequently incubated for 60 min with a primary rat-anti-mouse Ki-67 mAb (Clone: Tec-3; isotype: rat IgG2a; DakoCytomation, USA). After washing, sections were incubated with the biotinylated secondary reagent (rabbit-anti-rat Ig; absorbed with mouse Ig (DakoCytomation). Streptavidin-HRP complexes with 3,3'-diaminobenzidine as the chromogen were used for detection.

mRNA expression

RNA extraction of the homogenized tissues was performed using the NucleoSpin RNA II Kit (Macherey-Nagel, Germany). Total RNA was quantified using the Ribogreen RNA Quantitation Kit (Molecular Probes, USA), and the RNA quality was assessed by Agilent RNA 6000 Nano LabChip Kit (Agilent Technologies, USA). Total RNA (2 μ g) was reverse transcribed using MultiScribe reverse transcriptase (Applied Biosystems, USA). Real-time PCR was carried out using custom design Low Density Array (Applied Biosystems, X, USA). The quantitative PCR (qPCR) reactions were performed with 2 ng of cDNA on ABI PRISM 7900HT qPCR machine (Applied Biosystems, USA) piloted by SDS 2.2 software (Applied Biosystems, USA). Results of target mRNA are expressed as the number of specific copies for 10^6 GAPDH mRNA molecules in the same sample.

Statistical analysis

Statistical analysis was performed using the two-tailed Mann-Whitney *U* test. Differences were considered statistically significant when $P < 0.05$. All data are shown as median \pm interquartile-range (IQR) except for the body weight analysis.

RESULTS

Detection of *B. lactis* in fecal samples

In order to control the probiotic intake, detection of *B. lactis* in fecal samples was performed using PCR detection. No *B. lactis* was identified in the feces prior to administration of this strain in donor C57BL/6J and recipient RAG^{-/-} mice. All donor animals receiving the treatment were positive for *B. lactis* on the day of cell transfer (day 0,

Figure 2 *Bifidobacterium lactis* feeding significantly delayed weight loss. Weight curves for control-fed and *Bifidobacterium lactis* (*B. lactis*)-fed recipient mice following adoptive T cell transfer. Every three days or every other day following T cell transfer, body weight (BW) of control-fed and *B. lactis*-fed recipient mice was recorded. Results are expressed as the mean \pm SE ($n = 5$ mice per group) and statistical significance is indicated ($^aP < 0.05$).

data not shown). In the recipient animals, supplemented with the probiotic strain, approximately 1×10^8 CFU of *B. Lactis*/g fecal content could be measured at day 0 and day 27 (sacrifice day).

Effect of *B. lactis* on body weight loss

As already described in other studies^[29,30], control recipients of CD4⁺ T cells started to lose body weight from day 9 after adoptive cell transfer. Thereafter they continuously lost weight and on the day of sacrifice (day 27), their body weight was lower than on the day of initial T cell transfer (Figure 2). In contrast, *B. lactis*-fed recipient mice showed a marked delay of onset of body weight loss, starting only at day 18. Thereafter *B. lactis*-fed recipients also continued to lose weight until the day of sacrifice (day 27). At the end of the experimental period, body weight of *B. lactis*-fed recipients of CD4 T cells was comparable to the initial body weight at the time of colitis induction by adoptive T cell transfer (Figure 2).

Effect of *B. lactis* on colon histopathology

Histopathology scores, ranging from 0 (no colitis) to 16 (most severe colitis) (Table 1), were based on the analysis of 6 criteria as described in the methodology section. At sacrifice, the total colitis scores of *B. lactis*-treated and -untreated recipient groups were not significantly different (data not shown). When each of the histopathology criteria was assessed individually, differences between the two groups of recipients were nonetheless observed at the level of mucosal thickness; *B. lactis*-treated recipient mice showing a tendency for an attenuated mucosal thickening compared to control recipient mice (Figure 3B), resulting in a lower colitis score as shown in Figure 3A.

Beyond criteria used for histopathology scoring, epithelial proliferation is considered to be strongly associated with a gastrointestinal inflammatory status^[31]. In order to evaluate these criteria, paraffin-embedded colon sections were stained for Ki67 expression by immunohistochemical

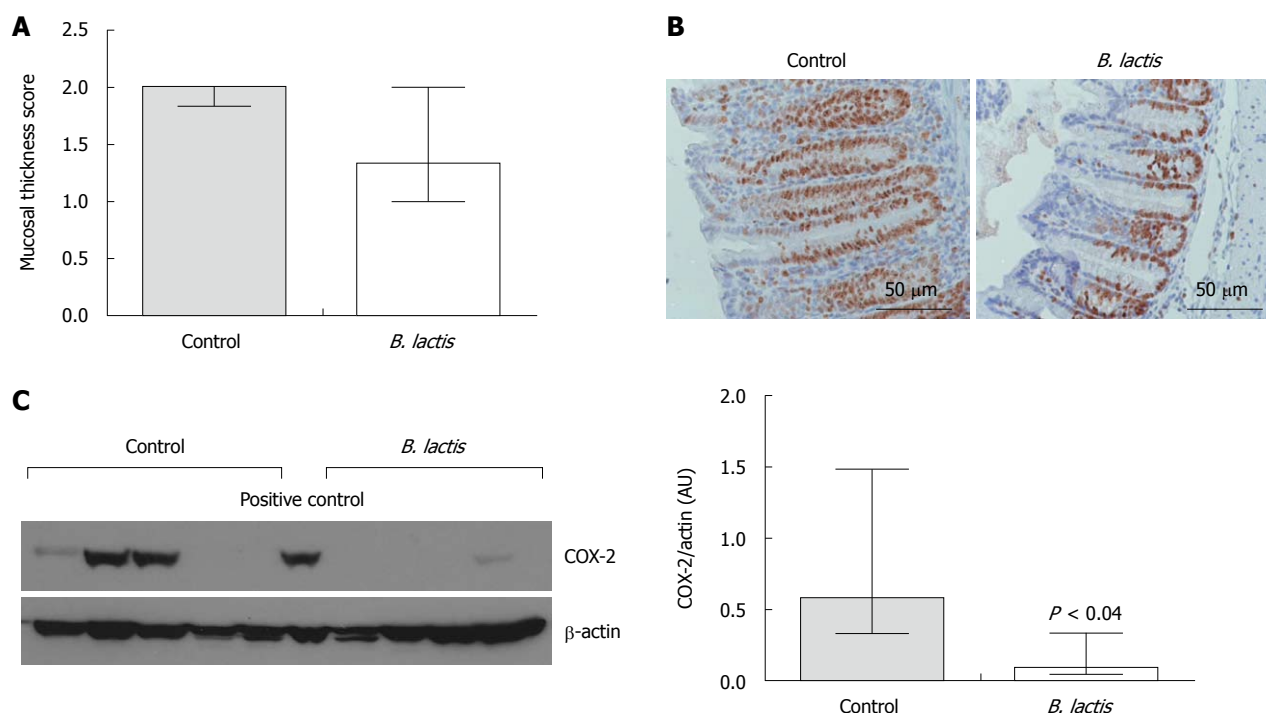

Figure 3 Histological assessment of colon inflammation for control- and *Bifidobacterium lactis*-fed recipient mice following adoptive T cell transfer. A: Mucosal thickness was assessed using a specific scored graduated from 0-3. Results are expressed as the mean \pm interquartile-range (IQR) ($n = 5$ mice per group); B: Assessment by immunostaining of the proliferation marker Ki67 (proliferating cells are characterised by the brown nuclear staining). Representative examples of longitudinal slices from colons of control colitic (left panel) and *Bifidobacterium lactis* (*B. lactis*)-fed colitic (right panel) mice are shown; C: Expression of cyclooxygenase 2 (COX-2) protein in colon tissue samples from colitic mice was quantified by Western blotting analysis (left panel). Individual expressions and relative densitometric quantification of the bands are presented (right panel). Results are expressed as the mean \pm IQR ($n = 5$ mice per group) and statistical significances is indicated.

labeling reaction to determine the proportion of proliferating cells in the colonic epithelium in colitic mice, treated or not with *B. lactis* (Figure 3B). Colonic epithelium from all recipient mice showed a high proliferation rate in the lower two-thirds of the colonic crypts (Figure 3B), whereas proliferation was only restricted to crypts in healthy controls (data not shown). Nevertheless, epithelial hyper-proliferation appeared markedly reduced in *B. lactis*-treated recipient mice (Figure 3B).

Effect of *B. lactis* on colonic pro-inflammatory markers

The effect of *B. lactis* feeding on the expression of well known proinflammatory markers, such as COX-2, IL-6 or TNF- α , in the colon of recipient mice was assessed. COX-2 is an enzyme known to be strongly induced in intestinal epithelial cells upon inflammatory conditions. Upon disease induction and in absence of treatment (control recipient group), the protein expression of COX-2 was strongly detected in two out of five samples and slightly in a third one (Figure 3C). Conversely, in the *B. lactis*-fed group, only one out of five samples had slight COX-2 protein expression (Figure 3C). Relative densitometric quantification of the bands clearly revealed a significant decrease of COX-2 expression in the *B. lactis*-fed group compared to control mice (Figure 3C).

Feeding with *B. lactis* also resulted in a significant decrease of IL-6 and TNF- α protein production in the colon of recipient mice compared to the non-treated recipient mice (Figure 4A and C). Accordingly, phosphorylation of the transcription factors STAT-3 and p38, associated

with the signaling pathways of these two cytokines, was also diminished by *B. lactis* feeding (Figure 4B and D).

Effect of *B. lactis* on dendritic cell markers

It is now well established that co-stimulatory interactions between antigen-presenting cells and cells of the adaptive immune system, such as the CD40/CD40 ligand (CD40L) and OX40/OX40 ligand (OX40L) (CD134/C134L) pathways, play a crucial role in colitis induction and severity of disease^[32,33]. mRNA expressions of these four molecules were thus assessed in colon tissue samples of recipient mice. Whereas they were all induced in recipient mice in comparison to healthy controls (Figure 5A-D), *B. lactis* feeding significantly down-regulated the expression levels of CD40L and OX40/OX40L when compared to non-treated colitic controls (Figure 5B-D). Expression of CD40 only showed a tendency to be down-regulated by *B. lactis* feeding.

Effect of *B. lactis* on colonic T cell markers

Colitis induction in the transfer model of colitis critically depends on the expansion and preferential differentiation of transferred T cells into Th1 T cells. Hence, T cell-related gene transcripts interferon (IFN)- γ , CD3 γ and T-bet were measured in colonic tissue samples in both groups of recipients. All of these T-cell transcripts, highly expressed in colitic animals when compared to healthy control mice, were significantly decreased in *B. lactis*-fed mice (Figure 6A-C). In order to gain insight into regulatory functions of T cells, mRNA expression of forkhead

Figure 4 *Bifidobacterium lactis* feeding significantly diminished protein expression and phosphorylation status of pro-inflammatory markers in colon of recipient mice following adoptive T cell transfer. Expression of interleukin-6 (IL-6) (A) and tumor necrosis factor- α (TNF- α) (C) protein was measured by enzyme-linked immunosorbent assay in colon tissue samples from colitic recipients. The ratios of phosphorylated signal transducer and activator of transcription-3 (pSTAT-3) vs STAT-3 (B) and of pp38 vs p38 (D) were assessed by Western blotting analysis in colon tissue samples of colitic mice. Relative densitometric quantifications of the Western blotting bands are presented. Results are expressed as the mean \pm interquartile-range (A and C, $n = 5$; B, $n = 3$; and D, $n = 4$ mice per group) and statistical significance is indicated. *B. lactis*: *Bifidobacterium lactis*.

box protein 3 (Foxp3) in colon samples was also quantified and showed that Treg cells were significantly potentiated by feeding with the probiotics, as a 9.2-fold increase of the expression of Foxp3 was observed in *B. lactis*-fed mice when compared to control colitic mice (Figure 6D).

DISCUSSION

The exact etiology of chronic IBD is still unknown but seems complex and multifactorial. From human studies and animal models of experimental colitis, increasing evidence has been generated that the resident intestinal flora play a critical role in the development of the intestinal inflammation in genetically susceptible individuals. Indeed, on given genetic backgrounds, such as in IL-2- and IL-10-knockout mice or in HLA-B27 transgenic rats, as well as in the present colitis model, colitis develops when animals are raised under specific pathogen-free conditions, but almost no disease can be observed under germ-free conditions^[34-36]. With regard to the importance of the quality of the microflora in colitis, clinical and preclinical observations have demonstrated beneficial effects of probiotic microorganisms in the treatment of IBD in humans^[11,12,14,15] and in experimental models of colitis^[20,37-39].

While most reports in the literature describe effects of mixes of probiotic strains or of synbiotics, only a few papers have investigated the beneficial potential of the use of single probiotic strains, and moreover of *Bifidobacterium* probiotic strains, to alleviate intestinal inflammation. As a preclinical model of IBD, the CD4⁺CD45RB^{high} naive T cell transfer model of colitis^[29,30] was exploited in this

study. This widely used model of colitis allows the study of the Th1 cell-mediated immune events leading, without treatment, to an irreversible colonic inflammation characterized by a massive influx of mononuclear cells into the colonic mucosa, an elevated level of pro-inflammatory cytokines, appearance of crypt abscesses and epithelial cell erosions^[40]. Noteworthy, as for experimental models using genetically modified animals, the composition of the intestinal flora is also clearly known to affect the kinetics and the severity of the colitis in this particular model^[41]. Moreover, in the present study, the fact that CD4⁺CD45RB^{low} T cells were also transferred to recipient mice permitted us to also study the role that Tregs play in suppressing or limiting the onset and/or regulation of inflammation. Thus, for all the above mentioned reasons, this is to our knowledge one of the few studies that shows the preventive effects of a *Bifidobacterium* strain on the development of IBD in the CD4⁺CD45RB^{high} T cell reconstituted RAG-2 deficient mouse model with insights on Tregs.

Hence, it was demonstrated in the present study that *B. lactis* actually possesses *in vivo* immuno-modulatory properties and was able to improve the inflammatory status of treated mice. Indeed, it was revealed that supplementation of mice with *B. lactis*, one week before and during onset of colitis, resulted in a diminished colitis-induced weight loss (Figure 2), a reduction of mucosal thickness (Figure 3), a decreased expression of pro-inflammatory cytokines and related transcription factors (Figure 4), a diminution of T cell infiltration (Figure 5) and an increase of regulatory T cell markers (Figure 6) when compared to non-supplemented control animals.

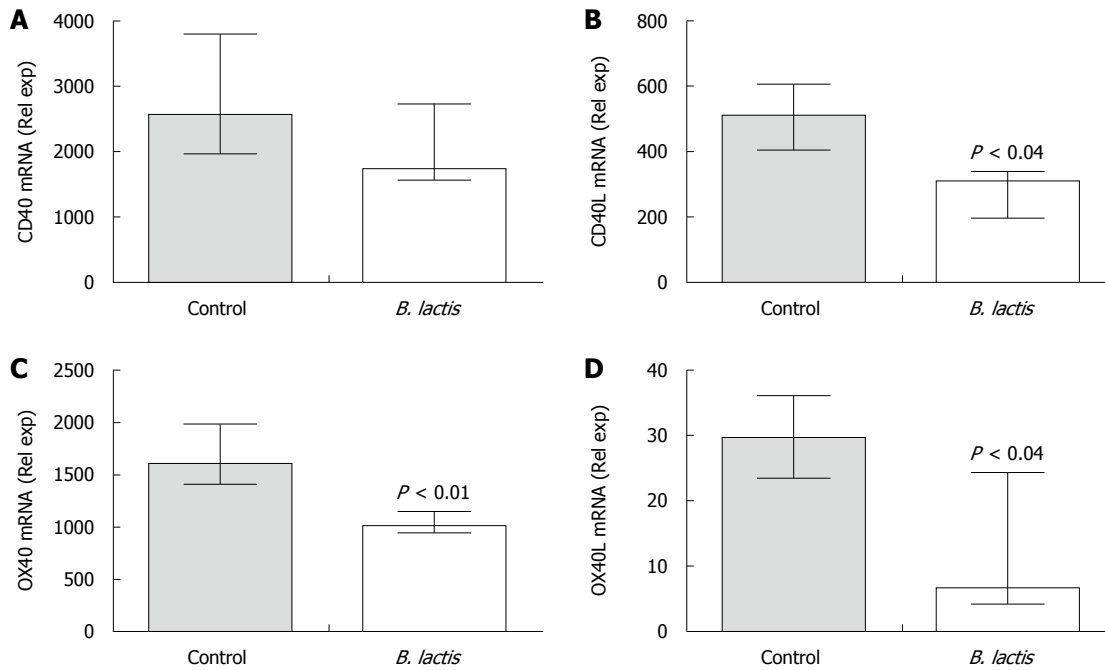

Figure 5 *Bifidobacterium lactis* feeding diminished the expression of mRNA coding for antigen-presenting cells and T cell costimulatory molecules in colon of recipient mice following adoptive T cell transfer. The expressions of mRNA coding for CD40 (A), CD40 ligand (CD40L) (B), OX40 (C) and OX40 ligand (OX40L) (D) were assessed in colon samples of colitic and healthy mice by real-time polymerase chain reaction using the low density array technology. Results are expressed as the mean ± interquartile-range ($n = 5$ mice per group) and statistical significance is indicated. *B. lactis*: *Bifidobacterium lactis*.

Figure 6 *Bifidobacterium lactis* feeding significantly diminished mRNA expression of Th1 cell markers and significantly increased mRNA expression of a Treg marker in colon of recipient mice following adoptive T cell transfer. The expressions of mRNA coding for interferon- γ (IFN- γ) (A), CD3 γ (B), T-bet (C) and FoxP3 (D) were assessed in colon samples of recipient mice by real-time polymerase chain reaction using the low density array technology. Results are expressed as the mean ± interquartile-range ($n = 5$ mice per group) and statistical significance is indicated. *B. lactis*: *Bifidobacterium lactis*.

Follow-up analysis of the weight of mice showed that *B. lactis* treatment significantly delayed the body weight loss observed in control recipient mice (Figure 2), revealing a major impact of the *B. lactis* supplementation on the overall metabolism of treated mice. After some gain of weight due to normal growth of the mice, weight loss was already

visible at day 9 in the control recipient mice whereas this only started at day 18 in the *B. lactis*-fed mice. In this latter group, no real weight loss was even observed at the end of the study, the mice having reached their starting weight. Whether this weight loss would continue under the starting weight should be tested in future studies.

Concerning histopathological analyses of the colons at sacrifice, even if the benefit observed regarding weight loss was not visible on total score, among all criteria investigated mucosal thickness was particularly improved by probiotic supplementation, suggesting a diminution of cellular infiltration in the mucosa (Figure 3A).

In line with this reduction of colonic thickness, a strong decrease of the reparative proliferative activity of colonic epithelial cells, assessed by immunostaining using the proliferative marker Ki-67, was observed in the mice fed with *B. lactis*. Indeed, colonic inflammation induces strong epithelial erosion due to uncontrolled apoptosis^[42]. This increased level of apoptosis, which contributes significantly to the IBD pathology^[11], is presumably due in part to a strong increase of inflammatory cytokines such as TNF and IFN- γ as observed in our study; cytokines known to be able to induce apoptosis directly by suppressing anti-apoptotic signals in the epithelium^[43,44]. Hence, since in our experimental setting mice were sacrificed at a late time point relative to onset of inflammation, reparative proliferation was the more relevant parameter to be investigated here rather than apoptosis.

The role of pro-inflammatory cytokines in IBD pathology has been firmly established^[45]. Dysregulation of the intestinal immune system both at humoral and cellular level constitutes an important element in the multifactorial pathogenesis of IBD. A strongly elevated expression of pro-inflammatory mediators, most notably IL-6 and TNF- α , has been identified in IBD patients and experimental models of colitis in mice^[46]. In cases of acute inflammation, IL-6 synthesized mainly by macrophages first binds to the IL-6 receptor (IL-6R); this complex then associates with gp130, inducing dimerization and the initiation of signaling through STAT-3. In the present study, the decrease of colonic IL-6 expression and STAT-3 phosphorylation induced by *B. lactis* strongly suggest that the probiotic could act, at least in part, on the IL-6 trans-signaling pathway and could by this process dampen the inflammation. Indeed, previous studies performed in both animal models and humans clearly described that abrogation of IL-6 pathway activation was associated with an improvement of colonic inflammation^[47-49].

Moreover, analysis of p38 phosphorylation has confirmed the beneficial impact of *B. lactis* feeding on inflammation. Indeed, p38 kinase regulates the production of key inflammatory mediators, including TNF- α or IL-1 β . In addition, p38 also acts downstream of cytokines such as TNF- α , mediating some of their effects^[50]. Hence, the significant diminution of p38 phosphorylation observed in this study upon *B. lactis* feeding (Figure 4) revealed the broad range of potential effects of the probiotic treatment on colitis.

B. lactis feeding also modulated COX-2 protein expression in the colon of mice (Figure 3C). COX-2, an enzyme responsible for formation of important biological mediators called prostanoids (including prostaglandins, prostacyclin and thromboxane), has been shown to be specifically induced in epithelial cells under IBD conditions^[51]. Among the prostanoids related to COX-2 activity,

prostaglandins represent one of the most important components of mucosal defence in the small intestine and colon. The weight of evidence collected so far suggests that prostaglandins derived from COX-2 are important in promoting the healing of mucosal injury, in protecting against bacterial invasion, and in down-regulating the mucosal immune system. Suppression of COX-2 in a setting of gastrointestinal inflammation and ulceration has been shown in experimental models to result in impaired healing and exacerbation of inflammation-mediated injury^[52-55]. Hence, at the intestinal level, expression of COX-2 is a natural response of the organism to prevent tissue damage due to inflammation and is sustained by this inflammation. In this way, COX-2 expression represents a good marker of the actual disease activity^[56]. In the present study, the observed attenuated COX-2 expression upon *B. lactis* feeding strongly indicates an anti-inflammatory effect of this probiotic bacterium.

Colitis, in the T-cell adoptive transfer model, is accompanied by the accumulation of dendritic cells (DCs) in the MLN as well as locally in the colon^[57]. DCs in the MLN express an activated phenotype with increased expression of CD40 and the TNF-like molecule OX40L^[58]. Indeed, activated T cells express the cell-surface costimulatory molecules CD40L and OX40. CD40L binds to CD40 on antigen-presenting cells (APCs) inducing OX40L expression, and leading to the transmission of further activatory signals to both the T cell and the APC^[59,60]. The CD40-CD40L and OX40L-OX40 pathways play functional roles in the inflammatory response in this model, as blockade of either pathway inhibits colitis^[58,61,62]. The overall decrease in these four costimulatory partners observed upon *B. lactis* feeding (Figure 5) thus revealed a diminished activity of the immune system in sustaining the adaptive inflammatory reactions. The diminution in the number of T cells present in the colonic mucosa of *B. lactis*-treated mice compared to control animals, as revealed by the measurement of the relative expression of CD3 γ mRNA (Figure 6B), might be considered as a partial consequence of this dampening of the costimulatory activity.

Beyond the intensity of the DC-T cell interaction, *B. lactis* feeding could interfere with the outcome of the interaction in the mucosa. Indeed, *B. lactis* was also able to significantly decrease T-bet and IFN- γ mRNA expression compared to untreated animals (Figure 6A and C). IFN- γ is the hallmark Th1 cytokine and T-bet is a critical factor for both the initiation and perpetuation of Th1-mediated colitis. Indeed, in another type of adoptive transfer model, T-bet-deficient CD4⁺CD62L⁺ T cells failed to induce Th1-mediated colitis in immunodeficient hosts, whereas T-bet-overexpressing CD4⁺CD62L⁺ T cells induced a more rapid onset of colitis^[63]. The observed diminution of the IFN- γ mRNA expression is fully in line with the decrease of T-bet, revealing a functional impact on activated T cells by *B. lactis*.

Development of colitis following transfer of CD4⁺CD45RB^{high} T cells into immunodeficient recipients can be modulated or even abrogated by cotransfer of cells from the antigen-experienced CD4⁺CD45RB^{low} population^[24], a potential source of Tregs. In the present study, as a small

proportion of such cells have been actually cotransferred, we performed a quantification of mRNA expression for Foxp3 in colon samples of recipient mice. This marker has been identified as being necessary for both the development and function of Tregs^[64-66]. It appeared that *B. lactis* feeding significantly potentiated the presence of these particular cells in the inflamed mucosa as treated mice showed a strong augmentation of Foxp3 mRNA expression compared to control mice (Figure 6D) whereas total number of T cells decreased in a converse fashion (Figure 6B). Moreover, while the dampened expression of all analyzed T cell-related proinflammatory markers might be a direct consequence of the diminution in T cell number in the colonic mucosa of *B. lactis*-fed animals, the fact that Foxp3 mRNA expression was up-regulated indicates a strongly increased prevalence of Tregs in the inflamed tissues. This increase of Treg cells may be one of the key players in the alleviation of the colitis observed in this study.

Despite the fact that mechanisms of action remain unclear, two different options could be hypothesized to explain the effect of probiotics on the Tregs. The classical one will be that probiotics in the colon generated antigenic peptides or molecules able to inhibit or modulate DC activation responsible for uncontrolled T cell proliferation which leads to colitis development, as supported by the diminished expression of the CD40-CD40L and OX40L-OX40 costimulatory partners. More recently, a new hypothesis could be proposed to explain the probiotic effect, involving the toll-like receptor (TLR) pathway. Indeed, it has been revealed that TLR molecules that recognize a vast range of microbial products, thought to be only restricted to cells of innate immunity, are also expressed by Tregs^[67]. Interestingly, a recent study demonstrated a role of the TLR2 pathway in the control of expansion and function of Tregs^[68]. Such a direct effect of TLR ligands on Tregs thus opens a new way to consider the impact of probiotics in the regulation of colitis. Future investigations on the impact of *B. lactis* on Tregs will provide interesting pieces of information regarding how and when probiotics exert their effect, as the present study does not allow discrimination as to whether Tregs are potentiated already in donor mice or only in recipient mice upon induction of inflammation.

In conclusion, it was shown in the present study that *B. lactis* is a *Bifidobacterium* probiotic strain able to provide anti-inflammatory properties in an adoptive cell transfer model of IBD. Mechanisms of actions are not completely elucidated and need further investigations, but a clear effect on Tregs may be suggested as a key influence.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Mark Waldron (Nestlé Research Center, Lausanne, Switzerland) for critically reading the manuscript.

COMMENTS

Background

Ulcerative colitis and Crohn's disease, commonly known as inflammatory

bowel disease (IBD), affect 0.5%-1% of the Western world's population and are increasing in the developing countries. IBD is a chronic disease that requires lifelong treatment. Many patients do not respond or do not comply well with the recent medications. This, in addition to the high cost of these approaches, urges the scientific community to develop new therapeutic approaches.

Research frontiers

Many probiotics have been identified as a powerful strategy to reduce intestinal inflammation in preclinical and human trials. However, despite a high number of publications there are very few explanations concerning their mechanism of action.

Innovations and breakthroughs

Using one of the most valuable murine models of colitis, we have highlighted the fact that a single *Bifidobacterium* probiotic strain was able to prevent intestinal inflammation by increasing the number of regulatory T cells in the gut.

Applications

Through this publication we would like to emphasize that *Bifidobacterium lactis* (NCC 2818) could be considered as a good auxiliary to current treatment used to reduce intestinal inflammation in IBD patients.

Terminology

According to the World Health Organization definition, probiotics are live microorganisms which when consumed in adequate amounts confer health benefits to the host.

Peer review

In the manuscript, the authors evaluated the anti-inflammatory properties of a *B. lactis* strain in a colitis mouse model. The experiments were carefully designed and the manuscript is easy to read.

Abstract

AIM: To explore the expression pattern of E2F5 in primary hepatocellular carcinomas (HCCs) and elucidate the roles of E2F5 in hepatocarcinogenesis.

METHODS: E2F5 expression was analyzed in 120 primary HCCs and 29 normal liver tissues by immunohistochemistry analysis. E2F5-small interfering RNA was transfected into HepG2, an E2F5-overexpressed HCC cell line. After E2F5 knockdown, cell growth capacity

and migrating potential were examined.

RESULTS: E2F5 was significantly overexpressed in primary HCCs compared with normal liver tissues ($P = 0.008$). The E2F5-silenced cells showed significantly reduced proliferation ($P = 0.004$). On the colony formation and soft agar assays, the number of colonies was significantly reduced in E2F5-silenced cells ($P = 0.004$ and $P = 0.009$, respectively). E2F5 knockdown resulted in the accumulation of G0/G1 phase cells and a reduction of S phase cells. The number of migrating/invasive cells was also reduced after E2F5 knockdown ($P = 0.021$).

CONCLUSION: To our knowledge, this is the first evidence that E2F5 is commonly overexpressed in primary HCC and that E2F5 knockdown significantly repressed the growth of HCC cells.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most com-

mon cancer and the third leading cause of cancer death worldwide^[1]. More than half a million cases are newly diagnosed every year, and a similar number of patients die each year. Given that the overall incidence of HCC is still rising and the prognosis remains poor, it is important to develop effective diagnostic and therapeutic modalities based on the biological knowledge of hepatocarcinogenesis^[2,3].

Our group previously explored the profiles of chromosomal alterations in primary HCC by performing a genome-wide, microarray-based, comparative genomic hybridization analysis and found that the 8q21.2 locus harboring the *E2F5* gene was recurrently amplified in HCC^[4]. *E2F5* is a member of the E2F transcription factor family that binds to the promoters of the target genes involved in cell cycle control and that consequently regulates the expression of these target genes^[5]. The E2F family, located in the downstream of the growth factor signaling cascades, plays a central role in cell growth and proliferation through regulating the genes involved in cell cycle progression^[6]. Therefore, it is possible for the members of the E2F family to become involved in oncogenesis. The members of the E2F family are divided into activator (E2F1-E2F3) and repressor (E2F4-E2F8) subclasses^[5]. Overexpression of the E2F activators has been reported to induce uncontrolled proliferation of cells in diverse human cancers such as breast, ovarian, lung and gastrointestinal cancers^[7-10]. Although the E2F repressors are expected to behave as tumor suppressors, a substantial amount of evidence instead indicates the possibility that some E2F repressors may have oncogenic effects in tumorigenesis^[5].

The overexpression or amplification of the *E2F5* gene has been reported in various solid tumors such as breast, colon, ovarian cancers and osteogenic sarcoma^[11-17]. When the *E2F5* gene was co-transfected with DP-1 and Ras into rat kidney cells, the number of transformed foci increased^[11]. However, there has been no report on the expression profile of *E2F5* in human HCC and its biological roles in hepatocarcinogenesis.

In this study, we explored the expression profiles of *E2F5* in primary human HCC and its biological effects by performing knockdown of the *E2F5* using specific small interfering RNA (siRNA) in a human HCC cell line.

MATERIALS AND METHODS

Tissue microarray

For screening *E2F5* expression in primary HCC, HCC tissue microarrays were prepared. Formalin-fixed, paraffin-embedded tissue blocks from 120 HCC patients were identified from the archives of the Department of Hospital Pathology under the approval of the Institutional Review Board of the Catholic University of Korea, College of Medicine (CUMC06U014). Tissue microarrays were constructed using a manual tissue arrayer (Quick-Ray Manual Tissue Microarrayer, Unimta Co., Ltd., Seoul, Korea). Hematoxylin-eosin stained sections from each sample were examined and then tumor cell-rich areas were selected for use in tissue microarrays. A microarray con-

sisting of 29 samples of normal liver tissue was also constructed. The tissue array paraffin block was then cut into 5- μ m paraffin sections for immunohistochemistry (IHC) analysis.

HCC cell line

HepG2 was obtained from ATCC (Manassas, VA, USA) and maintained in DMEM (Gibco BLR, Gaithersburg, MD, USA) supplemented with 10% FBS at 37°C containing 5% CO₂. As controls, THLE-2 and THLE-3 (human normal liver epithelial cell lines) were purchased from ATCC (Manassas, VA, USA) and maintained in DMEM supplemented with 10% FBS and 25 mmol/L HEPES.

IHC

E2F5 immunostaining was performed using tissue microarray slides. Briefly, the tissue sections were deparaffinized and quenched with 3% hydrogen peroxide for 10 min. Antigen retrieval was then conducted using 0.01 mol/L citrate buffer (pH 6.0) by heating the sample in a microwave vacuum histoprocessor (RHS-1, Milestone, Bergamo, Italy) at a controlled final temperature of 121°C for 15 min. The monoclonal mouse anti-*E2F5* antibody (220D1a, Abcam, Cambridge, UK) was then diluted 1:50 in Dako Antibody Diluent (Dako, Carpinteria, CA, USA) with background-reducing components, after which it was incubated overnight at 4°C and then detected using the Envision plus System (Dako, Carpinteria, CA, USA). The immunoreaction was developed by treating the samples with diaminobenzidine (Dako, Carpinteria, CA, USA) for 5 min, and hematoxylin counterstaining was applied.

Real-time quantitative reverse transcriptase polymerase chain reaction

Total RNA was isolated from the cells using the TRIzol reagent (Invitrogen, Carlsbad, CA, USA). Reverse transcription was performed using oligo-(dT) primer and SuperScript III reverse transcriptase (Invitrogen, Carlsbad, CA, USA). Quantitative reverse transcriptase polymerase chain reaction (qRT-PCR) was performed with a mixture containing cDNA, 1 \times SYBR Green *Thr* polymerase mixture (FINNZYMES, Espoo, Finland), 0.5 \times ROX, and primers using Mx3000P QPCR (Stratagene, La Jolla, CA, USA). The thermal cycling included one cycle at 95°C for 10 min, followed by 45 cycles of 95°C at 10 s, 55°C for 30 s and 72°C for 30 s. Relative quantification was performed by the $\Delta\Delta$ Ct method as described elsewhere^[4]. *E2F5* specific primers for qRT-PCR were as follows; 5'-TCAGGACCTATCCATGTGCTGCTT-3' for forward and 5'-TCAGAGACATGTTGCTCAGGCAGA-3' for reverse. The *GAPDH* gene was used as an internal control and its specific primers were as follows; 5'-GCGGGGCTCTCCAGAACATCAT-3' for forward and 5'-CCAGCCCCAGCGTCAAAGGTG-3' for reverse.

Transfection of *E2F5* siRNAs

Three types of *E2F5*-specific siRNAs were purchased (Invitrogen, Carlsbad, CA, USA), whose sequences were

as follows: UUAUAAGCAGCACAUGGAUAGGUCCG-GACCUAUCCAUGUGCUGCUUAAUAA for siE2F5-1; AAUUAAGUUGUAGUCAUCUGCCGCGCG-GCAGAUGACUACAACUUUAAUU for siE2F5-2; AUGAUAUCUCCACUAAUAGAUCUGCAG-GAUCUAUUAGUGGAGAUUAUCAU for siE2F5-3. The siE2F5-1, -2, and -3 target exons were 6, 7 and 8, respectively. To estimate the sequence-specific effectiveness of the E2F5 siRNAs, we used a negative control siRNA (siNEG) (Invitrogen, Carlsbad, CA, USA) that has no significant homology with any known sequences in the human genome. In total, 100 nmol/L of each siRNA was transfected onto 6×10^5 HepG2 cells in a 100 mm culture dish using lipofectamine RNAiMAX according to the manufacturer's instructions (Invitrogen, Carlsbad, CA, USA). Forty-eight hours following the transfection, the cells were harvested and E2F5 expression was measured by qRT-PCR and Western blotting.

Western blotting

Transfected cells were harvested and lysed in cell lysis buffer (50 mmol/L NaF, 150 mmol/L NaCl, 10 mmol/L sodium pyrophosphate, 2 mmol/L EDTA, 0.1% Triton X-100) with protease inhibitor. The resulting cellular proteins (30 µg per lane) were electrophoresed in a 10% SDS-polyacrylamide gel and separated proteins were transferred to a PVDF membrane (Millipore, Bedford, MA, USA). Membranes were blocked with 5% non-fat dried milk in TBST (20 mmol/L Tris-HCl, 150 mmol/L NaCl, and 0.1% Tween 20, pH 7.5), and then incubated overnight with anti-E2F5 (Abcam, Cambridge, UK) and anti α -tubulin antibodies (Sigma, St. Louis, MI, USA) at 4°C according to the manufacturer's instructions. After washing with TBST, the PVDF membrane was incubated with diluted HRP-conjugated anti-rabbit IgG for 1 h at room temperature. The blots were detected using an enhanced chemiluminescence system (Amersham-Pharmacia Biotech, Braunschweig, Germany). The expression of α -tubulin was used as a control.

Cell proliferation assay

Growth of HepG2 cells was determined using the cell proliferation reagent WST-1 (Roche, Indianapolis, IN, USA) according to the manufacturer's protocol. Optical density was read at 450 nm at various time points. Three independent experiments were carried out.

Invasion and migration assay

Invasion of HepG2 cells was assayed using the 24-well format transwell chambers (Becton Dickinson Labware, Franklin Dickinson, NJ, USA) of 8 µm-pore size. siRNA transfected cells were added onto the Matrigel (BD Biosciences, San Jose, CA, USA) coated filters in 200 µL of serum-free RPMI1640 (2×10^4 cells/filter). In the lower chambers, 500 µL of RPMI1640 media containing 10% FBS was added. After 20-h incubation at 37°C in the 5% CO₂ incubator, cells were stained with 0.5% crystal violet in 20% methanol and then examined under the micro-

scope. Cells on the top surface of the membrane were removed by wiping with a cotton swab. The numbers of cells were counted in five microscopic fields ($\times 40$). The migration assay was carried out in the same manner but using filters without Matrigel coating. Two independent experiments were performed for each assay.

Colony formation assay

Forty-eight hours after transfection with siRNA, 1×10^4 HepG2 cells were seeded in 100-mm culture dishes. Two weeks later, cultured cells were stained with 0.5% crystal violet and the number of colonies was counted. Three independent experiments were carried out for each assay.

Soft agar assay

To explore the effect of E2F5 on anchorage independent growth of HepG2 cells, a soft agar assay was performed. HepG2 cells were suspended in RPMI1640 containing 0.35% low melting agarose, and plated onto solidified 0.6% agarose containing RPMI1640 in six-well culture plates at a density of 1×10^5 cells per dish. After incubating for 2 wk at 37°C in the 5% CO₂ incubator, the number of colonies was counted. Two independent experiments were carried out for each assay.

Cell cycle analysis

Forty-eight hours after transfection with siRNA, the adherent cells were detached by trypsin treatment, washed twice with PBS, and then exposed to 70% ethanol on ice for 2 h. After washing, cells were incubated with 5 mg/mL propidium iodide and 50 mg/mL RNase-A in PBS for 15 min at 37°C. A flow activated cell sorter (FACS) analysis was carried out using a FACS Calibur flow cytometer (Becton Dickinson, Mountain View, CA, USA) with CELLQUEST software. A total of 10000 events were measured per run.

Statistical analysis

The statistical analysis was performed using the SPSS statistical software (SPSS Inc., Chicago, IL, USA). Statistical significance was determined by the Mann-Whitney test for continuous variables and by the χ^2 or Fisher's exact test for categorical variables. *P* values less than 0.05 were considered statistically significant.

RESULTS

Expression of E2F5 in primary human HCC

We examined the E2F5 protein expression level in the 120 primary HCCs and 29 normal liver tissues by tissue microarray-based IHC. E2F5 expression was mostly localized in the cytoplasm with occasional nuclear staining. Cytoplasmic staining was considered a positive result. We graded the E2F5 staining intensity from 0 (negative) to 3 (strongly positive) (Figure 1A-D). E2F5 expression was absent in all the normal liver tissues tested, while positive in 22 (18.3%) of 120 HCCs (*P* = 0.008); 17 cases of grade 1, 4 cases of grade 2, and one case of grade 3. Although E2F5 intensities showed a trend of positive correlation

Figure 1 Expression pattern of E2F5 in primary hepatocellular carcinoma by tissue microarray based immunohistochemistry. Cytoplasmic staining was considered E2F5 expression positive. E2F5 expression was absent in all normal liver tissues tested. A: No E2F5 expression; B-D: Grade 1 to 3 E2F5 expression, respectively ($\times 400$).

Figure 2 E2F5 RNA expressions of HepG2 and normal liver cell lines (THLE-2 and -3). E2F5 gene specific reverse transcriptase polymerase chain reaction was performed for HepG2, THLE-2 and THLE-3 as described in methods. In HepG2 cell line, E2F5 RNA expression was up-regulated more than 8 fold compared with that of the normal liver cells.

with tumor grades, it was not statistically significant (data not shown).

Repression of E2F5 expression by siRNA transfection

To assess the biological effects of E2F5 overexpression in hepatocarcinogenesis, we used E2F5 gene specific siRNA to disrupt its expression in the HepG2 liver cancer cell line. Before knockdown, we assessed the expression level of E2F5 in the HepG2 cells by qRT-PCR and confirmed that the E2F5 expression was up-regulated more than 8-fold compared with that of the normal liver

cells (Figure 2). Before transfection, we optimized the amount of lipofectamine to ensure the maximal transfection efficiency and minimal cellular toxicity (data not shown). Then we introduced three E2F5 gene specific siRNA constructs (siE2F5-1, -2, and -3) and siNEG into the HepG2 cells. The effect of each siRNA on the E2F5 expression level was examined by qRT-PCR and Western blotting analysis. Of the three siRNAs examined, siE2F5-1 and siE2F5-3 were shown to efficiently repress the RNA expression level (approximately 90% reduction) by qRT-PCR (Figure 3A). In the Western blotting analysis, both siE2F5-1 and siE2F5-3 also efficiently repressed the E2F5 expression, but the latter was slightly better than the former (Figure 3B). Therefore, all the downstream functional analyses were performed using siE2F5-3 (hereafter called siE2F5).

Effect of E2F5 knockdown on HepG2 cell growth

To explore the effect of E2F5 on HCC cell growth, we performed proliferation and colony formation assays. In the proliferation assay, the siE2F5 transfected cells showed reduced proliferation compared with that of the siNEG transfected cells by over 75% ($P = 0.004$, Figure 4A). In the colony formation assay, the number of colonies from the siE2F5 treated cells [median 119, interquartile range (IQR) 116-124] was significantly smaller than that from the siNEG treated cells (median 243, IQR 228-267, $P = 0.004$) (Figure 4B). Next, we examined the E2F5 knockdown effect on the anchorage independent growth of HCC

Figure 3 Small interfering RNA-mediated silencing of *E2F5* gene expression in HepG2 cells. A: After siE2F5 transfection into the HepG2 cells, *E2F5* expression was measured by real time quantitative reverse transcriptase polymerase chain reaction. Human *GAPDH* gene was used as an internal control. The X axis represents samples and the Y axis relative *E2F5* expression ratios (siE2F5 or siNEG/control); B: *E2F5* expression in Western blotting analysis was measured by densitometry. Alpha-tubulin was used as an internal control. *E2F5* specific signal intensities of siE2F5-treated cells are profoundly repressed compared with siNEG-treated cells. Control: HepG2 cells without transfection; siNEG: Negative oligonucleotide (siNEG) transfected HepG2.

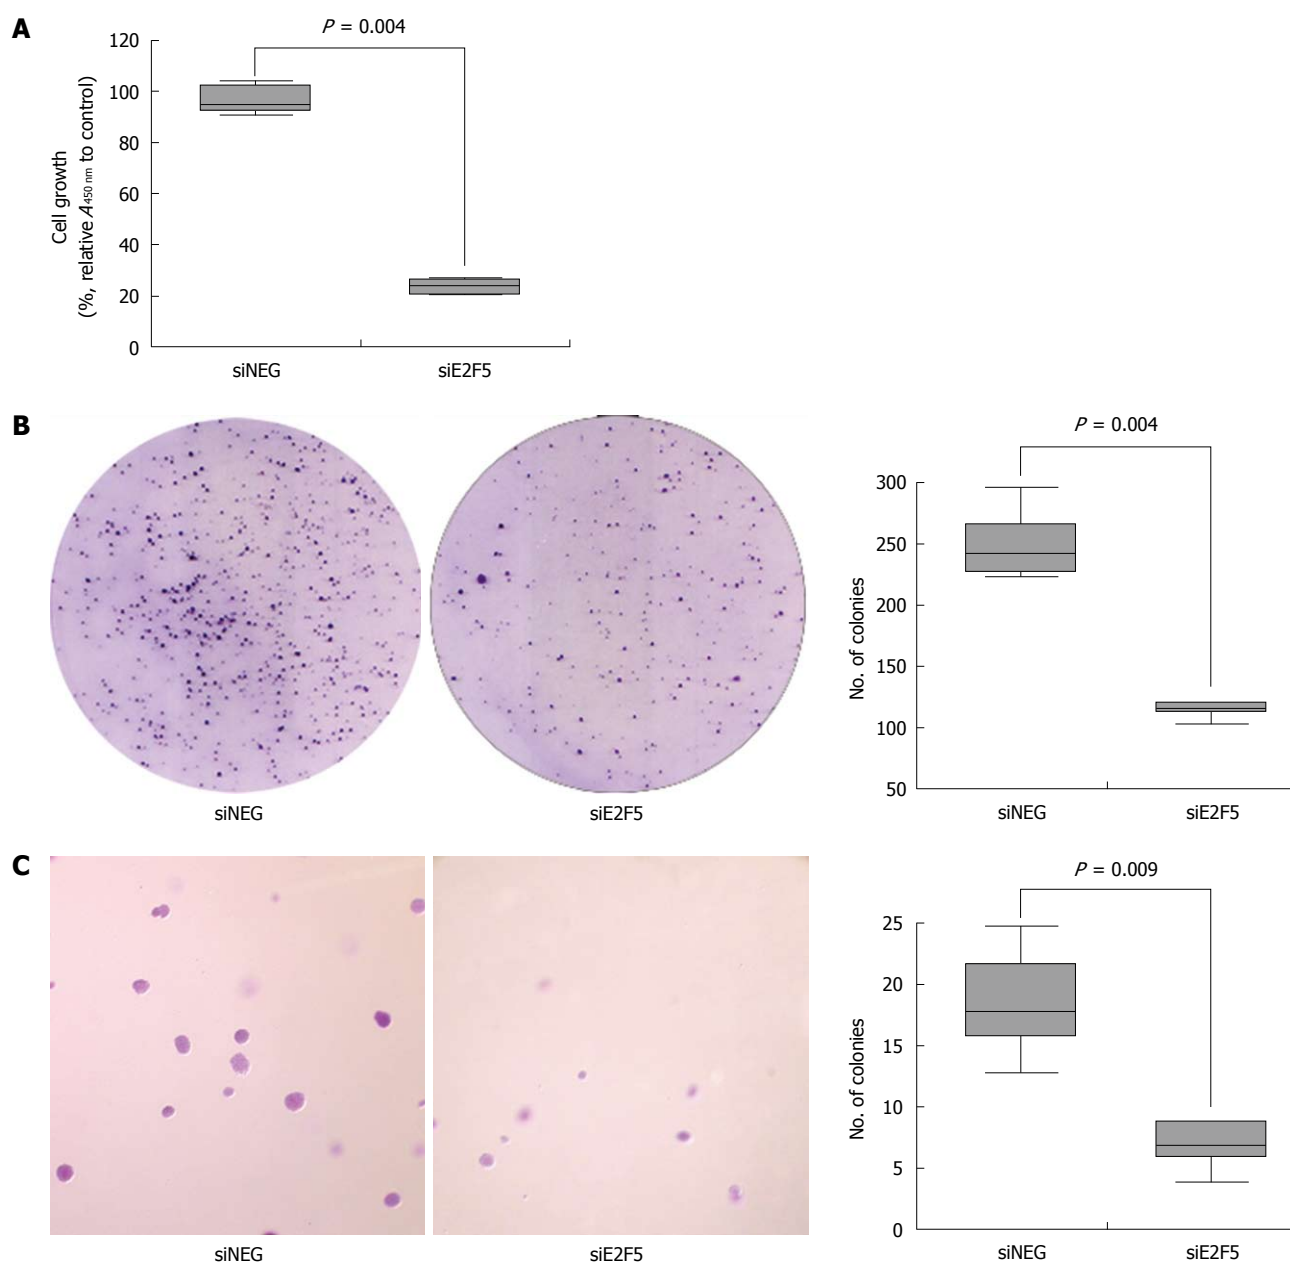

Figure 4 Effects of *E2F5* knockdown on HepG2 cell growth. Proliferation assay (A), colony formation assay (B), and soft agar assay (C) consistently demonstrated the inhibition of HepG2 cell growth by *E2F5*-specific small interfering RNA transfection ($\times 40$).

Figure 5 Effects of E2F5 knockdown on migration and invasion of HepG2 cells. A: The number of migrating colonies in siE2F5 treated cells was significantly lower than that in siNEG transfected cells on Matrigel uncoated transwell membrane ($P = 0.021$); B: The number of invading colonies in siE2F5 treated cells was significantly lower than that in siNEG transfected cells into Matrigel coated transwell membrane ($P = 0.021$).

cells using the soft agar assay. The number of anchorage-independent colonies of the siE2F5 treated cells (median 7, IQR 6-9) was significantly reduced as compared with that of the siNEG treated cells (median 18, IQR 16-22, $P = 0.009$) (Figure 4C).

Effect of E2F5 knockdown on HepG2 cell migration and invasion

The number of migrating cells was significantly reduced by E2F5 knockdown (median 339.5, IQR 331.5-354.5 in the siNEG treated cells *vs* median 253.5, IQR 236.5-263, $P = 0.021$). The number of invading cells was also significantly reduced (median 134.5, IQR 130.5-153.5 *vs* median 95, IQR 87-104, $P = 0.021$) (Figure 5).

Effect of E2F5 siRNA on cell cycle progression in HepG2 cells

To explore the mechanisms behind the anti-proliferative effect in the siE2F5 transfected cells, we observed the cell cycle profile of the HepG2 cells by performing FACS analysis after siE2F5 transfection. E2F5 knockdown resulted in the accumulation of G0/G1 phase cells and the reduction of S phase cells compared with that of the siNEG transfected cells. The proportion of G1-phase cells in the siE2F5 treated cells was 76.5%, while it was 71.7% in the siNEG treated cells. In contrast, the

proportion of S phase cells in the siE2F5 treated cells (5.2%) was much lower than that in the siNEG treated cells (11.9%) (Figure 6).

DISCUSSION

Amplification of the *E2F5* gene has been frequently observed in diverse human cancers^[11,12,16]. We previously reported that the 8q21.2 locus, which harbors the *E2F5* gene, was recurrently amplified in primary human HCC^[4]. These data suggest the oncogenic potential of *E2F5* amplification. However, the E2F repressors (E2F4-E2F8) among the E2F family members have been reported to show paradoxical behaviors in tumorigenesis^[5]. In *Rb*^{+/-} *E2f4*^{-/-} mice, *E2f4* loss suppressed the development of pituitary and thyroid tumors, which suggested its oncogenic role in these tissues^[18]. This phenomenon was also observed in *Rb*^{-/-} *E2f4*^{-/-} chimeric mice, where *E2F4* loss delayed the development and reduced the incidence of pituitary tumors^[19]. However, the same *Rb*^{-/-} *E2f4*^{-/-} chimeras developed ganglionic neuroendocrine neoplasms and urothelial transitional carcinomas, which indicates a tumor suppressive role for E2F repressors^[19]. In 3T3 mouse fibroblasts, artificially overexpressed *E2F4* and *E2F5* inhibited malignant transformation, while overexpressed *E2F2* and *E2F3a* showed an oncogenic capacity^[20]. Thus, E2F

Figure 6 Effect of siE2F5 treatment on HepG2 cell cycle progression. After siE2F5 transfection into the HepG2 cells, cell cycle profile was examined by flow cytometry analysis. DNA histogram shows the accumulation of G0/G1-phase cells in siE2F5 transfected HepG2 cells compared with the siNEG transfected cells.

repressors may play an oncogenic or tumor suppressor role in a tissue specific manner^[5].

In this study, we explored the biological consequences of E2F5 overexpression in hepatocarcinogenesis and the involved molecular mechanisms. To begin with, we examined the expression of E2F5 protein in 120 primary HCCs and 29 normal liver tissues by tissue microarray based IHC and found that 18.3% of HCCs were positive, while none of the normal liver tissues were positive ($P = 0.008$). Although there has been no report on E2F5 overexpression in HCC, E2F5 overexpression has been reported in ovarian and breast cancers^[11-15]. E2F5 overexpression was observed in both early and advanced stage ovarian cancer, and this suggested the potential involvement of E2F5 in the pathogenesis of ovarian cancer^[13,15]. In breast cancer, E2F5 overexpression was also significantly associated with an ER/PR/HER2 triple negative status and with a worse clinical outcome^[12]. In this study, we did not find a significant correlation between tumor grade and E2F5 expression, but the correlation cannot be excluded because the sample size may not have been large enough. Associations between E2F5 expression and other phenotypes were not able to be assessed due to the limited clinical information of the primary HCC used in this study.

We knocked down the E2F5 expression using E2F5 gene specific siRNA transfection to explore the biological

effects of E2F5 overexpression in hepatocarcinogenesis. We found that E2F5 knockdown profoundly repressed the growth of HCC cells compared with the untransfected cells. The repression of HepG2 cell growth after E2F5 knockdown was simultaneously observed in the proliferation, colony formation and soft agar assays. These data can be related to the results of Polanowska *et al.*^[11], where the amplification and subsequent overexpression of the E2F5 gene promoted cell transformation together with other oncogenes in human breast tumors. Our results as well as the previous observations suggested the involvement of E2F5 gene amplification and overexpression in the tumorigenesis of various cancers including HCC.

It is widely recognized that the E2F family, including E2F5, is involved in tumorigenic processes through deregulation of cell cycle progression^[5,21]. In order to understand the nature of the siE2F5-mediated growth inhibition, we analyzed the cell cycle of the HCC cell line by FACS analysis after E2F5 knockdown. Consistent with our prediction, treatment with siE2F5 seemed to arrest the cell cycle at the G0/G1 phase. In a previous study with human WI38 fibroblasts, the E2F5 mRNA expression was maximal in the mid-G1 phase before the E2F1 expression was detectable, which suggests the contribution of E2F5 to the regulation of early G1 events, including the G0/G1 transition^[22]. The extent of cell cycle arrest was relatively small considering the prominent growth suppression induced by knockdown of E2F5 in this study. This may indicate the existence of additional effects of unknown factors added to E2F5 overexpression in HCC tumorigenesis. Migration and invasion capacities of HepG2 cells were also significantly inhibited by E2F5 knockdown. However, we did not explore whether E2F5 was directly involved in the migration- or invasion-related pathways or if the inhibitory effect was due to repression of HepG2 cell proliferation. Further functional studies are required to fully understand the oncogenic roles of E2F5 in HCC. The E2F5-interacting molecules also need to be identified to properly understand the behaviors of HCC.

To our knowledge, this is the first evidence that E2F5 is commonly overexpressed in primary human HCC and that E2F5 knockdown profoundly repressed the growth of HCC cells. The overexpression of E2F5 may induce uncontrollable cell cycle progression in liver cells and eventually contribute to cancer transformation by working together with other carcinogenic factors. This study will help to understand hepatocarcinogenesis mechanisms and to define therapeutic targets of early HCC.

COMMENTS

Background

Although the incidence of hepatocellular carcinoma (HCC) is still high and the prognosis remains poor, the molecular mechanisms of HCC are largely unknown. To develop effective diagnostic and therapeutic modalities, it is important to understand the mechanisms underlying hepatocarcinogenesis.

Research frontiers

E2F5 is a member of the E2F transcription factor family, and plays a key role

in cell growth and proliferation. Overexpression of E2F5 has been reported in various human cancers, but not in liver cancer, and its biological implication is largely unknown. In this study, the authors investigated the expression profile of E2F5 in primary HCCs and explored the biological effects of E2F5 overexpression by knockdown of the gene.

Innovations and breakthroughs

This is the first evidence that E2F5 is relatively overexpressed in primary human HCC. Knockdown of E2F5 expression suppressed growth, invasion, and migration of HCC cell lines. Overexpression of E2F5 has been found to induce uncontrollable cell cycle progression, which may contribute to hepatocarcinogenesis.

Applications

Repressed proliferation of E2F5 silenced cells suggests that blocking this molecule could be used to decrease the growth of cancer cells in HCC patients. Expression of E2F5 can also be used as a diagnostic or prognostic marker in HCC.

Peer review

This is an interesting experimental study regarding the potential role of the transcription factor E2F5 in hepatocarcinogenesis.

pression of light chain 3 (LC3). Mitochondrial membrane potential was measured using the fluorescent probe JC-1. Western blotting analysis were used to determine the expression of proteins involved in apoptosis and autophagy including p53, p53 upregulated modulator of apoptosis (PUMA), damage-regulated autophagy modulator (DRAM), LC3 and Beclin 1. We detected the effects of p53-mediated autophagy activation on the apoptosis of SGC7901 cells with the p53 inhibitor pifithrin- α .

RESULTS: The viability of SGC7901 cells was inhibited after SN50 treatment. Inductions in the expression of apoptotic protein p53 and PUMA as well as autophagic protein DRAM, LC3 and Beclin 1 were detected with Western blotting analysis. SN50-treated cells exhibited punctuate microtubule-associated protein 1 LC3 in immunoreactivity and MDC-labeled vesicles increased after treatment of SN50 by MDC staining. Collapse of mitochondrial membrane potential $\Delta\psi$ were detected for 6 to 24 h after SN50 treatment. SN50-induced increases in PUMA, DRAM, LC3 and Beclin 1 and cell death were blocked by the p53 specific inhibitor pifithrin- α .

CONCLUSION: The anti-tumor activity of NF- κ B inhibitors is associated with p53-mediated activation of autophagy.

Abstract

AIM: To investigate the anti-tumor effects of nuclear factor- κ B (NF- κ B) inhibitor SN50 and related mechanisms of SGC7901 human gastric carcinoma cells.

METHODS: MTT assay was used to determine the cytotoxic effects of SN50 in gastric cancer cell line SGC7901. Hoechst 33258 staining was used to detect apoptosis morphological changes after SN50 treatment. Activation of autophagy was monitored with monodansylcadaverine (MDC) staining after SN50 treatment. Immunofluorescence staining was used to detect the ex-

INTRODUCTION

Nuclear factor- κ B (NF- κ B) is an ubiquitously expressed family of Rel-related transcription factors^[1]. Typically, in unstimulated cells, NF- κ B is sequestered in the cytoplasm by binding to inhibitory κ B proteins (I κ B). In response to a variety of stimuli, such as inflammatory cytokines, oncogenes, and viruses, the proteasome-dependent degradation of I κ B allows the translocation of NF- κ B to the nucleus, where it binds to the promoter region of target genes involved in the control of different cellular responses, including apoptosis^[2-4]. In many cancer cells, the constitutive activation of NF- κ B activity lowers cell sensitivity to apoptotic stimuli and consequently favors neoplastic cell survival^[5].

The mammalian NF- κ B family contains 5 members: p50/p105 (NF- κ B1), p52/p100 (NF- κ B2), c-Rel, RelB, and p65 (RelA). These proteins are characterized by their Rel homology domains, which control DNA binding, dimerization and interactions with inhibitory factors known as I κ B proteins^[4,6]. NF- κ B is first discovered and studied as a major activator of immune and inflammatory function *via* its ability to induce expression of genes encoding cytokines, cytokine receptors, and cell-adhesion molecules^[4,7]. NF- κ B recently has been found to be linked to the control of cell growth and oncogenesis. The role of NF- κ B in cancer appears to be complex, but is likely to involve the ability of this transcription factor to control programmed cell death (PCD) and cell-cycle progression, and possibly cell differentiation, angiogenesis and cell migration. It has been reported that NF- κ B is activated in cancer cells by several chemotherapies and by radiation, and that in many cases this response inhibits the radiotherapy- and chemotherapy-induced cell death^[8].

Recent studies have suggested that there are three types of PCD: apoptosis (PCD I), autophagic cell death (PCD II) and necrosis (PCD III)^[9]. Autophagy is a genetically programmed, evolutionarily conserved process that degrades the long-living cellular proteins and organelles. Autophagy is important in normal development and response to changing environmental stimuli and, in addition to its role in cancer, and in numerous diseases, including bacterial and viral infections, neurodegenerative disorders, and cardiovascular diseases^[10]. Autophagy involves the formation of a double-membrane vesicle, which encapsulates cytoplasm and organelles and fuses with lysosomes, thus degrading the contents of the vesicle. The formation of the double-membrane vesicle is a complex process involving 16 autophagy-related proteins (Atg proteins). Two ubiquitin-like conjugation systems are involved in autophagy. These systems produce modified complexes of autophagic regulators (Atg8-PE and Atg5-Atg12-Atg16) that may determine the formation and size of the autophagosome. Nucleation, expansion, uncoating, and completion of the autophagosome then occur, priming it to fuse with lysosomes^[11].

The term "autophagic cell death" describes a form of programmed cell death morphologically distinct from apoptosis and presumed to result from excessive levels of cellular autophagy^[12]. In classical apoptosis, or type I programmed cell death, there is early collapse of

cytoskeletal elements but preservation of organelles until late in the process. In contrast, in autophagic, or type II, programmed cell death, there is early degradation of organelles but preservation of cytoskeletal elements until late stages. Whereas apoptotic cell death is caspase-dependent and characterized by internucleosomal DNA cleavage, caspase activation and DNA fragmentation occur very late (if at all) in autophagic cell death^[13]. In contrast with necrosis, both apoptotic and autophagic cell death are characterized by the lack of a tissue inflammatory response. The mitochondrion may integrate cell death signals and autophagy activation. Mitochondria generate apoptotic signals but can be removed by autophagy when they are damaged; therefore, mitochondria represents a nexus at which autophagy may interact with apoptosis pathways^[14].

The mutual regulation of NF- κ B and autophagy has been reported^[15]. Autophagy degrades nuclear shuttle protein-interacting kinase (NIK) and I κ B kinase (IKK), and inhibits NF- κ B activation, while NF- κ B depresses autophagy^[16]. We predict that activation of autophagy by blocking NF- κ B may contribute to the anti-tumor actions of NF- κ B inhibitors. We examined the effects of the nuclear import inhibitor SN50 on the activation of apoptosis and autophagy and the contribution of autophagy to the cytotoxic effects of SN50 in gastric cancer cell line SGC7901. The results showed that p53-dependent activation of apoptotic and autophagic pathways was induced by blocking the NF- κ B nuclear transport, and autophagic activation contributed to SN50-induced death of cancer cells.

MATERIALS AND METHODS

Reagents

SGC7901 gastric cancer cells were purchased from the Shanghai Institute of Cell Biology, Chinese Academy of Sciences (Shanghai, China); RPMI1640 medium from Gibco (Rockville, MD, USA); fetal bovine serum from Hangzhou Sijiqing Biological Engineering Material Co., Ltd., (Hangzhou, China); L-glutamine, MTT from Sigma (St Louis, MO, USA); antibodies against p53 (1:500), p65 (1:500), PUMA (1:500), LC3 (1:200), Beclin1 (1:700) from Cell Signaling Technology (Beverly, MA, USA); and antibodies against DRAM (1:700) from Santa Cruz Biotechnologies (Santa Cruz, CA, USA).

Drug preparation

SN50 (BIOMOL, Plymouth Meeting, PA, USA) were diluted in distilled sterilization water to create a stock solution that was stored according to the manufacturer's suggestions. Pifithrin- α (Pft- α , Cell Signaling Technology, Beverly, MA, USA) was diluted in DMSO to create a stock solution that was stored according to the manufacturer's instructions. The final concentration of the SN50 solution used in the experiments was 18 μ mol/L, and that of Pft- α was 30 μ mol/L. This concentration of SN50 was selected on the basis of our pilot experiments on SGC7901 cells, and the concentration of Pft- α was selected following the manufacturer's suggestions.

Cell culture and viability assay

SGC7901 cells were maintained in RPMI1640 medium containing 10% heat-inactivated fetal bovine serum, 0.03% L-glutamine and incubated in a 5% CO₂ atmosphere at 37°C. Cells in a mid-log phase were used in experiments. Cell viability was assessed by MTT assay. To determine the time-course of response of SGC7901 cells to SN50, SGC7901 cells were plated into 96-well microplates (7×10^4 cells/well), and SN50 (18 μ mol/L) was added to the culture medium and cell viability was assessed with MTT assay 24, 48 and 72 h after drug treatment. MTT (Sigma, St Louis, MO, USA) solution was added to the culture medium (500 mg/L as a final concentration) for 4 h before the end of treatment, and the reaction was stopped by addition of 10% acidified SDS 100 μ L. The absorbance value (A) at 570 nm was read using an automatic multiwell spectrophotometer (Bio-Rad, Richmond, CA, USA). The percentage of cell death was calculated as follows: cell death (%) = $(1 - A \text{ of experiment well} / A \text{ of positive control well}) \times 100\%$.

Detection of mitochondrial potential ($\Delta\psi$)

Mitochondrial $\Delta\psi$ was determined using the KeyGEN Mitochondrial Membrane Sensor Kit (KeyGEN, Nanjing, China). The mitosensor dye aggregates in the mitochondria of healthy cells and emits red fluorescence against a green monomeric cytoplasmic background staining. However, in cells with a collapsed mitochondrial $\Delta\psi$, the dye cannot accumulate in the mitochondria and remains as monomers throughout the cells with green fluorescence^[17]. Briefly, SGC7901 cells were incubated with SN50 in 24-well plates for indicated times and then pelleted, washed with PBS, and resuspended in 0.5 mL of diluted mitosensor reagent (1 μ mol/mL in incubation buffer). After the cells were incubated with mitosensor reagent for 20 min, 0.2 mL incubation buffer was added and the cells were centrifuged and resuspended in 40 μ L incubation buffer. Finally, the cells were washed and resuspended in 1 mL phosphate buffered solution (PBS) for flow cytometric analysis.

Visualization of monodansylcadaverine-labeled vacuoles

Exponentially growing cells were plated onto 24-chamber culture slides, cultured for 24 h and incubated with the drug in 10% FCS/RPMI1640 for 6, 12 and 24 h. Autophagic vacuoles were labeled with monodansylcadaverine (MDC)^[18] (Sigma, St Louis, MO, USA) by incubating cells with 0.001 mmol/L MDC in RPMI1640 at 37°C for 10 min. After incubation, cells were washed three times with phosphate buffered solution (PBS) and immediately analyzed with a fluorescence microscope (Nikon Eclipse TE 300, Japan) equipped with a filter system (V-2A excitation filter: 380-420 nm, barrier filter: 450 nm). Images were captured with a CCD camera and imported into Photoshop.

Immunofluorescence staining LC3

SGC7901 cells were seeded onto 24-chamber culture slides and treated with SN50 (18 μ mol/L). After fixation in methanol for 10 min and blocked with a buffer containing 1% BSA 0.1% Triton X-100 for 1 h, cells were incubated

with either primary antibody against LC3 from Cell Signaling Technology (Beverly, MA, USA) diluted at 1:200 with PBS containing 1% bovine serum albumin (BSA) at 4°C overnight, and then incubated for 1 h with 1:500 secondary fluorescence conjugated antibodies (Sigma) to visualize the binding sites of the primary antibody under laser confocal microscope (Leica, Germany).

Hoechst 33258 staining

After treatment, cell cultures were washed twice with PBS and incubated with 2 μ mol/L Hoechst 33258 (Beyotime, Nantong, China) for 1 h in dark at 37°C. After washing thrice with PBS, the cells were viewed under a fluorescence microscope (Nikon, Tokyo, Japan) equipped with a UV filter. The images were recorded on a computer with a digital camera (DXM 1200, Nikon) attached to the microscope, and the images were processed by computer. The Hoechst reagent was taken up by the nuclei of the cells, and apoptotic cells exhibited a bright blue fluorescence.

Total cell and nuclear protein extraction and Western blotting analysis

For extraction of total cell proteins, cells were washed with pre-cooled PBS and subsequently lysed in pre-cooled RIPA lysis buffer [50 mmol/L Tris-HCl, pH 7.4, 150 mmol/L NaCl, 1 mmol/L dithiothreitol (DTT), 0.25% sodium deoxycholate, 0.1% NP-40] containing 1 mmol/L phenylmethanesulfonyl fluoride (PMSF), 50 mmol/L sodium pyrophosphate, 1 mmol/L Na₃VO₄, 1 mmol/L NaF, 5 mmol/L EDTA, 5 mmol/L EGTA, and protease inhibitors cocktail. Cell lysis was performed on ice for 30 min. Clear protein extracts were obtained by centrifugation for 30 min at 4°C. For nuclear protein extraction, the Nuclear Protein Extraction Kit (KeyGEN, Nanjing, China) was used according to the manufacturer's instructions. Protein extraction from SGC7901 gastric cancer cells was performed as previously described. Protein concentration was determined with a Bradford protein assay kit. Proteins were resolved on 8.5% polyacrylamide gels and subsequently transferred onto nitrocellulose membranes. For immunoblotting, nitrocellulose membranes were incubated with specific antibodies recognizing target proteins overnight at 4°C. The membranes were then incubated with HRP-conjugated secondary antibody (1:3000) for 1 h at room temperature and subsequently analyzed by enhanced chemiluminescence (ECL) detection system (Amersham Pharmacia Biotech) and visualized by autoradiography. Protein β -actin (1:5000; Sigma) was used as loading controls.

Statistical analysis

All data were presented as mean \pm SD. Statistical analysis was carried out by ANOVA followed by a Dennett's test, and $P < 0.05$ was considered statistically significant.

RESULTS**Blocking NF- κ B nuclear translocation activates autophagy and induces cell apoptosis**

To confirm the blockade of NF- κ B p65 nuclear trans-

location by SN50, we prepared nuclear proteins from in SGC7901 cells treated with SN50 (18 μ mol/L) for 6-24 h and the nuclear p65 protein levels were measured with Western blotting analysis. The results showed that SN50 lowered the nuclear p65 levels in SGC7901 cells, suggesting that NF- κ B activity can be inhibited by SN50 (Figure 1A). The autofluorescence substance MDC has been recently shown to be a marker for late autophagic vacuoles (L-AVs) but not endosomes. To determine if SN50 treatment increases the formation of autophagosomes, SGC7901 cells were treated with SN50 and then incubated with MDC. MDC was trapped in acidic, membrane-rich organelles and also exhibited increased fluorescence quantum yield in response to the compacted lipid bilayers present in L-AVs^[19]. When cells are viewed under a fluorescence microscope, autophagic vacuoles (AVs) stained with MDC appeared as distinct dot-like structures distributed in the cytoplasm or localizing in the perinuclear regions. This study found that there was an increase in the number of MDC-labeled vesicles after treatment of SN50 for 6-24 h (Figure 1B).

Microtubule-associated protein 1 light chain 3 (LC3), the mammalian ontology of Atg8, targets to the autophagosomal membranes in an Atg5-dependent manner and remains there even after Atg12-Atg5 dissociates. LC3 is considered to be the only credible marker of the autophagosome in mammalian cells^[20]. The present study used immunofluorescence to detect the expression and localization of LC3. The results showed that SN50 induced punctuate distribution of LC3 immunoreactivity, and the formation of autophagosomes was enhanced by SN50 (Figure 1C). There are two forms of LC3, LC3-I and LC3-II. During formation of autophagosomes, cytoplasmic form LC3-I is cleaved and liquefied to give rise to membranous form LC3-II. To determine if SN50 increases the production of LC3-II, Western blotting analysis was used to detect the protein levels of LC3-I and LC3-II. The results showed that the levels of LC3, particularly LC3-II, increased, leading to an increased ratio of LC3-II/LC3-I after SN50 treatment (Figure 1D). Beclin 1 is an autophagy regulator and plays an important role in tumorigenesis and autophagic activation. Similar increases in Beclin 1 proteins were also detected after SN50 treatment (Figure 1E). Treatment with 18 μ mol/L SN50 for 6, 12 and 24 h in SGC7901 cells produced intense Hoechst-positive staining for condensed nuclei indicative of apoptosis. Significant increase in Hoechst staining was observed along with apoptosis when cells were treated with 18 μ mol/L SN50. The result indicated that SN50 activated autophagy and induced cell apoptosis (Figure 1F).

Blocking NF- κ B nuclear translocation induces p53 and its target proteins

Inhibition of NF- κ B has anti-tumor effects. To confirm if SN50 induced expression of pro-apoptotic proteins in SGC7901 cells, Western blotting analysis were used to detect the expression of p53 and its target proteins. The analyses revealed a robust increase in p53 protein levels in SGC7901 cells 6 h after SN50 treatment (Figure 2A).

PUMA is a p53 target protein involved in p53-mediated apoptosis. To determine if SN50 increases the expression of PUMA, protein levels of PUMA in SGC7901 cells were detected with Western blotting analysis. The results showed that PUMA was significantly increased after the treatment with SN50 (Figure 2B). Crichton *et al.*^[21] recently identified a new p53 target gene damage-regulated autophagic modulator (DRAM). DRAM is a lysosomal protein with six membrane-spanning regions. Its exogenous expression leads to the accumulation of autophagosomes. The previous studies found that DRAM is required for p53-induced apoptosis and DRAM-dependent autophagy acts upstream of cytochrome c release from mitochondria^[21,22]. The present study indicated that SN50 treatment also resulted in a significant increase in DRAM protein levels in SGC7901 cells (Figure 2C).

P53 inhibitor blocks SN50-induced autophagic activation and cell apoptosis

Pifithrin- α (Pft- α) was used as a specific inhibitor of signaling by the tumor suppressor protein p53^[23]. To determine the contribution of p53 to SN50-induced expression of pro-apoptotic and autophagic proteins and apoptosis of SGC7901 cells, the cells were pre-treated with the p53 specific inhibitor Pft- α 6 h before the addition of SN50. The results showed that when p53 was inhibited, the induction of PUMA and DRAM was inhibited (Figure 3A and B). Similarly, pft- α significantly decreased the SN50-induced upregulation of LC3-II and Beclin 1 in SGC7901 cells (Figure 3C and D).

SN50 inhibited SGC7901 viability in a time-dependent fashion. MTT assays revealed that after 24 h of treatment, the rate of inhibition had reached 25.31% \pm 4.13% at the highest dose of 18 μ mol/L used. When the incubation time was prolonged to 72 h, the inhibition rate rose up to 44.79% \pm 1.65% and after 48 h of treatment the rate was about 34.19% \pm 2.06% (Figure 3E). To evaluate the contribution of p53 to SN50-induced death of SGC7901 cells, the cells were pre-treated with the p53 specific inhibitor Pft- α 6 h before SN50. As shown in Figure 3F, Pft- α significantly attenuated the inhibitory effects of SN50 in a time-dependent manner. Mitochondria plays a central role in regulating cell death and survival. Diverse proapoptotic stimuli act on mitochondria, triggering mitochondrial membrane potential collapse, cytochrome c release and caspase activation. We detected collapse of mitochondrial membrane potential $\Delta\psi$ as early as 6 h after SN50 treatment. This change reached a peak 24 h after SN50 treatment (Figure 3G).

DISCUSSION

NF- κ B signaling pathways play critical roles in a variety of physiological and pathological processes. One function of NF- κ B is to promote cell survival through induction of target genes, whose products inhibit components of the apoptotic machinery in normal and cancerous cells. NF- κ B can also prevent programmed necrosis by inducing genes encoding antioxidant proteins. Regardless of mechanism,

SGC7901 cells were incubated with SN50 (18 μ mol/L) and stained with MDC (100 μ mol/L). Fluorescence particles indicate L-AVs. (a) control, (b) 6 h, (c) 12 h, (d) 24 h after SN50 treatment ($\times 1000$) ($n = 3$); **C:** MAP1 LC3 expression and location in SGC7901 cells after treatment with SN50. Cells were treated

with SN50 (18 μ mol/L) for 6 h (b), 12 h (c) and 24 h (d), and observed under immunofluorescence microscope. (a) Control ($\times 1000$) ($n = 3$). SN50 increased the punctuate distribution of LC3 from 6 to 24 h; D: Western blotting analysis of the LC3 in the control and SN50-treated SGC7901 cells. Western blotting analysis was used to detect the protein levels of LC3 after SN50 treatment for 6-24 h. SGC7901 cells were treated with SN50 (18 μ mol/L) and were harvested for total proteins. It indicates that SN50 may up-regulate the expression of LC3 I and LC3 II. SN50 increased the ratio of LC3 II/LC3 I. Values were given as mean \pm SE. Statistical comparisons were carried out with Dennett's test. $^aP < 0.05$ vs control ($n = 3$); E: Western blotting analysis of the Beclin 1 in the control and SN50-treated SGC7901 cells. Western blotting analysis was used to detect the protein levels of Beclin 1 after SN50 treatment for 6-24 h. SGC7901 cells were treated with SN50 (18 μ mol/L) and were harvested for total proteins. It indicates that SN50 may up-regulate the expression of Beclin 1. Values were given as mean \pm SD. Statistical comparisons were carried out with Dennett's test. $^bP < 0.01$ vs control ($n = 3$); F: Hoechst 33258 staining showed apoptosis was induced after SN50 (18 μ mol/L) treatment. SGC7901 cells were incubated with SN50 (18 μ mol/L) and stained with Hoechst 33258 (10 mmol/L). Fluorescence particles showed apoptosis. (A) control, (B) 6 h, (C) 12 h, (D) 24 h after SN50 treatment ($\times 400$) ($n = 3$).

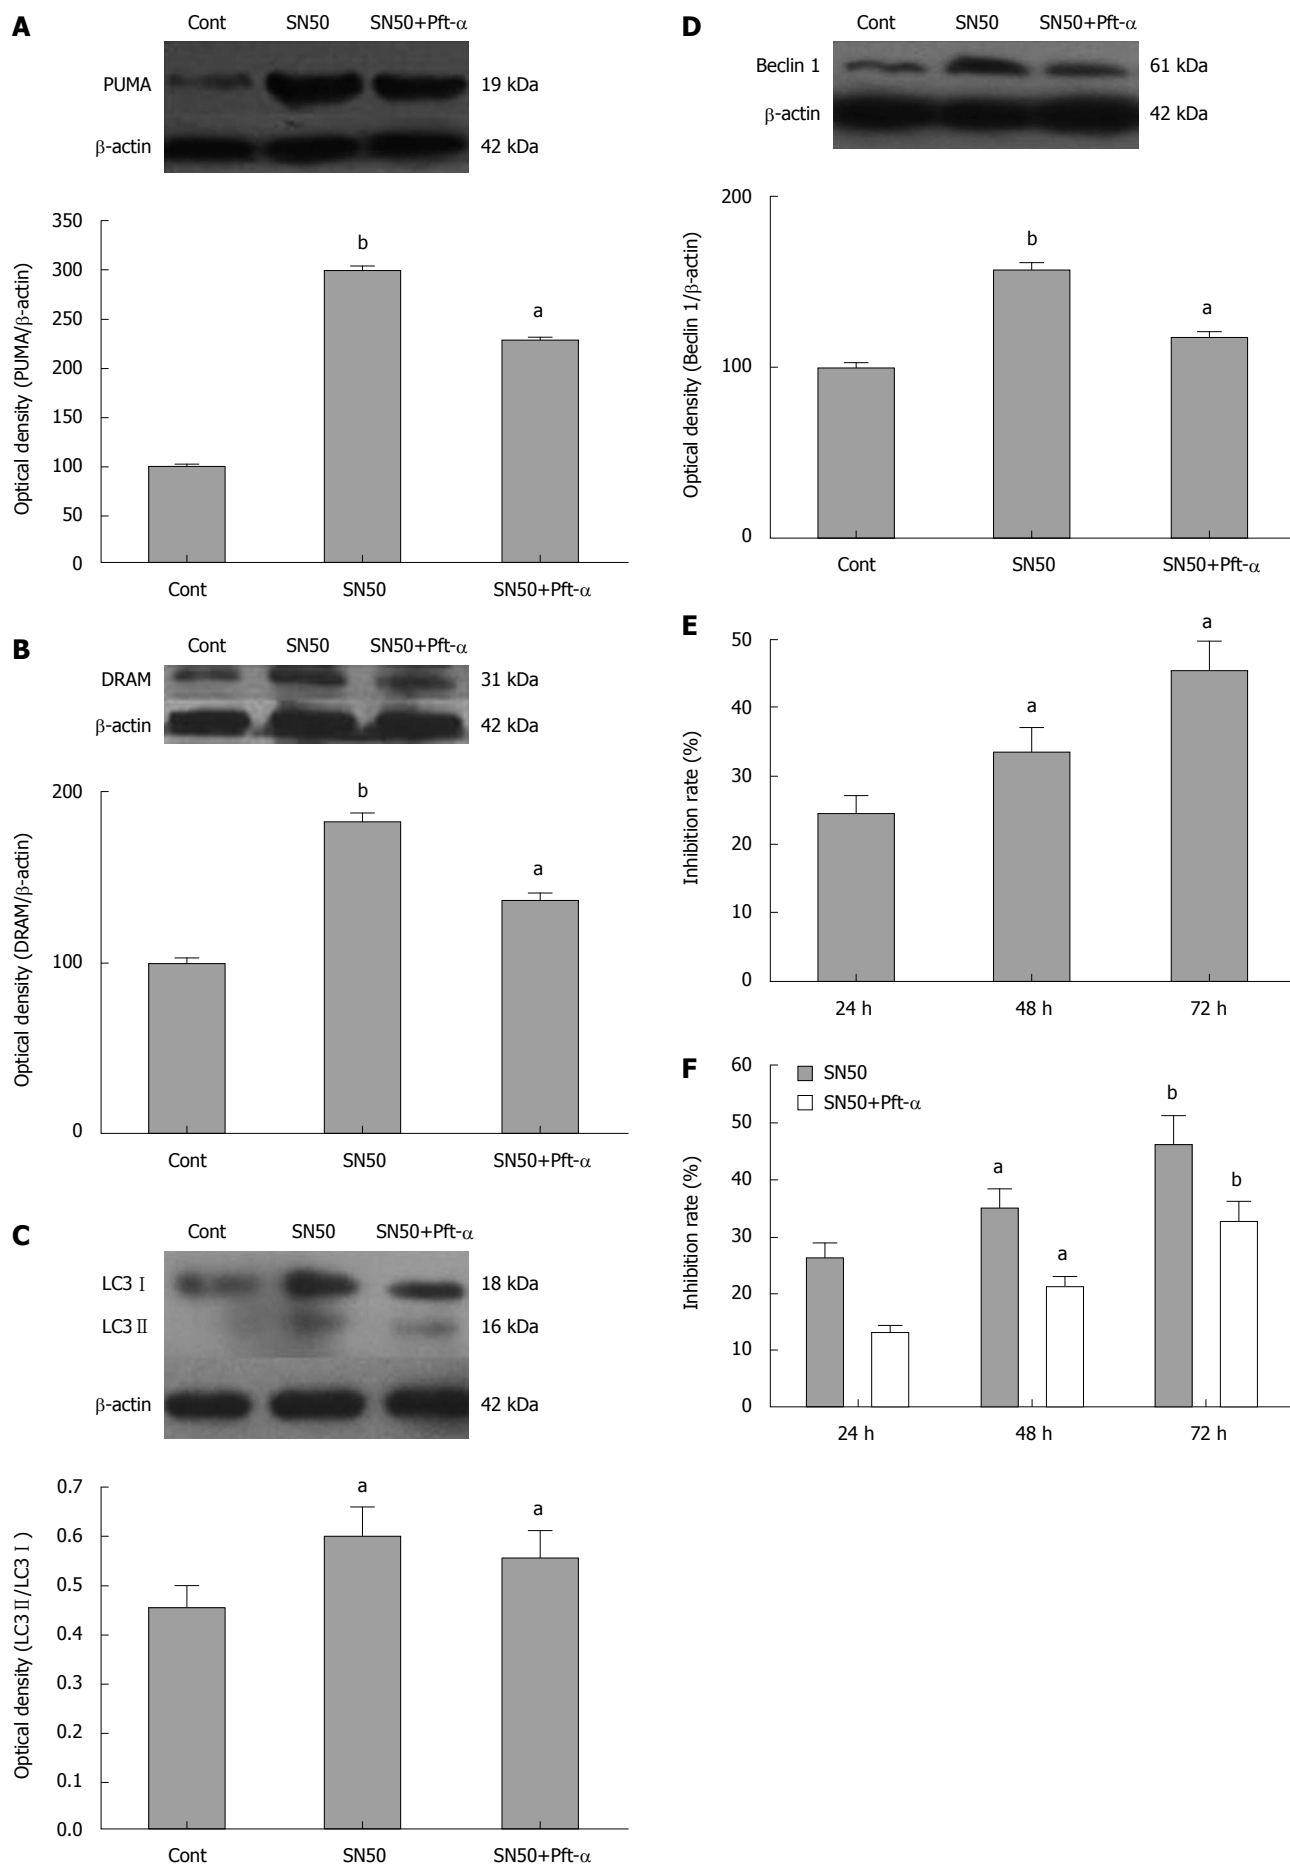

Figure 2 Blocking nuclear factor- κ B nuclear translocation induces p53 and its target proteins. A: Western blotting analysis of p53 of the control and SN50-treated SGC7901 cells. Western blotting analysis was used to detect the protein levels of p53 after SN50 treatment for 6-24 h. SGC7901 cells were treated with SN50 (18 μ mol/L) and were harvested for total proteins. It indicates that SN50 may up-regulate the expression of p53. Values were given as mean \pm SD. Statistical comparisons were carried out with Dennett's test. $^aP < 0.05$ and $^bP < 0.01$ vs control ($n = 3$); B: Western blotting analysis of P53 upregulated modulator of apoptosis (PUMA) of the control and SN50-treated SGC7901 cells. Western blotting analysis was used to detect the protein levels of PUMA after SN50 treatment for 6-24 h. SGC7901 cells were treated with SN50 (18 μ mol/L) and were harvested for total proteins. It indicates that SN50 may up-regulate the expression of PUMA. Values were given as mean \pm SD. Statistical comparisons were carried out with Dennett's test. $^bP < 0.01$ vs control ($n = 3$); C: Western blotting analysis of damage-regulated autophagy modulator (DRAM) of the control and SN50-treated SGC7901 cells. Western blotting analysis was used to detect the protein levels of DRAM after SN50 treatment for 6-24 h. SGC7901 cells were treated with SN50 (18 μ mol/L) and were harvested for total proteins. It indicates that SN50 may up-regulate the expression of DRAM. Values were given as mean \pm SD. Statistical comparisons were carried out with Dennett's test. $^aP < 0.05$ and $^bP < 0.01$ vs control ($n = 3$).

many cancer cells, of either epithelial or hematopoietic origin, use NF- κ B to achieve resistance to anticancer drugs and radiation. Hence, inhibition of NF- κ B activation offers a strategy for treatment of different malignancies and can induce apoptosis in gastric cancer SGC7901 cells.

NF- κ B plays an important role in proliferation and survival of tumor cells. NF- κ B binding sites have been identified in the promoter region of cyclin D1. NF- κ B promotes cyclin D1 expression and cell cycle progression^[24,25]. NF- κ B activity has been shown to inhibit activa-

Figure 3 P53 inhibitor blocks SN50-induced autophagy activation and cell apoptosis. A: Effects of p53 inhibitor Pifithrin (Pft)- α on SN50-induced P53 upregulated modulator of apoptosis (PUMA) expression of SGC7901 cells. SGC7901 cells were pretreated with Pft- α (30 μ mol/L) 6 h before SN50 (18 μ mol/L). Protein expression was evaluated by Western blotting at 24 h. Results were presented as mean \pm SD of three independent experiments. ^a P < 0.05 and ^b P < 0.01 vs control group; B: Effects of p53 inhibitor Pft- α on SN50-induced damage-regulated autophagy modulator (DRAM) expression of SGC7901 cells. SGC7901 cells were pretreated with Pft- α (30 μ mol/L) 6 h before SN50 (18 μ mol/L). Protein expression was evaluated by Western blotting at 24 h. Results were presented as mean \pm SD of three independent experiments. ^a P < 0.05 and ^b P < 0.01 vs control group; C: Effects of p53 inhibitor Pft- α on SN50-induced LC3 expression of SGC7901 cells. SGC7901 cells were pretreated with Pft- α (30 μ mol/L) 6 h before SN50 (18 μ mol/L). Protein expression was evaluated by Western blotting at 24 h. Results were presented as mean \pm SD of three independent experiments. ^a P < 0.05 vs control group; D: Effects of p53 inhibitor Pft- α on SN50-induced Beclin 1 expression of SGC7901 cells. SGC7901 cells were pretreated with Pft- α (30 μ mol/L) 6 h before SN50 (18 μ mol/L). Protein expression was evaluated by Western blotting at 24 h. Results were presented as mean \pm SD of three independent experiments. ^a P < 0.05 and ^b P < 0.01 vs control; E: Reduced viability of SGC7901 cells after SN50 treatment. SGC7901 cells (7×10^4 cells/mL) were cultured with 18 μ mol/L of SN50 and cell viability was analyzed by MTT assay. MTT assays revealed that the inhibition rate reached 25.31% \pm 4.13%, 34.19% \pm 2.06%, 44.79% \pm 1.65% after treatment of SN50 (18 μ mol/L) 24, 48 and 72 h. Values were given as mean \pm SD of three independent experiments. ^a P < 0.05 and vs control; F: P53 inhibitor may attenuate the inhibitory effects of SN50-induced death of SGC7901 cells. SGC7901 cells were pretreated with Pft- α (30 μ mol/L) 6 h before SN50 treatment (18 μ mol/L). Cell viability was evaluated by MTT assay at 24, 48 and 72 h. Results were presented as mean \pm SD of three independent experiments. ^a P < 0.05 vs control, ^b P < 0.01 compared with SN50 alone treated group; G: Flow cytometric analysis of mitochondria membrane potential in the control and SN50-treated SGC7901 cells. Cells were treated with SN50 (18 μ mol/L) for 6, 12 and 24 h and were stained with JC-1 (5 μ mol/L) for 30 min. Values were given as mean \pm SD. Statistical analysis was carried out with ANOVA followed by Dunnett's *t* test. ^a P < 0.05 vs control.

tion of caspase-8, thus inhibiting the apoptosis initiation^[26]. Activation of NF- κ B confers resistance of tumor cells to radiochemotherapy-induced cytotoxicity^[27,28]. In contrast, various NF- κ B inhibitors inhibit tumor cell growth and induce cell death through apoptotic mechanisms^[29].

The tumor suppressor p53 plays a central role in sensing various genotoxic stresses. Our results showed that blocking NF- κ B with SN50 induced expression of p53 remarkably. P53 downstream point such as the apoptosis gene PUMA was up-regulated after the treatment of SN50. P53 is known to play an important role in apoptosis by regulating expression of pro-apoptotic proteins. PUMA is one of p53 target genes involved in apoptosis. The activation of PUMA by DNA damage is dependent on p53 and is mediated by the direct binding of p53 to the PUMA promoter region^[30]. PUMA plays an essential role in p53-dependent and -independent apoptosis induced by a variety of stimuli^[31,32]. Here, we demonstrated that the inhibitor of NF- κ B p65 nuclear import, SN50, significantly up-regulated the levels of PUMA, indicating that apoptosis may be triggered by SN50. In supporting this notion, we found that mitochondria membrane potential was collapsed after SN50 treatment. Mitochondria plays a

central role in regulating cell death and survival. Diverse proapoptotic stimuli act on mitochondria, triggering mitochondrial membrane potential collapse, cytochrome c release and caspase activation. The mitochondrial permeability transition (MPT) represents an important event initiating apoptotic cell death.

Increasing evidence suggests that autophagy plays an important role in tumor cell growth, differentiation and response to anti-tumor drugs^[33]. Many classical anti-tumor drugs have been found to exert their cytotoxic actions by autophagic mechanisms^[34-36]. It has been suggested that autophagic death may play a role in both physiological and pathological cell death. This issue has been addressed by some recent reviews^[32,37]. In the present study, inhibitor of NF- κ B p65 nuclear import with SN50 resulted in a significant increase in the levels of DRAM, a newly identified p53 target gene involved in autophagy activation and cell death^[21]. We also found that SN50 increased the expression of LC3, Beclin 1, particularly the production of LC3-II. LC3 is an autophagosomal ortholog of yeast Atg8. LC3 has been best characterized as an autophagosomal marker in mammalian autophagy, and the levels of LC3 may also reflect the levels of autophagy^[38]. Beclin 1

is the mammalian orthologue of the yeast ATG6-Vps30 gene. It can complement the defect in autophagy present in ATG6^{-/-} yeast strains and stimulate autophagy when overexpressed in mammalian cells^[13]. Beclin 1 is monoallelically deleted in human breast and ovarian cancers and is expressed at reduced levels in those tumors^[13,39]. The present results suggest that autophagy is induced by SN50 and its activation may contribute to anti-tumor effects of NF- κ B inhibitors.

The evidence has shown that p53 is not only involved in apoptosis but also in autophagy. The present study investigated if p53 signaling plays an essential role in autophagy activation and cell death induced by NF- κ B inhibition. P53 signaling was blocked with a specific inhibitor pft- α , the compound has been shown to selectively inhibit p53 activity and p53-mediated apoptosis *in vitro* and *in vivo*^[40]. The results demonstrated that pft- α blocked SN50-induced increases in PUMA, LC3-II and Beclin 1. Moreover, SN50-induced cell death was significantly attenuated by pft- α . These data suggest that p53 mediates activation of apoptosis and autophagy and cell death following blockade of NF- κ B. This study shed new lights on elucidating molecular mechanisms of anti-tumor actions of NF- κ B inhibitors.

In summary, the present study revealed that a new mechanism associated with NF- κ B inhibition triggered impairment of cell proliferation and induction of apoptosis of cancer cells. Blocking NF- κ B increases expression of p53, induces pro-apoptotic and autophagic proteins. P53 contributes to NF- κ B inhibitor-induced apoptosis of cancer cells by activating autophagic mechanisms. Further investigation of the relationship between autophagy activation and anti-tumor effects of NF- κ B inhibitors will unveil new strategies for tumor therapy.

COMMENTS

Background

Nuclear factor- κ B (NF- κ B) signaling pathways play critical roles in a variety of physiological and pathological processes. The authors predicted that activation of autophagy by blocking NF- κ B may contribute to the anti-tumor actions of NF- κ B inhibitors.

Research frontiers

SN50 is a specific inhibitor of NF- κ B p65. The anti-tumor activity of SN50 might be related to the induction of apoptosis of tumor cells, but the precise mechanism of its anti-tumor activity is not well understood.

Innovations and breakthroughs

Blocking NF- κ B increases the expression of p53, and induces pro-apoptotic and autophagic proteins. P53 contributes to the NF- κ B inhibitor-induced apoptosis of cancer cells through both apoptotic and autophagic mechanisms. Further investigation of the relationship between autophagy activation and anti-tumor effects of NF- κ B inhibitors will unveil new strategies for tumor therapy.

Applications

Blocking NF- κ B increases expression of p53, induces pro-apoptotic and autophagic proteins. P53 contributes to NF- κ B inhibitor-induced apoptosis of cancer cells by activating autophagic mechanisms. And it will provide new idea for tumor treatment.

Terminology

NF- κ B: The NF- κ B comprises a family of transcription factors involved in the regulation of a wide variety of biological responses. SN50: SN50 is a kind of NF- κ B p65 nuclear translocation inhibitor. Autophagy: Autophagy is a general term for the degradation of cytoplasmic components within lysosomes. There are three

types of autophagy: macroautophagy, microautophagy, and chaperone-mediated autophagy, and the term "autophagy" usually indicates macroautophagy.

Peer review

The authors examined the effects of the nuclear import inhibitor SN50 on activation of apoptosis and autophagy and the contribution of autophagy to cytotoxic effects of SN50 in gastric cancer cell line SGC7901. The results showed that blocking NF- κ B nuclear transport leads to p53-dependent activation of apoptotic and autophagic pathways, and autophagy activation contributes to SN50-induced death of cancer cells.

type *EGF* +61 in 207 patients with gastric lesions (162 patients with gastric adenocarcinomas, 45 with atrophy or intestinal metaplasia) and 984 controls. All subjects were Caucasian.

RESULTS: Genotype distribution was 23.5% for GG and 76.5% for GA/AA in the control group, 18.4% for GG and 68.6% for GA/AA in the entire group with gastric lesions and 17.9% for GG and 82.1% for GA/AA in the group with gastric adenocarcinoma. No statistically significant associations were found between *EGF* +61 variants and risk for developing gastric cancer [odds ratios (OR) = 1.41, 95% confidence intervals (CI): 0.90-2.21, $P = 0.116$]. However, the stratification of individuals by gender revealed that males carrying A alleles (*EGF* +61A/G or AA) had an increased risk for developing gastric cancer as compared to GG homozygous males (OR = 1.55, 95% CI: 1.05-2.28, $P = 0.021$).

CONCLUSION: In summary, we found that males who were A carriers for *EGF* +61 had an increased risk for developing gastric cancer. This result may be explained by the suggestion that women secrete less gastric acid than men.

Abstract

AIM: To investigate the association between epidermal growth factor (*EGF*) +61A/G polymorphism and susceptibility to gastric cancer, through a cross-sectional study.

METHODS: Polymerase chain reaction restriction fragment length polymorphism analyses were used to geno-

casians. *World J Gastroenterol* 2011; 17(4): 488-492 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i4/488.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i4.488>

INTRODUCTION

Growth factors activate the complex processes of cellular signalling, promoting cell changes^[1,2]. They are “positive signals” in the cell and are regulated by “negative signals” which control amplitude and duration^[2]. The balance between these signals is all-important in cell homeostasis^[2]. Epidermal growth factor (EGF) performs a key role in promoting cell survival^[3]. After binding to its receptor (EGFR), it induces a signalling cascade that culminates in change of gene transcription^[3-5]. EGFR signalling is not only important in cellular proliferation but also contributes to several other cellular processes involved in cancer progression, including angiogenesis, metastatic spread, and inhibition of apoptosis^[6].

EGFR (also known as ErbB1) belongs to the family of ErbB (from avian erythroblastic leukaemia viral oncogene homologue) receptors which are involved in the development of several human cancers^[7]. The increase in EGFR signalling may be caused by overexpression of EGFR, increased concentration of ligand(s) (through autocrine/paracrine processes), the presence of aberrant receptors due to gene alteration, and alterations in molecules that control receptor signalling output^[6,8]. EGFR and ErbB-2 are frequently overexpressed in gastric carcinomas^[9].

EGF gene has a polymorphism in position +61 which consists of the substitution of adenine (A) for guanine (G). AA genotype carriers have lower levels of EGF expression than individuals with the GG or AG genotypes^[10]. Ethnic differences in the distribution of the EGF gene have been reported, and several studies have been carried out regarding the role of EGF genotypes in susceptibility to gastric cancer in Asian populations and in other organs.

In this cross-sectional study we analysed the association between this EGF polymorphism and the risk for gastric cancer in a high incidence Caucasian population.

MATERIALS AND METHODS

Subjects

This cross-sectional study was performed in 1191 individuals, including 207 patients histologically diagnosed with gastric lesions followed at the Portuguese Institute of Oncology-Porto (IPO-P), and a control group of 984 individuals without cancer disease history, all from the northern region of Portugal. All individuals provided informed consent according to the Declaration of Helsinki, and the patients in both groups were of Caucasian ethnicity.

Patients were further divided according to the type of lesions at histopathological diagnosis following multiple endoscopic biopsies. Patients included those who displayed lesions such as high-grade dysplasia and intestinal-type invasive gastric adenocarcinoma ($n = 162$) and patients with non-dysplastic lesions associated with gastric

adenocarcinoma such as atrophy or intestinal metaplasia ($n = 45$), who had received standardized follow-up since 2001. The group of patients with gastric adenocarcinoma included 73 females and 89 males (55%) with a median age at diagnosis of 54 years (mean 54.3 years, standard deviation 11.8 years), and the group of patients with atrophy or intestinal metaplasia included 25 females and 20 males (44%) with a median age at diagnosis of 59 years (mean 59.7 years, standard deviation 10.8 years).

The control subjects included 524 females and 460 males (46.7%) randomly recruited from the Blood Donor Bank of IPO-P and Hospital de S. Marcos, Braga, and had no current or history of neoplastic disease. The median age was 45 years (mean 46.2 years, standard deviation 11.1 years).

DNA was extracted from peripheral blood samples obtained by a standard venipuncture technique using EDTA-containing tubes, as previously described in studies from our group^[11,12].

EGF +61A/G genotype analysis

The +61A/G polymorphism was genotyped by PCR-RFLP (polymerase chain reaction-restriction fragment length polymorphism) analysis, as previously described^[10]. Briefly, amplification was carried out in a 50 μ L reaction mixture containing: 1 \times Taq Buffer, 1.5 mmol/L of $MgCl_2$, 0.2 mmol/L of dNTPs, 0.3 μ mol/L of each primer and 1U Taq DNA polymerase. The cycling conditions were: 95°C for 5 min, followed by 35 amplification cycles at 94°C for 60 s, 55°C for 60 s and 72°C for 60 s, followed by one elongation step at 72°C for 5 min. A 242 base pair (bp) fragment was amplified using primers: F-5'TGTCACCTAAAGGAAAGGAGGT3' and R-5'TTCACAGAGTTTAACAGCCC3'. The A61G variation was identified with the restriction enzyme *Afu I*. Two units of restriction enzyme were added to 10 μ L of PCR products in a final volume of 15 μ L. The incubation was performed at 37°C overnight. The products were separated on 3% agarose gels with 0.5% ethidium bromide and photographed under UV illumination.

After destruction of the recognition site by the restriction enzyme, the A allele produced 4 fragments: 15, 34, 91 and 102 bp, while the G allele produced 3 fragments: 15, 34 and 193 bp. In the gel only fragments 91, 102 and 193 bp were visible.

Statistical analysis

The computer software SPSS for Windows (version 15.0) and Epi Info (version 6.04) were used for all statistical analyses. The χ^2 test was used to compare differences between categorical variables, and verify that the observed allele distribution in the control group was in Hardy-Weinberg equilibrium. A 5% level of significance was used in the analysis. Odds ratios (OR) and 95% confidence intervals (CI) were calculated to assess the relationship between the polymorphic variants and gastric lesions.

RESULTS

The frequencies of EGF genotypes in the gastric lesions

Table 1 Associations between *EGF* +61A/G variants and clinicopathological parameters in patients with gastric lesions¹ *n* (%)

	Cases	Controls	OR (95% CI)	<i>P</i>

group and the control group are presented in Table 1. The frequencies were 23.5% for GG and 76.5% for GA/AA in the control group, 18.4% for GG and 68.6% for GA/AA in the entire group with gastric lesions and 17.9% for GG and 82.1% for GA/AA in the group with gastric adenocarcinoma. As shown in Table 1, no increased risk of developing non-tumor gastric lesions ($P = 0.109$) or gastric adenocarcinoma ($P = 0.116$) was found for individuals who carried the A allele.

When adjustments were made for allele genotype and sex, we found that males who were A carriers had an increased risk of developing gastric cancer in comparison to females (OR = 1.55, 95% CI: 1.05-2.28, $P = 0.021$) (Table 2).

No other associations were found for the other characteristics tested.

DISCUSSION

The EGF protein is a growth factor that activates signal transduction pathways promoting proliferation, migration and differentiation^[13]. In particular, EGF is involved in regulating proliferation of mucosal cells in the gastrointestinal tract, stimulating mucus production, and inhibiting gastric secretion^[14,15]. However, in gastric cancer, EGF displays oncogenic properties^[16,17], and its overexpression is correlated with deep invasion, advanced malignancy stage, and poor patient prognosis^[18].

In this cross-sectional study, we analysed the association between a functional polymorphism of the *EGF* gene (+61 A/G) and the risk for developing gastric cancer. Our data showed a statistically significant increased risk for developing gastric cancer in males who were A carriers (OR = 1.55, 95% CI: 1.05-2.28, $P = 0.021$); however, no statistically significant differences were found

Table 2 Associations between *EGF* +61A/G variants and gender

		Controls	Cases	OR (95%CI)	<i>P</i>
GG	M	117	14	1	
	F	114	15	1.04 (0.45-2.41)	0.913

when the entire cancer group was considered (male and female gastric adenocarcinoma patients, $P = 0.116$).

Salomon *et al*^[9] reported that EGFR is overexpressed in 33% of gastric adenocarcinomas, compared to only 3.8% in the early stages of gastric carcinoma development or in non-malignant specimens. Nevertheless, EGFR expression was more frequent in well-differentiated advanced stage adenocarcinomas, and EGFR immunoreactivity was significantly higher in tumor stages III and IV as well as in metastatic carcinomas^[9]. EGF and EGFR are expressed at a frequency of 42% and 41%, respectively, in poorly differentiated gastric carcinomas, and most frequently in tumors greater than 6 cm in size^[9]. Although EGF and EGFR are associated with poor prognosis, less than half of gastric tumors have expression or overexpression of these proteins.

In our study, the most interesting result was the increased risk for gastric cancer in male patients. A sexual dimorphism in gastric acid secretion has been reported, with females secreting less gastric acid (approximately 40%) than males^[19]. The mechanisms mediating this difference are unknown, but a role for oestrogens has been suggested which may inhibit gastric acid secretion through two oestrogen receptor (ER) subtypes present in the stomach^[19]. EGF decreases FSH (follicle-stimulating hormone) and particularly inhibits the expression of hormones produced in the ovary (oestrogen and progesterone), acting in the evolution of ovarian follicles^[20-26]. Therefore, in females with a lower expression of EGF (A carriers) we may consider that stomach cells may receive less information to proliferate. Nevertheless, in G carriers (with greater expression of EGF), the differences between genders are not significant, and according to our previous studies it is proposed that EGFR expression may be lower in G carriers, because EGF is involved in internalization of EGFR^[27,28]. However, more work is required to elucidate the correct mechanism.

Others studies regarding the association between gastric cancer and *EGF* polymorphism in Asian populations have been reported^[29-31]. Hamai *et al*^[29] and Jin *et al*^[30] associated A carriers with a lower risk of developing gastric cancer. However, Goto *et al*^[31] did not find any differences between this polymorphism and gastric cancer. When analyzing the frequency of *EGF* +61 genotypes among these reports, one can observe that Asians present a significant difference in comparison to Caucasians (our study), namely in AA and GG genotypes (Table 3). In our results, the frequency of EGF genotypes in the control

population was in agreement with other published studies with Caucasians populations^[10,32-34]. Two recent meta-analyses have discussed the role of *EGF* polymorphism in susceptibility to cancer^[35,36]. Future studies may confirm these results with adjustment for non-genetic putative risk factors for gastric cancer (ex: smoking, alcohol consumption, social class or *H. pylori*).

In conclusion, we found that female patients who were A carriers of *EGF* +61A/G had a decreased risk of developing gastric cancer. Furthermore, it has been suggested that women secrete less gastric acid than men^[19], which is consistent with our hypothesis that different effects of *EGF* +61A/G variants may occur in males and females in relation to gastric cancer risk.

COMMENTS

Background

Epidermal growth factor (EGF) performs a key role in promoting cell survival. After binding to its receptor (EGFR), it induces a signalling cascade that culminates in change of gene transcription. EGFR signalling is not only important in cellular proliferation but also contributes to several other cellular processes involved in cancer progression, including angiogenesis, metastatic spread, and inhibition of apoptosis. EGFR (also known as ErbB1) belongs to the family of ErbB (from avian erythroblastic leukaemia viral oncogene homologue) receptors which are involved in the development of several human cancers. *EGF* gene has a polymorphism in position +61 which consists of the substitution of adenine (A) for guanine (G). AA genotype carriers have lower levels of EGF expression than individuals with the GG or AG genotypes. In this cross-sectional study, the authors analysed the associations between this *EGF* polymorphism and the risk for gastric cancer in a high incidence Caucasian population.

Research frontiers

Although several gene loci have been associated with susceptibility to gastric cancer, the aetiology of gastric cancer is still unknown. The current study is the first to assess the impact of *EGF* gene polymorphisms and disease susceptibility in gastric cancer in a southern European Caucasian population.

Innovations and breakthroughs

It is important to investigate the genetic variation in susceptibility to gastric cancer and to identify markers that will facilitate identification of individuals at risk of developing this disease. The results suggest that the stratification of individuals by gender revealed that males carrying A alleles (*EGF* +61A/G or AA) have an increased risk of developing gastric cancer as compared to GG homozygous males.

Applications

The results of this study will help us to further understand the genetic determinants of gastric cancer.

Peer review

This population based case-control study that adds to the existing evidence for a role of *EGF*/EGFR in pathogenesis of gastric carcinoma. The validity of the control population may be mildly contentious. The findings raise questions regarding the role of gender and sex hormones in gastric carcinoma. This is a small study with somewhat limited results, however it is well done, with a good sample size and with a good interpretation for the results observed. It can be relevant to the field.

Abstract

AIM: To assess the clinical, biochemical and virological long-term outcome in chronic hepatitis C (CHC) patients with a sustained virological response (SVR) after peginterferon (PEG-IFN) plus ribavirin combination therapy.

METHODS: One hundred and fifty three patients with a SVR after treatment with PEG-IFN plus ribavirin were included in a 5-year follow-up study in a single Spanish center, based on standard clinical practice. Clinical anamnesis, biochemical analysis, hepatitis C virus RNA and alpha-fetoprotein measurement, ultrasonography and transient elastography were performed annually.

RESULTS: The mean follow-up period of the 153 patients was 76 ± 13 mo after they obtained a SVR. Five

patients (3.26%) presented with cirrhosis before treatment and 116 (75.8%) had genotype 1. No patient showed evidence of hepatic decompensation. One patient (0.65%) developed a hepatocellular carcinoma at month 30 after achieving SVR. There were no virological relapses during this follow-up period. Persistently elevated alanine aminotransferase was found in only one patient (0.65%). At the end of the 5-year follow-up, the mean value of transient elastography was 7 ± 4.3 kPa (F1). There were no deaths and no other tumors.

CONCLUSION: The long-term outcome of 153 CHC patients with SVR to PEG-IFN plus ribavirin was good. No evidence of a virological relapse was seen. One patient (0.65%) developed a hepatocellular carcinoma.

Long-term outcome of chronic hepatitis C patients with sustained virological response to peginterferon plus ribavirin. *World J Gastroenterol* 2011; 17(4): 493-498 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i4/493.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i4.493>

INTRODUCTION

The combination of peginterferon (PEG-IFN) plus ribavirin is the current standard of care for naïve chronic hepatitis C (CHC) patients, achieving a high sustained virological

response (SVR) rate^[1-4]. The long-term benefits of CHC combination therapy have been well established in several studies, but the results are limited by differing patient populations or treatment regimens and, importantly, a brief duration of follow-up^[5]; in addition, occult hepatitis infection by hepatitis C virus (HCV) has been proposed^[6]. The conclusions of long-term studies^[7-14] may be compromised by the small number of patients, and most studies using IFN monotherapy or IFN combined with ribavirin, while only 4 studies used PEG-IFN plus ribavirin combination therapy^[15-18].

We conducted an open-label cohort study in a single center in Spain from January 2000 to December 2009, and included patients with a SVR after antiviral combination therapy with PEG-IFN plus ribavirin achieved between 2000 and 2003, with a mean follow-up greater than 5 years. Our major aim was to assess the clinical, biochemical and virological outcomes, and the durability of the SVR.

MATERIALS AND METHODS

Study design

A total cohort of 303 CHC consecutive patients (18-65 years) treated with PEG-IFN plus ribavirin in 2000-2003 were included in this cohort study. All patients attended the Hepatology Unit, Hospital Universitario de La Princesa (a tertiary university care centre), CIBERehd, Madrid, Spain.

Patients

Eligible patients were those who achieved a SVR after PEG-IFN plus ribavirin for 24 or 48 wk (in genotypes 2/3 or genotypes 1/4, respectively), defined as negativization of HCV-RNA at the end of treatment and after 6 mo of follow-up. Criteria for exclusion were: alcohol or intravenous drug abuse; liver diseases not related to HCV infection (autoimmune, metabolic or toxicity by drugs); decompensated liver disease; coinfection with HBV or human immunodeficiency virus; and pregnancy.

All patients received the standard of care combination therapy: 60 (39%) patients had been treated with PEG-IFN α -2a (Pegasys, Roche) plus ribavirin (1-1.2 g/d) and 93 (61%) patients with PEG-IFN α -2b (Pegintron, Schering-Plough) plus ribavirin (1-1.2 g/d). Patients with genotypes 1 and 4 were treated for 48 wk and patients with genotypes 2 or 3 were treated for 24 wk^[19].

Clinical, biochemical and virological evaluation

We obtained data on patients' sex and age, treatment, virological data (genotype, baseline HCV-RNA), biochemical data [aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP), γ -glutamyl transpeptidase (GGT), α -fetoprotein (AFP)], and length of follow-up. Pre-treatment liver biopsy and transient elastography analysis during the follow-up was obtained in some patients taking into account that this study was performed as routine clinical practice.

Patients were evaluated as outpatients at sequential annual clinical visits (1, 2, 3, 4, 5 years after the completion of antiviral therapy and 6 mo of follow-up). Blood tests

with hematological, biochemical and virological assays were performed at the basal visit and thereafter. Serum HCV-RNA levels (IU/mL) were determined with Cobas Amplicor Hepatitis C Monitor Test (v2.0 Roche Diagnostics) and reverse transcription-polymerase chain reaction (RT-PCR), with a limit of detection < 50-100 IU/mL. HCV genotyping was performed by a reverse-hybridization line probe assay (INNO-LiPA HCV; Innogenetics, Zwijndrecht, Belgium).

Liver decompensation or failure was defined if a patient showed any of these findings: bleeding varices, hepatic encephalopathy, jaundice, or ascites. Patients were classified pretreatment by liver biopsy, and the establishment of cirrhosis was done using the METAVIR score for fibrosis stage. In addition, transient elastography was performed during follow-up after achieving the SVR. Hepatocellular carcinoma (HCC) was diagnosed if 2 coincident imaging techniques [ultrasonography, computed tomography (CT) or magnetic resonance imaging] showed a focal lesion larger than 2 cm with arterial hypervascularization or if one imaging technique showed a focal lesion larger than 2 cm with arterial hypervascularization in the presence of an AFP level > 400 ng/mL.

Statistical analysis

Quantitative variables are expressed as mean \pm SD. Qualitative variables are expressed as percentage with range. The Student *t*-test with Welch's and Fisher's correction, the chi-squared test, the Mann-Whitney *U* test and the Kruskal Wallis test were used for continuous or discrete variables as appropriate. Logistic regression was used to analyze if baseline factors could be associated with SVR. The Kaplan-Meier method was used to determine the rate of HCC occurrence. A value of *P* < 0.05 was considered to be statistically significant. Statistical analyses were performed using SPSS version 15.0.

RESULTS

Characteristics of patients

Among the 303 CHC patients, a total of 150 were excluded as they did not achieve a SVR. Those 153 patients with a SVR after treatment with PEG-IFN plus ribavirin (weight based) were included, with a mean age of 49 ± 9 years. There were 82 males (53.6%). Genotypes of HCV were distributed as follows: 116 genotype 1 (75.8%), one genotype 2 (0.6%), 32 genotype 3 (21%) and 4 patients with genotype 4 (2.6%). The baseline characteristics of patients with a SVR are shown in Table 1. One hundred and thirty patients (85%) were followed up for 5 or more after SVR. The median duration of follow-up was 76 ± 13 mo (range, 54-90) after the end of treatment, i.e., after achievement of a SVR was established.

Clinical outcomes

At the end of the follow-up, all patients were alive. Of 153 sustained responders, 5 patients had cirrhosis (F4) and 8 patients had F3 stage fibrosis before the start of the treatment, as determined by the METAVIR score. No

Table 1 Characteristics of 153 patients with a sustained virological response after peginterferon plus ribavirin combination treatment

	<i>n</i> (%)
Age (mean \pm SD, yr)	47 \pm 9

PEG-IFN: Peginterferon.

patient with a SVR developed signs of liver failure during the follow-up. These patients were hepatitis B surface antigen negative and HCV-RNA negative, and no other risk factors for liver disease were reported.

One patient, with cirrhosis on pre-treatment biopsy and genotype 1b, developed a HCC at 30 mo of follow-up. It was assessed by ultrasonography, AFP level and CT scan, was 3.5 cm in size and located sub-diaphragmatically at segment VIII. The patient was still negative for serum HCV-RNA at the time of HCC diagnosis, and at last follow-up, HCV-RNA remained undetectable. The patient received an orthotopic liver transplant. Given that 5 patients had cirrhosis pre-treatment and one developed HCC, this represents a 20% risk of HCC after SVR in individuals with pre-treatment cirrhosis. The incidence of HCC in this cohort of 153 SVR patients after a mean of 76 \pm 13 mo was 1/153 (0.65%).

Biochemical outcomes

All 153 SVR patients had at least 2 biochemical evaluations, and 123 (80.4%) had 5 or more years of laboratory data after achieving the SVR. There were significant reductions in ALT, AST, GGT and ALP levels between the samples collected pre-treatment and samples after the end of treatment, as shown in Table 2. However, there were no statistically significant differences ($P > 0.05$) between the first and last samples collected during the follow-up, in mean ALT (20 \pm 9 IU/L), AST (20 \pm 5 IU/L), AST/ALT ratio (1 \pm 0.5), ALP (70 \pm 19 IU/L), GGT (25 \pm 20 IU/L), and AFP (3 \pm 1 ng/mL) values.

Virological outcomes

Out of 153 patients, 138 (90.2%) had at least 4 serum

Table 2 Biochemical values pre-treatment and post-treatment (last sample of follow-up)

	Pre-treatment	Post-treatment	<i>P</i>
AST (IU/L)	73 \pm 70	20 \pm 5	< 0.001
ALT (IU/L)	138 \pm 178	20 \pm 9	< 0.001
ALP (IU/L)	70 \pm 19	98 \pm 55	< 0.001
GGT (IU/L)	51 \pm 46	25 \pm 20	< 0.001
AFP (ng/mL)	4.9 \pm 4	3 \pm 1	NS

AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; GGT: γ -glutamyl transpeptidase; AFP: α -fetoprotein; NS: Not significant.

HCV-RNA tests via RT-PCR. The mean number of samples tested per patient was 4 or 5 (range, 2-8). No patient had detectable HCV-RNA in serum *via* RT-PCR on any sample.

Liver fibrosis analysis

Liver biopsy and transient elastography evaluation were obtained only in a limited number of patients. Fifty four patients (45%) had pre-treatment liver biopsies. Eighty of these (53%) had a Fibroscan® analysis at least once during the follow-up with a mean number of 4 (range, 2-8) explorations. Mean time between 2 Fibroscan® analyses was 4 \pm 0.8 years. The technique was very well tolerated by all patients, without side effects. Results were obtained in all patients. The mean value of transient elastography after 4-5 years of follow-up was 7 \pm 4.3 kPa. One patient (0.8%) had a decrease in fibrosis stage from liver biopsy F3 to F1 by transient elastography. No progression of fibrosis was seen in any patient.

DISCUSSION

We assessed the long-term clinical, biochemical and virological outcomes of 153 patients with CHC who achieved a SVR after PEG-IFN plus ribavirin combination therapy. This study showed that a SVR is associated with permanent undetectable HCV-RNA in serum during a long-term follow-up. Nevertheless, it is difficult to say whether the treatment *per se* is important or whether a SVR is important because no controls were included. A late relapse of at least 0.8% after 4-5 years of follow-up has been reported^[7-11], however, introduction of more sensitive PCR methods may contribute to reduce this late-relapse rate.

There are some studies of the long-term clinical outcome of CHC patients with a SVR^[8,11-16,20-27] but the majority analyzed patients treated with recombinant IFN as monotherapy or in combination with ribavirin. At present, only 4 studies have enrolled patients treated with PEG-IFN plus ribavirin as shown in Table 3: in the study by Veldt *et al*^[15], 83 patients were analyzed; Chavalitthamrong *et al*^[16] studied 78 patients; George *et al*^[14] recently published the results of a long-term study of SVR patients including only 4 patients (3%) treated with PEG-IFN plus ribavirin; and Giannini *et al*^[18] included 231 patients treated with PEG-IFN plus ribavirin, but only 33.3% were genotype 1.

Table 3 Comparative results of other studies analyzing long term outcomes in chronic hepatitis C patients who achieved a sustained virological response *n* (%)

Study	IFN- α 2b alone or IFN- α 2b + RBV	PEG-IFN + RBV	Genotype 1	Genotype non-1	No data of genotype
George <i>et al</i> ^[14]	146 (97)	4 (3)	75 (53)	66 (47)	9
Veldt <i>et al</i> ^[15]	55 (39)	83 (59)	56 (39)	86 (61)	-
Chavalitdhamrong <i>et al</i> ^[16]	93 (54.4)	78 (45.6)	48 (28.1)	113 (66.1)	10
Giannini <i>et al</i> ^[18]	0	231 (100)	77 (33.3)	154 (66.7)	-
The current study	0	153 (100)	116 (75.8)	37 (24.2)	-

PEG-IFN: Peginterferon; RBV: Ribavirin.

It is noteworthy that we included only patients treated with PEG-IFN plus ribavirin with a high proportion being genotype 1 (75.8%), in contrast to other studies (Chavalitdhamrong *et al*^[16], where genotype 3 represented 62%; George *et al*^[14], genotype 1 represented 47%; and Giannini *et al*^[18] genotype 1 represented 66.6%).

Overall, our study showed that clinical events were rare in this population, indicating that SVR patients have an excellent prognosis, similar to previous studies^[8,9,11,14-16,20,21,25-29]. No patient developed decompensated liver disease. There were 5 (4.2%) patients with cirrhosis pre-treatment in this study. None of the patients with advanced fibrosis (F3) pre-treatment progressed to cirrhosis. Similar findings have been reported with PEG-IFN^[10,14,25]. In contrast, Pradat *et al*^[27] found that cirrhosis developed in 2 of 87 patients who were followed for at least 5 years after a SVR.

One patient with pre-treatment cirrhosis developed a HCC that represented a rate of 0.8%. This patient had no other risk factors such as obesity, alcohol intake or diabetes. This is a similar rate of HCC as reported in other studies^[12,15,20,21,23,24,26,30]. Veldt *et al*^[21] reported that 3/142 patients (2%) with a SVR and F3-F4 stage pre-treatment developed HCC during follow-up. Nevertheless, Japanese authors^[31,32] have reported a HCC rate of 0.02%-0.5% per year, slightly lower than our study. These data confirm that the risk of late development of HCC after a SVR is a real problem, and we must continue the follow-up of these patients for a long time. It is also important to take into account that HCV-RNA remains undetectable when HCC appears. Scientists speculate about the possibility of hepatocarcinogenesis, despite null replication of HCV, by other pathways^[29,33,34].

It is well-known that most patients with a SVR normalize their serum ALT, AST and total bilirubin, unless another liver disease is present^[8,9,11,24]. We found the same results in our study: 99% of patients had normal AST and ALT levels during the entire period of follow-up. The patient with HCC had persistently normal serum ALT values. Only one patient had elevated ALT and AST levels during follow-up period: a woman with fibromyalgia and relevant consumption of non-steroidal anti-inflammatory drugs. Nevertheless, ALP values were increased after treatment, but remained within the normal range (< 100 U/L). There is no explanation for this finding.

Limitations of our study are that not all patients had a period of follow-up greater than 5 years and, importantly, that analysis of outcomes of fibrosis (stability, improve-

ment or progression) are of limited value as no paired pre-treatment and post-treatment biopsies were analyzed from each patient. However, a large European study^[21] clearly demonstrated that the 5-year survival rate of patients achieving a SVR was similar to the overall population and that a SVR was associated with a decrease in fibrosis score; the authors speculated that excellent prognosis of sustained virological responders "is likely to hold true in the era of PEG-IFN and ribavirin". Our data confirm this important prognostic assumption. Moreover, extensive recent histological analyses have shown that most virological responders without cirrhosis had normalization of liver histology^[13]; that is, up to 82% had improved fibrosis scores^[14] and in addition to fibrosis stability/improvement in 88%, in 64% of patients (9 of 14) regression of cirrhosis was observed^[35]. Taken all together^[13,14,21,35], these data question the indication for a second liver biopsy in CHC patients with a SVR after antiviral combination therapy.

The long-term clinical outcome of patients with a SVR to PEG-IFN plus ribavirin is favorable. However, a risk of HCC development still remains, although it is very low, so we must clinically monitor SVR patients for a long time, even with undetectable HCV-RNA, normal ultrasonography, and normal aminotransferase and AFP levels after PEG-IFN plus ribavirin therapy.

COMMENTS

Background

The combination treatment of peginterferon (PEG-IFN) α plus ribavirin improved the sustained virological response (SVR) rate in chronic hepatitis C (CHC) patients. The long-term benefits of CHC combination therapy have been well established in several studies, but the results are limited by differing patient populations or treatment regimens and, importantly, a brief duration of follow-up.

Research frontiers

Occult hepatitis infection by hepatitis C virus (HCV) has been proposed and some cases of delayed relapses have been published.

Innovations and breakthroughs

The conclusions of long-term studies may be compromised by the small number of patients, and the fact that most studies used IFN monotherapy or IFN combined with ribavirin, with only 4 studies using PEG-IFN plus ribavirin combination therapy. This study analyzed patients with a SVR after antiviral combination therapy of PEG-IFN plus ribavirin with a mean follow-up greater than 5 years.

Applications

The study demonstrated that the long-term outcome of CHC patients who were sustained virological responders was good. It is important that evidence of a virological relapse must be assessed for a long time, as well as screening for hepatocellular carcinoma.

Terminology

A SVR is comparable with "clinical cure" in CHC patients. However, a minimal

percentage of patients present an activation of HCV replication, and are considered as "relapsers".

Peer review

The study has been well conducted and includes a large number of patients. Results have been described in a lucid and informative manner and are of clinical relevance.

EUS-guided drainage is more successful in pancreatic pseudocysts compared with abscesses. *World J Gastroenterol* 2011; 17(4): 499-505 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i4/499.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i4.499>

Abstract

AIM: To compare the results for endoscopic ultrasound (EUS)-guided drainage of clear fluid pancreatic pseudocysts with the results for abscess drainage.

METHODS: All patients referred for endoscopic drainage of a fluid collection were prospectively included. The outcome was recorded.

RESULTS: Altogether 26 pseudocysts or abscesses were treated in 25 (6 female) patients. One endoscopist performed the procedures. Non-infected pseudocysts were present in 15 patients and 10 patients had infected fluid collections. The cyst size ranged between 28 cm × 13 cm and 5 cm × 5 cm. The EUS drainage was successful in 94% of the pseudocysts and in 80% of the abscesses ($P = 0.04$). The complication rate in pseudocysts was 6% and in abscesses was 30% ($P = 0.02$). Recurrence of a pseudocyst occurred in one

INTRODUCTION

Endoscopic ultrasound (EUS)-guided drainage of pancreatic pseudocysts and abscesses has become a first line therapy in many centers^[1-4]. This is due to the ability of the EUS instrument to assess the wall thickness, identify major vessels and find the closest access to the fluid cavity^[5-7]. Moreover, this procedure will create an internal fistula and avoid the inconvenience of an external drainage and the risk for cutaneous fistula. A recent study has shown that percutaneous drainage failed in 36% of patients with normal pancreatic ductal anatomy. In patients with ductal abnormalities such as stricture, ductal cut-off and dilated duct the failure rate was 62%-100%. In those patients with an abnormal duct, cutaneous fistula developed in more than 50%^[8].

Surgery may be avoided in cases when successful

EUS-guided drainage is performed, with no recurrence of the cyst. However, acute surgery may be needed in some cases of complications such as perforation or major bleeding^[9,10].

In spite of these assumed advantages of EUS-guided drainage there are only a few prospective studies assessing the full scale of the advantages and shortcomings of this procedure. Moreover, prospective studies assessing this procedure in comparison to radiological intervention and surgery have not been performed. Furthermore, the results of non-infected pseudocyst drainage have not been prospectively compared with the drainage of abscesses. Kahaleh *et al*^[9] compared EUS-guided drainage and conventional transmural drainage in a prospective study. Long-term success assessed at 6 mo was 84% and 91%, respectively ($P = \text{NS}$). The complication rate was 18% and 19%, respectively ($P = \text{NS}$). The complications in this study by Kahaleh consisted of bleeding in three patients, infection in eight, stent migration into the cyst in three and pneumoperitoneum in five.

The aim of our prospective study was to compare the results for drainage of clear fluid pseudocysts with the results for abscess drainage. This prospective quality analysis may guide us in improving the performance of this procedure.

MATERIALS AND METHODS

All patients referred for EUS-guided drainage of a fluid collection were prospectively included in this study. The data were collected in the period between February 2006 and June 2010. Our center is the tertiary center for pancreatic surgery in the region of west Sweden, with access to EUS as well as interventional radiology.

The fluid collections were pseudocysts with clear fluid in 16 cases. The other fluid collections were 9 pseudocysts with infected fluid and one postoperative abscess. The abscess developed after an operation for a perforated duodenal ulcer. The indications for drainage were abdominal pain in 18 patients, infection in 10, food obstruction in one patient and jaundice in one patient. In some cases there was more than one symptom. All patients underwent a computed tomography (CT) scan before the procedure to assess accessibility of the pseudocyst from the stomach or duodenum and to assess an eventual communication between the cyst and the pancreatic duct. Hemoglobin, leucocytes, thrombocytes, CRP and INR were controlled before the procedure. The patients received verbal and written information about the procedure. The procedure was performed either under conscious sedation with pethidine and midazolam or, when possible, under intubation anaesthesia. Intravenous cefotaxime 1 g was administered before the procedure in patients without ongoing antibiotic treatment. After the procedure, therapeutic antibiotics were only given to patients with an infection. The procedures were performed by one endoscopist (RS) with extensive endoscopy experience.

A linear echoendoscope (Pentax EG3830UT and GF-

UCT 140, Olympus) was used to find the closest axes to the pseudocyst. Special attention was given to avoid vessels and to find areas of the wall that were not thicker than 1 cm.

Different procedures were used to enter and stent the cavity: (1) The Giovannini Needle Wire (Wilson-Cook Medical GI Endoscopy) stenting system was used to place a stent in one step^[10]. This was mainly used in clear fluid pseudocysts to place one stent; (2) A 19-gauge needle (Wilson-Cook Medical GI Endoscopy) was also used to access the pseudocyst and to place a 0.035-inch guide wire into the cyst before the opening was dilated using a balloon sized between 12 and 18.5 mm. The guide wire was then used to stent the cyst. This procedure was used to place more than one stent in infected cavities; and (3) A cystotome (Wilson-Cook Medical GI Endoscopy) was also used to enter the cyst and establish an opening. This procedure was also used to place more than one stent in infected cavities.

Both cut and coagulation current were used. Coagulation current and endocut (ERBE®) current were more often used in the procedures which took place during the later part of the study period in order to avoid bleeding.

Technical success of the EUS intervention was defined as the ability to improve clinical outcome of the pseudocyst or abscess without the need for surgical interventions. A complication was defined as an adverse event that led to a longer hospital stay and/or to emergency surgery. The ethics committee of the University of Göteborg had approved the study.

Statistical analysis

The primary endpoint was between-group differences in success rate and complication rate. McNemar's exact test was utilized to assess the difference between the results for pseudocysts and abscesses.

RESULTS

One patient with alcohol-related pancreatitis did not attend at the endoscopy department and was therefore excluded. All of the other 25 out of 26 referred patients were included in the study. Altogether 26 pseudocysts or abscesses were treated in 25 patients.

The mean follow up time of all patients was 20 mo, range 2-45 mo.

The EUS drainage was successful in 94% of the pseudocysts and in 80% of the abscesses ($P = 0.04$).

Table 1 shows the results for the patients with pseudocysts; Table 2 shows the results for abscesses; and Table 3 shows some technical aspects, etiologies and locations of the cysts.

Complications and recurrence

The complication rate after treatment of pseudocysts was 6% and after treatment of abscesses was 30% ($P = 0.02$). Overall, 3 patients (11.5% of the cases) needed surgery due to a procedure-related complication.

One of the patients developed a major bleed from

the gastropiploic artery that was not possible to control conservatively. In this case the Giovannini Needle Wire

with cut current was used to enter the cyst according to the manufacturer's recommendations. The patient was

operated upon immediately and received a cystoenteric anastomosis with a good final outcome.

In two patients perforation occurred in abscesses stented from the gastric fundus. The dilatation technique was used in one of them and a combination of diathermia and dilatation in the other. The first patient underwent surgical resection of the cyst with a good result. The second patient with a postoperative abscess was treated conservatively with total regression, and could be discharged in good health without further interventions.

A perforation after a technically successful stenting of the cyst occurred in one patient with a non-infected pseudocyst. This patient developed abdominal pain and a leak of both fluid and air was present on a CT-scan. The patient underwent surgery after two days with a resection of the cyst with a good outcome. The surgeon observed

that the stent was placed in a proper position; however, the pseudocyst was not attached to the gastric wall.

Two stents migrated during the procedure into the cyst and were retrieved endoscopically.

No procedure-related mortality was observed. One patient died of a non-procedure-related terminal renal insufficiency 3 mo after the aspiration of a pseudocyst.

Recurrence of a pseudocyst occurred in one patient (4%) after 6 mo (Pseudocyst No. 3 in Table 1). The patient underwent a repeat successful EUS drainage with a new follow up time of 29 mo (Pseudocyst no. 6 in Table 1).

Complicated cases

Nine patients had multiple pseudocysts. Two cases were complicated by gastric varices in the stomach. Despite this, it was possible to stent these patients. In the youngest patient (6 years) the pseudocyst was close to the heart; therefore, the cyst was aspirated and not stented. In two patients the distance between the cyst wall and the duodenum and stomach was 3 cm and 2 cm, respectively. Aspiration was therefore performed without stenting. In one patient the cyst was only accessible *via* the esophagus and was therefore not stented to avoid fistula formation to the esophagus.

Other procedures and aspects

Flushing of the abscess (Figures 1-3) and necrosectomy (Figure 4) were performed in 10 patients. Patients with

large amounts of necrotic material received a naso-cystic drain after a mechanical necrosectomy with a foreign body forceps. The naso-cystic drain was left in place for between a couple of days and three weeks. During this period the drain was flushed with 250-500 mL saline once or twice daily.

In six patients the stents were placed in the gastric fundus; in 12 patients in the gastric corpus; in one patient in the duodenum; and in one patient in the antrum.

The stents were withdrawn after 3 mo in four patients, in three other patients the stents were withdrawn after 4, 5 and 13 mo. In the other patients (13 patients) the stents have not been removed yet. Fluoroscopy was not utilized in 15 (58%) patients during the procedure.

Three patients underwent percutaneous drainage procedures before they were referred for the EUS-guided drainage. One patient received a percutaneous drainage after the EUS-guided aspiration without stenting because of the large distance (3 cm) between the duodenal wall and the cyst.

CT scan showed a communication between the cyst and pancreatic duct in three patients. These three patients underwent an endoscopic retrograde cholangiopancreatography (ERCP) to stent the pancreatic duct. The procedures were, however, not successful and the patients subsequently underwent an EUS-guided drainage.

In one patient a pseudocyst was clinically suspected and the appearance on the CT scan as well as the EUS findings supported the benign diagnosis. Accordingly, a drainage procedure was performed during the EUS session. The patient was stented to the duodenum and had a total regression of the cyst with symptom improvement. However, the patient developed jaundice after 5 mo and was then found to have a pancreatic cystadenocarcinoma.

DISCUSSION

This is the first prospective study to show that the success rate of EUS-guided drainage of pseudocysts is high compared with that of the drainage of abscesses. Moreover, the complication rate was lower for pseudocysts compared with abscesses.

The present study provides novel knowledge about the success rate of EUS-guided drainage of clear fluid pseudocysts and abscesses. The data indicate that the drainage of clear fluid pseudocysts is a more straightforward procedure whereas the success rate for abscesses is lower. This could be partially explained by the fact that patients with abscesses are sicker and more vulnerable and are therefore more prone to develop complications. Another contributing factor is that an abscess with necrosis is usually less clearly demarcated compared with a clear fluid pseudocyst. This may make the procedure more difficult. Moreover, the wall of an abscess with excessive inflammation may rupture more easily compared with the wall of a less inflamed pseudocyst. The data support a more cautious approach to abscesses compared with pseudocysts. Abscesses should be drained only when conservative therapy has failed and enough time has passed for the formation

of a well demarcated abscess wall.

The results presented in this work on pseudocyst drainage are comparable to previously reported data. A retrospective study by Cahen *et al.*^[11] showed a success rate of 97% and a complication rate of 34%. Kahaleh *et al.*^[9] published prospective data comparing EUS-guided drainage and conventional endoscopic drainage showing a long-term success rate of 84% and complication rate of 19% for EUS-guided drainage. There was no difference between EUS-guided drainage and conventional drainage. However, a recent prospective study^[12] has also compared the results of EUS-guided drainage and conventional endoscopic drainage, showing a clear advantage for EUS-guided drainage with a success rate of 100% and only 33% for conventional endoscopic drainage. The complication rate in the EUS group was 4% and 20% in the conventional group. The differences in success rate and complication rates between different series are probably due to different patient populations and heterogeneous interventions^[13].

EUS-guided drainage has been advocated as the first line treatment for pseudocysts^[12]. Moreover, there is an enthusiasm about the possibilities of EUS-guided procedures. However, our knowledge from large prospective studies is still limited. There is probably a publication bias for data coming from large and experienced centers with good results. Therefore, there is a need for large prospective multicenter studies to assess the full scale of advantages and complications of EUS-guided drainage.

Our results are comparable to previously published data. However, we do have to further improve the success rate and reduce the complication rate. Due to limited resources intubation anesthesia was possible only in a minority of our patients. This type of anesthesia should be adopted for the majority of patients whenever possible in order to provide stable conditions during the drainage procedure. However, the importance of anesthesia has not yet been addressed in a study. Available techniques also need further improvement and there are many issues that need to be addressed in multicenter studies. Whether to use a dilatation technique or diathermia to enter the cyst is such an issue. The type of current to use and the optimal site in the stomach in which to place the stents are other unanswered questions.

In our study we observed perforations in two abscesses stented from the gastric fundus. This area is rather thin and should be handled carefully during the procedure. The gastric cardia should be avoided because it is close to the diaphragm. In one patient we did not stent the cyst because it was only accessible from the esophagus. A stent to the esophagus may result in a permanent fistula^[8].

We experienced one perforation in a patient with a pseudocyst that was not attached to the gastric wall. This complication has been discussed for children but has not been published in adults so far. During the EUS procedure it can be difficult to know if the cyst is firmly attached to the gastric wall. However, a movement of the cyst under the gastric wall indicates that the cyst is not attached to the wall.

One of our patients developed a major bleed after the use of cutting current to enter a cyst from the stomach. After this complication more coagulation current and endocut (ERBE®) current was used to enter the cyst, rather than pure cut current, according to the manufacturer's recommendations. Moreover, the entrance to the cyst was performed slowly to avoid fast and large movements of the needle wire.

No procedure-related mortality was observed in this study. Mortality rate varies in different series between 1/29 in a patient who underwent conventional endoscopic drainage^[12] to 1% in retrospective material^[11]. We found a recurrence rate of 4%, which is comparable with 5% reported by Cahen *et al.*^[11].

Primary surgery may be an alternative treatment for pseudocysts and abscesses. There are no prospective studies comparing surgery with EUS-guided drainage. One study has addressed the results and complications of necrosectomy by open surgery or minimally invasive surgery. The study showed no difference between the two approaches and a mortality rate of 28% in these severely ill patients^[14]. Recent results from a large study by Seifert *et al.*^[15] indicate that initial endoscopic necrosectomy in the early phase of pancreatic necrosis is more risky and less successful and should be considered only if all other options have failed. Another study showed that delayed surgery correlated positively with reduced mortality^[16].

The length of time a stent should be left in place is still a matter for debate. In general, endosonographers tend to expand the time until the stent is withdrawn to avoid recurrence of the cyst. It has been recommended to leave the stent in place in selected patients^[13]. This is another issue that needs further studies to assess the optimal time for leaving the stent in place.

One patient was found to have a pancreatic adenocarcinoma and not a pseudocyst; this emphasizes the need for a close follow-up of the patients.

We have routine access to fluoroscopy during the drainage procedure. However, when the Giovannini Needle Wire was utilized there was no need for fluoroscopy in many cases. This is in agreement with a recent report showing that EUS-guided drainage was possible without access to fluoroscopy since not all endoscopy centers have fluoroscopy in the EUS room^[17].

In conclusion, this prospective study shows for the first time that the results of EUS-guided drainage are more favorable in pseudocysts compared with abscesses. This knowledge should guide the choice and timing of therapy in patients with fluid collection. Large and preferably multicenter studies are needed to further expand our knowledge regarding different aspects of EUS-guided drainage, including the optimal technical procedure.

COMMENTS

Background

Inflammation in the pancreas may cause the development of fluid collection in the abdomen. This fluid collection may become infected. These fluid collections may be treated by surgery or endoscopic ultrasound. Endoscopic ultrasound is an endoscope equipped with a camera and ultrasound probe. This instrument

gives a detailed visualization of the organs around the gut. These organs then become accessible for sampling and treatment. Using endoscopic ultrasound guidance it is possible to create a path between the fluid collection and the stomach to drain the fluid.

Research frontiers

Endoscopic ultrasound guidance is increasingly used to treat fluid collections instead of surgery. However, no study has compared the results of this treatment between infected and non-infected fluid collections.

Innovations and breakthroughs

This study shows that the results of endoscopic ultrasound treatment for non-infected fluid collections is very good and significantly better than the results for infected fluid collections.

Applications

Treatment using endoscopic ultrasound guidance should be applied in symptomatic patients with non-infected fluid collection. In patients with infected fluid collection the treatment should be applied when other non-surgical treatments have failed and not early in the course of the disease.

Peer review

Very interesting paper dealing with an alternative approach to one of the most frequent complications of chronic pancreatitis. Statistically sound (McNemar test was a fantastic choice), this study is very convincing.

RESULTS: Overall, 32 patients were included with a median follow-up of 31 mo. Eighteen patients responded well to 2-CdA. Patients responsive to 2-CdA had a statistically significant increased survival compared to those who were unresponsive. The overall 3- and 5-year survival was 83% in the responder and 63% and 22% in the non-responder group, respectively. The overall 2-year clinical, histological and immunological response rates were 81%, 47% and 41%, respectively. Progression into EATL was reported in 16%, all of these patients died.

CONCLUSION: Treatment of RCD II with 2-CdA holds promise, showing excellent clinical and histological response rates, and probably less frequent transition into EATL.

Abstract

AIM: To evaluate cladribine [2-chlorodeoxyadenosine (2-CdA)] therapy in refractory celiac disease (RCD) II.

METHODS: An open-label cohort-study of RCD II patients treated with 2-CdA was performed between 2000 and 2010. Survival rate, enteropathy associated T-cell lymphoma (EATL) occurrence, clinical course, and histological and immunological response rates were evaluated.

INTRODUCTION

Celiac disease (CD) is characterized by a permanent state of intolerance to dietary gluten leading to an inflammatory T-cell response in the small intestine with mu-

cosal injury in genetically susceptible individuals^[1,2]. Although reduction of this intestinal inflammatory activity is usually seen upon strict adherence to a gluten free diet (GFD), a small percentage (2%-5%) of the adult-onset CD patients, especially those diagnosed above the age of 50 years, display a lack of response to such a diet. They are regarded as suffering from refractory celiac disease (RCD) when clinical and histological symptoms persist or recur after a former good response to a strict GFD, despite strict adherence to the diet for more than 12 mo, unless earlier intervention is necessary^[3,4]. Immunologically, this syndrome can be subdivided into RCD I and RCD II, with immunophenotypically normal and aberrant intraepithelial T lymphocytes (IELs) in the small intestinal mucosa, respectively. Clonal expansion of these aberrant IELs, lacking the T-cell surface markers T cell receptor (TCR), CD3, CD4 and CD8^[5], but expressing cytoplasmic CD3, is supposed to be responsible for the occurrence of enteropathy associated T-cell lymphoma (EATL)^[4-6]. This type of lymphoma occurs in 60%-80% of RCD II patients within 5 years and has a poor prognosis with a 2-year survival of only 15%^[7,8]. The latter is mainly due to incomplete response to currently available therapies, high rates of life-threatening complications such as perforation of the gut, and poor nutritional conditions^[7,8]. Therefore, it is of utmost importance to evaluate new treatment strategies for RCD II in order to improve clinical course and prevent or delay progression to overt EATL.

Since the late 90's, researchers have become increasingly interested in therapeutic alternatives for treating RCD II, however as far as has been published there is no standardised approach yet^[9,10]. RCD II is, at least in part, resistant to most evaluated therapies so far^[10-12]. Until 2005 in our tertiary referral centre for RCD II, patients were initially treated with conventional immunosuppressive drugs, mainly azathioprine and prednisone, and if clinically and histologically unresponsive cladribine [2-chlorodeoxyadenosine (2-CdA)] was prescribed. Since then, a modified treatment strategy has been initiated with cladribine being drug of first choice.

2-CdA is a synthetic purine nucleoside homologue being equally toxic to proliferating as to non-dividing lymphoid cells. Because of this unique feature it is supposed to be especially active against low-grade malignancies, including hairy cell leukaemia. Cladribine is metabolised into its pharmacologically active cladribine triphosphate, which induces apoptosis, necrosis and inhibition of DNA/RNA synthesis (Figure 1). Clinically, 2-CdA is of proven value in the treatment of a number of haematological malignancies and selected autoimmune disorders, including multiple sclerosis^[13-15]. Our pilot studies showed that 2-CdA therapy^[16] is feasible and well tolerated in these patients. Survival at that time seemed promising, but follow-up was short.

This analysis evaluates cladribine therapy in a large prospectively studied open-label cohort of RCD II patients, during a mean follow-up time of 3 years.

MATERIALS AND METHODS

This cohort study includes reports of extended follow-up of 14 out of the 17 RCD II patients included in the open-label prospective phase I study performed by Al-Toma *et al*^[16] with 18 new patients added. Three patients out of the previous study were not included in this study as they were followed over time outside our hospital. Between January 2000 and April 2010, 2-CdA was prescribed to 32 RCD II patients at the VU University Medical Centre in The Netherlands.

Inclusion criteria

Patients diagnosed as having RCD II and treated with one or two courses of 2-CdA at the VU University Medical Centre were included. Cladribine was intravenously given in a dose of 0.1 mg/kg per day for 5 consecutive days. The diagnosis of RCD II was based on persisting or recurring clinical symptoms and small intestinal villous atrophy after a former good response to a strict GFD, despite strict adherence to the diet for more than 12 mo. Furthermore, the clinically validated cut-off value of more than 20% aberrant intraepithelial lymphocytes (IELs) detected by flow cytometric (FACS) analysis was used to distinguish RCD type I and type II^[5]. Although a clonal TCR gamma rearrangement determined by PCR is still a widely accepted method to define RCD II, Verbeek *et al*^[5] showed that the percentage of aberrant IELs detected by FACS analysis is a more accurate way to define RCD II. The presence of EATL was excluded by using selected investigations^[17-20] and its diagnosis was confirmed according to the World Health Organization Classification of Tumors of Haematopoietic and Lymphoid tissues^[21]. Furthermore, pre-treatment with immunomodulatory drugs within 6 mo or any experimental drug within 30 d of the study entry was not allowed.

Follow-up and criteria of response

Before and during follow-up after cladribine treatment a clinical assessment was carried out noting in particular signs and symptoms of malabsorption, body mass index (BMI), albumin, and haemoglobin (Hb). A nutritional screening was performed by a dietician who specialised in CD in almost all patients prior to treatment and nutritional support was given when indicated. Clinical remission was defined as improvement of the diarrhoea, abdominal discomfort and/or signs of malabsorption, combined with at least 2 out of the following parameters of intestinal integrity within the normal range or an improvement of ≥ 1 point: (1) Hb; (2) BMI; and (3) albumin. Multiple duodenal biopsies were taken by upper gastrointestinal endoscopy in order to detect histopathological abnormalities and to perform immunophenotyping of IELs by FACS analysis at different time points (planned at 3, 6 and 12 mo, and then every year during follow-up). Isolation of small intestinal T-lymphocytes and staining for immunophenotyping were performed as previously described^[5]. Complete histological remission has been defined as a normalisation of the architecture of the duodenum, clas-

sified as a Marsh 0 or I lesion according to the Modified Marsh classification^[22]. A decline of 20% or more in the percentage of aberrant IELs was considered a significant immunological remission. In addition, survival rate and EATL occurrence were evaluated during follow-up.

Furthermore, following on from Verbeek *et al.*^[10] who hypothesised that pre-treatment with common immunosuppressive drugs, including azathioprine and prednisone might influence the response to 2-CdA treatment, this study compared RCD II patients pre-treated with immunosuppressive agents before 2-CdA was prescribed (group I) to those treated with upfront 2-CdA (group II).

Ethical approval and informed consent

Approval for this open label study protocol was obtained from the local ethics committee in 2000 and all patients gave their informed consent.

Statistical analysis

Quantitative data were expressed as medians and means. Kaplan-Meier survival curves were constructed using SPSS software (SPSS Inc., Chicago, Illinois, USA). In addition, the log rank test was used to assess the statistical

significance. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

In total, 32 RCD II patients who were treated with 2-CdA were included with a median follow-up time of 31 mo (range 4-120 mo). Patient characteristics (Table 1) show a median age of > 50 years, with a male predominance. Prior to the start of 2-CdA therapy, 10 patients failed to respond clinically and histologically to conventional immunosuppressive drugs (defined as group I), including high dose prednisone in 2 and azathioprine or 6-thioguanine added to prednisone in 8 patients. The remaining 22 patients (defined as group II) were initially treated with 2-CdA following diagnosis of RCD.

Disease status

In agreement with our previous study, 2-CdA was feasible and well tolerated without serious adverse events^[10]. Overall, 18 (56%) of the RCD II patients were responsive to one or two courses of 2-CdA based on the clinical and complete histological and/or immunological response

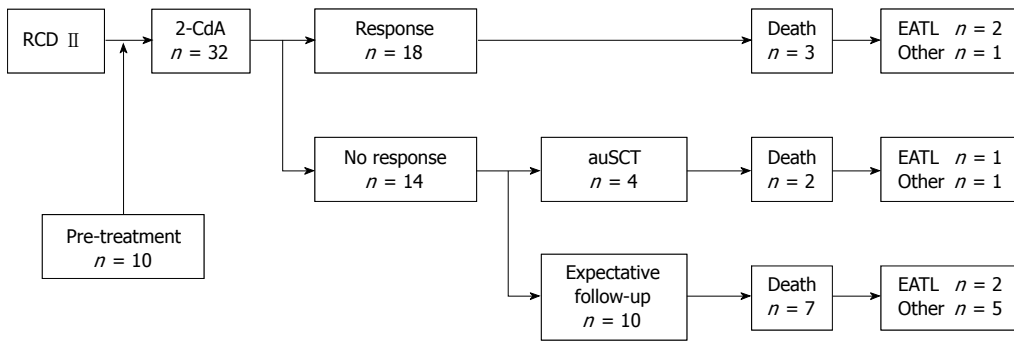

Figure 2 Flowchart of the response to cladribine treatment. RCD: Refractory celiac disease; 2-CdA: 2-chlorodeoxyadenosine; auSCT: autologous hematopoietic stem cell transplantation; EATL: Enteropathy associated T-cell lymphoma.

(Figure 2). Seven showed a clinical and histological response, 4 a clinical and immunological response, and 7 a clinical, histological and immunological remission. Out of the remaining 14 patients unresponsive to 2-CdA, 2 were admitted for a second course of 2-CdA in the last 6 mo and in anticipation of evaluation of response. Six non-responsive patients were evaluated for high dose chemotherapy followed by autologous hematopoietic stem cell transplantation (auSCT). In 2 of them stem cells could not be harvested, therefore 4 patients were actually transplanted^[23]. Another 6 patients had an expectative follow-up, 2 of them had an exacerbation after an initial response

to 2-CdA for almost 2 and 3.5 years.

Table 2 shows the clinical, histological and immunological 1- and 2-year response rates to 2-CdA treatment. In total, clinical remission was observed in 26 (81%), complete histological remission in 15 (47%) and immunological remission in 13 (41%) of the RCD II patients. The median levels of BMI, Hb and albumin increased from 20.9 kg/m², 7.8 mmol/L and 36 g/L at baseline to 23 kg/m², 7.9 mmol/L and 39 g/L at the end of follow-up, respectively. In addition to the 15 patients in whom complete histological remission, defined as Marsh 0 or I, was observed, 2 patients had a partial histological remission from Marsh 3B and 3C lesions at baseline to Marsh 2 and 3A at the end of follow-up respectively. The median percentage of intestinal aberrant IELs before 2-CdA treatment was 61% and declined to 56% after 2-CdA treatment. The time to a 50% response rate was 3 years. Approximately 33% of the patients lacked a clonal TCR-gamma gene rearrangement, although all patients had an aberrant IELs of more than 20%. A statistical significance between the percentage of aberrant IELs and the clonality status was not found.

Analysis of the overall response in patients pre-treated with immunosuppressive drugs prior to 2-CdA (group I)

and those with up-front 2-CdA treatment showed no statistical significance (log rank, $P = 0.856$). Immunological (log rank, $P = 0.030$) response, however, was significantly higher in group II. In addition, a trend towards a higher clinical response in group II (log rank, $P = 0.058$) was found. Yet, for the histological response rate a statistical significance was not observed (Table 2). Cox-regression analysis showed that the following parameters have no predictive value for response to 2-CdA: age at 2-CdA infusion ($P = 0.06$), sex ($P = 0.60$), TCR-gamma-clonality ($P = 0.604$), and percentage of aberrant IELs ($P = 0.646$), degree of small intestinal villous atrophy ($P = 0.610$), BMI ($P = 0.095$), albumin ($P = 0.936$) and Hb ($P = 0.953$) before treatment.

Survival

The overall median survival was almost 4.5 years. In total, 37% (12/32) of all included patients died, due to an EATL in 42% (5/12). All patients diagnosed with EATL (16%) died subsequently, having a median survival of only 4.4 mo (range 0-12 mo) after diagnosis.

The survival curve (Figure 3A) shows a statistically significant difference ($P = 0.037$) between responders and non-responders to 2-CdA treatment. The 3- and 5-years survival rate was 83% in the responding group and 63% and 22% in the non-responding group, respectively. One-sixth (3/18) of the responders died, 1 due to refractory disease status and 2 were diagnosed with EATL within 3 and 9 mo after the last infusion of 2-CdA. Approximately 65% (9/14) of the non-responders died, 3 as a consequence of developing an EATL within 8, 12 and 44 mo of 2-CdA treatment (Figure 2). The exceptionally delayed progression into EATL in the latter patient might be explained by treatment with high dose of chemotherapy followed by auSCT 8 mo after 2-CdA treatment. The remaining 6 unresponsive patients died as a result of refractory disease status; 1 treated with chemotherapy and auSCT died after 1 year of follow-up and 5 with expectative follow-up died despite lack of response to 2-CdA after a median follow-up of 18 mo (range: 4.5-60 mo). The patient in the latter group who died 5 years after 2-CdA treatment had an exacerbation after an initial remission to 2-CdA for 3.5 years and then refused further treatment.

In addition, there was no statistical significance ($P = 0.23$) between the overall survival in the pre-treatment group (I) and the upfront 2-CdA treatment group (II) as depicted in Figure 3B.

DISCUSSION

Approximately half of RCD II patients have an unfavourable clinical course as a consequence of non or partial response to current available therapies and subsequently the progression into EATL^[7,8]. For that reason clinicians have become increasingly interested in treating this condition alternatively and more effectively. However, there is no standardised approach reported so far. In this study a large cohort of RCD II patients treated

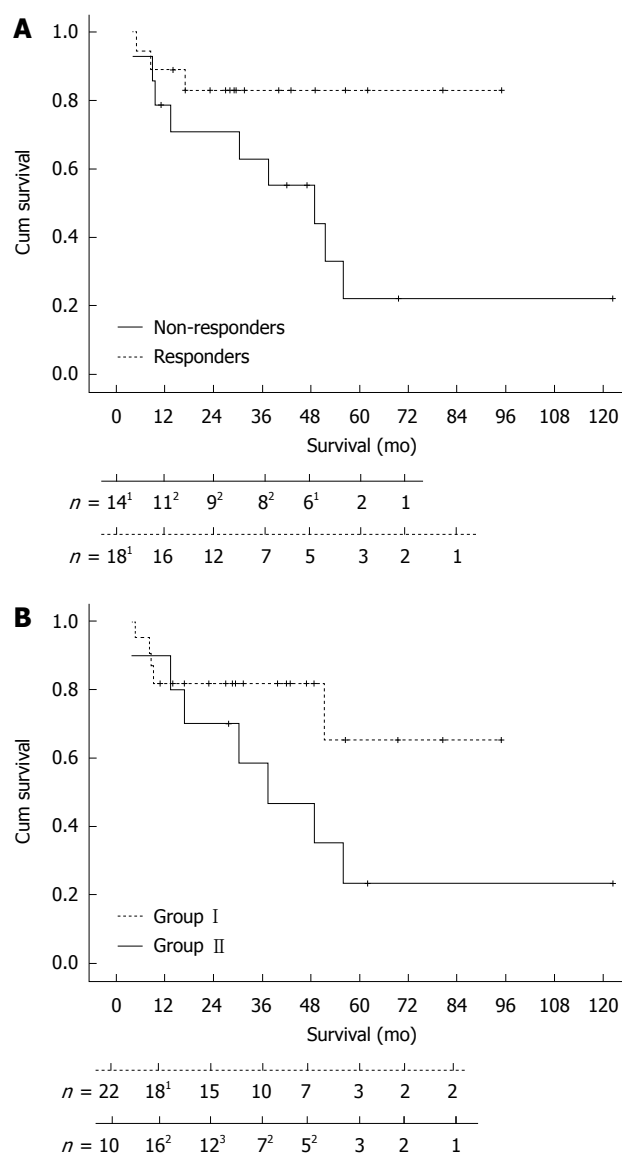

Figure 3 Kaplan-Meier survival curves. A: Survival rate of responders and non-responders to cladribine treatment (Log Rank: $P = 0.037$). ¹3 patients died in the 1st and 5th year; ²1 patient died in the 2nd, 3rd and 4th year of follow-up; B: Survival rate of the pre-treatment (I) and the upfront 2-chlorodeoxyadenosine (II) group (Log Rank: $P = 0.23$). ¹4 patients died in the 1st year; ²1 patient died in the 1st, 3rd and 4th year; ³2 patients died in the 2nd year of follow-up.

with 2-CdA has been analyzed.

In agreement with Al-Toma *et al.*^[16], this report describing almost twice as many patients with extended follow-up, showed that 2-CdA is indeed feasible and well tolerated without serious adverse events after short and long-term follow-up. Our data show that RCD II patients responsive to 2-CdA treatment have a statistically significant increased survival compared to those who are unresponsive. Although the median follow-up time was only 31 mo, after 1.5 year of follow-up none of the responders died compared to 4 non-responders, indicating a clear difference in survival rate. The overall 5-year survival rate of RCD II patients in this analysis is 46% so far, which is in line with other single-centre studies^[11,12], and is expected to improve after extended follow-up. Previous reports

included RCD II patients treated with diverse steroid-like drugs^[11,12], whereas in this study 10 RCD II patients unresponsive to such immunosuppressive drugs were included as well. However, unexpectedly the overall survival did not significantly differ between patients pre-treated with conventional immunosuppressive drugs (group I) compared to those with up-front 2-CdA treatment (group II). Nevertheless, a clearly increased median survival rate in group II was observed. The lack of statistical significance might be due to the small cohort included in group I. In addition, some of the RCD II patients treated with conventional immunosuppressive drugs died before 2-CdA treatment could be initiated as previously reported by our group^[24] and were therefore not included in the current analysis. Apart from favouring clinical course and increasing survival, preventing EATL represents the ultimate goal of treating RCD II. Although treatment with 2-CdA could not prevent progression into EATL, compared to previous reports showing EATL in 32%-52% of the RCD II patients within 5 years^[7,11], our results showed a much lower rate of lymphomagenesis (16%), yet approximately 50% had a 5-year follow-up.

Furthermore, our open-label and observational data showed that 2-CdA is an effective treatment in obtaining a clinical and immunohistological response in more than half of the RCD II patients. Previous studies reported a good clinical response after treatment, but histological response rates up to only 30% were found depending on the type of treatment^[11,12]. Consistent with these findings, a clinical response rate of 81% was found. The potential advantage of 2-CdA, however, seems to be a good histological response. In fact, histologic healing (Marsh 0 or I) was observed in almost half of the cases and a partial response of at least two Marsh scores in another 3 cases. Although not statistically significant, the 2-year histological response rate in up-front 2-CdA group (II) was twice that of the pre-treatment group (I), possibly indicating a beneficial effect of up-front 2-CdA treatment.

Furthermore, Malamut *et al.*^[11] recently described a 74% steroid-dependency in a large cohort of RCD II patients treated with corticosteroids. Since there is no need for corticosteroids if 2-CdA therapy is prescribed, steroid-dependency and its complications will not occur.

In this cohort, the proportion of RCD II patients lacking a clonal TCR-gamma gene rearrangement was relatively high (33%) compared with that reported in other studies^[4,11,12], although all patients had more than 20% aberrant IELs determined by FACS analysis. This discrepancy might be the result of some technical aspects of the DNA analysis, for instance a reduced DNA quality due to formalin fixation of the biopsies and a limited sensitivity of PCR in the case of a low percentage of aberrant IELs. Therefore, the tested polyclonal status in this cohort is most likely overestimated. However, we have previously shown^[5] that flow cytometry of aberrant IELs is superior to clonality analysis for risk stratification in RCD II.

Approximately 40% of the RCD II patients showed an immunological response after 2-CdA treatment, defined

as a decrease of more than 20% of the aberrant intestinal IELs determined by FACS analysis. However, the majority still showed more than 30% aberrant IELs during follow-up. Expansion of these aberrant T-lymphocytes, which reside in the intraepithelial as well as lamina propria layer of the small intestine^[25], is generally accepted as the culprit factor in the progression into EATL. Conversely, in our series the persisting high percentage of aberrant mucosal T-lymphocytes did not correlate with the relatively low EATL occurrence found during the time of follow-up so far. Unfortunately, reports from other centres on the immunological response determined by FACS analysis after treatment are lacking. Whereas the percentage of aberrant IELs is established to be important in the diagnostic work-up for distinguishing RCD type I and II^[5], apparently it is questionable whether this percentage is a predictive marker for progression into EATL during monitoring of the therapeutic response. Further research is mandatory to further elucidate EATL risk stratification. Immunophenotyping of the aberrant T-cells by FACS analysis of small intestinal biopsies and probably also genotyping seem to be appropriate methods to search for predictive markers. In addition, future studies on quantifying the mass of aberrant IELs using immuno-PET techniques, instead of the currently determined percentage of aberrant IELs, given the relatively equal depletion of normal and aberrant IELs upon 2-CdA treatment, have to be conducted.

In the current analysis approximately half of the RCD II patients were unresponsive to 2-CdA, for yet unknown reasons. A significant association with the degree of mucosal villous atrophy, the percentage of aberrant IELs, and levels of BMI, Hb and albumin before 2-CdA treatment, clonal TCR-gamma gene rearrangement and HLA-DQ status was not revealed. Although dose-finding studies with 2-CdA infusion in refractory celiac disease are not conducted, clinical dose-finding studies in lymphoproliferative diseases showed good response rates with an identical treatment schedule^[13,26]. In addition, compared to intravenous infusions and subcutaneous injections which provide identical plasma 2-CdA levels, oral administration has a much lower bioavailability (approximately 40%) due to degradation through acid in the stomach and intestinal bacteria^[14]. A higher dose and/or a prolonged treatment schedule might result in a higher response rate, yet the maximum tolerated dose established in lymphoproliferative diseases without serious adverse events was 0.1 mg/kg per day for 7 d^[13]. A recent clinical trial of oral cladribine for relapsing multiple sclerosis showed that short-course and high dose (3.5 mg/kg) therapy is effective, yet lymphocytopenia is frequently reported^[15]. Furthermore, the high sensitivity of hairy cell leukaemia (HCL) to treatment with 2-CdA showing low resistance levels is hypothesised to be the result of p53-dependent pathways required for killing resting cells and its inhibitory effect on the cholesterol metabolism which is highly active in HCL cells^[14]. Physiological conditions such as increased repair of DNA, increased anti-apoptotic effects and decreased activation of deoxycytidine kinase, an enzyme required for the cytotoxicity of 2-CdA, might be contributing factors

to resistance as well^[27]. Whether the same results regarding administration route, treatment schedule and resistance pattern of 2-CdA also correlate with such good response rates in RCD II, remains to be further elucidated. The registration of oral 2-CdA for multiple sclerosis in Europe, might be a further step forward towards the application of this drug in RCD as well as some other gastroenterological diseases refractory to currently available therapies, including Crohn's disease, ulcerative colitis and autoimmune hepatitis.

In conclusion, 2-CdA appears to be a promising treatment in RCD II. This analysis showed excellent clinical and histological response rates after 2-CdA treatment. Furthermore, 2-CdA therapy does not necessitate the additional use of corticosteroids and subsequently prevents steroid-dependency and its complications. Although EATL could not be fully prevented, its incidence was restricted to 16%. Multicentre, randomised clinical trials with 2-CdA and/or other new treatment options are mandatory to standardise the treatment strategy for RCD II, in order to further decrease morbidity and mortality in this patient group.

COMMENTS

Background

A small percentage (2%-5%) of patients with adult-onset celiac disease, especially those diagnosed above the age of 50, show a lack of response to a gluten-free diet. They are diagnosed as suffering from refractory celiac disease (RCD) when clinical and histological symptoms persist or recur after a former good response to a strict gluten-free diet and despite strict adherence to the diet for more than 12 mo, unless earlier intervention is necessary. RCD can be subdivided into type I with phenotypically normal and type II with aberrant intraepithelial T lymphocytes in the small intestinal mucosa. Patients with RCD I have a less dismal prognosis compared with those diagnosed as having RCD II: the 5-year survival rates are 96% and 58%, respectively. As the majority of RCD type II patients are unresponsive to common immunosuppressive therapy, it is of utmost importance to evaluate new treatment strategies. Apart from clinical and histological remission, the ultimate goal of treatment is to prevent progression into a lethal enteropathy associated T-cell lymphoma (EATL) which occurs in more than half the patients within 4-6 years.

Research frontiers

This is the first report evaluating a standardised treatment strategy for RCD type II with cladribine [2-chlorodeoxyadenosine (2-CdA)] therapy in a large cohort ($n = 32$) with a long-term follow-up (median 31 mo).

Innovations and breakthroughs

This report shows that cladribine was feasible and well tolerated without serious adverse events. More than half of the RCD II patients were responsive to cladribine therapy and had a significantly increased 3 and 5 year survival compared to those who were unresponsive. In line with previous reports, very high clinical response rates were observed. The potential advantage of cladribine, however, seems to be a good histological response. In fact, histologic healing (Marsh 0 or I) was observed in almost half of the cases and a partial response of at least two Marsh scores in another 3 cases, compared to reported histological response rates up to only 30%. Although EATL could not be fully prevented, its incidence was restricted to 17%. Furthermore, 2-CdA therapy does not necessitate the additional use of corticosteroids and subsequently prevents steroid-dependency and its complications.

Applications

The results suggest that cladribine therapy may represent a promising option for RCD II, however, multicentre randomised clinical trials with 2-CdA and/or other new treatment options are mandatory to standardise the treatment strategy for this group, in order to further decrease morbidity and mortality in this patient group.

Terminology

Aberrant IELs: Intraepithelial T lymphocytes are considered aberrant when expressing cytoplasmic CD3, but lacking surface expression of the T-cell markers CD3, CD4, CD8 and the T-cell receptor. 2-CdA: Cladribine, 2-chlorodeoxyadenosine, a synthetic purine nucleoside homologue. EATL: Enteropathy associated T-cell lymphoma. RCD: Refractory celiac disease. Immunologically, this disorder can be subdivided into two types: type I without and type II with aberrant IELs in the small intestinal mucosa. TCR: T-cell receptor.

Peer review

In this manuscript, the authors reported an open-label study on the treatment of type II refractory coeliac disease (RCD II) with cladribine (2-chlorodeoxyadenosine) in a cohort of 32 patients. After a mean follow up time of 3 years, cladribine, which was given to 22 patients as the first line treatment and 10 patients who failed to respond to conventional immunosuppressive drugs, was shown to have induced apparent clinical, histological and/or immunological response in over half of the patients. In addition, all the responders had a significantly increased 3 and 5 year survival compared to those who were unresponsive although progression of RCD-II to enteropathy associated T-cell lymphoma had not been prevented and overall 5 year survival (46%) was not different from that reported by other centres using alternative therapies. This open-label trial was uncontrolled. However, a favourable outcome was observed in most of patients treated with cladribine. The results suggest that cladribine therapy may represent a promising option for RCD II patients.

Abstract

AIM: To investigate sensations to multimodal pain stimulation in the metaplastic and normal parts of the esophagus in patients with Barrett's esophagus (BE).

METHODS: Fifteen patients with BE and 15 age-matched healthy volunteers were subjected to mechanical, thermal and electrical pain stimuli of the esophagus. Both the metaplastic part and the normal part (4 and 14 cm, respectively, above the esophago-gastric junction) were examined. At sensory thresholds the stimulation intensity, referred pain areas, and evoked brain potentials were recorded.

RESULTS: Patients were hyposensitive to heat stimulation both in the metaplastic part [median stimulation time to reach the pain detection threshold: 15 (12-34) s vs 14 (6-23) s in controls; $F = 4.5$, $P = 0.04$] and the normal part of the esophagus [median 17 (6-32) s vs 13

(8-20) s in controls; $F = 6.2$, $P = 0.02$]. Furthermore, patients were hyposensitive in the metaplastic part of the esophagus to mechanical distension [median volume at moderate pain: 50 (20-50) mL vs 33 (13-50) mL in controls; $F = 5.7$, $P = 0.02$]. No indication of central nervous system abnormalities was present, as responses were comparable between groups to electrical pain stimuli in the metaplastic part [median current evoking moderate pain: 13 (6-26) mA vs 12 (9-24) mA in controls; $F = 0.1$, $P = 0.7$], and in the normal part of the esophagus [median current evoking moderate pain: 9 (6-16) mA, vs 11 (5-11) mA in controls; $F = 3.4$, $P = 0.07$]. Furthermore, no differences were seen for the referred pain areas (P -values all > 0.3) or latencies and amplitudes for the evoked brain potentials (P -values all > 0.1).

CONCLUSION: Patients with BE are hyposensitive both in the metaplastic and normal part of esophagus likely as a result of abnormalities affecting peripheral nerve pathways.

INTRODUCTION

Barrett's esophagus (BE) is characterized by intestinalized

columnar epithelium in the esophageal mucosa, and patients have an elevated risk of developing esophageal adenocarcinoma^[1]. The etiology is still not fully elucidated, but is thought to involve excessive acid exposure^[2]. Abnormal acid exposure of the esophageal mucosa can be the result of increased reflux or slow esophageal clearing of acid. Several studies have confirmed that patients with BE have pathologic gastro-esophageal reflux and that the length of the Barrett's segment is correlated to reflux duration^[3,4]. However, the magnitude of pathological reflux in patients with BE and patients with erosive reflux disease without BE seems to be similar^[5]. Thus the progression to BE has yet to be clarified. The missing link could be slow clearance of acid and non acidic reflux from the esophagus due to a defect in the afferent (sensory) or efferent (motor) part of the reflex arch. This will reduce clearance due to less saliva production and less secondary contractions. When studying the motility related to BE, conflicting results have been found^[6-8]. More consistency is seen in studies of esophageal sensation, where most studies have reported a decreased sensitivity to esophageal acid in patients with BE^[8-11]. It is not yet known whether this change in esophageal sensation is a result of the characteristics of the metaplastic mucosa or whether it is present before development of the metaplasia. If the first assumption is true only the metaplastic part of the esophagus will be hyposensitive. However, if the hyposensitivity is a predisposing pathogenetic factor it will be expected to be present both in the metaplastic distal part and the normal proximal part of the esophagus, but this has never been investigated.

Esophageal sensitivity can be examined on several levels and with many stimulation modalities using the multimodal pain model previously developed in our group^[12]. The model has been used to study pain mechanisms in patients with erosive esophagitis, non-erosive esophagitis and non-cardiac chest pain, thereby proving its validity^[13-15]. We hypothesized that patients with BE are hyposensitive both in the metaplastic part and in the normal proximal part of the esophagus. Using the multimodal pain model in patients and healthy volunteers, the aims were as follows: (1) to compare the sensory response to thermal and mechanical pain stimuli in the metaplastic and normal part of the esophagus; and (2) to determine from the response to electrical stimuli, referred pain areas and evoked brain potentials, whether the origin of symptoms in BE is suggestive of peripheral or central nervous system (CNS) abnormalities.

MATERIALS AND METHODS

Ethics

The study was conducted according to the Declaration of Helsinki and approved by the local Ethical Committee (VN 2003/120mch). Oral and written informed consent was obtained from all participants.

Selection of patients

Fifteen patients with BE aged 18-70 years were selected

Figure 1 Probe design and probe placement in the esophagus during the study. After stimulation 4 cm above the esophago-gastric junction (EGJ) the probe was retracted 10 cm and the remaining protocol completed. Inlet and an outlet channels were used for circulation of water during mechanical and thermal stimulation. Electrodes were used for electrical stimulation (see text for details).

from our outpatient unit. All patients had typical endoscopic features of BE confirmed by histology within the last 2 years. Patients with a hiatus hernia rated by endoscopists as moderate or large were excluded as were patients who previously had esophageal surgery. In addition, we excluded patients with concomitant painful visceral diseases or other critical medical, surgical, or psychiatric illness. Patients were compared to a control group of 15 age- and sex-matched healthy volunteers.

Sensory assessment

Before the study all subjects were instructed in the use of a 0-10 visual analogue scale, where 1 = sensation threshold; 3 = vague perception of moderate sensation; 5 = pain threshold; and 7 = moderate pain. This scale has previously been described in detail, and has been shown to be reliable in discriminating sensations in the esophagus^[16]. The stimulation intensities at these defined sensory levels were measured for all stimulation modalities.

Probe design

The multimodal probe is illustrated in Figure 1. A custom-made esophageal probe measuring 60 cm in length with a diameter of 6.2 mm was fitted with a bag near the tip (Ditens A/S, Aalborg, Denmark). The bag was made of 25 μ m thick polyether urethanes had a maximum volume of 80 mL and was 5 cm long. An inlet and an outlet channel permitted recirculation of water in the bag during mechanical and thermal stimulation. A temperature wire with a tip sensor was placed in a separate channel for continuous temperature assessment during stimulation (TC Ltd., Uxbridge, England). Stainless steel electrodes for electrical stimuli were mounted on the probe 1 cm proximal to the bag. Detailed information on the probe and stimulation system has been described previously^[12].

Protocol

No analgesics or other medication potentially interfering with pain assessments were allowed in the 24 h prior to

Figure 2 Schematic illustration of the stimulation protocol. The following stimulations were applied in the metaplastic part 4 cm above the esophago-gastric junction: three mechanical preconditioning stimuli to the pain threshold [visual analogue scale (VAS) = 5]; mechanical stimulation to moderate pain (VAS = 7); thermal stimulation to the pain threshold; electrical stimulation to moderate pain; 50 electrical stimulations at the pain threshold were done to record evoked brain potentials. The mechanical, thermal and electrical stimulations were repeated 14 cm above the sphincter.

experimental testing. Treatment with proton pump inhibitors was stopped 4 d before the study day and the subjects fasted 4 h prior to probe intubation. The probe was inserted through the mouth. The bag close to the tip of the probe was positioned in the stomach and filled with 25 mL water. Retraction of the probe until resistance was met identified the position of the esophago-gastric junction (EGJ) corresponding to the middle of the bag. Finally, the bag was emptied and retracted 4 cm to ensure placement above the EGJ and the probe was taped to the chin.

Figure 2 shows the stimulation protocol. Initially, three mechanical distensions were applied to precondition the tissue and to train the subjects in assessing sensations from the esophagus. These distensions were stopped at the pain threshold and have previously been shown to facilitate discrimination of the different sensory ratings^[17]. Hereafter, pain tests were initiated: mechanical distension until moderate pain, heat stimulation to the pain threshold, and electrical stimulation until moderate pain. The participants outlined the area of referred pain after each stimulation type. Recordings of pain-specific evoked brain potentials were performed twice following 50 electrical stimulations at the pain threshold. The probe was then retracted 10 cm corresponding to 14 cm above the EGJ, and the mechanical, thermal and electrical stimulations were repeated after a break of 10 min.

Mechanical stimulation

Mechanical distension was done by inflating the bag with water (37°C) at a rate of 15 mL/min using a syringe pump (PHD 22/2000, Harvard Apparatus, Holliston, Massachusetts, USA). The maximum volume was set at 50 mL for safety reasons. The bag cross-sectional area, pressure and volume were continuously registered and stored for later analysis. If the maximum of 50 mL failed to evoke

moderate pain, the remaining sensory levels were assigned a volume of 50 mL.

Heat stimulation

Heat stimulation was done by recirculating heated water (60°C) using the above described pump at a rate of 180 mL/min. The stimulation was terminated at the pain threshold as a safety precaution and has been described in detail previously^[18]. Time from stimulation onset until the patient reached the predefined sensory levels was measured.

Assessment of the CNS response

The sensory response to (1) electrical stimulation; (2) the size of the referred pain area; and (3) the pain specific evoked brain potentials served as proxies for abnormalities in CNS pain processing. When the CNS is sensitized clinically or experimentally these measurements change with a decrease in pain threshold, increase in referred pain area and shortened latency of the evoked brain potential^[18-20].

Electrical stimulation: Mucosal contact was secured by keeping the inter-electrode impedance below 3 kΩ during stimulations. A computer-controlled constant-current stimulator (University of Aalborg, Denmark) delivered the electrical stimulations to the esophagus^[12]. A single stimulus consisted of five square-wave constant-current pulses at 200 Hz with duration of 1 ms, and each stimulation in total had a duration of 25 ms. The current intensity was increased in 0.5 mA increments with random sham stimulations having the same or lower intensity until moderate pain was evoked. Calculations were based on current at the predefined sensory levels.

Referred pain area: After each stimulation the subjects outlined their referred pain area on transparent paper. The size of the referred pain area was later digitized (Trust, 1200 wireless tablet, Trust International BV, Dordrecht, The Netherlands).

Electroencephalographic recordings and evoked brain potentials

The electroencephalographic (EEG) was recorded with a 64 surface electrode cap (Quick-Cap, Neuroscan, El Paso, TX, USA) and an amplifier (Nuamp, Neuroscan, Compumedics, Hamburg, Germany). Four additional electrodes for eye movement detection were used. Electrode gel was applied to reduce the electrode impedance below 8.2 kΩ.

Fifty identical esophageal stimulations were applied at 0.2 Hz with a current intensity corresponding to the pain threshold. The subjects relaxed quietly with open eyes in light-dimmed room. The EEG signals were recorded in continuous mode with a sampling rate of 1000 Hz and the online notch filter switched off (SynAmp, Neuroscan, El Paso, TX, USA).

The evoked potentials from each session were analyzed offline (Neuroscan software v 4.3.1, Neuroscan, El Paso, TX, USA) and stimulations containing artefacts (from eye

¹Overall statistically significant difference between patients and controls. Heat stimulation is expressed as stimulation time to reach the thresholds. On the visual analogue scale, 1 = the sensation threshold, 3 = vague perception of moderate sensation, 5 = the pain threshold, and 7 = moderate pain. VAS: Visual analogue scale; NA: Not applicable.

blinking or movements) were rejected. Amplitudes and latencies for the evoked potentials were obtained from the vertex electrode (Cz) with the electrodes above the ears (TP7 and TP8) as reference. Data was processed in the following steps: (1) zero-phase notch filtering (49-51 Hz) with a filter order of 24; (2) zero-phase band-pass filtering (1-70 Hz) with a filter order of 12; (3) epoching in the time window 50 ms prestimulus to 350 ms post-stimulus; (4) baseline correction; (5) linear detrending; (6) rejecting artefact sweeps manually, and (7) calculating average of accepted sweeps. Peak latencies to negative (N) and positive (P) deflections (N1, P1, N2, and P2) and peak-to-peak amplitudes were extracted for each subject.

Statistics

Normality was checked by QQ-plots and the assumption of variance homogeneity by the Levene median test. Descriptive statistics for data that were normally distributed are reported as mean (standard deviation), not normally distributed data as median (range). The Student *t*-test was used for measurements with single endpoints and the Mann-Whitney Rank Sum test for non-parametric data. Two-way analysis of variance was used for measurements where stimulus intensities were measured at several sensory thresholds. The Holm-Sidak method was chosen for *post hoc* comparisons^[21]. The chi-square test compared the dichotomous data. SigmaPlot 11.0 statistical software was used and *P* < 0.05 was considered statistically significant.

RESULTS

Thirty-three patients were invited to participate: 17 patients declined and 16 accepted. One of the 16 patients could not tolerate the probe and was excluded. The 15 remaining patients (12 male) had a mean age of 54 years (range, 25-68 years) and mean body mass index (BMI) of 30 kg/m² (range, 23-56 kg/m²). Seven patients had long segment BE and the remaining patients had short segment BE, e.g. less than 3 cm. Three patients did not complete the protocol 14 cm above the EGJ due to nausea evoked by the mechanical distension. Mechanical

Figure 3 Mechanical stimulation evoking moderate pain in patients with Barrett's esophagus and healthy volunteers. Patients were hyposensitive to mechanical stimulation 4 cm above the esophago-gastric junction compared to healthy volunteers, *P* = 0.02. On the visual analogue scale, 1 = the sensation threshold, 3 = vague perception of moderate sensation, 5 = the pain threshold, and 7 = moderate pain. ^a*P* < 0.05.

and thermal data from one patient were discarded due to technical errors.

The patients were compared to 15 healthy volunteers (10 male) with a mean age of 47 years (range, 28-63 years) (*P* = 0.07), and mean BMI of 25 kg/m² (range, 19-30 kg/m²) (*P* = 0.1). Volunteers were recruited among hospital staff and had no gastrointestinal symptoms. All volunteers completed the protocol. No adverse events were observed.

BE patients were hyposensitive to distension and heat in the metaplastic segment

It was possible to evoke moderate pain in 13 of 15 healthy volunteers compared to only 5 of 14 patients when stimulating mechanically in the metaplastic part 4 cm above the EGJ (*P* = 0.01). Four of these hyposensitive patients, but none of the controls, responded with nausea or vomiting rather than pain (*P* = 0.03). To achieve moderate pain, patients with BE required higher mechanical stimulus intensity compared to healthy volunteers (*F* = 5.7, *P* = 0.02; Table 1, Figure 3). Furthermore, patients required heat

Figure 4 Response to heat stimulation in patients with Barrett's esophagus compared to healthy volunteers. Patients were hyposensitive to heat stimulation 4 cm above the esophago-gastric junction ($P = 0.04$). On the visual analogue scale, 1 = the sensation threshold, 3 = vague perception of moderate sensation, 5 = the pain threshold. $^aP < 0.05$.

Figure 5 Response to mechanical and thermal stimulations at maximum pain in patients with Barrett's esophagus and healthy volunteers. Patients were hyposensitive to mechanical and thermal stimuli 4 cm above the esophago-gastric junction (EGJ). Heat hyposensitivity was also found in the normal part of the esophagus 14 cm above the EGJ. Both patients and controls were less sensitive to mechanical stimulation 4 cm above the EGJ, whereas the sensitivity for heat was the same on the two levels. Numbers on the X-axis indicate the level of stimulations 4 and 14 cm above the EGJ. $^aP < 0.05$.

stimulation for a longer time to reach the pain threshold ($F = 4.5$, $P = 0.04$; Table 1, Figure 4).

Patients were hyposensitive to heat in the normal mucosa

Patients with BE were also hyposensitive to heat in the normal part of esophagus 14 cm above the EGJ ($F = 6.2$, $P = 0.02$), but not to mechanical distension ($F = 0.2$, $P = 0.6$) (Table 1, Figure 5).

Lower esophagus is less sensitive to mechanical but not to heat stimulation

Both patients and controls were less sensitive to mechanical pain stimulation 4 cm above compared to 14 cm above the EGJ (patients with BE: $F = 26.9$, $P < 0.001$; controls: $F = 25.2$, $P < 0.001$) (Table 1, Figure 5). In contrast, no differences in sensitivity were found for thermal pain

Table 2 Traditional peaks in evoked brain potentials as response to esophageal electrical stimulations in patients and controls, mean \pm SD

	Patients	Controls
N1 latency (ms)	76 (20)	69 (14)
P1 latency (ms)	105 (19)	106 (15)
N2 latency (ms)	177 (15)	172 (25)
P2 latency (ms)	255 (35)	266 (39)
N1P1 amplitude (mV)	2.5 (2.5)	3.0 (1.7)
P1N2 amplitude (mV)	6.8 (5.1)	9.3 (5.5)
N2P2 amplitude (mV)	7.6 (5.9)	12.6 (7.6)

There were no overall differences between groups ($F = 2.7$, $P = 0.1$).

stimuli comparing stimulations 4 cm and 14 cm above the EGJ (patients with BE: $F = 0.3$, $P = 0.6$; controls: $F = 1.1$, $P = 0.3$) (Table 1, Figure 5).

BE patients had normal central pain processing

Electrical stimulation: No differences between patients and controls were found for the response to electrical pain stimuli in the metaplastic part 4 cm above the EGJ ($F = 0.1$, $P = 0.7$) (Table 1). Furthermore, no differences were found for the normal area 14 cm above the EGJ ($F = 3.4$, $P = 0.07$) (Table 1). Within groups, the area 4 cm above the EGJ was less sensitive to current compared to the area 14 cm above (patients with BE: $F = 32.5$, $P < 0.001$; controls: $F = 21.7$, $P < 0.001$) (Table 1).

Referred pain areas: Referred pain areas to the following stimulations did not differ between patient and control groups in the metaplastic part: mechanical [median 8.9 cm^2 (0.8-66.6) *vs* controls 14.9 cm^2 (2.3-38.6), $P = 0.5$], thermal [mean 23.7 cm^2 (20.7) *vs* controls 16.0 cm^2 (14.8), $P = 0.3$], and electrical [median 2.3 cm^2 (0.1-33.4) *vs* controls 3.2 cm^2 (0.2-40.7), $P = 0.7$]. Also in the upper part of the esophagus the results from both patients and controls were comparable: referred pain area in response to mechanical [median 14.5 cm^2 (2.1-72.9) *vs* controls 10.0 cm^2 (1.0-53.5), $P = 0.4$], thermal [mean 23.2 cm^2 (22.8) *vs* controls 19.5 cm^2 (23.2), $P = 0.5$], and electrical stimulation [median 20.6 cm^2 (2.9-70.0) *vs* controls 15.1 cm^2 (1.2-92.2), $P = 1.0$].

Recordings of evoked brain potential: No differences were found between patients and controls for the evoked brain potentials ($F = 2.7$, $P = 0.1$) (Table 2).

DISCUSSION

In this study the main findings were that patients with BE were hyposensitive to heat stimulation both in the metaplastic and normal parts of the esophagus. Furthermore, they were hyposensitive to noxious mechanical distension in the metaplastic part of the esophagus and many reported nausea rather than pain in response to noxious stimulations. The hyposensitivity is most likely a result of abnormalities affecting peripheral nerves, since there were no differences between groups for the response to

the stimuli reflecting central pain processing.

In clinical assessment, characterization of symptoms may be confounded by psychological, cognitive, and social aspects of the illnesses. To encompass these problems, human experimental pain models have been developed. In this study, we used one of these models: the multimodal pain model that has proven reliable as an esophageal research tool^[18,22]. An abnormal response to one or more of the stimulation modalities indicate pathology in different receptors or visceral nerve pathways^[23,24]. Validity has been proven in studies of pain mechanisms in erosive esophagitis, non-erosive esophagitis and non-cardiac chest pain proving its validity^[13-15]. Patients with both short and long segment BE were included. When stimulating the "metaplastic area", the balloon reached from 1.5-6.5 cm above the EGJ, therefore patients with short segment BE were stimulated partly in an area with normal mucosa and partly in the metaplastic area. However, as the patients were hyposensitive both low and high in the esophagus, bias was not a problem in the present study. The controls were slightly but non significantly leaner than the patients, but this is not thought to have influenced the results.

Thermal sensation

To our knowledge, studies examining thermal sensation in BE have not previously been conducted. In the current study, patients were hyposensitive both in the metaplastic part of the esophagus as well as in the normal control area 14 cm above the EGJ. The hyposensitivity in BE patients is interesting as these patients often have pathological reflux and could be expected to have sensory thresholds comparable to patients with gastro-esophageal reflux disease. However, both patients with erosive and non-erosive reflux disease have previously been shown to be hypersensitive to heat and have signs of CNS abnormalities underlining the differences between them and patients with BE^[13,15]. The hyposensitivity to heat in the normal part of the esophagus in BE patients suggests that heat hyposensitivity may be generalized in the esophagus and therefore independent of the metaplastic mucosa. Hence, it can be hypothesized that dysfunction of the afferent pathways may be one of several pathogenetic factors in BE. This fits well with previous studies that have demonstrated hyposensitivity to acid in patients with BE, and several acid sensitive receptors could potentially be involved^[5,9,10,25]. One of them - the transient receptor potential vanilloid 1 (TRPV1) - is of special interest as it is activated by heat and acid^[26]. Although speculative, the hyposensitivity to both heat and acid found in patients with BE could therefore be due to a defect or downregulation of TRPV1 receptors in the esophagus. A study involving assessment of heat and acid sensitivity as well as TRPV1 quantification in biopsies could elucidate this further.

Mechanical sensation

Trimble and coworkers found that patients with BE were mechanically hyposensitive, but their data may have been

biased by the large age difference between the patients and the control group^[27,28]. Compared with an age-matched control group we also found patients with BE to be hyposensitive to mechanical stimulation in the metaplastic area 4 cm above the EGJ. Some patients developed nausea rather than pain in response to noxious esophageal distension. It should be kept in mind that nausea rather than pain for some BE patients may be their only "warning response" to noxious distension, and further studies are needed to establish if nausea is a predictor of serious disease.

We found no differences for the response to mechanical distension between patients and controls in the area with normal mucosa 14 cm above the EGJ. There were four dropouts and a statistical type 2 error could be responsible. Hence, it is not possible to conclude from this study whether mechanical hyposensitivity is present in the normal part of the esophagus.

No indication of central sensitisation

Changes in the sensory response to electrical stimulation, referred pain areas, and evoked brain potentials has been shown to reflect changes in the CNS, such as seen experimentally after esophageal acid perfusion^[18-20]. Electrical stimulation bypasses the receptors stimulating the nerve fibers directly, and the sensitivity increases after sensitization. Referred pain areas increase, possibly as a result of stimulation of sensitized neurons receiving converging neural information from the esophageal nerves and the somatic nerves in the chest. Pain specific EEG recordings evoked brain potentials are believed to change due to faster spinal conduction and altered brain processing. Such changes have been reported in erosive reflux disease, non-erosive reflux disease and non-cardiac chest pain, where central sensitization is thought to play a role in symptom generation^[24,29]. We found comparable results in patients with BE and controls to electrical stimulation, referred pain areas, and waveforms of evoked brain potentials. Consequently, the cause of sensory changes in patients with BE is probably not found in the CNS, but rather at receptor level in the peripheral nervous tissue.

The distal oesophagus is less sensitive

We measured differences between the sensory responses evoked 4 and 14 cm above the EGJ and found that both the patients and the controls were more sensitive to mechanical and electrical stimuli 14 cm above the EGJ. Patel *et al.*^[30] previously found the same in healthy volunteers for mechanical stimulation and an explanation could be a greater number of nociceptors and mechanoreceptors proximal in the esophagus as seen in animal studies^[31,32]. However, other nociceptors seem to be responsible for heat sensation as no differences in heat sensitivity was observed at the two esophageal levels.

In conclusion, patients with BE are hyposensitive both in the metaplastic and normal part of the esophagus likely as a result of abnormalities affecting peripheral nerves. Hence, hyposensitivity is likely not to be a consequence of sensory changes due to the metaplastic epithelium, but

may be a pathogenetic factor in the development of the disease.

COMMENTS

Background

Barrett's esophagus (BE) is a complication of long-term severe acid reflux to the esophagus and patients are at higher risk of developing esophageal cancer. In several studies it has been demonstrated that patients with BE are less sensitive to acid than healthy controls. It is not known if this decreased sensitivity precedes the development of the condition or if it is a result of the mucosa changes of the disease. This study investigated the sensitivity in the esophagus of patients with BE in comparison to healthy controls. The esophagus was examined both in the part where the disease was present and in the normal part. Furthermore, the pain processing of the spinal cord and brain was examined.

Innovations and breakthroughs

In the patients, a decreased sensitivity to heat both in the normal part and the diseased part of esophagus was demonstrated. Distension was also felt later in the diseased part of esophagus. The spinal cord and brain was not responsible for the decreased sensitivity as they had a normal reaction to esophageal pain. The decreased sensitivity in the normal part of the esophagus could indicate that sensory changes are present before development of BE.

Applications

Results of this study has led to a better understanding of the disease and may, in the future, help to identify subjects with a higher risk of developing this disease. When identified, a more aggressive treatment of their acid reflux can be chosen and perhaps thereby prevent development of BE.

Terminology

BE is a metaplastic mucosal change in the distal esophagus resulting from long term acid exposure.

Peer review

This is an excellent work, carefully done and very well interpreted. The data are extremely original and represent a major breakthrough in the understanding of hyposensitivity in BE.

Abstract

AIM: To investigate the accuracy of T2*-weighted magnetic resonance imaging (MRI T2*) in the evaluation of iron overload in beta-thalassemia major patients.

METHODS: In this cross-sectional study, 210 patients with beta-thalassemia major having regular blood transfusions were consecutively enrolled. Serum ferritin levels were measured, and all patients underwent MRI T2* of the liver. Liver biopsy was performed in 53 patients at an interval of no longer than 3 mo after the MRIT2* in each patient. The amount of iron was assessed in both MRI T2* and liver biopsy specimens of each patient.

RESULTS: Patients' ages ranged from 8 to 54 years with a mean of 24.59 ± 8.5 years. Mean serum ferritin level was 1906 ± 1644 ng/mL. Liver biopsy showed a moderate negative correlation with liver MRI T2* ($r = -0.573$, $P = 0.000$) and a low positive correlation with ferritin level ($r = 0.350$, $P = 0.001$). Serum ferritin levels showed a moderate negative correlation with liver MRI T2* values ($r = -0.586$, $P = 0.000$).

CONCLUSION: Our study suggests that MRI T2* is a non-invasive, safe and reliable method for detecting iron load in patients with iron overload.

INTRODUCTION

Conventional treatment of beta-thalassemia major requires regular blood transfusions to maintain pre-transfusion hemoglobin level above 90 g/L^[1]. A major drawback of this treatment is transfusion siderosis, which, in association with the increased intestinal iron absorption, apoptosis of the erythroid precursors and peripheral hemolysis,

leads to inexorable iron accumulation in various organs such as the heart, liver and endocrine organs^[2]. The assessment of body iron is still dependent upon indirect measurements, such as levels of serum ferritin, as well as direct measurements of the liver iron content^[3]. Serum ferritin has been widely used as a surrogate marker but it represents only 1% of the total iron pool, and as an acute phase protein, it is not specific because the levels can be raised in inflammation (e.g. hepatitis) and liver damage^[4]. Liver iron concentration measured by needle biopsy is the gold standard for evaluation of siderosis. However, it is an invasive technique which is not easily repeated and its accuracy is greatly affected by hepatic inflammation-fibrosis and uneven iron distribution^[4]. More recently, biomagnetic susceptometry and magnetic resonance imaging (MRI) have been validated for measuring iron overload, and these techniques have great merit in being noninvasive^[5]. Biomagnetic susceptometry is a non-invasive, well calibrated and validated method as a quantitative measurement technique, but it has limited clinical value because of its high cost and technical demands^[6]. MRI has been considered a potential method for assessing tissue iron overload, as iron accumulation in various organs causes a significant reduction in signal intensity stemming from a decrease in the T2 relaxation time^[7,8].

The objective of the present study was to report our experience of the MRI technique in assessing hepatic iron overload in thalassemic patients.

MATERIALS AND METHODS

Between January 2008 and April 2009, 210 patients with beta-thalassemia major (114 females, 96 males) referred to the thalassemia clinic of Firuzgar Hospital were consecutively enrolled in this cross-sectional study. Ages ranged from 8 to 54 years with a mean of 24.59 ± 8.5 years.

Patients were treated conventionally with regular blood transfusion, in order to maintain the pre-transfusion hemoglobin concentration above 90 g/L. Regarding chelation therapy, all patients were receiving deferoxamine at a dose of 40 mg/kg, 5-7 times per week, by 8-hourly subcutaneous infusion.

The study was approved by the Institutional Review Board Ethics Committee of Iran University of Medical Sciences and written informed consent was obtained from all patients for the procedures studied.

Serum ferritin

A 5 mL blood sample was obtained from each patient for routine laboratory tests and measurement of ferritin level. Serum ferritin concentrations were assayed in all patients before the MRI scan, using an enzyme-linked radioimmunoassay method (Monobind Kit, USA).

Liver biopsy

Liver biopsy was performed with a 16-gauge Tru-Cut needle (TSK Laboratory, Japan) in 53 patients who gave written informed consent to undergo the biopsy for this

study. Each specimen was at least 2 cm in length. The specimens were kept in 10% formaldehyde solution, and were sent to the Department of Pathology of Firuzgar Hospital. The specimens were stained with hematoxylin & eosin and viewed by an expert pathologist. The amount of stainable iron was graded 0-4 according to the Scheuer *et al.*^[9] method.

It is notable that the interval between liver biopsy and MRI of the liver and heart was less than 3 mo in all patients.

MRI technique

MRI scans were performed using a 1.5 Tesla Magnetom Siemens Symphony scanner (Siemens Medical Solution, Erlangen, Germany). Each scan lasted about 10-15 min and included the measurement of hepatic and myocardial T2* quantities. A standard quadrature radiofrequency body coil was used in all measurements for both excitation and signal detection. Respiratory triggering was used to monitor the patients' breathing. Cardiac electrocardiographic gating was used. Spatial presaturation slabs were used to suppress motion-related artifacts.

The MRI T2* of the liver was determined using a single 10 mm slice through the center of the liver scanned at 12 different echo times (TE 1.3-23 ms). Each image was acquired during an 11-13 s breathhold using a gradient-echo sequence (repetition time 200 ms, flip angle 20°, base resolution matrix 128 pixels, field of view 39.7 cm × 19.7 cm, sampling bandwidth 125 kHz).

Statistical analysis

All statistical analyses were performed using the Statistical Package for Social Sciences, version 15 for Windows™ (SPSS® Inc., Chicago, IL). Continuous variables are presented as mean \pm SD and count (percent) for categorical variables. The relationship between continuous variables was evaluated by the Pearson correlation coefficient for normally distributed data and Spearman's Rank correlation coefficient for non-normally distributed data. All tests of significance were two-tailed and considered to be significant at $P < 0.05$.

RESULTS

All patients underwent MRI and 53 patients had a liver biopsy. The mean serum ferritin level of all patients was 1906 ± 1644 ng/mL. Serum ferritin levels showed a moderate negative correlation with liver T2* MRI values ($r = -0.586$, $P = 0.000$) (Figure 1). Of the 53 patients who had a liver biopsy, 5 patients had grade I liver siderosis, 19 had grade II, 17 had grade III and 12 had grade IV liver siderosis. The degree of siderosis assessed by liver biopsy showed a moderate negative correlation with liver T2* MRI ($r = -0.573$, $P = 0.000$) and a low positive correlation with ferritin level ($r = 0.350$, $P = 0.001$).

DISCUSSION

It is evident that different non-invasive methodologies

Figure 1 Serum ferritin levels showed a moderate negative correlation with liver T2* magnetic resonance imaging values. MRI: Magnetic resonance imaging.

have been implemented for the detection of organ-specific iron burden in patients with thalassemia major. Among these, MR relaxometry has the potential to become the method of choice for non-invasive, safe and accurate assessment of organ-specific iron load^[10]. Until recently serum ferritin levels and liver biopsy have been the most commonly used methods for estimating body iron stores in the thalassemic population. However, ferritin levels are not fully acceptable because there have been significant variations due to inflammation, infections and chronic disorders^[3].

Liver iron load vs serum ferritin

We found a moderate correlation ($r = -0.59$, $P < 0.001$) between serum ferritin levels and hepatic T2* levels. These findings are compatible with other reported studies with highest correlation^[3,11,12]. Attempts to correlate serum ferritin levels and hepatic iron concentrations have failed to demonstrate a linear relationship between the two parameters^[11].

Histological grade of siderosis vs liver T2*

Liver biopsy has been regarded as the most precise method to measure body iron content if direct measurement of the iron concentration was applied. However, this is an invasive procedure which is not available in most clinical settings.

Our results revealed no reasonable correlation between histological grade of siderosis (HGS) and serum ferritin. However, a moderate correlation with liver T2* ($r = 0.57$, $P < 0.001$) indicated that HGS could still be considered as a method of evaluating thalassemic patients. Liver iron concentration showed significant correlation with hepatic T2* ($r > 0.9$). These results indicated that MRI T2* measurement is of more value than HGS in thalassemic patients.

The most important limitation of our study was the lack of a consideration of intervening factors that may affect the serum ferritin levels such as C-reactive protein,

white blood cell count and liver function tests.

In conclusion, although hepatic iron content and serum ferritin levels have been considered as the gold standards in evaluating body iron load for several years, iron accumulation in different organs proceeds independently. This emphasizes the importance of direct iron load measurement in each involved organ and direct evaluation of the efficacy of different therapeutic measures.

According to our study, the serum ferritin level is not a reliable method for estimating the level of iron overload in thalassemic patients. MRI T2* is a more accurate and non-invasive method which we recommend for measurement of iron load in these patients.

COMMENTS

Background

Iron overload is a common and serious problem in thalassemic major patients. As iron accumulation is toxic in the body's tissues, accurate estimation of iron stores is of great importance in these patients to prevent iron overload by an appropriate iron chelating therapy.

Research frontiers

Liver biopsy is the gold standard for evaluating iron stores but it is an invasive method which is not easily repeatable in patients. Introduction of other more applicable methods seems to be necessary.

Innovations and breakthroughs

The authors found that MRI T2* might be an accurate method for estimation of whole body iron.

Applications

According to the findings, the authors suggest that clinicians consider MRI as an accurate method to evaluate the iron overload in patients with thalassemia major.

Peer review

This is an interesting report.

of gastric cancer cells with or without 5-aza-2'-deoxycytidine treatment.

RESULTS: HIN-1 was not expressed in 4 of 5 gastric cancer cell lines. The demethylation reagent 5-aza-2'-deoxycytidine was able to induce or upregulate *HIN-1* expression in gastric cancer cell lines, which is associated with reduction of tumor cell viability. Furthermore, methylation of the *HIN-1* gene promoter was shown in 57.8% (26/45) of the primary gastric cancer and 42.1% (17/38) of adjacent tissue samples, but was not shown in normal gastric mucosa (0/10). From the clinicopathological data of the patients, methylation of the *HIN-1* gene promoter was found to be associated with tumor differentiation ($P = 0.000$).

CONCLUSION: High methylation of *HIN-1* gene promoter results in silence of HIN-1 expression in gastric cancer. 5-aza-2'-deoxycytidine reverses *HIN-1* methylation and reduces viability of gastric cancer cells.

Abstract

AIM: To clarify the role of high in normal-1 (*HIN-1*) gene promoter methylation during gastric cancer development.

METHODS: Gastric cancer cell lines and tissue specimens were analyzed for expression of HIN-1 mRNA and protein using the semi-quantitative reverse transcription polymerase chain reaction and immunohistochemistry. The methylation of the *HIN-1* gene promoter was detected in gastric carcinoma cells and tissues using methylation-specific polymerase chain reaction. The 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium cell viability assay and flow cytometry were used to assess the changes in behaviors

INTRODUCTION

Gastric cancer is the second most common cause of can-

cer death worldwide after lung cancer^[1,2]. Gastric carcinogenesis, like all other cancers, is a multistep process, involving numerous genetic and epigenetic alterations, such as abnormalities in growth factors/receptors, angiogenic factors, cell cycle regulators, and DNA mismatch repair genes. These abnormalities also define biological characteristics of gastric cancer cells, which can serve as therapeutic targets for gastric cancer^[3,4]. Although genetic abnormalities including gene mutation and deletion are prominent in causing oncogene activation and tumor suppressor gene inactivation, epigenetic silence of tumor suppressor genes via aberrant promoter hypermethylation have also been shown to be frequent events in gastric carcinoma^[5,6]. DNA high methylation of tumor suppressor genes frequently occurs in the early stage of human carcinogenesis, and investigating the methylation of these gene promoters may contribute to the diagnosis, prognosis and target therapy in gastric carcinoma^[7,8].

High in normal-1 (*HIN-1*) gene was originally isolated through a serial analysis of gene expression from normal and ductal carcinoma *in situ* luminal mammary epithelial cells. The latter is believed to be the precursor of invasive ductal carcinoma^[9]. *HIN-1* is highly expressed in normal luminal mammary epithelial cells but lost in the majority of breast cancers. Restoration of *HIN-1* expression suppressed growth of breast cancer cells^[10]. *HIN-1* can also regulate cell-cycle reentry, suppresses tumor cell migration and invasion, and induces apoptosis in breast cancer cell lines^[10]. Although *HIN-1* processes the putative tumor suppressor function, no somatically genetic changes of *HIN-1* gene were found in breast cancer^[9]. Previous studies demonstrated frequent methylation of *HIN-1* gene promoter in breast cancer, prostate cancer, malignant mesotheliomas, non-small cell lung cancer, lymphoma, retinoblastoma, Wilms' tumor, and rhabdomyosarcoma^[11-14].

However, expression of this putative tumor suppressor gene in gastric cancer has not been fully studied. Therefore, in this study, we first confirmed the methylation of *HIN-1* gene promoter in human gastric cancer cell lines and determined the role of 5-aza-2'-deoxycytidine [5-aza-dc, a drug that inhibits the DNA methyltransferase (DNMT)-mediated hypermethylation of promoter region CpG islands] in regulation of *HIN-1* expression in gastric cancer cells. We also detected the methylation of *HIN-1* gene promoter in tissue specimens and found the association between *HIN-1* gene promoter methylation and clinicopathologic characteristics of gastric cancer.

MATERIALS AND METHODS

Cell lines and culture

Gastric carcinoma cell lines KATOIII, AGS, PHM82, NUGC3, and BCG823 were obtained from American Type Culture Collection (Manassas, VA) and cultured in either RPMI 1640 medium or RPMI 1640/Ham's F-12 medium (all from Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum in a humidified incubator with 5% CO₂ and 95% air at 37°C. These cells were pas-

saged at a ratio of 1:3 with trypsin once they reached confluence (approximately 10⁶ cells) into 75 cm² culture flasks (Sarstedt, Newton, NC). For treatment with 5-aza-2'-deoxycytidine, these cell lines were split and cultured at a low density (30% confluence) overnight and then treated with 5-aza-2'-deoxycytidine (Sigma, St. Louis, MO) at a concentration of 1 μmol/L for up to 96 h. The growth medium was refreshed every 24 h, and at the end of the treatment, DNA and RNA from these cells were isolated as described below.

Human tissue samples

In the current study, 45 surgically resected and pathologically confirmed gastric tumors and 38 adjacent non-tumor tissues were obtained from the PLA General Hospital, Beijing, China between January 2009 and January 2010 and stored in liquid nitrogen until use. Ten cases of normal gastric mucosa were also obtained from the gastric endoscopic biopsies of tumor-free patients. This study was approved by our hospital's Institutional Review Board.

DNA extraction and methylation-specific polymerase chain reaction

Genomic DNA from these cell lines and tissue specimens were extracted using a proteinase-K method described previously^[15]. The extracted DNA was then dissolved in Tris-EDTA (TE) buffer and stored at -20°C. To assess the methylation levels of the *HIN-1* gene promoter, genomic DNA from gastric cancer cell lines and tissue specimens were first subjected to bisulfite treatment and then methylation-specific polymerase chain reaction (MSP) as described previously^[16]. The MSP primers for *HIN-1* were designed and synthesized according to genomic sequences skirting the presumed transcription start sites for *HIN-1*. The *HIN-1* MSP primers spanned a region of 92 base pairs for unmethylation (location is from +128 to +41) and 88 base pairs for methylation (location is from +131 to +40). The primer sequences were: *HIN-1*-UN 5'-GAAGTTTGTGGTTTGTGTTGGGTAGTT-3', *HIN-1*-UN-AS 5'-CACACAAAACCCCAAAAAACAACA-3', *HIN-1*-ME-S 5'-GTTTCGTGGTTTGTTCGGGTAGTC-3' and *HIN-1*-ME-AS 5'-GCAAAACCCCAAAAAACGACG-3'. Each MSP reaction incorporated approximately 100 ng of bisulfite-treated DNA, 25 picomoles of each primer, 100 pmoles dNTPs, 2.5 μL 10 × PCR buffer, and 1 unit of JumpStart Red *Taq* Polymerase (Sigma) in a final reaction volume of 25 μL. The PCR amplification conditions were an initial 95°C for 5 min and then 35 cycles of 95°C for 30 s, 60°C for 30 s, and 72°C for 30 s and a final extension at 72°C for 5 min and then stored at 4°C. The MSP products were separated on 2% agarose gel electrophoresis and visualized under the ultraviolet (UV) light.

RNA isolation and semi-quantitative reverse transcription PCR

Total cellular RNA from the cell lines was isolated using the TRIzol reagent (Invitrogen) according to the manu-

facturer's instructions. RNA quality and quantity were assessed using agarose gel electrophoresis (1%) and spectrophotometric analysis of 260/280 ratios. The RNA was stored at -70°C prior to use. The first strand cDNA was synthesized with oligo-(dT) primer using a reverse transcriptase kit from Invitrogen.

Two micrograms RNA was subjected to the first strand cDNA synthesis, and 1 µL cDNA from RT reaction was subjected to PCR amplification of gene expression in a total 25 µL reaction volume. The PCR amplification was carried out using primer sets derived from the published *HIN-1* gene sequences: *HIN-1* primers were 5'-TCTGCGTGGCCCTGTCCTG-3' (sense) and 5'-GCTCAGCCAAACACTGTCAG-3' (antisense)^[14]. This primer set, designed to cross the intronic sequences, can prevent from amplification of genomic DNA for control of genomic DNA contamination during RNA isolation. A total of 32 cycles of PCR amplification were performed based on our pre-experiment for semi-quantitative measurement of *HIN-1* gene expression levels. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was amplified for 25 cycles as an internal control of equal loading and cDNA quality and quantity. The sequence of GAPDH primers: 5'-GACCACAGTCATGCCATCAC-3' (sense) and 5'-GTCCACCACCCTGTTGCTGTA-3' (antisense). The PCR products were then electrophoresed in 1.5% agarose gels containing ethidium bromide and reviewed under the UV light.

Protein extraction and Western blotting

The cells were grown and treated with or without 5-aza-2'-deoxycytidine for 6 d and total cellular protein was then extracted from these cells in 200 µL ice-cold mild lysis buffer containing 10 µL nonidet P-40, 0.15 mol/L NaCl, 0.01 mol/L sodium phosphate (pH 7.2), 2 mmol/L EDTA, 50 mmol/L sodium fluoride, 0.2 mmol/L sodium vanadate, and 1 µg/mL aprotinin. The cell mixture was centrifuged at 20000 r/min for 15 min and supernatants were then collected. The concentration of protein was quantified by the BCA protein assay from Pierce (Rockford, IL, USA) and an equal amount of protein was separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and then transferred onto PDVF membranes (Millipore, Billerica, USA). Western blotting analyses were then carried out using an anti-HIN-1 (Novus Biologicals, Littleton, USA) or an anti-β-actin antibody (Boster, Wuhan, China). The blots were developed with chemiluminescence substrate solution from Pierce and exposed to X-ray film.

3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium assay

Gastric cancer cells were grown in 96-well plates and treated with or without 5-aza-2'-deoxycytidine for up to 6 d, and then cell proliferation was determined using CCK-8 solution (Beyotime, China) according to the manufacturer's instructions. The optical density was measured at 492 nm using an ELISA plate reader (TECAN, Switzerland). The

experiments were performed in triplicate and repeated three times.

Detection of apoptosis

Gastric cancer cells were treated with or without 5-aza-2'-deoxycytidine for up to 6 d. Both attached and floating cells were harvested and fixed with 70% ethanol for at least 48 h. After resuspension in 50 µg/mL, the cells were treated with 100 µg/mL RNase for 30 min and stained with propidium iodide and then analyzed by flow cytometry (FACScalibur; Becton Dickinson, Franklin Lakes, NJ).

Immunohistochemistry

Sections 5 µm thick were formalin-fixed and paraffin-embedded in xylene and rehydrated through an ethanol series. Antigen retrieval was carried out at this stage in a microwave oven. Sections were then blocked with 3% hydrogen peroxidase followed by incubation with a 50% protein blocking agent. Fetal bovine serum (10%), with or without HIN-1 antibody (1:60), was applied to each slide, and the slides were incubated for 30 min, and counter-stained with hematoxylin. Tissues without the specific antibody were used as negative controls. Anti-HIN-1 (Novus Biologicals, Littleton, USA) and PV-6000-G Kit (Beijing Zhongshan Jinqiao Biotechnology, Beijing, China) were used for the immunohistochemical (IHC) staining. HIN-1 expression was regarded as positive when 10% or more cancer cells exhibited HIN-1 expression.

Statistical analysis

The statistical analyses of the experimental data were carried out using SPSS 13.0 software for Windows (Chicago, IL). *P* values for dichotomous variables were two-tailed and based on the Pearson χ^2 test or the Pearson χ^2 test with continuity correction. Continuous variables were analyzed with Student's *t* test. A value of *P* < 0.05 was considered statistically significant.

RESULTS

Silence of HIN-1 expression through methylation of HIN-1 gene promoter and 5-aza-2'-deoxycytidine induction of HIN-1 gene expression in gastric cancer cell lines

To find out whether the silence of *HIN-1* gene expression is caused by methylation of the *HIN-1* gene promoter, we first detected the methylation status of *HIN-1* in 5 gastric cancer cell lines. The MSP analysis showed that *HIN-1* gene promoter was highly methylated in AGS, PHM82, and BCG-823 cells, but not methylated or partially methylated in NUGC 3 and KATOIII cell lines (Figure 1A). We detected HIN-1 expression in five gastric cancer cell lines and found that HIN-1 mRNA was not expressed in AGS, PHM82, and BCG 823 cells, but expressed in NUGC 3 and weakly expressed in KATOIII cells. HIN-1 expression was induced or upregulated in these cell lines after we treated them with 5-aza-2'-deoxycytidine (Figure 1B).

Figure 1 Silencing of *high in normal-1* gene expression due to methylation of *high in normal-1* gene promoter in gastric carcinoma cell lines. A: Methylation-specific polymerase chain reaction analysis of *high in normal-1* (*HIN-1*) gene promoter methylation in five gastric carcinoma cell lines. U: Unmethylated alleles; M: Methylated alleles. *In vitro* methylated DNA (IVD) and DNA from normal human peripheral lymphocytes were used as methylated and unmethylated controls; B: Gastric cancer cell lines were treated with or without 5-aza-CdR (-AZ) for up to 96 h. *HIN-1* mRNA levels were measured by semi-quantitative reverse transcription polymerase chain reaction analysis, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) served as control. The 1-kb marker indicated an appropriate size for the amplified products. *HIN-1* expression varied among cell lines. The presence of methylation of *HIN-1* corresponds directly to the loss of expression of the genes in each cell line.

Suppression of gastric cancer cell viability with 5-aza-2'-deoxycytidine treatment

We determined the ability of 5-aza-2'-deoxycytidine to regulate gastric cancer cell viability using BCG-823 cells treated with 5-aza-2'-deoxycytidine. The results showed that treatment with 1 $\mu\text{mol/L}$ of 5-aza-2'-deoxycytidine for up to 6 d significantly upregulated expression of *HIN-1* but reduced the number of the viable cells (Figure 2A) and induced them to undergo apoptosis compared with the untreated tumor cells ($20.46\% \pm 1.24\%$ vs $11.28\% \pm 1.01\%$, $P = 0.001$, Figure 2B). These data were associated with *HIN-1* expression induced by 5-aza-2'-deoxycytidine (Figure 1B and Figure 2A).

Aberrant hypermethylation of *HIN-1* gene promoter in primary gastric carcinomas

To translate this *in vitro* finding into *ex vivo* tissue specimens, MSP analysis of *HIN-1* gene promoter methylation was conducted in 45 patients with human gastric carcinoma (32 male and 13 female). The patients' average age was 55 ± 13 years and other clinicopathological data are listed in Table 1. MSP analysis showed that methylation of the *HIN-1* gene promoter was frequently detected in gastric cancer (57.78%, 26/45) and adjacent non-tumor tissues (42.1%, 17/38), but not in normal gastric mucosa. Statistically, there was no difference in methylation of the *HIN-1* gene promoter between gastric cancer and adjacent non-tumor tissues. However, there were statistically significant differences between gastric cancer and normal gastric mucosa, and between adjacent non-tumor tissues and normal mucosa (Figure 3A and B, $P = 0.002$ and $P = 0.005$, respectively). To correlate *HIN-1* gene promoter methylation with *HIN-1* expression, 29 gastric cancer tissues (GCs) were subjected to immunohistochemistry analysis. Representative immunostaining is shown in Figure 4A and B. GC cases with low *HIN-1* immunostaining had more frequent DNA methylation than GCs with high immunos-

Table 1 Association of *high in normal-1* methylation with clinicopathologic characteristics in gastric cancer

taining (53.33% vs 14.29%, $P = 0.027$, Figure 4C). These data demonstrate that DNA methylation contributes to the decreased expression of *HIN-1* in GCs.

Association of *HIN-1* gene promoter methylation with clinicopathological data in gastric cancer patients

Methylation status of *HIN-1* gene promoter was associated with tumor differentiation. The methylation frequency in well-differentiated and moderately/poorly-differentiated tumors was 34.78% (8/23) and 80.95% (17/21), respectively, indicating that *HIN-1* was more frequently methylated in poorly-differentiated gastric cancer than that in well-differentiated gastric cancer ($P = 0.000$, Table 1). However, there was no correlation between *HIN-1* methylation and other parameters (such as age, tumor size, and lymph node metastasis) (Table 1).

DISCUSSION

In the current study, we determined *HIN-1* gene expression and the methylation status of the *HIN-1* gene promoter in gastric cancer cells. We found that the expression of *HIN-1* mRNA was lost in gastric cancer cells. MSP analysis revealed high methylation of the *HIN-1* gene promoter in these tumor cells. 5-aza-2'-deoxycytidine treatment induced *HIN-1* expression, but reduced viability of gastric cancer cells. Furthermore, *ex vivo* data demonstrated that the *HIN-1* gene promoter is frequently methylated in gastric cancer and the adjacent non-tumor tissues, but not in normal gastric mucosae. *HIN-1* gene promoter methylation was associated with differentiation of gastric cancer. This study demonstrated frequent methylation of the *HIN-1* gene promoter in gastric cancer. Therefore, the

HIN-1 gene promoter methylation may be further evaluated as a biomarker for early detection of gastric cancer.

Inactivation of tumor suppressor genes contributes to cancer development. Such inactivation may be caused by genetic or epigenetic alterations, including gene mutation, deletion, promoter methylation, abnormal splicing, deregulation of imprinting and haploinsufficiency^[4]. Among these abnormalities, loss of heterozygosity (LOH) was

shown to cause inactivation of most candidate tumor suppressor genes in the critical regions of chromosomes 3p, 5q, 8p and 9p^[17-20]. However, changes in methylation status of these genes also frequently occur. The *HIN-1* gene is located at 5q35 and plays a role in epithelial cell differentiation. *HIN-1* can also regulate cell-cycle reentry, suppresses tumor cell migration and invasion, and induces apoptosis in breast cancer cell lines^[10]. The *HIN-1* gene is

Figure 4 Immunohistochemical analysis of high in normal-1 protein expression in gastric cancer tissue samples. A, B: IHC, $\times 200$.

frequently methylated in different cancers, but not by mutation^[11]. For example, *HIN-1* gene promoter hypermethylation was found in the majority (70%) of breast cancer and pre-invasive lesions. Hypermethylation of the *HIN-1* promoter region also occurs in cancer and the adjacent tissues of the lung, prostate, pancreas, and esophagus, but not in normal tissues^[21]. Methylation of the *HIN-1* gene promoter was associated with esophageal squamous carcinoma progression^[14]. Our current data demonstrated aberrant methylation of *HIN-1* gene promoter regions and subsequent loss of *HIN-1* expression in gastric cancer cell lines and tumor tissue specimens. These results are consistent with previous studies on other cancers^[9,12]. *HIN-1* methylation existed in 57.78% (26/45) of gastric cancer and 42.1% (17/38) of adjacent non-tumor tissues, which indicated that it is a common feature of gastric cancer and may be the early stage accident in gastric carcinogenesis.

The pathogenesis of intestinal-type gastric cancer is usually initiated or caused by *Helicobacter pylori* (*H. pylori*) infection^[22]. However, the underlying mechanism remains to be defined, and a better understanding of pathogenesis of gastric cancer could help develop molecular diagnostic and patient-tailored therapeutic targets^[23]. In the previous studies, we reported that field defect, an area of abnormal tissue that precedes and is predisposed to the development of cancer, could be predicted by detection of gene promoter methylation^[24]. Such abnormal fields are of interest because they give insight into the early

stages of carcinogenesis and may provide biomarkers of cancer risk^[25,26]. Aberrant promoter hypermethylation has been shown to be a common event in human cancer mainly due to the loss of function of tumor suppressor. This neoplasia-related event is thought to occur early in carcinogenesis, and hence, promoter hypermethylation is being widely studied as a biomarker for the diagnosis and detection of early lesions. In this context, *HIN-1* was frequently methylated in gastric carcinoma adjacent tissues but not in normal gastric mucosa. It suggests that *HIN-1* methylation may represent the field defect of gastric carcinoma. *HIN-1* gene promoter methylation may be an early event in gastric cancer. However, further studies are required to determine whether *H. pylori* infection is responsible for this.

Our current data showed a statistical difference between methylation of the *HIN-1* gene promoter and gastric cancer differentiation, *HIN-1* was more frequently methylated in poorly-differentiated gastric carcinomas than in well-differentiated ones, which may suggest the role of *HIN-1* in regulation of cell differentiation.

We also found that methylation of *HIN-1* gene promoter only occurred in gastric cancer but not in normal gastric mucosa. 5-aza-2'-deoxycytidine induced expression of *HIN-1*, which is associated with reduced viability of gastric cells, indicating that *HIN-1* plays an important role in suppressing gastric carcinogenesis. However, we cannot rule out whether other tumor suppressor genes

are also induced and restored by 5-aza-2'-deoxycytidine, which plays a role in regulation of tumor cell viability. The latter warrants further studies because some other studies showed that epigenetic modification of pro-apoptotic genes is one of the mechanisms by which the tumor cells are resistant to chemotherapy^[27,28]. Therefore, treatment with a demethylating agent like 5-aza-2'-deoxycytidine prior to chemotherapy may help improve the therapeutic efficacy for gastric cancer.

In summary, silence of HIN-1 expression is achieved through the gene methylation in gastric cancer. Methylation of *HIN-1* is correlated with tumor differentiation. Future studies will evaluate whether *HIN-1* gene promoter methylation can be used as a biomarker for the early detection of gastric cancer.

COMMENTS

Background

Gastric cancer is the second most common cause of cancer death worldwide. However, the cause of gastric cancer development remains to be determined. Lost expression of tumor suppressor genes, such as high in normal-1 (*HIN-1*), may contribute to the development of gastric cancer. This study determined the cause of *HIN-1* gene inactivation: epigenetic silence through methylation of the gene promoter.

Research frontiers

Silence of *HIN-1* gene through hypermethylation of the gene promoter is a common event in different cancers including breast, prostate, and non-small cell lung cancers and malignant mesotheliomas, lymphoma, retinoblastoma, Wilms' tumor, and rhabdomyosarcoma. This study investigated the role of *HIN-1* in gastric cancer and showed for the first time that the hypermethylation of *HIN-1* gene promoter was the mechanism for *HIN-1* gene silence in gastric cancer.

Innovations and breakthroughs

The authors confirmed the methylation of *HIN-1* gene promoter in human gastric cancer cell lines and determined the role of 5-aza-2'-deoxycytidine in regulation of *HIN-1* expression in gastric cancer cells.

Applications

The *HIN-1* gene promoter methylation may be further evaluated as a biomarker for early detection of gastric cancer.

Terminology

HIN-1 gene was originally isolated through a serial analysis of gene expression from normal and ductal carcinoma *in situ* luminal mammary epithelial cells. *HIN-1* gene promoter is frequently methylated in gastric cancer and the adjacent non-tumor tissues, but not in normal gastric mucosa.

Peer review

This manuscript demonstrated promising data illustrating the methylation status of *HIN-1* gene promoter and its potential role in suppression of gastric carcinoma development.

Abstract

AIM: To present the experience and outcomes of the surgical treatment for the patients with anorectal melanoma from the Cancer Hospital, Chinese Academy of Medical Sciences.

METHODS: Medical records of the diagnosis, surgery, and follow-up of 56 patients with anorectal melanoma who underwent surgery between 1975 and 2008 were retrospectively reviewed. The factors predictive for the survival rate of these patients were identified using multivariate analysis.

RESULTS: The 5-year survival rate of the 56 patients with anorectal melanoma was 20%, 36 patients underwent abdominoperineal resection (APR) and 20 patients underwent wide local excision (WLE). The rates of local recurrence of the APR and WLE groups were 16.13% (5/36) and 68.75% (13/20), ($P = 0.001$), and the median survival time was 22 mo and 21 mo, respectively ($P = 0.481$). Univariate survival analysis

demonstrated that the number of tumor and the depth of invasion had significant effects on the survival ($P < 0.05$). Multivariate analysis showed that the number of tumor [$P = 0.017$, 95% confidence interval (CI) = 1.273-11.075] and the depth of invasion ($P = 0.015$, 95% CI = 1.249-7.591) were independent prognostic factors influencing the survival rate.

CONCLUSION: Complete or R0 resection is the first choice of treatment for anorectal melanoma, prognosis is poor regardless of surgical approach, and early diagnosis is the key to improved survival rate for patients with anorectal melanoma.

INTRODUCTION

Anorectal malignant melanoma (ARMM) is an infrequent fatal tumor. ARMM accounts for $< 1\%$ of anorectal malignant tumors and approximately 1%-2% of all melanomas^[1]. Although there has been progress in the treatment of melanomas, the prognosis of ARMM is still very

poor, and the 5-year disease-specific survival (DSS) is 10% or less. In most cases, when patients are diagnosed with ARMM, local invasion or distal metastasis already exists^[2], and because ARMM is not sensitive to radiotherapy and chemotherapy, selection of treatment methods is limited. At present, surgical treatment remains the main therapeutic method for ARMM, with abdominoperineal resection (APR) and wide local excision (WLE) as the most common approaches used. Nevertheless, there are controversies regarding which technique is superior in terms of long-term survival and overall quality of life. Because of the low incidence and poor biological behavior of ARMM, there has been no consensus about the therapeutic method for ARMM^[3]. The current study involved a retrospective analysis of 56 patients with ARMM who underwent surgery in our hospital between 1975 and 2008. We compared the survival status of the patients after APR and WLE to determine the relationship between the surgical approaches and prognosis of ARMM. Cases with distal metastasis at the time of diagnosis were not included in this study.

MATERIALS AND METHODS

Clinical data

Among the 56 patients, 22 were men and 34 were women; the ratio of males to females was 1:1.55. The mean age of the patients was 55 years (range, 36-81 years). The main symptoms were hematochezia in 32 cases, anal tumors in 11 cases, change in bowel habits in 6 cases, and bulge or pain in the anus in 7 cases. The distance from the tumor to the anal verge was < 5 cm in all the 56 patients, and < 3 cm in 47 (83.92%) patients. Misdiagnoses occurred in 32 (57.14%) cases. Thirteen cases were misdiagnosed as hemorrhoids, 8 cases as adenomas or polypus, 4 cases as cancer, and 1 case each as carcinoid, fibroma, malignant fibroma, eczema, and dysentery.

Pathologic examination

Routine pathologic examinations were carried out in all 56 cases and the diagnoses were made by two pathologists. There were 49 cases of pigmented melanomas, 7 cases of amelanotic melanomas, 50 cases of single lesions, 6 cases of multiple lesions. Ten cases had lesions invading into the mucosa, 6 cases into the submucosa, 19 cases into the muscle layer and 7 cases into the fibrous membrane, and the depth of lesion was not recorded in 14 cases. Among 36 patients undergoing APR, lymph node metastases occurred in 21 cases, while no lymph node metastases were noted in 14 cases, and the status of metastasis was not identified in 1 case. Immunohistochemical examinations were carried out for differential diagnosis in 28 cases.

Surgical methods

Thirty-six cases underwent APR, 19 cases underwent WLE, 1 case underwent WLE+ lymph node dissection, Assisted radiotherapy was performed in 4 cases, and assisted biotherapy and chemotherapy were carried out in

19 cases. The main biological agent was interferon, and the main chemotherapeutic agents were dacarbazine and vincristine.

Follow-up and statistical analysis

Postoperative follow-ups were made until December 2009 through outpatient visits, telephone interviews, and questionnaires, with a rate of 91% (51/56). The survival time was calculated from the day of surgery. SPSS13.0 software was used for statistical analyses. χ^2 test was used to ascertain the relationship between the clinical pathologic parameters and local recurrence. The Kaplan-Meier method and long-rank univariate analysis were used for calculating the survival rates and multivariate analysis was conducted for the COX model.

RESULTS

Comparison of different surgical methods between local recurrence and distal metastasis

All 56 cases underwent tumorectomy. The local recurrence rate was 32.14% (18/56) and the rate of metastasis was 58.92% (33/56). Thirty-six cases underwent APR, with a local recurrence rate of 16.13% (5/36). Twenty cases underwent WLE, with a local recurrence rate of 68.75% (13/20). The results of the χ^2 test showed that there was a correlation between the surgical method and local recurrence ($P = 0.001$).

Comparison of different surgical methods in survival time

The 5-year overall survival rate for all the patients was 20%. The 5-year overall survival rate was 24.6% in the APR group and 9.9% in the WLE group. The median survival time was 22 mo in the APR group and 21 mo in the WLE group ($P = 0.645$, Figure 1A).

Overall prognosis and its influencing factors

In this study, the mean follow-up period was 4-144 mo, the median survival time was 21 mo, and the 5-year overall survival rate was 20%. Based on univariate analysis, the factors correlated with prognosis were the number of tumors and the depth of invasion (Table 1). When these factors were subjected to a Cox model with stepwise regression, the results showed that the number of tumors [$P = 0.017$, OR = 3.755, 95% confidence interval (CI) = 1.273-11.075 (Figure 1B)] and the depth of invasion [$P = 0.015$, OR = 3.079, 95% CI = 1.249-7.591 (Figure 1C)] were the most important influencing factors for prognosis.

DISCUSSION

ARMM is an infrequent fatal tumor and accounts for 1%-2% of all melanomas. The rectum and the anal canal are the most common organs for ARMM onset, except the skin and eyes. In this study, the clinical characteristics of ARMM included: an age of onset of 55 years, hematochezia as the most common primary symptom, similar

Figure 1 Overall survival by different surgical methods and prognosis factors. A: Survival curves for different surgical methods ($P = 0.645$); B: Survival curves for number of tumors ($P = 0.001$); C: Survival curves for depth of invasion ($P = 0.002$). APR: Abdominoperineal resection; WLE: Wide local excision.

incidences of the tumor in the rectum and anal canal, more females than males affected, and a ratio of males to females of 1:1.6, which is consistent with a previous report^[4]. Although the gastrointestinal tract contains melanocytes, ARMM is most likely located around the anocutaneous line, including the anocutaneous line and the anal canal. In our study, the distance from the tumor to the anal verge was < 5 cm in all 47 cases; < 3 cm in 43 (91.5%) cas-

es; and < 2 cm in 16 cases. Zhang *et al*^[4] summarized 216 cases of ARMM, carried out a descriptive analysis of the characteristics of tumor growth, and found that ARMM was more likely benign. For example, the maximum diameter of the tumor was relatively small; 43.6% were polypoid type in gross morphology, and only 23.6% of the tumors were invading the surrounding tissues and fixed. Although most tumors have hard surfaces and ulcers on the surface, there are tumors with soft and smooth surfaces. Melanin has been reported under light microscope in 70%-80% of tumors; however, the percentage was 91% in the current study.

Misdiagnosis is a significant characteristic of ARMM. Because ARMM is rare and its clinical features lack specificity, the rate of misdiagnosis is high. In this study the rate of misdiagnosis was 57.14% (32/56), which is similar to Zhang's report^[5]. The early symptoms of ARMM resemble some anorectal benign diseases, such as thrombosed hemorrhoids, mixed hemorrhoids, and rectal adenomas. In the advanced stage, ARMM is similar to rectal cancer. Amelanotic ARMM is more likely to be misdiagnosed. The causes of misdiagnosis are as follows: (1) physicians do not have sufficient knowledge about this disease; (2) the clinical features lack specificity; and (3) the pathologic diagnosis is difficult; in particular, immunohistochemical methods are needed for a correct diagnosis of amelanotic melanomas. The data of this study suggest that the prog-

nosis for ARMM is better when the tumor is limited in the mucosa and submucosa, and in such cases the tumor can be treated by WLE, therefore, lowering the misdiagnosis rate is very important for early treatment. There are several methods that can help improve the diagnosis of ARMM. (1) Rectal examination and endoscopy: ARMM is most likely located in the anocutaneous line and the anal canal. In this study, the distance from the tumor to the anal verge was < 5 cm in all cases, therefore, the rectal examination and the endoscopy are very important. Most patients with such melanomas complained of bleeding, pain, or an anal mass. Digital examination provides information concerning size, fixation and ulceration of the tumor, and proctosigmoidoscopy may be suggestive of anorectal melanoma^[6]. When the pathologic examination is performed in patients with suspected ARMM, the whole tumor should be resected to prevent iatrogenic dissemination; (2) Light microscopy: Light microscopy can localize pigment granules in the cytoplasm of tumor cells in most cases. If the existence of pigment granules is not clear, other methods, such as Fontana-Masson-stained sections for melanin, dopamine staining, or enzyme reactions, can be used to confirm the diagnosis; and (3) Immunohistochemical staining: Because the aforementioned methods can not diagnose amelanotic ARMM, the immunohistochemical method combining HMB45, S-100 protein, and the vimentin test can be used^[7].

The malignancy of ARMM is high. The 5-year disease-specific survival (DSS) is < 10% and the mean survival time is 12-18 mo^[8,9]. ARMM is not sensitive to radiotherapy or chemotherapy; surgical excision remains the most important therapy. APR and WLE are the most common surgical methods used; however, since the tumor is located in the anorectal area, there have been differences in the viewpoint regarding which surgical method is most suitable for long-term survival and overall life quality^[10]. At present, the results of most studies have indicated no difference between the two surgical methods with respect to the survival rate. Yeh *et al*^[11] performed a retrospective analysis of 46 patients with ARMM who were treated surgically; among them, 19 patients underwent APR and 26 patients underwent WLE. The rates of local recurrence were 21% and 26%, respectively, and there were no statistical differences. The DSS was 34% and 35%, respectively. The neural invasion around the tumor was the only independent prognosis factor ($P = 0.01$). It was considered that the range of surgical excision was not correlated with the prognosis. Because WLE has significant advantages, such as minor surgical trauma, quick recovery, less effect on the function of the intestinal tract, and preservation of anal function, it was suggested that WLE should be the first choice for treatment of ARMM. Another point of view considered that APR has a certain advantage in the control of local recurrences, thus it should be the first choice for patients with early-stage disease.

Because of the infrequency of ARMM, it is difficult to carry out a prospective, randomized, controlled study, and there have been only some retrospective data of small

samples studied. Thibault *et al*^[12] summarized 24 references involving 428 cases of AMM patients who underwent APR and WLE. There was no significant difference between the two groups with respect to the 5-year DSS. A series of 26 patients from the MD Anderson Cancer Center reported fewer local recurrences after APR (29%) than after wide local excision (58%), but these authors noted that the majority of recurrences occurred in patients who also had regional or systemic metastases and that local recurrence did not affect survival^[13]. In our series, the 5-year overall survival rate was 24.6% in the APR group and 9.9% in the WLE group ($P = 0.645$). The rate of local recurrence was lower in the APR group than in the WLE group (16.13% and 68.75%, respectively, $P = 0.001$). It is suggested that APR can decrease local recurrence, but no significant difference between the two groups with respect to the 5-year overall survival rate.

The definition of relevant pathological prognostic parameters which might be able to guide the clinical decision is also lacking in anorectal melanomas. Tumor thickness less than 2 mm has been advocated as a good prognostic factor by Roumen in his study^[14]. Weyandt *et al*^[15] reported that, in early-stage disease with a tumor thickness below 1 mm, a local sphincter saving excision with a 1-cm safety margin would be appropriate. In the cases of a tumor thickness between 1 and 4 mm, a local sphincter saving excision with a safety margin of 2 cm seems to be adequate. In this study, multivariate analysis showed that a single lesion and the depth of tumor invasion were the most important factor influencing prognosis. Therefore, early diagnosis is the key to improved survival rate for patients with anorectal melanoma^[16].

In this study, the surgical method affected the rate of local recurrence, but it did not affect the prognosis of ARMM, confirming that the quick development of a tumor over the body obscures the effect of surgical method on the control of a local tumor. Hence, as with other malignant tumors, the metastatic capability of ARMM was determined at the moment of tumorigenesis, and it is independent from other factors, such as the size of tumor and metastasis to the lymph nodes^[17]. ARMM is a systemic disease and its prognosis is not affected by the surgical method, so that the goal of surgical therapy is to improve the quality of life of those patients maximally, by now, most scholars hold the same view^[18].

Because ARMM is highly invasive and the blood supply to the area of the anocutaneous line is abundant, lymph node and distal metastases may occur. Therefore, biotherapy and chemotherapy are necessary as postoperative adjunctive therapies. The rate of complete remission is 11% when metastatic ARMM is treated by chemotherapy and biotherapy^[19]. Cytotoxic chemotherapeutics (cisplatin, catharanthine, or dacarbazine), combined with immunomodulators (interleukin-2 and interleukin- α) can improve the survival status of some patients. Ballo *et al*^[20] reported postoperative radiotherapy in a retrospective analysis of 23 patients with AM who were managed with sphincter-sparing procedures and adjuvant radiotherapy.

Although the overall survival was not improved, the actuarial 5-year local and nodal control was 74% and 87%, respectively. This degree of locoregional control is superior to the standard WLE alone, in which local control is typically poor (a crude estimate of 35%). This study did not investigate the effects of adjuvant chemotherapy and postoperative radiotherapy on the prognosis, which is also a controversial topic. Further studies are needed to demonstrate the benefits of adjuvant chemotherapy and postoperative radiotherapy.

It can be concluded that the surgical method does not affect the prognosis of ARMM. If the tumor can be resected totally, WLE should be the first choice of treatment. APR can be performed as a rescue therapy when WLE is impossible, the margins of the local excision are positive, or in the event of recurrence^[21].

Endorectal ultrasonography is increasingly employed in the preoperative staging of rectal cancers. Accuracy in evaluating tumor depth ranges from 81% to 94%, and accuracy in detecting lymph node metastases ranges from 58% to 80%^[22], and preoperative magnetic resonance imaging (MRI) is often of great importance when planning rectal cancer surgery^[23]. Use of endoanal ultrasonography and MRI for preoperative staging of patients with anorectal melanoma has rarely been reported. In this study, no patient underwent preoperative ultrasonographic and MRI evaluation, but some patients are being followed postoperatively in an attempt to detect early recurrence. We are currently evaluating the accuracy of endoanal ultrasonography and MRI in the preoperative assessment of melanoma as well as other anal canal malignancies.

This study was hampered by several limitations. First, it is retrospective, based mainly on data from medical documentation. Second, data are incomplete. In some patients, medical documentation was absent, and follow-up data were missing. Finally, patients received heterogeneous treatment and no prospective protocol was followed. Therefore, planning of surgery after thorough clinical and radiological investigations, including MRI of the pelvis and endoluminal ultrasound for tumor depth, may aid in defining the appropriate surgical approach for anorectal melanoma.

COMMENTS

Background

Anorectal malignant melanoma (ARMM) is an infrequent fatal tumor. ARMM represents < 1% of anorectal malignant tumors and approximately 1%-2% of all melanomas. Although there has been progress in the treatment of melanomas, the prognosis of ARMM is still very poor, and the 5-year disease-specific survival (DSS) is 10% or less. At present, surgical therapy remains the main treatment method for ARMM, with abdominoperineal resection (APR) and wide local excision (WLE) as the most common methods used. Nevertheless, there are considerable controversies regarding which technique is superior in terms of long-term survival and overall quality of life. Because of the low incidence and poor biological behavior of ARMM, there has been no consensus reached about the treatment method for ARMM.

Research frontiers

The authors compared the survival status of the patients after APR and WLE to determine the relationship between the surgical approaches and prognosis of ARMM, and found that complete or R0 resection is the first choice of treatment

for anorectal melanoma, prognosis is poor regardless of surgical approach, and early diagnosis is the key to improved survival rate for patients with anorectal melanoma.

Innovations and breakthroughs

It can be concluded that the surgical method does not affect the prognosis of ARMM. If the tumor can be resected totally, WLE should be the first choice of treatment. APR can be performed as a rescue therapy when WLE is impossible, the margins of the local excision are positive, or in the event of recurrence.

Applications

Planning of surgery after thorough clinical and radiological investigations, including MRI of the pelvis and endoluminal ultrasound for tumor depth, may aid in defining the appropriate surgical approach for anorectal melanoma.

Terminology

ARMM is an infrequent fatal tumor. At present, surgical therapy remains the main treatment method for ARMM, with APR and WLE as the most common methods used. If the tumor can be resected totally, WLE should be the first choice of treatment. APR can be performed as a rescue therapy when WLE is impossible, the margins of the local excision are positive, or in the event of recurrence.

Peer review

The authors should address how the decision was made as to which of the treatments was recommended to the patients. This may very well have influenced the results in local recurrence.

Li XP, Liu WF, Ji SR, Wu SH, Sun JJ, Fan YZ. Isolated pancreatic granulocytic sarcoma: A case report and review of the literature. *World J Gastroenterol* 2011; 17(4): 540-542 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i4/540.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i4.540>

INTRODUCTION

Granulocyte sarcoma (GS), also known as chloroma, is a localized malignant tumor composed of myeloid cells, and is difficult to establish its diagnosis. GS may precede or occur concurrently with acute or chronic myeloid leukemia or less often with polycythemia vera and primary myelofibrosis. It was reported that GS occurs in a variety of tissues but presents as an abdominal mass, and infiltration of the pancreas is particularly rare^[1]. In this paper, we report an unusual case of pancreatic GS in a patient without acute myeloid leukemia.

CASE REPORT

The patient was a 48-year-old woman with no significant past medical history. She was referred because of acute abdomen with no history of abdominal trauma. She complained of persistent severe epigastric pain accompanying a high fever for three days, but not of vomiting, diarrhea or shortness of breath. On physical examination, the patient appeared to be in acute distress with pale complexion. Her abdomen was slightly distended with tenderness. No mass was palpable and bowel movements were decreased. Laboratory test showed 79 g/L hemoglobin, 6400/mm³ white blood cells, 60 × 10³/mm³ platelets, 128 U/L aspartate aminotransferase (AST), 270 U/L alanine aminotransferase (ALT), 1365 U/L lactate dehydrogenase (LDH), and 17.4 U/L carbohydrate antigen 19-9 (CA19-9). Computed tomography scan revealed a 4.5 cm × 4.0 cm fuzzy mass at the pancreatic tail with splenomegaly and splenic infarction (Figure 1). Bone marrow infiltration was assessed and no evidence of acute myeloid leukemia (AML) was

Abstract

Granulocytic sarcoma (GS) is an extramedullary tumor mass consisting of immature myeloid cells. Isolated pancreatic granulocyte sarcoma is extremely rare. We report a very unusual pancreatic granulocytic sarcoma in a patient without acute myeloid leukemia. The patient presented with acute epigastric pain because of splenic infarction due to a mass consisting of myeloblasts in the pancreatic tail. The patients underwent splenectomy and distal pancreatectomy. Pathology and immunohistochemistry suggested a GS. Despite local surgery, an isolated tumor recurred 2 mo after operation and the patient died 3 mo after removal of the tumor. Only 7 reported cases of pancreatic GS were identified in the literature and the mass was located in the pancreatic head. This is the first report of GS in the pancreatic tail with splenic infarction.

Figure 1 Computed tomography scan showing a low density mass at the pancreatic tail (A), splenomegaly and splenic infarction (B), and a mass at the pancreatic tail (C) in a patient with isolated pancreatic granulocytic sarcoma.

Figure 2 Hematoxylin and eosin staining showing infiltration of immature neoplastic myeloid cells in pancreatic tissue (A, magnification at $\times 100$) and positive reaction of myeloid cells to myeloperoxidase antibodies (B, magnification at $\times 200$) in a patient with isolated pancreatic granulocytic sarcoma.

found. Barium meal examination was negative. Exploratory laparotomy was performed because of persistent severe abdominal pain probably due to pancreatic mass and splenic infarction. An invasive tumor was detected in the pancreatic tail with lymphadenectasis around the hilus of spleen. Consequently, the patient underwent splenectomy and distal pancreatectomy. Histological examination revealed diffusely infiltrating mono-morphous immature blast-like cells (Figure 2A), which were round to oval in shape with mild-moderate basophilic cytoplasm but without granules. Paraffin-embedded sections were examined with immunohistochemical staining. The tumor cells reacted to myeloperoxidase (MPO) antibodies (Figure 2B) but not to CD20 monoclonal antibodies. Therefore, a diagnosis of GS was made and intensive AML-type chemotherapy was recommended. Unfortunately, the patient refused further chemotherapy and was discharged from hospital. Follow-up showed an isolated tumor recurred 2 mo after operation and the patient died 3 mo after operation.

DISCUSSION

GS, also known as chloroma for their green appearance, occurs in association with different hematological diseases, especially FAB M1 and M2 AML^[2,3]. Translocation t (8; 21) is the most common cytogenetic abnormality found in

leukemia patients with GS, which is associated with a relatively good prognosis when treated with chemotherapy^[4]. GS is often confused with non-Hodgkin lymphoma of the lymphoblastic type, Burkitt lymphoma, large-cell lymphoma and small round cell tumor^[5]. It is more difficult to isolate pancreatic GS than to diagnose GS during the course of AML. Immunohistochemical methods are essential to obtain the correct diagnosis. GS cells often react to MPO, CD43, CD68 antibodies, but not to lymphoid antigens such as CD20 and CD30 monoclonal antibodies^[6,7].

Isolated pancreatic GS is most commonly located in periosteum, soft tissue, bone, lymph nodes and skin^[8,9]. However, it is extremely uncommon. Only 7 cases of isolated pancreatic GS, located in the pancreatic head, are available in the literature^[10,11] (Table 1). Consequently, the symptoms of these patients were jaundice and epigastric pain. This is the first report of isolated pancreatic GS located in the pancreatic tail accompanying splenic infarction. The isolated pancreatic GS in the present case invaded the splenic vessels, leading to splenomegaly and splenic infarction and finally severe epigastric pain.

Although isolated pancreatic GS can be treated with radiotherapy or surgical resection, it would recur if not treated with intensive AML-type chemotherapy^[12]. Different strategies are available for improving the disease-free interval of patients with isolated pancreatic GS^[10,11]. All the reported

Abstract

A gastric intrinsic factor output under 200 U/h after pentagastrin stimulation ($V > 2000$ U/h) is specific for pernicious anemia. The other findings are either variable or non specific. Serum intrinsic factor antibodies, considered as specific in general practice, are present only in half of the patients with pernicious anemia. In their absence, since the disappearance of the Schilling tests, the gastric tubage currently used for the study of gastric acid secretion, is obligatory for the simultaneous study of intrinsic factor output. This study is important to eliminate another disease much more frequent than pernicious anemia, the protein bound to cobalamin malabsorption was observed in achlorhydric simple atrophic gastritis in the presence of intrinsic factor secretion.

TO THE EDITOR

The recent article entitled "new insights in pernicious anemia (PA) from a gastroenterological point of view" published in issue 41 of the *World Journal of Gastroenterology* 2009^[1], does not clearly describe the actual diagnosis criteria for PA. The recent disappearance of Schilling tests and the difficulties in finding a laboratory able to appreciate the intrinsic factor (IF) output have raised the question about the secure diagnosis of this disease.

A gastric IF output under 200 U/h post pentagastrin stimulation ($N > 2000$ U/h) is specific for PA. The other findings are either variable or non specific. Variable findings include elevated serum gastrin, serum IF antibodies (considered specific in current general practice), normal antral mucosa, normal or elevated serum level of folate and reduced level of erythrocyte folate. Non specific findings include fundic atrophic gastritis, achlorhydria, and hypergastrinemia^[2]. Hyperplasia of enterochromaffin-like cells exists in atrophic gastritis with hypergastrinemia, achlorhydria with conservation of good IF secretion^[3]. Parietal cells antibodies (PCA) are observed in a high proportion of normal middle aged women.

In fact, PA diagnosis is easily feasible in half of the patients in the presence of IF serum antibodies and hypergastrinemia. The absence of any these findings does not eliminate the diagnosis. Replacement of hypergastrinemia by a fundic atrophic gastritis is perhaps admissible. However, this gastritis alone and hypergastrinemia alone are not sufficient. PCA have no place^[4].

In old patients with cobalamin deficiency, the demand is evidently less once intestinal diseases (gluten enteropathy being not forgotten) are eliminated.

In scientific studies, particularly in those on the relation between *Helicobacter pylori* and PA, however, the demand has to be greater than in recent articles^[5,6] to make sure that the patient does not have a simple atrophic gastritis with achlorhydria and conservation of good IF secretion, a disease much more frequent than PA and responsible for a non dissociation of alimentary cobalamin from protein nutriment. In this disease (food bound to cobalamin malabsorption^[7]), the most common disorder of cobalamin absorption^[4], cobalamin deficiency is moderate (the role of chlorhydric acid

in the dissociation of cobalamin from alimentary proteins varies with the nature of these proteins. Moreover IF secretion is important for the reabsorption of cobalamins from bilio-pancreatic and intestinal secretions), the anemia is discrete and sometimes only macrocytosis is observed. Schilling tests show a good absorption of crystalline cobalamin and a malabsorption of various proteins bound to cobalamins^[8]. Treatment can be oral cobalamin^[4]. Longitudinal studies^[4,9] showed that the frequency of the evolution of this gastritis toward PA is very low. This disease is another disease rather than PA. The presence of cobalamin deficiency in these simple achlorhydric gastritis can explain the demand of the earliest authors^[2,9,10] for the diagnosis tests of PA in patients without IF serum antibodies. These diagnosis tests include either gastric tubage with study of the IF output by 15 min fractions in the hours before and after stimulation or Schilling test done in good conditions, that is using the two-stage test (with then without oral administration of IF eventually repeated for the elimination of cobalamin malabsorption due to the cobalamin deficiency's effect itself on the intestinal mucosa)^[10].

Since Schilling tests are no longer available, the diagnostic criteria have changed^[4,11]. In the absence of serum IF antibodies in a patient with a low serum cobalamin level, the gastric tubage for study of IF output is obligatory for scientific purposes.

Deficiency in IF secretion is the "gold standard" for the diagnosis of PA, which should be used to evaluate the value of associations between serological markers, including eventually new PCA.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organizations]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of *Gastroenterology*

World J Gastroenterol 2011 February 7; 17(5): 545-680

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1144 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 60 countries, including Albania (1), Argentina (8), Australia (29), Austria (14), Belgium (12), Brazil (10), Brunei Darussalam (1), Bulgaria (2), Canada (20), Chile (3), China (69), Colombia (1), Croatia (2), Cuba (1), Czech (4), Denmark (8), Ecuador (1), Egypt (2), Estonia (2), Finland (8), France (24), Germany (75), Greece (14), Hungary (10), India (26), Iran (6), Ireland (7), Israel (12), Italy (101), Japan (112), Jordan (1), Kuwait (1), Lebanon (3), Lithuania (2), Malaysia (1), Mexico (10), Moldova (1), Netherlands (29), New Zealand (2), Norway (11), Pakistan (2), Poland (11), Portugal (4), Romania (3), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (10), South Africa (2), South Korea (32), Spain (38), Sweden (18), Switzerland (11), Thailand (1), Trinidad and Tobago (1), Turkey (24), United Arab Emirates (2), United Kingdom (82), United States (249), and Uruguay (1).

Scaldaferri F, Lancellotti S, Pizzoferrato M, De Cristofaro R

ORIGINAL ARTICLE

- 609 Bacteriocinogeny in experimental pigs treated with indomethacin and

Escherichia coli Nissle

Bures J, Smajs D, Kvetina J, Förstl M, Smarda J, Kohoutova D, Kunes M, Cyrany J,

Tachei I, Rejchrt S, Lesna J, Vorisek V, Kopacova M

- 618 Analysis of the urinary peptidome associated with *Helicobacter pylori* infection

Xiao D, Meng FL, He LH, Gu YX, Zhang JZ

- 625 Influence of CXCR4/SDF-1 axis on E-cadherin/ β -catenin complex expression in HT29 colon cancer cells

Wang L, Li CL, Wang L, Yu WB, Yin HP, Zhang GY, Zhang LF, Li S, Hu SY

BRIEF ARTICLE

- 633 Natural history of cytomegalovirus infection in a series of patients diagnosed with moderate-severe ulcerative colitis

Criscuoli V, Rizzuto MR, Montalbano L, Gallo E, Cottone M

- 639 Natural history of heartburn: A 10-year population-based study

Olafsdottir LB, Gudjonsson H, Jonsdottir HH, Thjodleifsson B

- 646 Percutaneous aspiration and drainage with adjuvant medical therapy for treatment of hepatic hydatid cysts

Yasawy MI, Mohammed AE, Bassam S, Karawi MA, Shariq S

- 651 A population-based case-crossover study of polyethylene glycol use and acute renal failure risk in the elderly

Choi NK, Chang Y, Jung SY, Choi YK, Lee J, Lee JH, Kim JY, Park BJ

- 657 Effects of intestinal mucosal blood flow and motility on intestinal mucosa

Wang YB, Liu J, Yang ZX

- 662 Suspended moxibustion relieves chronic visceral hyperalgesia and decreases hypothalamic corticotropin-releasing hormone levels

Zhou EH, Wang XM, Ding GH, Wu HG, Qi L, Liu HR, Zhang SJ

- 666 Narrow-band imaging endoscopy with and without magnification in diagnosis of colorectal neoplasia

Zhou QJ, Yang JM, Fei BY, Xu QS, Wu WQ, Ruan HJ

- 671 Fast-track rehabilitation program *vs* conventional care after colorectal resection: A randomized clinical trial

Wang G, Jiang ZW, Xu J, Gong JF, Bao Y, Xie LF, Li JS

CASE REPORT

- 677 *In-vivo* characterization of DALM in ulcerative colitis with high-resolution probe-based confocal laser endomicroscopy

De Palma GD, Staibano S, Siciliano S, Maione F, Siano M, Esposito D, Persico G

ACKNOWLEDGMENTS I Acknowledgments to reviewers of *World Journal of Gastroenterology*

APPENDIX I Meetings
I-VI Instructions to authors

ABOUT COVER Cromer WE, Mathis JM, Granger DN, Chaitanya GV, Alexander JS.
Role of the endothelium in inflammatory bowel diseases.
World J Gastroenterol 2011; 17(5): 578-596
<http://www.wjgnet.com/1007-9327/full/v17/i5/578.htm>

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

FLYLEAF I-VII Editorial Board

EDITORS FOR THIS ISSUE

Responsible Assistant Editor: *Xiao-Fang Liu*
Responsible Electronic Editor: *Wen-Hua Ma*
Proofing Editor-in-Chief: *Lian-Sheng Ma*

Responsible Science Editor: *Li Xu*
Proofing Editorial Office Director: *Jian-Xia Cheng*

Abstract

Ulcerative colitis and Crohn's disease (CD) are the two major forms of inflammatory bowel disease (IBD). In this highlight topic series of articles, the most recent advances in the IBD field are reviewed, especially the newly described cytokines, including the therapeutic implications for their manipulation. In addition, the interplay between the intestinal microbiota and the host is reviewed, including the role of defensins and dysbiosis in CD pathogenesis. Finally, the importance of the non immune systems such as endothelial cells and the hemostatic system are highlighted as new players in IBD pathogenesis.

Danese S. What's hot in inflammatory bowel disease in 2011? *World J Gastroenterol* 2011; 17(5): 545-546 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i5/545.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i5.545>

(*WJG*), we have selected an expert group that is actively involved in the investigation of inflammatory bowel disease (IBD) pathogenesis.

Crohn's disease (CD) and ulcerative colitis (UC) are the two major forms of IBD.

These diseases still pose major clinical and therapeutic challenges to the gastroenterological community.

It is now clear that CD and UC represent two distinct forms of chronic inflammation of the gastrointestinal tract and have different causes and pathogenic mechanisms. Still, the factors underlying the appearance of both CD and UC are roughly the same, and include a temporal association with progressive changes in the environment, an intrinsic genetic predisposition, the existence of a rich enteric flora, and an abnormal immune reactivity which is ultimately responsible for damaging the gut and causing clinical manifestations. Even though the categories of underlying factors are roughly the same, there are variations in each category as well as differences in how the underlying factors interact. The end result is two related but distinct disorders named CD and UC. In this special issue of *WJG*, differences and similarities of the etiopathogenic factors in each form of IBD will be illustrated and discussed in each review assessing the newly described cytokines^[1], the interplay between the intestinal microbiota and the host^[2], the role of defensins and dysbiosis^[3] and the importance of extraluminal factors^[4] and non immune systems such as endothelial cells^[5] and the hemostatic system^[6] as new players in IBD pathogenesis.

Since the recognition of IBD as a perplexing and challenging clinical entity, the investigation of its pathogenic mechanisms has gone through repeated cycles of new hopes, new knowledge, and new realities. Infectious, allergic, dietary, psychosocial, environmental, microbial, vascular, metabolic, immune and other basic theories have been put forward, most of them to be rebuked, if not ridiculed. At the moment, we appear to have settled down on a unifying but still wide-ranging hypothesis that IBD results from complex interactions between evol-

In this special issue of *World Journal of Gastroenterology*

ing environmental changes induced by society progress, a still undefined number of predisposing genetic mutations, an incredibly complex gut microbiota that may be constantly varying, and the intricacies of individual immune systems. The ability to integrate all these various components into a single cohesive and logical pathway of disease that explains all aspects of IBD appears still a bit distant at the moment. On the other hand, if we look back at where we stood only two or three decades ago, the progress achieved in our understanding of IBD pathogenesis and the way it has changed our approach to therapy is just short of spectacular.

Although we have made tremendous advances in disease pathogenesis, among the many diseases that exist, IBD is the one for which the exact etiology remains obscure and the mechanisms underlying tissue injury appear to be exceedingly complex. This certainly seems to be the case for the two main forms of IBD, namely CD and UC.

Abstract

Inflammatory bowel diseases (IBDs) are complex and chronic disabling conditions resulting from a dysregulated dialogue between intestinal microbiota and components of both the innate and adaptive immune systems. Cytokines are essential mediators between activated immune and non-immune cells, including epithelial and mesenchymal cells. They are immunomodulatory peptides released by numerous cells and these have significant effects on immune function leading to the differentiation and survival of T cells. The physiology of IBD is becoming a very attractive field of research for development of new therapeutic agents. These include cytokines involved in intestinal immune inflammation. This review will focus on mechanisms of action of cytokines involved in IBD and new therapeutic opportunities for these diseases.

Key words: Inflammatory bowel disease; Ulcerative colitis; Crohn's disease; Cytokine; Pathophysiology; Biological therapy

INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease (CD) are immune-mediated disorders of the intestine^[1]. Accumulating data suggests that inflammatory bowel disease (IBD) results from an inappropriate inflammatory response to intestinal microbes in a genetically susceptible host^[2]. Emerging evidence suggests that disease development implicates a dysregulated dialogue between the intestinal flora and components of both the innate and adaptive immune systems^[3,4].

Active IBD is defined as an infiltration of the lamina propria by innate immune cells [neutrophils, macrophages, dendritic and natural killer (NK) T cells] and adaptive immune cells (B and T cells). Increased numbers and activation of these cells in the intestinal mucosa enhance local levels of tumor necrosis factor- α (TNF- α) and several proinflammatory interleukins (IL)^[2,5]. Cytokines are essential mediators of the interaction between activated immune cells and non-immune cells, including epithelial and mesenchymal cells^[6,7].

Recent advances in the study of the regulation of key cytokines during major forms of IBD promise the development of more effective mechanism-based therapies^[8]. Given that many of these involve regulation of dynamic biological processes, it is likely that the most effective agents will fall within the broad rubric of biologic therapy.

The prototypic example of the ability of a biologic agent to effectively change the therapeutic landscape is provided by anti-TNF- α , first demonstrated through clinical validation of the prototypic agent infliximab^[8]. The advent of anti-TNF- α agents has changed the way of treating IBD refractory to standard medications^[3,9].

Advances in the understanding of IBD pathophysiology have become a very active area for the development of novel therapeutic agents. New targets for biologics include cytokines involved in intestinal immune inflammation that have led to new therapeutic opportunities^[10,11]. Although IBD etiology is unknown, some molecules which are involved in the physiopathology have been identified and can be targeted by biological therapies^[12]. This review will focus on cytokines involved in the dysregulated inflammatory response in IBD and targeted by biological therapies.

CYTOKINE NETWORK AND IMMUNITY

Cytokines (from greek cyto: cell; kinos: movement) are substances that are secreted by specific cells of the immune system and carry signals locally between cells, with extensive use in cellular communication. The term “cytokine” encompasses a large and diverse family of polypeptide regulators that are produced widely throughout the body by cells of diverse embryological origin. Basically, the term “cytokine” has been used to refer to the immunomodulating agent. Interferon was the first cytokine to be described in 1957^[13]. The clinical efficacy of targeting TNF- α indicates that cytokines are potential therapeutic targets in IBD^[6].

Cytokines have profound effects on immune functions^[14]. Beyond the classical T helper Th1/Th2 paradigm indicating predominant Th1-mediated responses dominated by the production of interferon- γ (IFN- γ) in CD and an exaggerated Th2-like inflammation in UC characterized by an increased production of IL-13^[2,15], there has been a surge of information with regard to the role of innate immunity in IBD pathogenesis. Thus new data on adaptive immunity are emerging, indicating that: (1) the mucosal Th1 and Th2 responses of CD and UC may be actually secondary to defects of the innate immune response; (2) the dysfunction of regulatory T cells may be contributing to mucosal immune abnormalities; and (3) the newly described Th17 cells are also prominently involved in the gut inflammatory response in both forms of IBD^[5,15].

The differentiation and survival of T cells depend on the relative amount of key regulatory cytokines produced mainly by macrophages and dendritic cells^[12]. In the presence of IL-12 and IFN- γ , naive CD4⁺ T cells adopt a Th1 phenotype which then activate macrophages that release IL-1, IL-6 and TNF- α . Thus this creates a positive feedback loop^[3,6,12]. In the presence of IL-4, naive CD4⁺ T cells adopt a Th2 phenotype^[12,16]. The Th17 development is triggered by both IL-6, IL-21, IL-23 and transforming growth factor- β (TGF- β), leading to secretion of the IL-17 cytokine family and IL-22^[6]. Although the function of Th17 cells is not clearly known, there is probably an important part of this T cell population which expresses

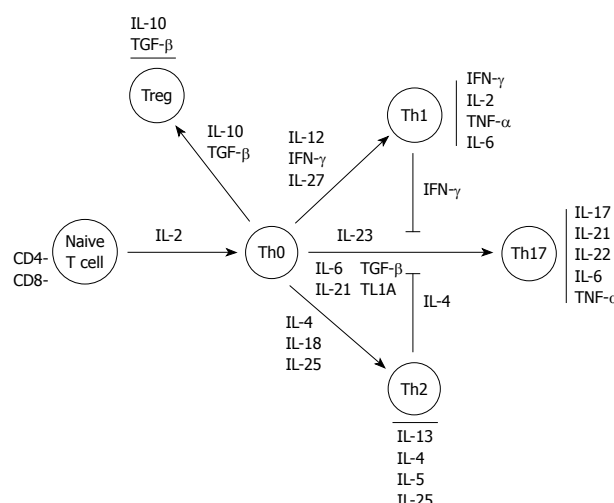

Figure 1 Overview of T cell differentiation and interleukin pathways. IL: Interleukin; IFN: Interferon; TGF: Transforming growth factor; TNF: Tumor necrosis factor; TL1A: TNF-like factor 1A.

IL-23 receptors. This has been recently demonstrated as an IBD susceptibility gene in genome-wide association studies.

In contrast, TGF- β and IL-10 modulate differentiation of naive T cells to T regulatory cell subgroups leading to high amounts of IL-10 and TGF- β , and are able to suppress bystander T cell activation. This could be defective in IBD^[17-20]. There is a complex network between these different cell populations in the case of inflammation as, for example, in the negative crossregulation of the differentiation of Th17 cells by Th2 cells (IL-4, IL-27) and Th1 cells (IFN- γ) (Figure 1)^[21].

PROINFLAMMATORY CYTOKINES

TNF family: TNF- α and TNF-like factor 1A

Mechanisms of action: TNF- α is a major mediator of inflammation in the gut^[22-25]. It is synthesized by several cells including intestinal epithelial cells but predominantly by cells of the monocyte line and T lymphocytes^[14]. TNF- α is a homotrimeric protein that mediates its diverse biologic effects through 2 distinct receptors known as TNF- α receptor type I expressed on all nucleated cells and TNF- α receptor type II restricted to cells of hematopoietic lineage^[26]. Through the activation of nuclear factor- κ B (NF- κ B), TNF- α induces the expression of various genes such as urokinase plasminogen activator, cyclooxygenase II (COX II) and vascular endothelial growth factor (VEGF)^[26]. By this method, TNF- α has multiple biological effects such as increasing leukocyte recruitment (induction of leukocyte adhesion molecules)^[27,28], modulation of nitric oxide (NO) production (increasing the vascular permeability)^[29,30], induction of secretion of proinflammatory cytokines^[31], and the proliferation and differentiation of immune cells^[26]. *TNFSF15* encodes TNF-like factor 1A (TL1A), which is a TNF-like molecule that mediates co-stimulation of Th1 and Th17 cells. It is required for optimal differentiation of

Th17 cells^[21,32]. Variants in the *TNFSF15* gene contribute to overall CD susceptibility^[33,34] and an increased production of TL1A has been observed in CD^[35]. Interestingly, in mice, colitis was prevented and attenuated by an anti-TL1A antibody^[36].

Results of clinical trials (Table 1): Three anti-TNF agents, namely infliximab, adalimumab and certolizumab pegol have been approved by the US Food and Drug Administration for the treatment of luminal CD. In Europe, certolizumab has not yet received approval for IBD. Infliximab has also been approved for fistulizing CD and UC. In luminal CD, infliximab was effective in inducing clinical remission in 33% of patients compared with only 4% of a placebo group at week 4 ($P = 0.005$)^[37], and in maintaining clinical remission (45% in the infliximab group *vs* 21% in the placebo group, $P < 0.005$). Adalimumab was also significantly more effective than placebo in inducing clinical remission (36% *vs* 12%, $P < 0.001$)^[38], and more effective than placebo in maintaining clinical remission at week 56 (36% *vs* 16%). Infliximab and adalimumab have also been shown to be more effective than placebo in maintaining steroid-free remission at 1 year^[39,40]. Regarding certolizumab pegol, results from large randomized, placebo-controlled trials are more controversial, with no improvement at week 6 and different long-term response rates between trials^[41,42]. In fistulizing CD, 55% of the patients who received 5 mg/kg infliximab had complete fistula closure, as compared with only 13% of the patients assigned to placebo ($P = 0.001$)^[43]. In UC, 2 large randomized, placebo-controlled studies, namely the ACT 1 and ACT 2 trials, evaluated the efficacy of infliximab for induction and maintenance therapy in UC^[44]. In both trials, at week 8, nearly two-thirds of patients in the group receiving 5 mg of infliximab had had a clinical response, as compared with one-third of patients in the placebo group ($P < 0.001$).

Regarding the safety of anti-TNF agents, the Crohn's Therapy, Resource, Evaluation, and Assessment Tool registry, including 3179 CD patients who received infliximab, demonstrated that this agent was not an independent predictive factor of serious infections^[45]. In a meta-analysis of 21 placebo-controlled trials enrolling 5356 individuals, anti-TNF therapy did not increase the risk of death, malignancy or serious infection when compared to control arms^[9]. However, a longer duration of follow-up and a larger number of patients are required to better assess the safety profile of anti-TNF agents in CD.

Mechanisms of action of anti-TNF- α agents remain poorly known. Neutralization of TNF- α in the inflamed mucosa is unlikely to be a sufficient explanation. Antibody-dependent cytotoxicity also induces apoptosis or lysis of TNF- α -producing cells. This mechanism involves the Fc portion of antibodies that increases the pro-apoptotic factor caspase-3^[46].

IL-12, p40/IL-23, p40

Mechanisms of action (Figure 2): IL-12 is a key cytokine that drives the inflammatory response mediated by Th1 cells^[47,48]. As such, it underlies both normal host responses to a variety of intracellular bacterial, fungal and protozoan pathogens, and abnormal inflammatory responses linked to many autoimmune diseases, such as CD^[49]. Indeed CD is characterized by increased production of IL-12 by antigen-presenting cells in intestinal tissue^[50,51]. IL-23, secreted by antigen-presenting cells, is also a central cytokine involved in the differentiation and function of Th17 cells^[2]. The IL-23-Th17 interaction mediates microbial defenses and intestinal inflammation^[52,53]. Individual properties of IL-23 are also underscored by identification of the gene encoding the receptor for this cytokine as modifying host susceptibility^[8,54,55]. These 2 most potent Th1- and Th17-activating cytokines, IL-12 and IL-23 are both composed of a p40 subunit and therefore, a p40 antibody may have therapeutic potential in inhibiting both Th1-activating IL-12 and Th17-activating IL-23^[21].

Results of clinical trials (Figure 2 and Table 2): IL-12 and IL-23 are targeted by one humanized IL-12/23 antibody, ABT-874. It has shown promising results in a phase II dose-ranging study comprising 79 patients with CD^[49]. Seven weeks of uninterrupted treatment with 3 mg/kg ABT-874 resulted in higher response rates than placebo (75% *vs* 25%, $P = 0.03$). Another dose-ranging study comparing efficacy, safety and pharmacokinetic of intravenous infusions of ABT-874 *vs* placebo in subjects with active CD is ongoing. A double-blind, placebo-controlled, parallel-group, crossover study, assessing ustekinumab in 104 patients with CD has been completed^[56]. The clinical response to ustekinumab was significantly greater than the group given placebo at weeks 4 and 6 (52%-54% *vs* 22%-39%, $P < 0.05$) but not at week 8 (49% *vs* 40%, $P = 0.34$). Interestingly, the effect was most prominent in patients treated previously with infliximab at weeks 4, 6 and 8 (59% in the ustekinumab group *vs* 25%-26% in the placebo group, $P < 0.05$). A phase 2, randomized,

double-blinded, placebo-controlled study has evaluated the efficacy of apilimod mesylate, an oral IL-12 and IL-23 inhibitor in treating 220 patients with moderate-to-severe CD. The enrollment was closed early because it did not demonstrate efficacy over placebo^[57].

IL-6

Mechanisms of action: IL-6 is produced by various cells such as T cells, B cells, monocytes, fibroblasts, osteoblasts, keratinocytes, endothelial cells, mesangial cells and some tumor cells^[58]. This cytokine specifically binds to the IL-6 receptor (IL-6R) or a soluble IL-6R, forming the IL-6/IL-6R complex that binds to gp130 and activates intracellular pathways including JAK/STAT signaling, tyrosine phosphatase SHP2 and NF- κ B^[59]. Many cells express gp130, hence IL-6 is a pleiotropic multi-functional cytokine acting as both a proinflammatory and an antiinflammatory cytokine^[12,59]. It is involved in terminal differentiation of B cells, differentiation and activation of T cells, induction of a hepatic acute-phase response, hematopoiesis and fever^[60,61]. Thus activated IL-6 plays a major role in its own amplification and then in the chronic phase of inflammation helped by mononuclear cell accumulation at the site

of injury, through continuous monocyte chemoattractant protein-1 secretion, angioproliferation and antiapoptotic functions of T cells^[59,62]. Plasma soluble IL-6R is increased in patient with CD and IL-6 plasma concentrations increase in active CD^[63].

Results of clinical trials (Table 2): Tocilizumab binds to both the membrane-bound and the soluble forms of human IL-6R with high affinity and specificity^[3,64]. Tocilizumab has shown promising results in a small phase I / II study ($n = 36$) that met its primary endpoint. At 12 wk, the response rate was higher in patients given an 8 mg/kg infusion of tocilizumab every 2 wk than in those given placebo (80% *vs* 31%, $P = 0.019$) and is accompanied by a decrease in C-reactive protein concentration^[3,64]. However, only 2 of 10 patients went into remission, compared with none of 13 in the placebo group ($P = 0.092$), without significant improvement in mucosal healing^[3,64]. Improvement in disease activity in a patient with UC associated with Takayasu arteritis has been reported after treatment with tocilizumab^[65]. A placebo-controlled phase I study on the safety and biological effects of c326, an inhibitor of IL-6, in CD is ongoing.

IFN- γ

Mechanisms of action: Type II INF, also called IFN- γ , is a proinflammatory cytokine secreted by Th1-cells^[66]. IFN- γ drives expression of major histocompatibility complex class II on antigen-presenting cells, modulates lipopolysaccharide responsiveness in intestinal epithelial cells, and increases chemokine secretion. It also activates macrophages, Th1 lymphocytes in a positive feedback loop, NK cells and endothelial cells^[12,66,67]. Concentrations of IFN- γ are increased both in UC and CD.

Results of clinical trials (Table 2): Fontolizumab has been assessed in 3 phase I / II dose-ranging studies enrolling a total of 374 patients with moderate to severe CD^[68-70]. Fontolizumab at doses of up to 4 mg/kg improved endoscopic lesions and decreased concentrations of C-reactive protein^[68-70], but no study met its primary endpoint, which was defined as induction of clinical response at 1 mo^[68-70]; thus the development of fontolizumab for CD has been stopped^[3].

IL-2 family

Mechanisms of action: IL-2 is produced mainly by activated T cells^[71]. In addition to promoting T cell proliferation and activation, IL-2 increases cytokine production and modifies the functional properties of B cells, NK cells, and macrophages. Thus, it improves the activated macrophage microbicidal and cytotoxic activities and promotes secretion of hydrogen peroxide, TNF- α and IL-6^[72]. IL-2 signals through a heterodimeric ($\alpha\gamma$) or trimeric $\alpha\beta\gamma$ high-affinity receptor complex^[72]. Studies have proved a role for IL-2 in IBD pathogenesis, for example the calcineurin inhibitor cyclosporin, which inhibits IL-2 production, is effective in the treatment of severely active UC^[73]. IL-21, an IL-2 cytokine family member expressed by activated CD4+ T cells and NK T cells, is a key regulator in production of Th17 cells. It also increases the proliferation of Th1 cells, CD4+ and CD8+ lymphocytes and regulates the profile of cytokines secreted by these cells^[19,74]. Indeed, IL-21-deficient mice are protected from experimental colitis, possibly through the failure to generate the Th17 response^[75]. Furthermore, blockade of endogenous IL-21, with an antagonistic IL-21R/Fc, ameliorated dextran sulphate sodium colitis in mice^[75]. No studies have been performed in humans as yet.

Results of clinical trials (Table 2): Two antibodies against the α -chain of the IL-2 receptor (CD25), namely daclizumab and basiliximab, have been studied to mimic the activity of cyclosporine^[76-78]. Despite promising response rates observed in an uncontrolled trial, a randomized, double-blind, placebo-controlled, dose-ranging trial failed to demonstrate an increased remission or clinical response both at high (2 mg/kg intravenously at weeks 0, 2, 4, and 6) and low doses (1 mg/kg intravenously at weeks 0 and 4) in 159 treated patients with daclizumab for active UC^[79].

ANTIINFLAMMATORY CYTOKINES**IL-10**

Mechanisms of action: IL-10 is secreted by a wide variety of cells and has pleiotropic effects on T cells, B cells, myeloid cells, and other cell types^[80]. IL-10 has suppressive antiinflammatory activity on T cells, macrophages, and dendritic cells (among other cells) in humans, as well as in animal models of inflammatory diseases^[80]. In particular, mice deficient in IL-10 or the IL-10 receptor undergo spontaneous development of intestinal inflammation, similar to human disease^[81,82]. Even though IL-10 effectively treats colitis in mouse models and suppresses inflammatory cytokine production *in vitro* in intestinal cells from IBD patients^[83], unfortunately clinical trials using recombinant IL-10 to treat IBD in humans have been largely disappointing^[84].

Results of clinical trials: A placebo-controlled study was conducted in 329 patients with moderate-to-severe CD and in 94 patients with UC and did not demonstrate any significant improvement in response and remission rates compared to placebo^[85,86]. Also, no evidence of prevention of endoscopic recurrence in CD by subcutaneous IL-10 injections was observed in a placebo-controlled trial of 65 CD patients^[87]. Animal studies showed that local administration of IL-10 to the colon *via* genetically engineered *Lactococcus lactis* bacteria administered orally allowed for the achievement of high colonic mucosal concentrations of IL-10, potentially resulting in increased efficacy^[12,88].

IL-11

Mechanisms of action: IL-11 is a pleiotropic cytokine from mesenchymal cell origin^[89]. It exhibits potent antiinflammatory activity on macrophages and T cells by inhibiting the secretion of pro-inflammatory cytokines^[90-92] and has shown beneficial effects on intestinal mucosa in several animal IBD models^[89,90]. However one study suggested that the expression of the IL-11 receptor α -chain in the mucosa was restricted to epithelial cells, and although reducing apoptosis, it had no antiinflammatory effects on these cells^[93].

Results of clinical trials: In a placebo-controlled study in 76 active CD patients, subcutaneously administered recombinant human IL-11 was shown to be safe and well tolerated^[94]. In a second placebo-controlled study in 148 patients comparing 2 doses of subcutaneously administered recombinant human IL-11, it was significantly superior in inducing remission after 6 wk when compared to placebo^[95]. In contrast, a recent trial showed significant inferiority of recombinant human IL-11 when compared to prednisolone in inducing remission in active CD and in obtaining a clinical response^[90].

Type I IFNs

Mechanisms of action: Type I IFNs consist of 14 α

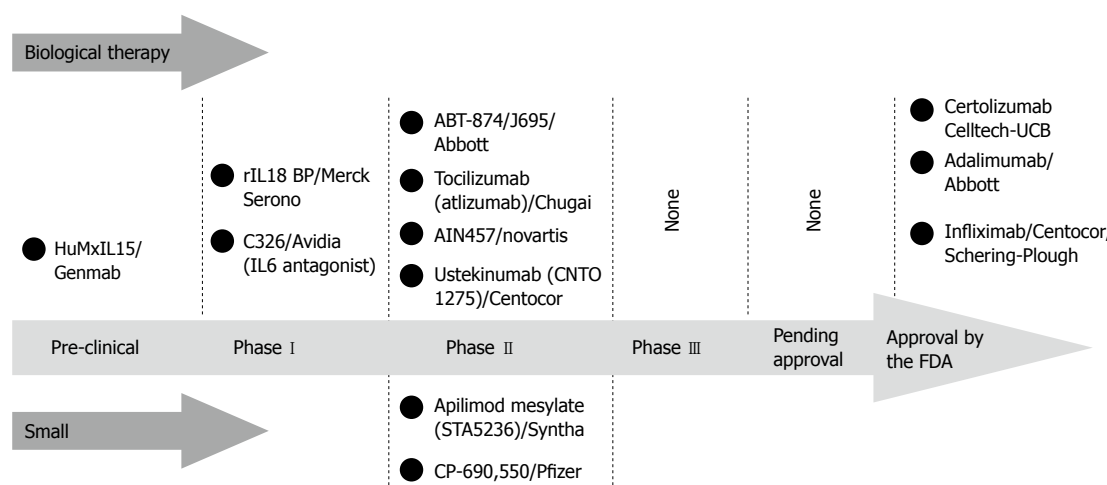

Figure 3 Cytokine therapies and inflammatory bowel disease: pipeline compounds.

isoforms and β , ϵ , ω , and κ isoforms^[66]. Immunoregulatory therapy with type I IFNs such as IFN- α or IFN- β can inhibit production of TNF- α and IFN- γ , antagonize the IFN- γ signaling pathway and increase production of the antiinflammatory cytokine IL-10. It has also been shown to be immunoregulated by enhanced regulatory T lymphocyte and NK cell activity^[66].

Results of clinical trials: Several type I IFNs have been studied in UC. A phase 2 placebo-controlled, dose-ranging trial, studied IFN- β 1a in 194 patients with moderately active UC. Clinical outcomes, including the proportion of patients achieving endoscopically confirmed remission, were not statistically significantly superior in the IFN- β 1a treatment groups over placebo^[96]. A randomized, placebo-controlled trial of pegylated IFN- α in 60 patients with active UC did not show any efficacy in clinical response and response rate despite a significant decrease in levels of C reactive protein^[97].

WHERE DO WE GO FROM HERE?

In 2010, infliximab represents the pinnacle of the therapeutic pyramid of IBD treatment. However, this anti-TNF agent has several limitations. First, despite its widespread use in IBD, 20% of patients still require surgery^[98]. Second, about 10% of patients are primary non-responders to infliximab and only one-third of IBD patients are in clinical remission at 1 year^[9,98]. Third, the annual risk of loss of response is 13% per patient-year^[99]. Finally, infliximab treatment optimization with combination therapy can be considered, but this must be weighed against the increased risk of serious infections and perhaps lymphoma. These data underscore the urgent need to develop new drug classes.

Humanized IL-12/23 antibodies seem the most promising therapy for the future: (1) IL-23 is an essential mediator for the differentiation and amplification of the proinflammatory Th17 pathway; (2) its role is underscored by the increased host susceptibility for IBD in cases of polymorphism of the gene encoding the receptor for this

cytokine; and (3) the effective results observed in a recent randomized, controlled trial, particularly in cases of infliximab withdrawal. Phase III trials are ongoing in IBD patients.

Recent advances in the pathophysiology of IBD have led to the identification of additional cytokine pathways representing potential therapeutic targets. Numerous other cytokines are currently under investigation: IL-27, produced mainly by dendritic cells, acting in the differentiation of both Th1 and Th2 cells; IL-32, produced by NK cell-activated lymphocytes and epithelial cells, providing a proinflammatory amplification pathway in the innate immune responses to bacteria^[7]; IL-31, preferentially produced by T cells skewed towards a Th2 phenotype, playing a role in the acute phase of inflammation by maintaining proliferation of B and T cells^[6]. Further studies are needed to fully explore their different roles in human IBD, and their biological significance, to eventually determine the therapeutic implications (Figure 3).

To overcome anti-TNF therapy failure in IBD, one way would be to develop more targeted therapy^[100]. A humanized TNF receptor-1 specific antagonistic antibody for selective inhibition of TNF action has shown interesting results in animal experiments^[100]. Avimer proteins or nanobodies look promising, offering multiple advantages with a low immunogenicity, a high ligand affinity, a high specificity, oral bioavailability and a low cost^[101]. Another way would be to use cytokine therapy in association with other anti-cytokine agents. The efficacy of TNF- α antagonist agents alone reflects probably the pleiotropic effects of TNF- α ^[2]. An effective treatment strategy for patients might therefore involve the blockade of multiple cytokines in order to intervene in several pathways^[102]. Animal studies in rheumatoid arthritis showed that anti-CD4 therapy acts synergistically with anti-TNF- α in improving established collagen-induced arthritis^[103]. In IBD, a safety study suggested several positive trends in improving efficacy when natalizumab was added to infliximab treatment^[104]. Further investigations are necessary to better evaluate the cost-effectiveness and long-term safety profile of these associations.

CONCLUSION

Despite recent advances in the pathophysiology of IBD, leading to the identification and understanding of several cytokine pathways, anti-TNF- α agents still represent the pinnacle of the therapeutic pyramid of IBD treatment. The humanized IL-12/23 antibodies appear to be the most promising therapy. Future directions could include the development of more targeted therapy or therapeutic blockade of multiple cytokines in order to intervene in several pathways.

Abstract

Inflammatory bowel disease (IBD) arises from disruption of immune tolerance to the gut commensal microbiota, leading to chronic intestinal inflammation and mucosal damage in genetically predisposed hosts. In healthy individuals the intestinal microbiota have a symbiotic relationship with the host organism and possess important and unique functions, including a metabolic function (i.e. digestion of dietary compounds and xenobiotics, fermentation of undigestible carbohydrates with production of short chain fatty acids), a mucosal barrier function (i.e. by inhibiting pathogen invasion and strengthening epithelial barrier integrity), and an immune modulatory function (i.e. mucosal immune system priming and maintenance of intestinal epithelium homeostasis). A fine balance regulates the mechanism that allows co-existence of mammals with their commensal bacteria. In IBD this mechanism of immune tolerance is impaired because of several potential causative factors. The gut microbiota composition and activity of IBD patients are abnormal, with a decreased prevalence of dominant members of the human commensal microbiota (i.e. *Clostridium* IXa and IV groups, *Bacteroides*, bifidobacteria) and a concomitant increase in detrimental bacteria (i.e. sulphate-reducing bacteria, *Escherichia coli*). The observed dysbiosis is concomitant with defective

innate immunity and bacterial killing (i.e. reduced mucosal defensins and IgA, malfunctioning phagocytosis) and overaggressive adaptive immune response (due to ineffective regulatory T cells and antigen presenting cells), which are considered the basis of IBD pathogenesis. However, we still do not know how the interplay between these parameters causes the disease. Studies looking at gut microbial composition, epithelial integrity and mucosal immune markers in genotyped IBD populations are therefore warranted to shed light on this obscure pathogenesis.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic, relapsing inflammatory disorder affecting the gastrointestinal tract which involves an imbalanced host-commensal microbiota interaction. Crohn's disease (CD) and ulcerative colitis (UC) are commonly included in the collec-

tive term IBD, although the two diseases present with distinct pathogenesis, symptomatology, inflammatory profiles and gut microbiota composition. Inflammation associated with CD is discontinuous, may extend deeply into the submucosal regions and occurs anywhere along the alimentary canal. In UC, inflammation involves only the superficial layers of the intestinal mucosa and is localised to regions of the gut most highly colonized by bacteria, starting at the distal colon and moving proximally along the large bowel^[1]. CD is predominantly associated with a type 1 helper-T-cell (Th1) and type 17 helper-T-cell (Th17) immune responses, characterized by increased production of interleukin (IL)-12, IL-23, IL-27, interferon- γ (IFN- γ) and tumor necrosis factor (TNF)- α . Diversely, UC seems to be associated with a type 2 helper-T cell (Th2) immune response, mainly leading to raised levels of IL-5 and transforming growth factor- β (TGF- β)^[2]. The etiology of IBD is complex and multifactorial, where environmental, genetic and immunological components appear to play a role^[3].

A consistent body of evidence implicates the gut microbiota in the pathogenesis of IBD, including the consideration that inflammation mainly occurs in the intestinal sites with the highest bacterial concentration (in UC), that antibiotic treatment often results in amelioration of disease symptoms^[4], and that germ-free mice do not spontaneously initiate colitis^[5]. The most extensively investigated hypothesis is that IBD development might be due to an altered immune response and a disrupted mechanism of host tolerance to the non-pathogenic resident microbiota, leading to an elevated inflammatory response.

THE HUMAN INTESTINAL MICROBIOTA

The adult human gut contains around 10^{14} bacterial cells and up to an estimated 1000 different bacterial species, thus constituting the largest microbial community associated with the human body^[6]. Recent studies using culture-independent molecular microbiological techniques have shown that the most abundant bacterial phyla found in the healthy human large intestine are the Gram-negative *Bacteroidetes* and the Gram-positive, low GC% *Firmicutes*^[6,7]. *Proteobacteria*, *Actinobacteria*, *Fusobacteria* and *Verrucomicrobia* phyla are relatively less abundant, but nonetheless are known to play important roles in human health^[6]. The same studies have described the vast diversity of bacterial species and identified the dominant bacterial groups to be *Clostridium coccoides* (*C. coccoides*)-*Eubacterium rectale*, *Clostridium leptum* (*C. leptum*), *Bacteroides-Prevotella*, *Bifidobacterium* species and *Atopobium* species^[8]. The gut microbial species composition varies greatly between individuals, with each individual harboring a unique collection of bacterial species, which is highly stable over time^[9]. Zoetendal *et al.*^[10] also showed that the gut microbiota composition of spouses, who were living in the same environment and had similar eating habits, showed the least degree of species similarity, while siblings showed increased similarity in species make-up. Interestingly, the gut microbiota profiles of identical twins showed a high degree of similarity, but

were yet distinct. These findings highlight that genetic factors play an important role in gut microbiota development, although environment also drives species acquisition. Studies have shown that the vast majority of intestinal bacteria are novel, new to science and so far resist cultivation using traditional culture techniques, necessitating the use of culture-independent molecular microbiology techniques, such as 16S rRNA gene probing and polymerase chain reaction (PCR)-based strategies.

Recently, the human body together with its gut microbiota has been referred to as a “superorganism” comprised of human and bacterial genes^[11]. It has been estimated that the human gut microbiome consists of 100 times more genes than the human genome. Therefore, the presence of the intestinal microbiota enriches the human organism with important functions, especially functions involved in deriving energy from nutrients which escape digestion in the upper gut and the metabolism of xenobiotics. The gut microbiota acts as a “metabolic organ”, through breakdown of complex indigestible dietary carbohydrates and proteins, with consequent generation of fermentation end-products (short chain fatty acids, ethanol and gas) and also through production of vitamins, ion absorption and conversion of dietary polyphenolic compounds into their active form^[12,13]. The commensal microbiota contribute to the “barrier effect”, which constitutes a real obstacle to pathogen invasion of the intestinal mucosa. Recent studies have shown that a modulation of the gut microbiota through dietary supplementation with a prebiotic (i.e. oligofructose) increases epithelial barrier integrity by increasing the expression of tight junctions proteins (i.e. ZO-1 and occludin), with a mechanism that is dependent on the augmented secretion of the GLP-2 gut hormone^[14]. The immune regulatory function of the intestinal microbiota consists of priming the mucosal immune system and maintenance of intestinal epithelium homeostasis. Studies in germ-free animals have demonstrated that the normal functioning of intestinal epithelial cells (IEC) and of the underlying immune cells are impaired in the absence of the gut microbiota. IEC expression of microbial recognition receptors, defensins and antimicrobial peptides are reduced in germ-free animals^[15,16]. Defective development of gut-associated lymphoid tissues, antibody production (i.e. sIgA) and maturation of isolated lymphoid follicles have also been shown in germ-free animals, together with reduced Peyer’s patches and mesenteric lymph node number and dimension^[17,18].

IMMUNE TOLERANCE TO THE COMMENSAL MICROBIOTA

In health, finely balanced mechanisms regulate the host’s immunological tolerance to the continuous stimulus of the resident gut microbiota and their metabolic end-products. Microbial recognition by antigen presenting cells (i.e. dendritic cells, DC) and epithelial cells is mainly carried out through sensing of conserved microbial-associated molecular patterns (MAMPs) by toll-like receptors (TLR), capable of detecting a variety of bacterial components, such

as lipopolysaccharide (LPS), lipoproteins, CpG DNA^[19], and by nucleotide-binding oligomerisation domain (NOD)-like receptors (NLR), which recognise peptidoglycan molecules on the bacterial cell wall^[20]. In healthy hosts the pro-inflammatory pathways associated with TLR and NLR are suppressed by inhibitory molecules of both human and bacterial origin [i.e. cyclooxygenase-2 (COX-2) inhibitors; LPS; A20; peroxisome proliferator-activated receptor- γ (PPAR- γ); nuclear factor- κ B (NF- κ B) inhibitor I κ B- α ; interferon- α/β (IFN- α/β); interleukin-10 (IL-10); TGF- β ; eicosanoids]^[21,22]. Activated innate immune cells, such as mucosal DC, constantly sample luminal microbial antigens and present them to adaptive immune cells. Recent studies have shown that the intestine is home to specialised DC, whose function it is to induce a highly tolerogenic response from T and B cells, through induction of regulatory T cells (Treg) and secretion of IgA, respectively^[23,24]. Commensal bacteria actively coordinate the host tolerogenic response, either through DC-mediated conversion of naïve T cells into Treg, or through direct ligation of TLRs on the surface of Treg. Certain resident bacterial populations, often referred to as “beneficial bacteria” (i.e. lactobacilli and bifidobacteria) can influence DC differentiation towards a more undifferentiated and monocyte-like phenotype, which may account for DC immune tolerance^[25]. Moreover, incubation of monocyte-derived DC with probiotic bacteria was shown to induce DC maturation and cytokine secretion, with strain-specific cytokine secretory profiles^[26]. Repetitive TLR stimulation due to commensal bacterial exposure induces down-regulation of the NF- κ B pathway and stimulates production of antimicrobial peptides (i.e. defensins)^[27]. Also, chronic NOD-2 stimulation has been demonstrated to lead to down-regulation of pro-inflammatory cytokines (TNF- α , IL-8, IL-1 β) in primary human monocyte-derived macrophages after pre-treatment with muramyl dipeptide (MDP) and re-stimulation with NOD-2, TLR-2 and TLR-4 ligands^[28]. Therefore, the host’s mechanism of tolerance to the resident microbiota offers, at the same time, protection from unwanted inflammatory responses and from pathogen invasion. Microbial ligands have also been shown to modulate the expression levels of miR-155, a miRNA that is involved in immune homeostasis and whose absence causes a reduction in Treg numbers in miR-155-deficient mice^[29]. However, since commensal and pathogenic bacteria possess many common motifs that are immunologically recognised by the host, how the host can tolerate resident bacteria whilst being able to mount an effective inflammatory response to invading pathogens is still not fully understood. Nonetheless, pathogenic bacteria do differentiate themselves from commensals by their behaviour; breaching the intestinal epithelial barrier and, in healthy individuals, eliciting strong inflammatory reactions when they trigger MAMPs basolaterally on epithelial cells^[30].

In IBD, the homeostatic mechanisms that allow co-existence of the host organism and the commensal microbiota are disrupted. Polymorphisms in TLR (*TLR4* D299G associated with CD and UC; *TLR1* L80P and *TLR2* R753G, associated with pancolitis) and NLR (i.e.

three mutations in *NOD 2/CARD15* gene, *Arg702Trp*, *Gly908Arg*, and a frameshift deletion mutation at *Leu1007*, accounting for about 80% of all CD-associated mutations) have been implicated in increased susceptibility to IBD^[19,31-33]. However, not everyone who carries these mutations develops IBD, indicating that other etiologic mechanisms might underlie IBD pathogenesis.

INTESTINAL MICROBIOTA IN IBD

Evidence from several recent studies has highlighted that gut microbiota composition and activity in IBD patients are abnormal. In particular, several studies have demonstrated that IBD patients are characterized by a reduced abundance of dominant members of the gut microbiota. Through a combination of PCR of total bacterial genomic DNA with universal bacterial primers and clone sequencing of 16S rRNA genes, Frank *et al*^[34] showed that in mucosal biopsies taken from CD and UC patients there was reduced abundance of rRNA sequences associated with *Firmicutes* and *Bacteroidetes*, and a concomitant increase in 16S rRNA sequences of *Proteobacteria* and *Actinobacteria*, compared to non-IBD controls. In particular, the decreased relative abundance of the *Firmicutes* phylum was due to decreases in populations of *Clostridium* IXa and IV groups. As a consequence of this dysbiosis, the relative abundance of *Enterobacteriaceae* was increased in IBD patients compared to healthy controls, although their absolute numbers remained unaltered. No differences were observed in fecal and mucosal bacterial population numbers between CD and UC patients. These findings are common to several other studies, which also observed decreased clostridia concentrations in IBD^[35,36], although not always accompanied by a decrease in *Bacteroides*^[34,37].

Aberrancies in *Bifidobacterium* populations in IBD have also been previously observed in another study, where significantly lower counts of bifidobacteria were found in rectal biopsies of patients with UC compared to patients without UC^[38]. By employing fluorescent *in situ* hybridization (FISH), Macfarlane *et al*^[38] showed that bacteria belonging to the *C. leptum* phylogenetic group were significantly less abundant in fecal samples of CD patients compared to healthy individuals. Moreover, through a metagenomic approach, the same authors reported a conspicuous loss of microbial diversity in CD, mainly due to a reduction of operational taxonomic units (OTU) within the *C. coccoides* group and the *C. leptum* group. A reduction in bacterial diversity was also previously observed by Ott *et al*^[39] after analysis of mucosa-associated microbiota of CD and UC patients through a combination of single strand conformation polymorphism (SSCP) fingerprint, cloning and real time PCR. Additionally, Zhang *et al*^[40] more recently showed that bacterial diversity of lactobacilli and *C. leptum* group as determined by denaturing gradient gel electrophoresis (DGGE) analysis was also lower in ulcerated tissues compared to the non-ulcerated tissues within the same UC individual. These results suggest that microbial alteration in IBD patients might be caused by the physiological state of the intestinal mucosa. How-

ever, little is known about how inflammatory mediators (e.g. pro-inflammatory cytokines and chemokines) on the gut wall affect bacterial populations *in vivo*. We do know, however, that altered microbial composition may impact on important physiological processes in the intestinal environment. *Clostridium* and *Bacteroides* species are the main producers of short chain fatty acids (SCFA) in the human colon. Decreased clostridia of groups IV and XIVa, the main butyrate-producing bacteria in the gut, could therefore explain the decreased SCFA concentrations found in fecal samples of IBD patients. Among the SCFA produced upon carbohydrate fermentation, butyrate serves as a major source of energy for colonic epithelial cells^[41] and as an inhibitor of pro-inflammatory cytokine expression in the intestinal mucosa, through a mechanism that involves hyperacetylation of histones and suppression of NF- κ B signaling^[42]. Moreover, butyrate reinforces the mucosal barrier by inducing production of mucin and antimicrobial peptides, and by strengthening epithelial barrier integrity through directly increasing the expression of tight junction proteins^[43]. A decrease of butyrate levels could therefore be involved in the increased inflammatory state characteristic of IBD, and butyrate is already considered to be of possible therapeutic value in treating IBD^[44-46]. Stimulation of butyric acid production could be achieved through repopulation of clostridial clusters IV and XIVa, or even through probiotic therapy with lactic acid bacteria, by increasing butyrate production through enhancement of carbohydrate fermentation (i.e. by supplementation with butyrogenic prebiotics such as inulin or oligofructose). Lactic acid can be employed as substrate for the production of high concentrations of butyrate by clostridial cluster XIVa, in a process also known as cross-feeding^[47]. *Faecalibacterium prausnitzii* (*F. prausnitzii*), a prevalent member of the human gut microbiota belonging to clostridial cluster IV and an important butyrate producer, has been recently shown to be less abundant in the intestinal microbiota of IBD patients^[48,49]. *In vitro* and *in vivo* animal studies have also demonstrated the anti-inflammatory and anti-colitic properties of supernatants from *F. prausnitzii* cultures in peripheral blood mononuclear cells or in mouse models of colitis, respectively^[48]. This effect appeared to be due to an as yet unidentified metabolite produced by the microorganism, but was shown to be independent of butyrate production.

Overgrowth of a class of microorganisms referred to as sulphate-reducing bacteria (SRB) was also previously observed in IBD gut microbiota in concomitance with a decrease in clostridia of groups IV and XIVa, especially in UC and pouchitis patients^[50]. SRB metabolize sulphate into hydrogen sulphide, which is toxic to colonocytes, blocks butyrate utilization, induces cell hyperproliferation, and inhibits phagocytosis and bacterial killing^[51]. It was previously demonstrated that the presence of intestinal microorganisms is necessary for induction of dextran sodium sulphate (DSS) colitis in animal models, thus emphasizing the possible role of SRB in IBD, through their reduction of sulphate in DSS into the cytotoxic and inflammatory trigger molecule H₂S^[52]. SRB numbers or their metabolic activity were found to be significantly

higher in studies comparing UC patients to controls or to UC patients in remission^[53-55].

In the search for a putative microbial cause of IBD, the theory of bacterial pathogen-induced intestinal inflammation has also been put forward. A wide range of microorganisms have been suggested as etiologic agents of IBD, including mycobacteria, *Listeria monocytogenes* (*L. monocytogenes*), *Chlamydia*, *Enterobacteriaceae* [including strains of *Escherichia coli* (*E. coli*) and *Helicobacter*] and also reoviruses and paramyxovirus^[56-58]. However, when considering the diversity of IBD lesions and disease course, and the fact that no single pathogenic agent can routinely be isolated from diseased tissue, there is no conclusive evidence that a single pathogen is the cause of the disease. Among the *Enterobacteriaceae* genus, *E. coli* is the bacterium most commonly related to IBD. It was observed that IBD patients harbor increased *Enterobacteriaceae*, in particular *E. coli* belonging to the B2+D group (i.e. with increased virulent potential), compared to controls^[59]. Adherent invasive *E. coli* was commonly found in ileal CD patients, particularly associated with ileal mucosal lesions^[60,61]. On the other hand, *E. coli* isolated from UC patients was less invasive compared to CD^[62]. *Mycobacterium avium* subspecies *paratuberculosis* (MAP) is an obligate intracellular pathogen that causes spontaneous granulomatous enterocolitis in cattle by evading phagocytosis. Therefore, MAP infection would be favored in those individuals with defective innate immunological defenses, such as CD patients. MAP presence was found with significantly higher frequency in CD patients compared to non-IBD controls, but not in all individuals^[63]. No significant correspondence was found between CD-associated *NOD-2* polymorphisms, especially in ileal CD, and MAP infection^[64,65]. Moreover, clinical studies failed to demonstrate the efficacy of antimycobacterium triple antibiotic therapy in inducing persistent response in CD patients^[66]. Detection of MAP by molecular techniques (i.e. detection of insertion element-900 (IS-900) by PCR) has the limitation of picking up environmental mycobacteria and presents high variability among laboratories^[67-69]. Hence, the etiologic role of MAP in IBD pathogenesis remains to be demonstrated.

Therefore, microbial dysbiosis consisting of a decrease in beneficial bacteria and their metabolic end-products, together with an increase of detrimental bacterial populations and their toxic metabolites, might alter gut luminal environment; thus contributing to the pathogenesis of IBD.

COMPROMISED EPITHELIAL BARRIER FUNCTION, DEFECTIVE INNATE IMMUNE RESPONSE TO BACTERIA AND LOSS OF IMMUNOTOLERANCE

Efficient functioning of the gut mucosa is achieved by means of a combination of intact epithelial barrier and effective bacterial killing through secretion of antimicrobial peptides (e.g. defensins), secretory IgA and phagocytosis.

Figure 1 Suggested mechanism of inflammatory bowel disease pathogenesis. Intestinal dysbiosis in inflammatory bowel disease (IBD) consists of decreased prevalence of putative beneficial bacteria (e.g. bifidobacteria) and concomitant increase in detrimental bacterial (e.g. sulphate-reducing bacteria). This microbial imbalance causes reduced intraluminal levels of butyrate (because of decreased production through fermentation and decreased utilization due to increased H_2S levels), thus contributing to down-regulation of epithelial tight junction protein expression and increased epithelial permeability. Epithelial barrier dysfunction brings about increased bacterial translocation through the lamina propria, which is worsened by decreased luminal IgA and defensin concentrations. Killing of bacteria reaching the lamina propria through the "leaky" epithelium is also impaired by a genetically predisposed defective phagocytosis by macrophages. Ineffective bacterial clearance leads to excessive toll-like receptor (TLR) stimulation, secretion of pro-inflammatory cytokines and activation of innate and T-cell mediated immune responses. The disrupted mechanism of tolerance in epithelial cells and antigen presenting cells (APC) amplifies innate immune cell recruitment (i.e. neutrophils). Additionally, defective T-reg and APC cause excessive T-cell response (Th1 and Th17), with consequential intensification of the inflammatory response and granulomatous reaction. IL: Interleukin; IFN- γ : Interferon- γ ; TNF: Tumor necrosis factor; TGF- β : Transforming growth factor- β ; LPS: Lipopolysaccharide.

In IBD these mechanisms of mucosal defence are compromised at all levels and they all contribute to disease progression. A potential mechanism of pathogenesis of IBD is summarized in Figure 1. Disease arises from the initial epithelial barrier dysfunction that brings about increased bacterial translocation through the lamina propria, where microbial antigens elicit a strong inflammatory response, due to ectopic (i.e. basolateral) TLR stimulation, activation of the NF- κ B pathway and consequent induction of pro-inflammatory chemokine and cytokine secretion. This inflammatory process is aggravated by the decreased innate immune defense (i.e. reduced luminal defensin and IgA, defective phagocytosis in IBD), which amplifies the magnitude of bacterial translocation through the "leaky" epithelial layer. Disease progression mainly results from a more global defective immunoregulation and immunotolerance in response to the initial inflammatory insult, due to overaggressive T cell reaction, dysfunctional regulatory T cells and antigen presenting cells (APC) (Figure 1).

IBD, and especially CD, presents with a characteristic increased epithelial permeability, due to underexpression of certain tight junction proteins [e.g. claudins, junction adhesion molecule-A (JAM-A)] concomitant with up-regulation of other pore-forming proteins (i.e. claudin-2)^[70,71]. Defective bacterial clearance due to impaired defensin and IgA production contributes to increased bacterial translocation from the gut lumen across the lamina propria. α -Defensins (i.e. human defensin 5 and 6 (HD5 and HD6)) are antibactericidal compounds produced by Paneth cells efficacious against *Enterobacteriaceae* (e.g. *E. coli*, *Salmonella typhimurium*, *L. monocytogenes*) and *Bacteroides vulgatus*, and were found significantly reduced in association with ileal CD, in particular in patients with *NOD-2* mutations^[72,73]. On the other hand, colonic CD, but not UC, was observed to be associated with lower copy number of β -defensins 2 and 3, which are the main antimicrobial peptides found in the colon. This reduction in β -defensins was shown to be due to a chromosomal polymorphism,

since chromosome 8 presented with a lower copy number of β -defensin 2 in colonic CD^[74,75].

Microbial clearance can also be impaired because of reduced levels of protective secretory IgA (SIgA) in IBD. IgA constitutes the most abundant immunoglobulin phenotype present in the human body^[76]. In the gut, IgA is produced by lamina propria B cells, then translocates to the lumen by attaching to a basolateral receptor on epithelial cells, and finally is transported to the luminal surface of epithelial cells, where it forms SIgA clusters that elicit multiple roles in the intestinal lumen. Firstly, IgA in the mucus layer entraps bacteria and dietary antigens, down-regulates epitope expression on the bacterial cell surface and, therefore, regulates microbial intestinal colonization^[77-79]. Moreover, SIgA prevents pathogen attachment and invasion of epithelial cells and removes bacteria breaching the epithelial barrier by translocating them back to the lumen and by promoting their clearance by dendritic cells, neutrophils and phagocytes^[80-82]. In IBD, intestinal IgA is usually reduced and this is compensated for by increased secretion of IgG, which induces pro-inflammatory cytokine production and mounting of adaptive immune responses to the resident microbiota^[83]. Mucosal secretory IgG was found to be significantly higher in UC and CD patients compared to control patients with irritable bowel syndrome^[84]. In addition, the same study showed that both CD and UC patients presented with increased mucosal IgG bound to fecal bacterial cytoplasmic antigens compared to control patients with irritable bowel syndrome and to non-IBD controls with intestinal inflammation^[84].

Malfunctioning bacterial killing in IBD has also recently been linked to dysfunctional autophagy. Autophagy is a constitutive pathway of cellular homeostasis and organelle turnover. However, it has recently been demonstrated that autophagy plays a key role in innate and adaptive immunity. Macrophages use autophagy to capture and effectively kill intracellular and extracellular invading bacterial pathogens, including *Legionella*, *E. coli*, *Streptococcus* and *Mycobacterium* species, by fusion of the phagocytic compartment with the lysosome^[85,86]. Epithelial cells also employ autophagy to kill invading bacteria and the gene *ATG 16L1* has been shown to be necessary for starting the autophagic process against the cytoplasmic invasion of *Salmonella typhimurium*^[87]. Mutations in *ATG 16L1* have recently been associated with CD, thus implicating defective bacterial killing by autophagy in IBD^[87]. Autophagy impairment might also influence the adaptive immune response to bacteria, since autophagy is involved in major histocompatibility complex (MHC) class II loading in the lysosome, where the autophagic cytoplasmic content is also delivered^[88]. Therefore, a defect in the autophagy pathway could influence antigen presentation by APC, epithelial cells and immune surveillance. Finally, autophagy has been implicated in the regulation of T cell death and proliferation, and *ATG 16L1* is central to these autophagy-regulated processes^[89]. Alteration of *ATG 16L1* in CD might therefore, at least in part, explain the pathologic behaviour of T cells in IBD. In IBD the coexistence of compromised epithelial barrier and defective

innate immunity aggravates the impaired mechanism of tolerance to the resident microbiota and causes inflammatory granulomatous reaction (Figure 1). Defective interaction between regulatory T lymphocytes in the lamina propria and epithelial cells is central to the process of loss of tolerance, through a mechanism that involves NF- κ B signaling. Epithelial NF- κ B activation in healthy hosts is normally suppressed by anti-inflammatory cytokines produced by the underlying T lymphocytes, such as TGF- β and IL-10, while in IBD Th1- and Th17-type immune responses are predominant and lead to chronic inflammation and worsening of the epithelial layer damage^[90]. Perpetuation of the epithelial damage causes increased basolateral as opposed to physiological apical stimulation of TLR-9 receptors, thus causing activation, rather than blockade, of NF- κ B signaling^[30]. This leads to a vicious cycle of aberrant immune response, mucosal inflammation, altered microbiota composition and/or activity and increased mucosal permeability, which would explain the persistent and recurrent nature of IBD.

THERAPEUTIC IMPLICATIONS OF GUT MICROBIOTA-HUMAN HOST INTERACTION

The increasing understanding of the gut microbiota-host immune system interaction has recently drawn interest towards a modulation of intestinal bacterial communities as a novel potential adjuvant in IBD therapy. Although antibiotic therapy constitutes an established therapeutic tool for the treatment of specific IBD-associated symptoms (e.g. abscesses and fistulae), as well as a possible preventive measure, research studies that demonstrate antibiotic efficacy in IBD are still limited^[91]. Promising outcomes have been observed after gut microbiota modulation through probiotic, prebiotic and synbiotic supplementation in CD and UC to change IBD-associated dysbiosis. Treating CD patients with the probiotic strain *E. coli* Nissle 1917 has been shown to induce remission more rapidly than untreated control patients, although it did not influence the number of patients achieving remission^[92]. In UC, *E. coli* Nissle 1917 was proven as effective as mesalazine in maintaining remission^[93,94]. Maintenance of remission after probiotic supplementation was observed in a study with the yeast probiotic *Saccharomyces boulardii* (reduced percentage of relapses in probiotic + mesalamine-treated CD patients, compared to control mesalamine-treated CD patients), although the significance of the study is somewhat restricted because of the low number of subjects involved ($n = 32$)^[95,96]. Positive results were also observed in a double-blind, randomised controlled trial with *Bifidobacterium breve* and *Bifidobacterium bifidum* fermented milk supplementation in 20 UC subjects for 12 wk, where a significant decrease of clinical indices was observed compared to unsupplemented controls^[97]. The probiotic mixture VSL#3 showed convincing effects in the maintenance of remission in UC patients^[98-100], and it was later shown to prevent the onset of pouchitis^[101]. On the other

hand, the data with regard to VSL#3 supplementation in CD are still preliminary. VSL#3 supplementation did not result in a reduction in post-surgical relapse when administered to pediatric CD patients, compared to control mesalamine-treated patients^[102]. In general, it appears that this probiotic supplementation is more effective in reducing disease onset or recurrence, rather than diminishing active inflammatory symptoms.

Prebiotic supplementation with inulin was shown to improve clinical condition in pouchitis patients, and to increase tolerance (i.e. through decreased TLR-2 and TLR-4 expression on DC) and fecal bifidobacteria levels in CD patients^[103-105]. Synbiotics (i.e. a synergy of pro- and pre-biotics in a single preparation) also showed potential therapeutic effect, although the number of studies in IBD is still limited. Supplementation of the inulin-derived prebiotic, Synergy-1, together with *Bifidobacterium longum*, in 18 UC patients for 4 wk significantly decreased rectal pro-inflammatory cytokine levels and down-regulated the expression of inflammation-associated β -defensins^[106].

In summary, some evidence has already indicated a promising therapeutic effect of pro-, pre- and synbiotics in IBD. However, the studies are still very few, underpowered and their design and selection of active agent are sometimes less than optimal. Indeed, this topic deserves further investigation in studies using an adequate number of subjects and employing functional food products targeting the gut microbiota, that have been specifically selected for their anti-inflammatory properties from preliminary *in vitro* and animal studies.

CONCLUSION

Despite the observation that IBD is associated with an abnormal gut microbiota composition, the question as to whether the altered gut microbial dysbiosis is a cause of disease or a consequence of the inflammatory state of the intestinal environment still remains unanswered. Although several studies implicate the gut microbiota in IBD pathogenesis, so far no pathogenic/infectious microorganism has been identified as sole disease causing agent. It is more likely that microbial dysbiosis and lack of beneficial bacteria, together with genetically predisposed increased epithelial permeability, bacterial translocation into the lamina propria, defective innate immunity and loss of tolerance to the resident microbiota, may lead to the abnormal inflammatory response and granulomatous reaction characteristic of IBD. A modulation of the gut microbiota through pro-, pre- and synbiotics, specifically designed to reduce IBD-associated dysbiosis and inflammation, constitutes an interesting approach in the field of novel therapeutic approaches for IBD.

INTRODUCTION

So far, *in silico* mining of human genomic databases have identified or predicted more than one hundred defensin-related sequences^[1,2]. Based on their amino-acid sequences, these human peptides are divided into two categories, the α - and β -defensins (DEFA and DEFB, respectively). Although some defensins are not fully characterized, these molecules are cationic polypeptides smaller than 4 kDa. DEFA and DEFB possess six conserved cysteine residues that are linked in a 1-6, 2-4 and 3-5 pattern for DEFA and in a 1-5, 2-4 and 3-5 pattern for DEFB. Structural studies showed that the tertiary configuration of both DEFA and DEFB consist of triple-stranded β -sheet structures that are stabilized by three intramolecular disulfide bonds. DEFA and DEFB are stored within proteinaceous granules and are secreted through molecular mechanisms that still remain to be elucidated.

Of at least six human DEFA that are expressed within the gut mucosa, DEFA1-4, also referred to as Human Neutrophil Peptide 1 to 4, are predominantly secreted from azurophilic granules of polymorphonuclear leukocytes, while DEFA5 and DEFA6 are primarily contained in the apically-oriented secretory granules of Paneth cells.

Abstract

Antimicrobial peptides, including defensins, are essential effectors in host defence and in the maintenance of immune homeostasis. Clinical studies have linked the defective expression of both α - and β -defensin to the reduced killing of certain microorganisms by the intestinal mucosa of patients suffering from ileal and colonic Crohn's disease (CD), respectively. Only recently have the events leading to defective expression of defensins in CD been further elucidated, and are discussed herein. These events may account for CD-associated alterations in the microbiome and may subsequently precipitate the development of granulomatous inflammatory lesions in genetically-predisposed patients. We also address how these discoveries may pave the way for the development of a molecular medicine aimed at restoring gut barrier function in CD.

The latter is one of the four major epithelial cell lineages that reside at the base of the crypt of Lieberkühn in the small intestine. In addition to DEFA, only four human β -defensins (DEFB1 to DEFB4) have been studied in the past few decades. DEFB1 to DEFB4 are primarily expressed by epithelia of diverse gastrointestinal tissues, including stomach, small intestine and colon^[3].

Biologically-active defensins are released upon the proteolytic processing of their proforms by certain enzymes^[4], including trypsin for DEFA5 and DEFA6 in humans^[5] and matrilysin for cryptidins in mice^[6]. This suggests that appropriate control of homeostatic quantities of both defensins and defensin-activating proteases may ultimately dictate the outcome of the gut immunological response to intruding pathogens and to commensal microorganisms that are permanently present. Our understanding of the regulatory mechanisms that maintain appropriate expression of these antimicrobial factors, which are discharged within the intestinal lumen, is at an early stage. However, recent experimental and clinical findings, which are discussed hereafter, provide us with preliminary answers on how failure to maintain optimal defensin function may lead to dysbiosis and to the development of chronic inflammatory lesions.

THE ANTIMICROBIAL ACTIVITY OF DEFENSINS

The membrane integrity of a broad spectrum of microorganisms, including enveloped viruses, protozoa, bacteria and some fungi, is sensitive to the amphiphilic nature of defensins (Figure 1). Over the past decade, several models have been proposed to explain how defensin may induce non-oxidative killing of microorganisms. Notably, the Shai-Matsuzaki-Huang model provides a reasonable structure-function explanation for the antimicrobial character of defensins^[7], whereby the cationic property of these antimicrobial effectors may disrupt the phospholipid bilayer as a detergent. Defensins may promote the formation of micelles by electrostatic forces to negatively-charged components of the microbial membrane, including lipopolysaccharide from Gram negative bacteria and lipoteichoic acids from Gram positive bacteria. Conversely, the nosocomial Gram positive bacteria *Staphylococcus epidermidis* and *Staphylococcus aureus* are thought to repulse the killing activity of defensins by expressing a membrane-bound molecule with a high density of negative charge^[8] and by modifying its lipid membrane through Mprf^[9], respectively. Similarly, both the two-component system PhoP/PhoQ and lipopolysaccharide are involved in resistance to defensins in the facultative intracellular bacterium *Salmonella typhimurium* (*S. typhimurium*)^[10], providing a mechanism whereby certain pathogens may circumvent innate immune mechanisms. Additional investigations are now eagerly awaited to determine whether luminal secretion of certain defensins may influence immune homeostasis in any part of the gastrointestinal tract.

Genetically engineered mice that express the human DEFA5 showed oral resistance to salmonellosis^[11]. Con-

versely, matrilysin deficiency is linked to enhanced susceptibility to oral infection by *S. typhimurium*^[6]. Similarly, genetic ablation of the Crohn's disease (CD) predisposing NOD2 gene leads to reduced expression of certain cryptidins and to enhanced susceptibility to orogastric *Listeria monocytogenes* infection^[12]. More importantly, molecular analyses point to profound changes in the composition of the gut microbiome from DEFA5-transgenic mice^[13]. As a consequence, an abnormal T cell homeostasis, including fewer interleukin 17 (IL-17)-producing lamina propria T cells, and an overt resistance to colonization of the ileum by segmented filamentous bacteria were observed in DEFA5-transgenic mice^[13]. The gastrointestinal tract, in a large proportion of the human population, is colonized by Gram positive anaerobic segmented filamentous bacteria that are thought to regulate both Th17 differentiation^[14,15] and secretory immunoglobulin A production^[16,17]. Besides DEFA5, a physiological role for mouse β -defensin 1 (mDefB1) in host defence has been primarily unveiled in the pulmonary and urinary tract. Genetic ablation of mDefB1 expression failed to impede the outcome of lung infection by *Haemophilus influenzae*^[18], but also resulted in enhanced bacterial burden of *Staphylococcus* in the bladder when compared to controls^[19]. However, even if certain pathogenic microorganisms inhibit the secretion and/or killing activity of defensins^[20], the latter still provide partial protection against infection, suggesting another prophylactic role for these key elicitors of mammalian immunity.

THE IMMUNOREGULATORY FACET OF DEFENSINS

In essence, defensins are regarded as "natural antibiotics", but accumulating immunological investigations revealed that these long-held antimicrobial peptides may also educate the gut immune system through multiple mechanisms (Figure 1). Indeed, it has been known for some time that DEFA1 is not only involved in the attraction of monocytes to inflammatory sites^[21], but also of T cells and immature dendritic cells^[22]. Recent immunological investigations have now revealed that this phenomenon is not restricted to α -defensins. Notably, β -defensins were chemotactic for T cells^[23], dendritic cells^[23], monocytes^[24,25] and mast cells^[26]. Interestingly, the presence of a disulfide bridge was required for DEFB2 to recruit immunocytes through the C-C chemokine receptor 6^[27]. Besides their direct chemoattracting function, certain defensins may also contribute to the recruitment of immune cells by eliciting the expression of co-stimulatory molecules and secretion of a subset of cytokines and chemokines by a myriad of cell types through receptor-dependent mechanisms^[28]. Notably, DEFB2 and DEFB3 have been characterized as signalling ligands *per se* for some membrane-bound pathogen-recognition receptors, including the toll-like receptors 4 and 2, respectively^[29,30]. The expression of the co-stimulatory molecules CD80, CD86 and CD40 is consistently enhanced after exposure of monocytes and dendritic cells to recombinant DEFB3 in a MyD88-dependent manner^[29]. Likewise, treatment of immature

Figure 1 Model of defensin-mediated control of luminal microbiota and maintenance of immune homeostasis in the gut. PPAR: Peroxisome proliferator-activated receptor.

dendritic cells with exogenous recombinant DEFA1 and DEFB1 enhanced the expression of CD80, CD86, CD40, the maturation marker CD83, and HLA-DR^[31]. Moreover, both neutrophil-derived defensins and DEFB2 have been involved as positive regulators of neovascrogenesis and wound healing^[32-34], but our understanding of the underlying mechanisms still remains incomplete.

TOWARDS A CAUSAL LINK BETWEEN DEFENSINS AND CROHN'S DISEASE DEVELOPMENT

In recent years, defensins have been observed to be negative regulators of both infectious diseases and of chronic inflammatory diseases, including CD. As many as 4 million adults are affected by CD in Europe and North America, and there is no cure for this relapsing-remitting granulomatous illness. CD is traditionally characterized by the development of transmural inflammatory lesions that may affect any part of the bowel. The ileal and colonic mucosa of patients with CD show impaired antimicrobial activity against major components of the microbiota, which is not found in biopsies of healthy subjects or patients with ulcerative colitis, another inflammatory bowel disease^[35,36]. In a clinical study by Wehkamp and collaborators, decreased expression of both DEFA5 and DEFA6 was linked to the development of CD-associated lesions in the small intestine^[35,37]. More recently, decreased expression of DEFB1 was observed in CD patients with colonic involvement^[38]. While the transcript level of the neutrophil chemoattractant IL-8 is a surrogate marker of inflammation, it failed

to correlate with *DEFA5* and *DEFB1* transcript levels in Crohn's ileitis and colitis, respectively^[35,38]. Similarly, levels of DEFA5 and DEFB1 were not modulated by most current therapies for CD^[39]. Collectively, these findings reinforce the notion that decreased expression of defensins may result in excessive inflammation which is the basis of CD. Furthermore, consistent with the chemoattracting function of defensins, trauma to intestinal or cutaneous epithelia in CD patients is also associated with impaired neutrophil attraction when compared to controls^[40]. Decreased expression of defensins in CD may account for defective local microbial killing and for reduced attraction of immunocytes to mucosal breaches, but what causes the impaired expression of defensins?

To determine the mechanisms underlying the defect in defensins in ileal and colonic CD, the promoter of both DEFA5 and DEFB1 were screened for potential disease-associated variants. Genetic errors in a regulatory region downstream of the human *DEFA5* gene were found to predispose to ileal CD development^[41]. In the ileum, both NOD2 and the Wnt-signalling pathway transcription factor Tcf7l2 were characterized as positive regulatory molecules of DEFA5 expression in human and of certain cryptdins in mice^[12,35,42]. Notably, patients carrying the 1007fs NOD2 mutation and those with lowered expression of Tcf7l2 showed a significantly decreased transcript level of DEFA5^[43]. We recently showed in the colon, that engagement of the peroxisome proliferator-activated receptor peroxisome proliferator-activated receptor (PPAR)- γ with rosiglitazone triggered epithelial DEFB1 expression *in vitro* and *in vivo*^[38]. Dysregulated PPAR- γ production consistently results in reduced antimicrobial activity of the

mucosa against major components of the microbiota in mice^[38]. Furthermore, the single nucleotide polymorphism rs1800972, which is located within the promoter region of the human *DEFB1* gene, was also found to be protective towards colonic CD development^[38,44] and to positively regulate the expression of *DEFB1*^[45].

CONCLUSION

At present, the therapeutic management of CD is far from optimal. Approximately 25% of patients fail to respond to current biologics and/or to immunosuppressive drugs. Given the essential role of defensins in maintaining gut homeostasis, defensin deficiency requires to be corrected in CD. Recent experimental investigations provided preliminary answers to this problem by identifying the PPAR- γ agonist rosiglitazone as a potent inducer of a subset of β -defensin in mouse colon^[38], opening the way for the potential correction of gut barrier function in CD. The development of a mucosal-delivery system for PPAR- γ agonists is now eagerly awaited to improve their therapeutic efficacy, while avoiding potential systemic side effects. Finally, it is worth noting the regulatory role of additional nuclear receptors, including vitamin D and PPAR- β , in regulating the expression of other antimicrobial peptides, including certain defensins^[46-49]. The potential synergistic effects of these regulatory factors on the expression of intestinal defensins remains to be addressed. Drugs and diets which can modulate the expression of defensins may thereby protect against colitis and colitis-associated cancer by maintaining sufficient levels of these versatile antimicrobial peptides.

INTRODUCTION

The genome-wide association studies in recent years have contributed significantly to the understanding of the pathogenesis of inflammatory bowel disease (IBD)^[1]. The results obtained from these studies have not only confirmed the relevance of earlier characterized pathways, but equally have opened novel avenues. One possible hypothesis for the etiology of IBD is that the mucosal immune system is hyper-responsive to luminal antigens (e.g. dietary factors, commensal bacteria) in genetically predisposed individuals^[2]. This hypothesis is limited to the intestinal lumen and wall. Focusing on Crohn's disease, the inflammation is not restricted to the luminal side of the intestinal wall. Rather, transmural inflammation presents as the dominant phenotype, which leads to the question of whether extraintestinal/extraluminal structures contribute to the inflammatory process. In the present overview, three extraluminal structures are discussed, which have been demonstrated to play a role in the regulation of intestinal inflammation, namely the mesenteric fat tissue, microvasculature and lymphatics (Figure 1).

MESENTERIC FAT TISSUE

Historic view

Crohn BB himself provided the first evidence that the mesenteric fat tissue might play a role in the pathogen-

Abstract

Many identified and yet unknown factors contribute to the pathogenesis of inflammatory bowel disease (IBD). The genome-wide association studies clearly support the earlier developed concept that IBD occurs in genetically predisposed individuals who are exposed to distinct environmental factors, which together result in dysregulation of the mucosal immune system. Thus, the majority of previous studies have focused on the immune response within the intestinal wall. The present review aims to emphasize the contribution of three extraluminal structures to this inflammatory process, namely the mesenteric fat tissue, the lymphatics and the microvasculature. Broadening our view across the intestinal wall will not only facilitate our understanding of the disease, but will also us to identify future therapeutic targets.

esis of Crohn's disease, by describing local hypertrophy of the mesenteric fat adjacent to inflamed intestinal segments^[3]. This phenomenon, which is also called "creeping fat" or "fat wrapping" is restricted to Crohn's disease, and is not observed in ulcerative colitis or other forms of chronic intestinal inflammation.

Anatomical view

The characteristic "fat wrapping" seen only in Crohn's disease represents fat hypertrophy that results in partial cover of the intestinal circumference, which is defined as > 50% coverage of the intestinal surface by adipose tissue and occurs in both the large and small bowel. The localization of this "creeping fat" correlates with transmural inflammation, ulceration, and stricture formation^[3]. These observational results have been underlined by magnetic resonance imaging that quantified the amount of intra-abdominal fat in relation to total body fat, which indicates that the intra-abdominal fat but not total body fat increases^[4]. Adipocytes within this hypertrophied fat are significantly smaller, but a fourfold increase in the total number of adipocytes is present in the mesentery of Crohn's disease patients as compared to controls^[5]. How can we explain this observation and what might be the possible contribution to disease?

Adipocytes and chronic inflammation

Each lymph node in our body is in close proximity to adipose tissue. Once the lymph nodes are activated, the number of adipocytes increases, which allows for the supply of sufficient energy for a functional immune system^[6-8]. However, is the role of the mesenteric fat tissue restricted to energy supply? In the first studies to analyze the expression of pro-inflammatory mediators in fat tissue, an increase of tumor necrosis factor (TNF)- α and the adipokine leptin was demonstrated in the fat tissue of Crohn's disease patients, in comparison to non-inflammatory controls^[4]. In addition, adipocytes express C-reactive protein, and there is a significant correlation between serum C-reactive protein levels and increased mesenteric fat density in Crohn's disease^[9]. What is the relevance of these mediators released by the adipose tissue?

Adipokines

Various adipokines are released by adipose tissue. The relevance of adipokines in IBD has been summarized

recently in broad detail^[10]. The adipokines characterized best with regard to intestinal inflammation are leptin and adiponectin, respectively.

Leptin is a 16-kDa peptide predominantly produced by adipocytes, which signals the status of satiety to the hypothalamus^[11]. Leptin deficiency or non-function of the long isoform of the leptin receptor (OB-Rb) is associated with massive obesity in mice and humans. From a structural point of view, leptin can be classified as a helical cytokine^[12]. Thus, the structure of leptin suggests a regulatory function within the immune system. In humans, leptin deficiency is rare, but results in impaired T-cell proliferation and is associated with increased mortality in childhood due to infection^[13,14]. In mice, leptin deficiency has been associated with protection from dextran sodium sulfate (DSS)-, oxazolone- and trinitrobenzene sulfonic acid (TNBS)-induced colitis. In addition, results from the transfer model of colitis indicate that leptin serves as crucial T-cell stimulator in intestinal inflammation^[15-17]. In addition, leptin stimulates the proliferation of naive CD4⁺ T cells and affects T-cell polarization^[15,18,19]. In Crohn's disease, increased expression of leptin mRNA as well as protein in the hypertrophic mesenteric fat has been reported^[20,21]. Together with data from animal studies, a pro-inflammatory role for leptin in Crohn's disease has been suggested.

Adiponectin, a 30-kDa polypeptide, contributes 5-10 $\mu\text{g/mL}$ to 0.01% of plasma proteins, and hence is the most abundant adipokine in the circulation^[22]. Adiponectin has a high affinity to form trimers that can further multimerize to polymers, which results in various high and low molecular isoforms. The biological significance of the different high and low molecular forms is not finally understood. In Crohn's disease patients, adiponectin mRNA and protein release is upregulated in hypertrophied adipose tissue, as compared to normal adipose tissue from the same subjects, or mesenteric adipose tissue from ulcerative colitis patients and controls^[23]. Data concerning the effects on disease severity in experimental models of colitis are conflicting. Whereas one group has observed increased susceptibility to the chemically induced model of DSS colitis^[24], another has reported protection against DSS- as well as TNBS-induced colitis in adiponectin-deficient mice^[25]. To confuse the issue even more, a third study has reported that adiponectin deficiency does not affect the outcome of disease in interleukin (IL)-10-deficient mice that develop colitis spontaneously^[26]. In the model of chronic TNBS-induced colitis in rats, the size of mesenteric adipocytes is decreased, and production of adiponectin, besides other mediators, is increased in perinodal mesenteric fat^[27]. As a result of the conflicting effects mediated by adiponectin on immune cells, both pro- and anti-inflammatory consequences of altered adiponectin production in IBD are possible. However, adiponectin does seem to modulate immune responses, and abnormal production could thus be involved in the altered responsiveness of immune cells that occurs in IBD.

Recent data from genetic studies have added independent support for such dysregulated production of adiponectin and leptin in Crohn's disease. In mice, deficiency

of the autophagy gene Atg16L1 results in upregulation of leptin as well as adiponectin mRNA expression^[28]. In humans, the ATG16L1 risk allele is associated with an increased risk of developing Crohn's disease^[28,29]. Further cross-population studies are needed to ascertain whether this mutation is the cause of the altered leptin and adiponectin production in the hypertrophic fat of Crohn's disease patients. However, so far, it is tempting to speculate that the ATG16L1 risk allele and the subsequent altered production of adipokines might contribute to the predisposition to Crohn's disease.

The data described above indicate that adipokines are able to regulate the acquired immune response and that the production of some is altered in mesenteric fat of IBD patients. What kind of stimulus is required to modify the production of these adipokines in patients with Crohn's disease? Translocation of luminal antigens (e.g. bacteria) from the intestinal lumen to the adipose tissue could offer this stimulus, presuming that adipocytes and pre-adipocytes express innate receptors.

Adipocytes as cells of the innate immune system

The release of free fatty acids by adipocytes following lipopolysaccharide (LPS) stimulation, and hence responsiveness of fat cells to bacterial components, was first detected over 30 years ago^[30]. In line with these historic data, the expression of toll-like receptor (TLR)4 and TLR2 was described in adipocytes generated from the 3T3-L1 cell line^[31]. Furthermore, our group and others have demonstrated that adipocytes and their precursors from mice and humans express TLR1-TLR11 and that specific stimulation induces secretion of immune regulatory mediators^[32-34]. In addition, data from our group indicate expression of functional nucleotide oligomerization domain (NOD) proteins-1 and -2 on pre-adipocytes^[35]. Expression of these NOD proteins in adipocytes and pre-adipocytes is further regulated by TNF- α or LPS (NOD2), respectively, IFN γ (NOD1)^[35]. This observation is of particular interest, since mutations in the NOD2 gene have been associated with an increased risk of developing Crohn's disease^[36-38]. Thus, adipocytes and pre-adipocytes share functional properties of immune cells, which suggest an active role in defense against bacterial and viral antigens *in vivo*. Hence, adipocytes and pre-adipocytes could represent a yet ignored population of innate immune cells.

A working model could be that primary increased production of pro-inflammatory mediators in the mesenteric fat due to genetic predisposition might contribute to the development of Crohn's disease. Additionally, the massive cytokine production in the inflamed colon, in addition to translocating bacteria, could further induce the production of pro-inflammatory mediators in the adjacent adipose tissue, thus inducing a vicious cycle, in which inflammatory conditions in the intestine and the mesenteric fat support each other.

et al^[39] reminded us of their presence in a concise review. They reviewed the pathological descriptions of Crohn's disease in the era before antibiotic, corticosteroid, immunomodulatory and biological therapy. These pathologists described lesions in the basal portion of the lamina propria, in the superficial and deep submucosa, and in the subserosa, which suggested lymphatic disease. These lesions comprised lymphocytic thrombi within the lymphatics and multiple large aggregates of lymphocytes with or without multi-nucleated giant cells, a picture consistent with chronic lymphangitis^[39]. The granulomas of Crohn's disease appear to be in and around the very thin-walled lymphatics that are found adjacent to small vessels^[40]. This further supports the idea that lymphatics might directly contribute to the pathogenesis of this disease.

Almost more intriguing are the rat and pig models in which regional lymphatics of the small intestine were obstructed with sclerosing agents^[41,42]. These animals subsequently developed segmental intestinal disease that was characterized by many of the alterations that occur in Crohn's disease, including lymphocytic and granulomatous changes. Remarkably, enterocutaneous as well as enterocutaneous fistulas developed in these models, which are not seen in animal models routinely used today^[41,42]. Additional observations have pointed out that the distribution and character of these lesions represent obstructive lymphocytic lymphangitis^[43]. In these older studies, the connection between the shorter segments of Crohn's disease in the jejunum and the longer segments in the ileum, with the shorter vasa recta of the jejunum and the longer lymphatic collecting ducts of the ileum, was emphasized^[39,43].

Very recent work by Vetrano *et al*^[44] has provided further experimental data underlining the relevance of lymphatics in IBD^[44]. They have concentrated on the expression of D6, a promiscuous decoy receptor and scavenger for CC chemokines that plays a non-redundant role in the control of the inflammatory response in various organs. Vetrano *et al*^[44] have demonstrated upregulation of D6 in human colitis. The expression could be localized to lymphatic vessels and leukocytes in the mucosa. D6-deficient mice showed an increased susceptibility to experimental colitis when compared to wild-type mice. *Via* bone-marrow chimeras, the regulatory function of D6 in colitis has been tracked to the stromal/lymphatic compartment, and a contribution of hematopoietic cells could be excluded. Thus, these data further emphasize the regulatory role of the lymphatic system in intestinal inflammation.

In line with these observations, Van Kruiningen *et al*^[39] have suggested recently to focus again on the lymphatic damage in Crohn's disease, and the identification of possible harmful agents that cause lymphangitis and lesions in the lymphatic endothelium. Although the lymphatics are not completely separated from the intestine, they represent the second structure that should be reevaluated in Crohn's disease.

LYMPHATICS

The lymphatic system is closely connected to and within the intestine, and is a neglected structure. In 2008, Van Kruiningen

MICROVASCULATURE

In similar close proximity to the intestinal wall is the

microvasculature that is embedded in the mesenteric fat tissue, which thus provides an additional link as outlined below.

Whether increased vascularization as assessed by mesenteric angiography or Doppler ultrasound reflects Crohn's disease activity is disputed^[45]. Recent evidence for angiogenesis playing a role in IBD pathogenesis has prompted interest in anti-angiogenic therapies for IBD^[46,47]. Remarkably, angiogenesis plays a crucial role in various chronic inflammatory disorders such as atherosclerosis, rheumatoid arthritis, peptic ulcer, IBD, psoriasis, and Alzheimer's disease^[48]. Growth of new blood vessels is intrinsic to inflammation and is associated with structural changes, including activation and proliferation of endothelial cells and capillary and venule remodeling, all of which result in an expansion of the tissue microvascular bed^[49-51]. As inflammation evolves, vessels expand to supply nutrients that sustain the accumulation of activated immune cells, and in the chronic phase, local immune cells overproduce endothelial cell growth factors^[49].

This expansion of the vascular network facilitates several mechanisms. The influx of inflammatory cells increases the nutrient supply that allows the metabolically active immune response to take place, and the activated endothelium contributes to the local production of cytokines, chemokines, and matrix metalloproteinases^[52,53]. In chronic inflammatory disorders, infiltration by macrophages and lymphocytes, tissue damage and repair occur concurrently, and the newly formed vessels become permanent^[51,54]. The anatomical expansion and increased activation of the remodeled microvascular bed foster further influx of immune cells, and angiogenesis and inflammation become co-dependent processes^[55]. Both innate as well as adaptive immune responses promote angiogenesis.

Thus, the endothelium, and more specifically, the endothelial cells of the microvasculature seem to assume a central function, because they are not only capable of generating a range of mediators, but also display distinct adhesive molecule patterns, to activate a unique sets of genes and form capillaries^[56-58]. In addition, endothelial cells act depending on the body compartment heterogeneity^[56,59-61]. An example is the expression of mucosal addressin cellular adhesion molecule-1 by Peyer's patches and high endothelial venules to recruit $\alpha 4\beta 7$ homing receptor-positive naïve lymphocytes^[62]. Similarly, endothelial cells from brain, liver, and other organs express distinct surface markers, protein transporters, and intracellular enzymes^[61-63]. This heterogeneity becomes of particular interest when considering the regulation of organ-specific inflammation; in our case, intestinal inflammation. The distribution and infiltration of leukocytes is tightly regulated by numerous homing and adhesion molecules on the surface of microvascular and immune cells^[64]. At inflamed sites, endothelial cells still control the type and number of immune cells that extravasate into the interstitium in a dysregulated fashion^[65,66].

An additional cell population has been identified to play a crucial role in the process of cell infiltration *via* the endothelium in areas of inflammation, namely platelets. They normally circulate without attaching to the endotheli-

um, but do so when the endothelial cells become activated, and platelet adherence triggers inflammation^[67]. Activated platelets produce massive amounts of pro-inflammatory mediators and interact with various other cell populations^[68,69]. In inflamed areas, the microvasculature can recruit leukocytes through a platelet-dependent mechanism, but at the same time, platelet recruitment is leukocyte dependent^[70]. The details of this crucial interaction have been summarized by other reviews^[71].

A number of animal studies have proven that the process of angiogenesis can be taken advantage of as a therapeutic approach. Hence, in models of DSS-induced inflammation, as well as spontaneous colitis in IL-10-deficient mice, angiogenesis occurs. However, when this angiogenesis is inhibited, clinical severity and the signs of histological inflammation decrease significantly^[47]. Furthermore, vascular endothelial growth factor A that induces angiogenesis has been recently shown to be up-regulated in samples from patients with IBD, and in mice with colitis. The overexpression of VEGF-A in mice exposed to DSS was followed by deterioration of disease and an additional increase in angiogenesis when compared to DSS-exposed wild-type mice^[72].

PERSPECTIVE

Considering the factors that contribute to intestinal inflammation, particularly in Crohn's disease, we should avoid restricting ourselves to the luminal site and immune-cell infiltration, but rather include the extraluminal structures discussed in this review. This broadened view might help us in understanding the disease, and more importantly, in identifying novel therapeutic targets.

Abstract

Inflammatory bowel diseases (IBD) are a complex group of diseases involving alterations in mucosal immunity and gastrointestinal physiology during both initiation and progressive phases of the disease. At the core of these alterations are endothelial cells, whose continual adjustments in structure and function coordinate vascular supply, immune cell emigration, and regulation of the tissue environment. Expansion of the endothelium in IBD (angiogenesis), mediated by inflammatory growth factors, cytokines and chemokines, is a hallmark of active gut disease and is closely related to disease severity. The endothelium in newly formed or inflamed vessels differs from that in normal vessels in the production of and response to inflammatory cytokines, growth factors, and adhesion molecules, altering coagulant capacity, barrier function and blood cell recruitment in injury. This review examines the roles of the endothelium in the initiation and propagation of

INTRODUCTION

Inflammatory bowel diseases (IBD) include Crohn's disease (CD), ulcerative colitis (UC) (and indeterminate colitis), which share several inflammatory characteristics with other chronic immune disturbances including immune activation, leukocyte infiltration into tissues and increased vascular density^[1]. In UC, the colon shows a continuous, superficial inflammation, while CD occurs as patchy transmural inflammation which may affect any region of the gastrointestinal tract. Genetic susceptibilities may play an important role in the development of IBD^[2-6] with polymorphisms in CARD15/NOD2 haplotypes (especially in Caucasians) and HLA-DR haplotypes (especially in Asian IBD) and possible defects in interleukin (IL)-23, IL-2, and IL-10 signaling^[2,7-10]. IBD is more prevalent in developed nations^[11], with several mechanisms being considered to explain disease pathology including environment, hygiene

and altered gut flora^[11-13]. These different contributing causes may underlie divergent forms and patterns of IBD, which ultimately may lead to a redefinition of different sub forms of UC and CD.

While the mechanisms initiating and sustaining IBD may differ, both UC and CD may reflect dysfunction within antigen-presenting cells (e.g. dendritic cells) or excess activation of CD4⁺ T-cells (resembling T-cell disturbances in psoriasis). Reduced activation of T-cells in some forms of CD appear to allow gut microbiota that have breached the gut epithelium to trigger microvascular inflammation^[1,5,9,14-16]. The activation of immune responses in IBD release inflammatory cytokines [e.g. tumor necrosis factor (TNF)- α] and growth factors [e.g. vascular endothelial growth factor (VEGF)-A] into gut tissues provoking gut inflammation and injury^[5,17]. Antibodies produced against “normal” gut antigens (e.g. anti-colon, anti-mucin, anti-tropomyosin) have been found in IBD and are suggested to activate cytotoxic T lymphocytes, further increasing inflammation^[7]. As IBD progresses, cytokine-mediated inflammation and epithelial apoptosis disturb the intestinal barrier, to allow penetration of gut flora beyond the lamina propria causing intense inflammatory responses^[18] while also provoking endothelial microvascular permeability^[19].

Another key event in IBD progression is the expansion of the intestinal microvasculature. Angiogenesis in IBD sustains inflammation through alterations in the endothelial lining of these vessels. The endothelium regulates recruitment of inflammatory cells, tissue damage (e.g. vasogenic edema), and production of inflammatory mediators^[19-22]. In this review we describe the key roles of the endothelium in mediating and aggravating inflammation in IBD (Figure 1).

ENDOTHELIAL CELLS IN IBD

Endothelial cells (ECs) are the major constituent of the microvasculature that line blood and lymphatic vessels. ECs during IBD undergo rapid and remarkable changes in response to elevated levels of cytokines and growth factors often producing injury to gut tissues. Normally ECs provide an anti-adhesive and selectively permeable exchange barrier^[23]. Even though ECs have long been recognized as participants in inflammation their roles in intestinal inflammation during IBD are not yet clear. The unique physiological and molecular characteristics of gut microvessels may help explain several characteristics of IBD. The close relationships between gut metabolism, tissue perfusion, microvascular expansion and immune cell infiltration are unclear but suggest that microvascular alterations may be maladaptive in IBD. Intestinal vascular ECs basally exhibit unique properties which may contribute to IBD. Haraldsen *et al.*^[24] first described characteristics of human intestinal ECs (HIMECs) in long-term cultures and differences from ECs of different origin. For example lipopolysaccharide (LPS) only transiently increases HIMEC adhesion molecule ex-

pression, while causing long-lasting increases in human umbilical vein ECs (HUVECs)^[25]. Nilsson *et al.*^[26] found that HIMEC cultures produce different cytokines (IL-1 β , IL-3 and IL-6) upon stimulation with inflammatory cytokines (e.g. TNF- α , IL-1) compared to HUVECs. Binion *et al.*^[27,28] have shown distinctive HIMEC properties such as constitutive inducible nitric oxide (NO) synthase (iNOS) as well as unique adhesive determinants, and that these properties were altered in IBD and may underlie endothelial dysfunction in IBD development.

ENDOTHELIAL NO IN IBD

Endothelial-derived NO reduces leukocyte and platelet adhesion to the endothelium^[29,30], mediates flow-dependent and agonist-dependent vasodilatation, and couples VEGF-A signaling with NO-dependent permeability^[31,32]. NO-mediated endothelial permeability involves 2 separate mechanisms: (1) increased guanylate cyclase and phospholipase C activity which increases intracellular Ca²⁺; and (2) permeability mediated by Erk1/2 *via* Ras/Raf/PKC causing increased actin contractility^[29,33,34]. Increased p38 mitogen-activated protein kinase (MAPK) signaling, Rho-GTPase activity and increased Ca²⁺ release mediated by upregulated cytokines and growth factors may also represent possible mechanisms for increased endothelial permeability^[35-37].

Endothelial nitric oxide synthase (eNOS)-derived NO is a radical scavenger not only absorbing O₂ but also generating the potent oxidant ONOO⁻. eNOS expression is reduced in IBD; eNOS deficiency in IBD is exacerbated by arginase-mediated depletion of substrate as well as eNOS uncoupling^[38-40]. Decreased eNOS activity in IBD reduces endothelium-dependent vasodilatation, leading to uncontrolled oxidant formation, prominent in IBD^[41]. Deletion of eNOS (eNOS^{-/-}) increases severity of experimental IBD^[42,43] consistent with protective roles of NO against inflammation. NO may prevent development of endothelial inflammatory and hyper-adhesive phenotype in IBD by suppressing cytokine-induced EC adhesion molecules (ECAMs) and matrix metalloproteinases (MMPs)^[44]. Increased endothelial oxidant stress (e.g. in IBD) also disturbs tight junctional organization *via* p38, p42/44 MAPK^[45-47].

Sera from patients with CD reduce, while UC sera increase eNOS in HUVECs; both UC and CD sera increase iNOS^[48]. This may reflect differences in anatomic origins of the endothelium i.e. venous *vs* intestinal. HIMEC iNOS expression appears to be a unique feature of gut microvessels. In HIMECs, iNOS appears at least as important a source of NO as eNOS. Binion *et al.*^[30] have shown that HIMECs persistently express iNOS, and that iNOS-derived NO limits leukocyte adhesion in normal HIMECs. Paradoxically iNOS inhibition increases binding of leukocytes. Thus, while leukocyte-derived iNOS may drive inflammation, HIMEC expression of iNOS limits the inflammatory responses (leukocyte adhesion, permeability, vasodilatation) in the gut, and decreased endothelial iNOS abundance and activity in IBD may represent an

Figure 1 Inflammation triggers a change in the endothelium of the intestinal vasculature in response to the cytokines, chemokines and growth factors released by immune cells leading to increased angiogenesis, adhesion molecule expression, leukocyte extravasation, decreased endothelial barrier function and increased coagulation. TNF: Tumor necrosis factor; IL: Interleukin; iNOS: Inducible nitric oxide synthase; eNOS: Endothelial nitric oxide synthase; VEGF: Vascular endothelial growth factor; MMPs: Matrix metalloproteinases; VCAM: Vascular cell adhesive molecule; ICAM: Intracellular adhesive molecules.

underrated basis of IBD pathology^[27,30]. HIMECs derived from CD patients also show a persistent loss of iNOS expression^[27]. Interestingly, iNOS can be decreased by injury to normal HIMECs (opposite to most tissues which mobilize iNOS in response to injury^[27]) suggesting that during injury, reduced iNOS might trigger inflammatory responses. Even with the loss of endothelial iNOS, there is often increased NO in tissues surrounding the area of inflammation. Despite decreased endothelial iNOS derived-NO, IBD frequently exhibits increased leukocyte recruitment and activation of gut epithelial cells to increase overall NO production^[44]. Kriegstein *et al.*^[49] found that tissue-derived iNOS, and to some extent leukocyte iNOS, mediate colitis injury, but could not specifically distinguish between tissue and endothelial contributions of iNOS in colitis. Aoi *et al.*^[50] have suggested that iNOS-derived NO plays an important role in gut healing after injury through induction of VEGF, necessary for angiogenesis in wound healing. We have previously shown that excess NO may play an important role in IBD exacerbation. Using STAT-6^{-/-} mice (which have high iNOS levels) in dextran sulfate sodium (DSS) colitis, we found more severe IBD in STAT-6^{-/-} mice correlate with extraordinary NO flux suggesting that excess NO may also drive gut injury^[51].

Despite elevated NO abundance, downstream guanylate cyclase signaling appears to be depressed in DSS colitis leading to decreased cGMP in the inflamed intestine^[52]. Under these conditions, cGMP dependent protective NO effects may be masked by pro-oxidant effects of NO metabolites. Conner *et al.*^[53] and Grisham *et al.*^[54] revealed an important role of the 26S proteasome in the regulation of endothelial nuclear factor-κB (NF-κB) and cumulative iNOS NO production and adhesion molecule expression. Cumulatively, these studies suggest that intestinal homeostasis is controlled by distinctive and compartmentalized NO sources, and that excess NO formation may support the pathophysiology of IBD.

ENDOTHELIAL TOLL-LIKE RECEPTORS AND IBD

The gut is an organ supporting a high bacterial load; despite physical and chemical barriers, some bacterial antigens will ultimately penetrate the gut wall to activate gut microvascular ECs through Toll-like receptor (TLR) signaling^[18,55]. The intestinal microvascular endothelium also differs from ECs of other origins in TLR responses. For example, repeated exposure and activation of TLR4 in HIMECs

leads to development of lipopolysaccharide tolerance; however HUVECs lack such a mechanism, indicating the importance in controlling endothelial-dependent inflammation and host commensal interactions^[25,56,57]. Protease activated receptors activate transforming growth factor (TGF)- β to induce TLR4 and lead to increased disease severity in IBD^[58,59]. TLR5 is constitutively expressed in all ECs, and is of particular interest in gut pathophysiology. TLR5, a receptor for flagellin^[60], is constitutively expressed on the basolateral surface of the gut endothelial (an epithelial) layers^[61]. TLR5 signaling induces endothelial intercellular adhesion molecule-1, TNF- α production and leukocyte binding and emigration^[61]. Loss of TLR5 activity in murine models leads to the development of infectious as a result of deficient and improper responses to normal flora and pathological microorganisms^[61,62]. Conversely, endothelial TLR3 has been shown to be protective in the DSS model of acute colitis. This process is mediated by interferon (IFN) type 1 induction of IL-10, a potent anti-inflammatory cytokine^[63]. However, Heidemann *et al.*^[64] in 2007 found that IL-12 expression and its associated gene products were also induced by TLR3 signaling in addition to increased adhesion and transmigration of leukocytes and TLR functions in the gut remain complex, and requires further study.

IBD-ASSOCIATED CYTOKINES AND CHEMOKINES EFFECTS ON GUT ECs

During inflammation there is an increase in plasma levels of inflammatory cytokines, including IL-6, IL-23, IL-12 and TNF- α , in both human IBD and animal IBD models^[1,2,15]. Kawachi *et al.*^[65,66] examined cytokine alterations in the adoptive T-cell transfer and the IL-10^{-/-} IBD models and found IL-1, IL-6, IL-18 and TNF- α were upregulated in both models. Many of the inflammatory cytokines that are upregulated in IBD are pro-angiogenic, the best examples being IL-17 (produced by invasive Th17 cells) and TNF- α produced by several tissue types, including infiltrating immune cells (macrophages and monocytes)^[67,68] and the endothelium^[69]. EC produce inflammatory mediators in response to activation by immune cells and alterations in the tissue microenvironment^[64,70].

TNF- α is one example of a cytokine with pleiotropic effects on the endothelium in IBD, ranging from adhesion molecule induction [vascular cellular adhesion molecule (VCAM)-1 and mucosal addressin cellular adhesion molecule (MAdCAM)-1], promoting interaction of platelets with ECs and inducing expression of pro-angiogenic growth factors such as VEGF-A^[25,44,71-73]. Defects in the activity of the anti-inflammatory cytokines such as IL-10 may play a role in the establishment of some IBD, and IL-10 deficient mice (IL-10^{-/-}) develop IBD spontaneously, while other animal models of colitis show reduced injury when treated with exogenous IL-10^[2,74-76]. Interestingly Oshima *et al.*^[19] observed that pretreatment of ECs with IL-10 prevented IFN- γ mediated endothelial barrier

disruption, indicating that an important role of IL-10 may be to prevent cytokine mediated EC barrier disturbances which initiate and exacerbate disease. This is supported by the finding that several EC adhesion molecules such as intercellular adhesion molecule (ICAM)-1, VCAM-1 and MAdCAM-1 are increased in IL-10^{-/-} mouse colitis and may mediate leukocyte recruitment in this model^[66].

Over 40 chemokines in 4 separate families interact with as many as 19 receptors to regulate trafficking of leukocytes. Of these, several chemokines may mediate leukocyte trafficking to the gut and colon dysfunction in IBD. Papadakis *et al.*^[77] showed that CCL2 and CCL5^{-/-} mice are protected from colitis. Interestingly, Barcelos *et al.*^[78] and Wu *et al.*^[79] showed that CCL5 and CCL3 can induce inflammatory angiogenesis in a murine sponge model and promote angiogenesis in murine tumors. Eyman *et al.*^[80] have also shown that CCL5 upregulates pro-angiogenic genes. CCL25 interacting with its receptor on CCR9⁺ leukocytes plays a major role in the early stages of experimental IBD pathogenesis^[81]. CXCL8 (IL-8) another pro-angiogenic chemokine, is known to be stored in EC Weibel-Palade bodies, can be rapidly secreted, and induces HIMEC proliferation in culture *via* binding to CXCR2^[82,83]. Although angiogenesis may support injury IBD, IL-8 may be dysregulated in some forms of IBD. IL-8 seems to be downregulated in leukocytes and in the endothelium of patients with CD. There appears to be no upregulation in the endothelium of UC patients, suggesting a possible link to TGF- β 1 over expression in IBD^[84-86]. In contrast, Scaldaferri *et al.*^[87,88] found that intestinal fibroblasts treated with TNF- α produce IL-8 and monocyte chemoattractant protein-1 *via* p38/p42/44 mitogen-activated protein kinase.

CX3CL1/fractalkine is a chemokine expressed by EC, can be upregulated by TNF- α , IL-1, LPS and IFN- γ , and is highly upregulated in IBD^[89,90]. CX3CL1 can function as an endothelial adhesive determinant to recruit a subpopulation of dendritic cells and macrophages that have high CX3CR1 expression. CXCL1 can be shed from the surface of the ECs (in response to increased IL-1 β in IBD). This form of CX3CL1 acts as a chemoattractant for CD4⁺ and CD8⁺ T-cells^[90]. Sans *et al.*^[91] reported that in fact there is enhanced recruitment of CX3CR1 expressing T-cell to the gut *via* interactions with CX3CL1. CXCR4/SDF-1 α and its ligand CXCL12 is an important chemokine/receptor pair in angiogenesis, but have received very little attention in IBD. Heidemann *et al.*^[92] reported that blocking this CXCR4/CXCL12 interaction is sufficient to inhibit migration and proliferation of HIMECs in response to VEGF-A. CXCR4/SDF-1 α plays an important role in the recruitment of EC precursors to sites of angiogenesis, and may be impaired in IBD, leading to the conclusion that this pathway may be interrupted^[93-95]. Midkine, another chemokine of great interest is increased in serum and is associated with tumor drug resistance and poor cancer prognosis^[96-98]. Midkine is also upregulated in IBD serum, and has prognostic value like VEGF, TNF- α , sVCAM and VCAM^[20,99-102]. Midkine has a pronounced

angiogenic effect, like some other inflammatory factors, and also increases the levels of surface glycosaminoglycans on ECs to favor recruitment of circulating leukocytes in IBD^[103].

INCREASED ENDOTHELIAL ADHESION MOLECULE EXPRESSION IN IBD

Inflammation in IBD is characterized by increases in both blood and lymphatic vessels in the intestine. This increase in endothelial surface area provides a powerful means of increasing leukocyte recruitment with the mobilization of ECAMs including selectins^[28]. Animal models of IBD (IL-10^{-/-}, IL-2^{-/-}, SAMP1/Yit and T-bet^{-/-}), like human IBD, all show ECAM upregulation is linked to disease severity^[66,104-106], allowing use of adhesion antagonists in IBD therapy^[55,102,107]. Endogenous endothelial-derived inhibitors of leukocyte binding (e.g. sVCAM-1) may also be downregulated in IBD^[21,108-111] and could provide new diagnostic or anti-adhesive strategies.

P and E-selectins, glycoproteins expressed on the surface of platelets and other leukocytes, are also expressed on the surface of activated or inflamed endothelium in IBD. P-selectin can interact with ECAMs such as VCAM-1/ICAM-1, as well as with O-glycans collectively referred to as peripheral lymph node addressins (PNAds) containing sialyl Lewis X moieties^[112,113]. P-selectin at least partially mediates rolling and recruitment of gut-infiltrating leukocytes in IBD, with approximately 50% increase in gut P-selectin in UC *vs* control groups; serum levels of soluble P-selectin, an inhibitor of selectin binding, are decreased in IBD patients^[109,114,115]. Increased platelet P-selectin, with the enhanced prothrombotic surface of the gut EC in IBD increases thrombus formation and tissue damage by ischemic injury^[115]. E-selectin, a relative of P-selectin is expressed solely on the surface of activated ECs during inflammation and is a major contributor to leukocyte rolling injury. E-selectin is not stored in Weibel-Palade bodies and must be produced in response to inflammatory stimuli such as IL-1, TNF- α and VEGF-A^[116,117]. In contrast to sP-selectin, sE-selectin is not downregulated in IBD and in CD, and actually increases in comparison to controls^[109].

High endothelial venules (HEV) are specialized post-capillary venules that allow trafficking of leukocytes between immune (e.g. Peyer's patches) and vascular compartments, and are increased in IBD^[113]. L-selectin expressed on leukocytes (after activation) binds PNAd on HEV and recruits leukocytes expressing L-selectin in IBD. The gut and brain selective adhesion determinant, MAdCAM-1 is also expressed on HEV, and in UC MAdCAM-1 O-glycosylation increases, allowing greater L-selectin binding^[118]. MAdCAM-1 interacts with $\alpha 4\beta 7$ integrins on the surface of a subset of naive CD4⁺ T-cells^[119,120]. MAdCAM-1 induction is found only in chronically inflamed gut endothelium and suggests that in IBD there is a fundamental alteration in the phenotype and gene expression pattern in the inflamed intestinal EC^[28]. Mizushima *et al.*^[121] dem-

onstrated that inhibition of angiotensin-II type 1 receptors reduced TNF- α dependent MAdCAM-1 expression and reduce the severity of DSS-induced colitis, possibly linking vasoregulation and inflammation. In HIMEC MAdCAM-1 is also expressed inversely with cell density, with proportionally greater levels of MAdCAM-1 found at low densities. This indicates that in newly formed vessels, larger amounts of MAdCAM-1 may be available to recruit leukocytes to these "leaky and permissive" vessels^[122,123].

ICAM-1, another important ECAM in IBD binds LFA-1 (aLb2), Mac-1 (aMb2) and $\alpha 4\beta 2$ integrins, and is expressed by inflamed ECs to mediate the firm adhesion of leukocytes to activated ECs^[124,125]. ICAM-1 has a unique relationship with VEGF-A; Goebel *et al.*^[125] reported that HIMECs constitutively express ICAM-1, which is significantly upregulated following treatment with 50 ng/mL VEGF-A, linking inflammation and angiogenesis. In addition to direct activation and upregulation of ICAM-1 by VEGF, Zitterman *et al.*^[117] found that VEGF treatment also sensitizes cells to TNF- α induced ICAM-1 mobilization. Normally ICAM-1 concentrates at EC junctions, but is redistributed to apical surfaces of ECs under inflammatory conditions where it supports firm adhesion of leukocytes^[25]. In the adoptive T-cell transfer model of murine IBD, Ostanin *et al.*^[126] found that T-cells that lack LFA-1, (a T-cell ICAM-1 ligand), fail to induce disease, revealing a critical role for EC modulated immune responses. ICAM-1 was the one of the first clinical targets in IBD, but an antisense IBD therapy showed limited success^[21].

VCAM-1, an ECAM highly expressed on the luminal surface of activated ECs in IBD, mediates the adhesion of $\alpha 4\beta 1$ expressing lymphocytes. In HIMECs, the expression of VCAM-1 is regulated by the PI3K/NF- κ B signaling pathway and its stimulation by mediators can be inhibited by curcumin^[127]. Like ICAM-1, VCAM-1 can also up regulated by VEGF-A *via* NF- κ B^[117,128]. Studies in the picrylsulfonic acid model of UC using radiolabeled anti-VCAM-1 antibodies show that leukocyte infiltration and histological damage are proportionate to VCAM-1 expression in the gut microvasculature^[129]. In addition, in the DSS model of UC, there is an upregulation of VCAM-1 which if blocked (by specific antibodies) attenuates disease activity, while ICAM-1 and MAdCAM-1 blockade do not protect in this manner^[129,130].

CD31/PECAM-1 expressed by ECs and leukocytes mediates homophilic binding between activated ECs and leukocytes especially during extravasation. CD31 is found on the endothelial surface and in endothelial junctions. Work by Romer *et al.*^[72] found that CD31 is not upregulated in response to inflammatory cytokines but is redistributed from cellular junctions. CD31 blockade inhibits leukocyte transmigration, and CD31 inhibition in IBD reduced leukocyte rolling and firm adhesion suggesting a unique role for CD31 in IBD or in the function of the gut microvasculature^[131].

Originally considered a mesenchymal stem cell marker^[132-134], CD146 is now described as a novel immunoglobulin super family adhesion molecule which is increased in

gut tissue of IBD patients^[108]. The function of CD146 in IBD is not completely understood, but has potential roles in inflammation since it supports rolling and invasion of natural killer T-cells^[135]. The upregulation of CD146 in IBD, like ICAM-1 and VCAM-1, may be driven by VEGF-A overexpression during IBD^[100]. Additionally, the soluble form of CD146, regulates endothelial and leukocyte CD146 interactions with their ligands, and is reduced in IBD, enhancing leukocyte extravasation^[100,108,135]. Interestingly Tsiolakidou *et al.*^[100] determined that new vessels formed in IBD are disproportionately CD146⁺. Inflamed ECs from CD and UC patients show an increased ability to recruit naïve T-cells and macrophages to the intestinal immune compartment after stimulation with several inflammatory cytokines, but not with LPS^[28,120]. These data are consistent with IBD not being initially driven by immune cells, but rather by the endothelial response to an increased inflammatory mediatory load.

PLATELETS AND COAGULATION IN IBD

Platelet and leukocyte aggregation as well as activation of the coagulation cascade increase during IBD, reflecting loss of the non-thrombogenic EC phenotype in IBD. Thrombi aggravate inflammation by binding of micro infarcts to the endothelial surface often leading to ischemic inflammation in the intestinal microvasculature^[136]. Mesenteric venous thrombosis has been observed in a fraction of IBD cases, and thrombotic processes are being recognized in altered perfusion, inflammation and tissue injury in IBD^[137]. Indeed, subclinical thrombosis is common in IBD, and is a major source of morbidity in approximately 25% of IBD deaths^[136]. Increased markers of coagulation include thrombin anti-thrombin complex, tissue factor and fibrinopeptide B^[55], and can be described early in IBD. Factor XIIIa, a fibrin-stabilizing coagulation factor (and agonist for VEGFR-2), is increased in IBD, while factor XIII T_T has an increased number of mutations in IBD patients compared to controls suggesting links between thrombosis, angiogenesis and inflammation. However, Bernstein *et al.*^[138], Dardik *et al.*^[139] and Vrij *et al.*^[140] reported that factor XIII activity is reduced in IBD patients.

In addition to increased levels of coagulation cascade proteins in IBD, CD40, CD40L and soluble CD40L are increased in IBD. CD40, expressed on several cell types (including ECs) is involved in inflammatory and immune activation, and interacts with CD40L on T-cells. Danese *et al.*^[141] suggested that the primary source of sCD40L was from activated platelets. CD40 signaling increases production of pro-inflammatory cytokines and chemokines by ECs and surrounding tissue^[142]. CD40L release also leads to binding of platelets and immune cells to ECs by increasing tissue factor, ECAM expression and pro-thrombotic phenotype in HIMECs^[141-143]. Danese *et al.*^[71] suggested that a possible therapeutic benefit of TNF- α blockade was downregulation of CD40/CD40L signaling in IBD. A still unanswered question is whether coagulation is a secondary or initiating event in inflam-

mation. It is worth mentioning that individuals with coagulation cascade disorders (e.g. hemophilia, factor V deficiency and von Willebrand disease) rarely develop IBD^[55]. The opposite of the previous observation is also true; patients with IBD have an increased likelihood of having genetic pro-thrombotic disease Factor V Leiden^[144]. This evidence strongly links thrombus formation as a possible trigger of IBD and suggests prognostic factors which may increase risk of IBD development.

ENDOTHELIAL BARRIER DYSFUNCTION IN IBD

The maintenance of normal vascular barrier supports nutrient and O₂ exchange, osmotic balance and leukocyte abundance in the extracellular compartment. In IBD, increased vascular permeability leads to tissue edema and damage in both human IBD and animal models of IBD^[19]. This alteration in solute permeability of the vasculature is not restricted to the gut microcirculation but is widespread affecting the vasculature of other organs including the brain^[145]. Several classes of mediators in IBD alter both solute permeability and angiogenic balance, including angiogenin (an angiogenic peptide with ribonuclease activity), chemokines (e.g. IL-8, IL-10), coagulation factors (thrombin), cytokines (IFN- γ , IL-13), and growth factors, most notably VEGF, the most potent and important blood vascular angiogenic growth factor and an important inflammatory mediator^[19,36,37,47,146-148]. Tolstanova *et al.*^[149] found that VEGF-A inhibition by neutralizing antibodies reduced vessel permeability in the iodoacetamide model of colitis. Downregulation of anti-inflammatory cytokines e.g. IL-10 may play an equally important role in increasing endothelial permeability. Oshima *et al.*^[19] have shown increased vascular permeability in the IL-10^{-/-} colitis model due to loss of IL-10 inhibition of IFN- γ induced junctional degradation; also IL-10 protects against IFN- γ mediated loss of human microvascular barrier.

Leukocytes, e.g. neutrophils and monocytes, can degrade endothelial junctions through protease secretion and upregulation. Cytokines and growth factors also induce MMP-9, MMP-3 and MMP-1^[150,151], resulting in degradation of junctional and matrix targets^[152]. Neutrophil elastase is elevated in IBD and can degrade vascular endothelial cadherin, important in maintaining junctional apposition, adhesion and barrier function^[153-156]. Endothelial junctional adhesion molecule-A is also dysregulated in IBD, and is closely linked to disease activity in DSS colitis^[57,157].

ANGIOGENESIS IN IBD

Angiogenesis (increased blood vessel density) in IBD increases the area of endothelium available for exchange, but also for extravasation of blood constituents into surrounding tissue to increase disease severity in IBD^[158]. Increased vessel formation in IBD may represent recruitment of endothelial progenitor cells, vascular intussuscep-

tion (splitting) and extension from existing vessels^[159]. Increased angiogenesis is observed in animal (2,4,6-trinitrobenzene sulphonic acid (TNBS), DSS and iodoacetamide) colitis models and in human colitis. However, inflammatory angiogenesis in IBD does not simply match increased tissue mass. Vessels formed during inflammation are different from those formed during normal development. These vessels are immature, lacking investment with pericytes. They express ECAMs, leak, are hypoperfused, often stenose and are hyperthrombotic, with an elevated ability to respond to growth factors^[160-163] actively supporting IBD progression^[149,164-168]. Spalinger *et al.*^[158] and Maconi *et al.*^[169] concluded that there is an increased blood vessel density in the intestines of CD and UC patients and that increased vascular density in IBD was directly correlated with increased IBD disease severity. This is also true in animal models of IBD like TNBS- and DSS-induced colitis models^[166,170].

Growth factors, especially VEGF-A, dramatically alter several aspects of the colon microvascular endothelial phenotype, resembling a de-differentiation (loss of maturity) of the vessels which can reflect changes in vascular support cells, e.g. pericytes/smooth muscle, that surrounds the capillaries. Inflamed tissues display increased vascular density resulting from the formation of new vessels during angiogenesis. These changes result in decreased perfusion, increased solute permeability (*via* cytokines and VEGF-A induced junction remodeling) and contractility, as well as increased leukocyte and platelet adhesiveness^[161,171,172]. Ganta *et al.*^[163] have demonstrated that in angiotensin-2 knockout mice (using the DSS model of UC), loss of the pericytes around vessels resulted in diminished angiopoietin-1 signaling that destabilized the endothelial layer, increased leukocyte recruitment to the tissue, increased vessel permeability and induced vessel hyper-proliferation. Blood and lymphatic vessels are hyperstabilized by angiopoietin-2 deficiency, and show diminished inflammatory remodeling as well as decreased capacity to recruit leukocytes suggesting a link between maturity and inflammatory capacity^[163].

ENDOTHELIAL CELL AND ANGIOGENIC GROWTH FACTOR INTERACTIONS IN IBD

VEGF-A is the first described and best known VEGF, which controls developmental angiogenesis, wound healing and pathology^[173,174]. Bousvaros *et al.*^[175], Kapsoritakis *et al.*^[101] and Ozawa *et al.*^[176] all found elevated VEGF-A levels in plasma and tissue during active human and animal IBD, often twice normal^[101,109,166,175,176]. However, Chidlow *et al.*^[166] have reported that DSS diminishes levels of VEGF-A as well as VEGF-C and VEGF-D, suggesting complex, concentration-dependent and inhibitor-regulated effects of VEGF in different animal models of IBD. Danese *et al.*^[177] and Scaldaferrì *et al.*^[167] have shown that inhibition of VEGF signaling can attenuate disease activity in the DSS model of UC while overexpression of VEGF-A in-

creases disease severity in the same model^[167,177]. VEGF-A is released by several cell sources (e.g. neutrophils, platelets, macrophages, pericytes, fibroblasts, ECs, and colonic epithelial cells) and is transcriptionally activated by hypoxia through hypoxia inducible factor 1 α , and message stabilization *via* eukaryotic translation initiation factor 4e^[70,178-183]. Interestingly Birmingham *et al.*^[184] have shown that activated colonic epithelium represents an important source of VEGF-A, and injury or inflammation of the colon epithelium may provide a local stimulus for blood vessel growth. Invasive leukocytes, specifically neutrophils, granulocytes, macrophages and platelets, are increased in tissue during active IBD, and are also important sources of VEGF-A in inflamed tissues^[178,179,185-187]. Salivary secretions also contain high levels of VEGF-A and VEGF-C, which have been suggested as important sources of these growth factors in IBD^[188] released site-specifically during denudation. Apart from VEGFs, other angiogenic growth factors, e.g. basic fibroblast growth factor (bFGF), TGF- β and platelet-derived growth factor (PDGF) are upregulated in IBD and may be of clinical relevance^[86,189].

TGF- β is an important regulator of the cell cycle and apoptosis, especially in mucosal immune cells. The expression of TGF- β and its 2 receptors (TGFR1 and TGFR2) are increased in IBD, specifically UC; however, it appears that the levels are decreased in CD^[190]. In IBD either tachyphylaxis develops for TGF- β (UC), or the lack of TGF- β (CD) allows mucosal immune cells to proliferate when they would have undergone apoptosis^[190,191]. Early studies on the role of TGF- β in IBD indicated a protective role; more recent studies may point to a pathological role of TGF- β signaling in IBD^[191,192]. In fact, TGF- β is important in the formation of fibrosis in the colon of IBD patients by stimulating the transition of many cell types to fibroblasts^[193]. Over one-third of the fibroblasts responsible for inflammatory fibrotic injury may actually originate from the transformation of ECs to fibroblasts (not counting contributions of pericytes to fibroblast formation). Therefore the vasculature may provide a significant proportion (if not the majority of fibroblasts) and associated fibrosis in IBD^[194,195]. bFGF, a potent mitogen for the cells of mesodermal origin, stimulates EC proliferation, activates MMPs resulting in proteolysis of extracellular matrix, and increases cellular motility^[191]. Even though levels of bFGF are elevated in IBD there is no correlation with the stage or severity of the disease. However, the contribution of bFGF in the initiation or maintenance of IBD should not be discounted^[196]. PDGF is a close relative to VEGF and is upregulated in IBD. PDGF is predictive of both oxidative stress and angiogenesis in the intestine^[189]. PDGF is released in response to inflammatory and thrombotic stimuli. PDGF increases P-selectin expression on ECs and induces histamine secretion which induces other effects such as increased vascular leakage^[197,198].

ENDOTHELIAL PROGENITOR CELLS AND VESSEL SPROUTING IN IBD

Recruitment of endothelial progenitor cells (EPCs) may

contribute to angiogenesis in IBD, although reduced numbers of VEGFR2⁺, CD34⁺, CD133⁺ cells (endothelial, bone marrow, and stem cell markers) have been reported in IBD^[199], and EPCs from IBD have reduced antigenic activity^[95]. These findings suggest that recruitment of EPCs is unlikely to be a source of increased vessels, however, these findings are from patients with established disease as initial angiogenesis in early stages of IBD may rely on EPCs. Apart from EPC recruitment, angiogenic sprouting is active in IBD; sprouting ECs referred to as “tip” cells, are highly motile with distinct gene expression compared to that in quiescent ECs^[200]. VEGF-A induces the tip cell phenotype and also guides vessel sprouting, indicating that in IBD, VEGF might induce new vessel formation in this way^[201]. Normally, not all sprouts survive, many undergoing apoptosis, (vessel “pruning”) suggesting that high levels of VEGF prevent endothelial apoptosis resulting in increased numbers of surviving sprouts in IBD^[201].

INHIBITORS OF VASCULAR ENDOTHELIAL EXPANSION IN IBD

While increased pro-angiogenic growth factors increase angiogenesis, reductions in anti-angiogenic factors (seen in the DSS model of colitis) may be as important for permitting expansion of the vascular endothelium^[166,167]. Angiopoietin-1 a competitive inhibitor of Ang-2, binds to the Tie-2 receptor and inhibit vascular remodeling. Angiopoietin-2 is upregulated during inflammation and angiogenesis^[163,202] and competes with angiopoietin-1, to allow ECs to maximally respond to cytokines and growth factors. Work by Ganta *et al.*^[163] found that angiopoietin-2 signaling also appears to be necessary for neutrophil infiltration, and blood and lymphatic vessel proliferation in DSS colitis. Interestingly angiopoietin-2 can be upregulated by both bFGF and VEGF, potent pro-angiogenic growth factors also upregulated in IBD^[203-205].

Angiostatin, a fragment of plasminogen generated by MMPs has anti-angiogenic and anti-proliferative effects on ECs and blocks vessel maturation^[206]. During IBD, levels of MMPs are elevated and generate angiostatin^[153]. In fact 2 models of experimental colitis (iodoacetamide, TNBS) show increased angiostatin, and may represent a feedback control for angiogenesis^[207]. Interestingly, the effect of angiostatin hinges less on inhibition of EC proliferation, but more on inhibiting final vessel maturity^[208]. Much like angiostatin, endostatin results from the cleavage of collagen type XVIII yielding an anti-angiogenic fragment that is upregulated in experimental colitis^[207,209]. Endostatin reduces EC migration and proliferation; however like angiostatin, endostatin fails to block angiogenesis in the TNBS model, but may play a role in disease progression and maintenance by impairing vessel maturity and tissue healing by antagonizing VEGF-A induced tissue repair^[207]. Interestingly Deng *et al.*^[210] showed mesalamine treatment of iodoacetamide colitis restored levels of endogenous angiogenesis inhibitors, endostatin and angiostatin helping reduce disease severity.

Soluble VEGF receptors (sVEGFRs) are truncated forms of VEGFR1 or VEGFR2 genes^[211] that under normal physiological conditions maintain tissue avascularity (e.g. in the cornea) and might be dysregulated in IBD. During inflammation, sVEGFR1 inhibition seems to be lost (e.g. in the case of an alkali burn)^[211,212]. sVEGFR2 seems to play an important role in the inhibition of lymphangiogenesis compared to sVEGFR1, but sVEGFR2 blocks transplant rejection which points out its greater immunomodulatory effect^[213]. Additionally, Scaldaferrri *et al.*^[167] found that over expression of sVEGFR1 reduced disease severity in the DSS model of colitis, suggesting that loss of this molecule in IBD would be detrimental. Interestingly the anti-angiogenic VEGFs, alternate splice variants of VEGFs, are downregulated in several inflammatory diseases, and are linked to the alteration of the cytokine milieu in the tissues^[214-217]. These inhibitory VEGFs make up a majority of the VEGF load in the normal intestinal micro-environment with approximately 20 times greater levels in the healthy gut^[217]. Currently, the levels of these inhibitory VEGFs are unknown in IBD, but may provide a new avenue for anti-angiogenic therapies, we are pursuing this possibility which is currently showing great promise (unpublished data).

IBD THERAPIES

It is increasingly clear that IBD therapies affect the microvasculature, and that the microvasculature is a central target in IBD, coordinating cell infiltration, solute permeability, cytokine/chemokine production and gut immunological responses. An increasing number of drugs that show efficacy in treating IBD have now been found to affect the endothelium. Accumulating evidence suggests inhibition of angiogenesis as a secondary mechanism of action for many IBD therapies including anti-TNF- α antibodies, and some immunosuppressive agents (cyclosporine A)^[218-220]. Scaldaferrri *et al.*^[167] found TNF- α mediated lymphocyte adhesion and chemotaxis across intestinal microvascular ECs depends on expression of ICAM-1, VCAM-1 and fractalkine in the affected ECs mediated by p38 MAPK, p42/44 MAPK and JNK. Danese *et al.*^[71] found that anti-TNF- α therapies can reduce thrombus formation and adhesion to the endothelium by interfering with CD40/CD40L signaling. Integrin-blocking antibodies have been used in the treatment of IBD, but not without a controversial side effect. Natalizumab (Tysabri), an α 4-integrin blocking monoclonal antibody originally developed for use in the treatment of multiple sclerosis, but has recently been approved for the treatment CD^[21,221]. AJM300, a peptide blocker for α 4 integrins, successfully blocked α 4-VCAM-1 and MAdCAM-1 adhesion and prevented exacerbation in IBD models^[20,21]. However, recent preclinical trials using AJM300 failed to inhibit disease progression^[20,21]. Rafiee *et al.*^[222] found that 2 drugs used in IBD, thalidomide and cyclosporine-A, are anti-angiogenic; thalidomide targets TNF- α and VEGF-A, while cyclosporin-A targets VEGF-A alone^[222,223]. Studies by Ogawa *et al.*^[224] determined that HIMEC expression of the inflammatory mediators IL-6 and cyclooxygenase (COX)-2

by LPS were inhibited by butyrate, and that butyrate also inhibited HIMEC angiogenesis^[224-226]. Despite its anti-inflammatory properties^[223,227,228], cyclosporin-A increases leukocyte binding, unlike thalidomide which reduces leukocyte binding to HIMECs^[227,228].

IBD-INDUCED ANGIOGENESIS AND COLORECTAL CANCER

The risk of developing cancer is elevated by inflammation, and the link between IBD and colorectal cancer (CRC) is convincing^[229-231]. Inhibition of angiogenesis in CRC by bevacizumab (anti-VEGF monoclonal antibody) improves clinical outcomes, revealing the importance of angiogenesis in the progression from IBD to CRC^[232]. As stated before, IBD in human disease and animal models is associated with an increase in vascular density, and it is possible this vascular endothelial expansion may enable CRC^[158,163,169]. CRC incidence may depend on COX expression (seen in adenomatous polyposis coli, pre-cancerous lesions enriched in COX^[233-235]). COX-2 is increased in human IBD and IBD models, and may promote CRC through angiogenesis^[236,237]. COX-2 promotes EC proliferation by prostaglandin induction of VEGF-A, important for tumor angiogenesis^[237,238]. Chan *et al.*^[239] reported that the regular use of aspirin, a non-selective COX inhibitor, significantly reduced the risk of COX-2⁺ CRC, which constitutes approximately 67% of human CRC^[239,240]. Additionally COX-2 inhibition reduces tumor growth and increased tumor apoptosis, and is associated with reduced tumor angiogenesis^[238,241,242]. Conversely, Ishikawa *et al.*^[243] found that COX-deficient animals were not protected from tumor formation in azoxymethane (tumor promoter)-induced colorectal cancer, and concluded that COX expression was not a major determinant of tumor formation in UC. While COX expression may not be necessary for tumor formation in UC, COX-2 upregulation is only one mechanism for increased angiogenesis in IBD^[86,166,189]. VEGF-A and other angiogenic factors are upregulated independent of COX-2 in IBD; therefore, while COX-2 may be important in CRC in the absence of IBD, expansion of the vasculature in IBD through other mechanisms may contribute to the development and growth of CRC^[166,244].

CONCLUSION

A unique combination of genetic and environmental factors may contribute to development of IBD. ECs are now recognized as central and fundamental elements in IBD pathophysiology. ECs are indirectly affected by many IBD medications, which are increasingly targeting ECs directly. As treatments for IBD are developed and refined there will be an increased interest in inhibiting functions of ECs in IBD such as immune cell recruitment and inflammatory angiogenesis, and improving beneficial lymphatic function. Use of endogenous inhibitors of leukocyte binding (sVCAM) and peptides (AJM300) may become novel therapies which supplement or replace current anti-

adhesion treatments. Additional studies on the interactions between the gut microvasculature, platelets and their regulation of inflammatory angiogenesis may provide new avenues for treatments that not only reduce thrombosis but also several clinical manifestations of IBD. Inhibition of inflammatory growth factors, cytokines and chemokines that promote angiogenesis by the use of “traps” or decoy receptors, alone or in combination, in addition to current treatments could provide greater anti-inflammatory effects by reducing endothelial expansion in IBD. More importantly, work in our laboratory suggests that endogenous angiogenic inhibitors (VEGF164b) have great potential in the treatment of IBD. Future studies promoting therapeutic intervention by combining anti-angiogenic, anti-immune and anti-inflammatory agents as treatment options focusing on the endothelium as core/vital for IBD pathogenesis will provide greater specificity and efficacy for treating CD and UC patients.

Abstract

Inflammation and coagulation constantly influence each other and are constantly in balance. Emerging evidence supports this statement in acute inflammatory diseases, such as sepsis, but it also seems to be very important in chronic inflammatory settings, such as inflammatory bowel disease (IBD). Patients with Crohn's disease and ulcerative colitis have an increased risk of thromboembolic events, and several abnormalities concerning coagulation components occur in the endothelial cells of intestinal vessels, where most severe inflammatory abnormalities occur. The aims of this review are to update and classify the type of coagulation system abnormalities in IBD, and analyze the strict and delicate balance between coagulation and inflammation at the mucosal level. Recent studies on possible therapeutic applications arising from investigations on coagulation abnormalities associated with IBD pathogenesis will also be briefly presented and critically reviewed.

INTRODUCTION

Inflammation and coagulation are two crucial systems in mammals. They constantly influence each other and are constantly in balance. In particular, inflammatory processes can promote coagulation which, in turn, can also sustain inflammation. The inter-dependence of the two processes is confirmed by clinical settings where the inherited or acquired deficiency of natural anticoagulants is associated with an increase in inflammatory processes^[1].

This observation is particularly relevant in acute inflammatory diseases, such as sepsis^[1], but it also seems to be very important in chronic inflammatory conditions, such as inflammatory bowel disease (IBD).

Patients with Crohn's disease (CD) and ulcerative colitis (UC) have an increased risk of thromboembolic events^[2], which appears to be more frequent when IBD is in an active phase^[3-5] and is affecting the whole colon^[3,6,7]. However, it is worth noting that, in a large study, one-third of thromboembolic complications occurred during

disease quiescence, supporting the hypothesis of a greater prothrombotic tendency in IBD, independent of disease activity^[3].

The incidence of thromboembolic events in patients with IBD has been reported to be 1%-8%^[4,8,9]. Patients with IBD have a 3-fold increased risk for deep vein thrombosis and pulmonary embolism compared with the general population^[8,10,11]. In addition, IBD patients experience more thromboembolic events at a younger age than the general population or patients affected by rheumatoid arthritis or celiac disease^[4,8].

Finally, indirect evidence that vascular thrombosis may be involved in the pathogenesis of IBD was provided by an epidemiological study performed on a large cohort of subjects with hemophilia or von Willebrand's disease^[3,12]. In this population, in which more than 9000 patients were included (6000 patients with hemophilia and more than 3000 with von Willebrand's disease), IBD occurred less frequently than expected, and it was suggested that inherited hemorrhagic disorders might be protective against IBD^[3].

Most available reports tried to explain the increased thromboembolic risk in IBD by analyzing different components of the coagulation cascade, such as serological/phenotypical markers and genetic pro-thrombotic mutations/polymorphisms. Several studies exist on major pro-thrombotic genetic predispositions and IBD. Most published data demonstrate that there is no difference in the prevalence of Factor V Leiden between IBD patients and healthy controls^[3,13-15], as well as PT gene G20210A mutation^[3,15-17]. Polymorphisms of Methylenetetrahydrofolate reductase, the enzyme involved in the re-methylation pathway of homocysteine metabolism, have been found to have discordant results in IBD patients compared to controls^[3,15,18]. Other studies looking at the prevalence of Antithrombin III deficiency^[17,19], Protein C^[20] and Protein S deficiencies^[21] in IBD have been contradictory or equivocal^[22,23], suggesting that these factors, although possibly related to IBD pathogenesis, are not genetically related to IBD^[23]. Finally, the inherited Val34Leu factor XIII polymorphism, which is protective against thrombosis, has been evaluated in IBD patients^[3,24]. Available data demonstrated no significant difference in the prevalence of this polymorphism in IBD patients with respect to the general population^[25].

Taken together, the information on genetic factors does not explain the greater risk of venous thrombosis in CD and UC^[26,27]. On the contrary, a pathogenesis-oriented approach suggests that the coagulation abnormalities occurring in IBD are very likely the result of the biological and biochemical effects exerted by the activation of the inflammatory machinery (cells, cytokines, *etc.*) in these disorders. Furthermore, activation of the coagulation cascade can in turn sustain activation of inflammatory reactions, promoting the vicious circle between chronic inflammation and thrombosis.

In this review, we will firstly describe single quantitative abnormalities of coagulation factors observed in IBD and cellular components closely involved in the co-

agulation pathway. We will then describe the mechanisms by which these abnormalities interfere with intestinal mucosa homeostasis. Finally, the possible therapeutic implications emerging from the unraveling of coagulation abnormalities associated with IBD pathogenesis will also be briefly presented and critically reviewed

QUANTITATIVE ALTERATIONS OF HEMOSTATIC FACTORS IN IBD

Coagulation is a complex system, which can be schematically divided into different pathways, referred to as "intrinsic", "extrinsic" and "common" pathways^[28]. An important role is also played by the fibrinolysis system, which controls clot dissolution, and the family of serine protease inhibitors, which inhibits many coagulation enzymes. We will use this classification to better summarize findings concerning the linkage between the coagulation system and inflammation associated with IBD.

The extrinsic pathway

The extrinsic pathway is initiated by tissue damage that exposes tissue factor (TF) to blood, causing the formation of TF/FVIIa, which circulates at low levels in the bloodstream. It is thought that high factor VIIa activity is associated with an increased risk of ischemic myocardial events in men over 40 years of age^[8,29]. It is the main determinant of the laboratory assay referred to as prothrombin time (PT). No definitive data are available on changes of the extrinsic pathway in IBD. Most of the data available report no significant difference in PT among active UC and/or CD and control patients^[3,8,30]. Other studies reported different findings showing that PT values and platelet levels are predictors of CD activity index in female patients^[2]. Levels of factor VIIa seem to be higher in active IBD compared to controls^[3,31,32]. This finding suggests the existence of a pro-thrombotic tendency in IBD patients, arising from activation of the extrinsic pathway.

The intrinsic pathway

Activation of the "intrinsic" pathway of coagulation leads to formation of factor Xa (FXa)^[28]. This process stems from previous activation of Factor IX and FVIII, with formation of the tenase complex, that is FVIIIa-factor IXa on the membrane of platelets and endothelial cells^[28]. As FVIII strongly accelerates the formation of FXa, recent studies showed that inherited high levels of FVIII (> 140%) can be considered a risk factor for venous thromboembolic disorders^[33]. No significant difference in APTT value or FVIII level was observed in IBD patients compared to controls^[8,34]. However, higher APTT levels were found in other reports, although this finding may be the expression of mere consumption of some coagulation factors upon their activation^[2]. Other investigations found that factor XIa and XIIa levels, were higher in active IBD patients compared to patients in the quiescent phase^[8,35]. This finding may be in agreement with studies showing that higher levels of FXIa and FXIIa may be considered coagulation

markers associated with increased risk for thromboembolic disorders^[36-38].

The common pathway

FXa thus occupies a central position in the coagulation cascade as a convergence point between the intrinsic and extrinsic pathway. In fact, in the presence of its cofactor FVa, FXa converts prothrombin to thrombin^[28]. The common pathway is considered the main determinant of both PT and APTT assays. In observational studies, FXa and FVa levels were significantly elevated in active IBD patients compared to those in patients with disease remission^[3,8,39]. The protease-mediated stimulus for inflammatory reactions, particularly for FXa and thrombin, is mediated by cleavage of membrane cleavable receptors and will be discussed below.

The thrombin-generating system

Markers of the thrombin generating system directly involve zymogen prothrombin but also other side-products of prothrombin cleavage such as prothrombin fragment 1+2 (F₁₊₂) and the thrombin-antithrombin complex (TAT). Prothrombin levels in active IBD patients were significantly higher than those in patients with inactive disease or control patients^[8,30,32,39-41]. The same observation was also made for F₁₊₂ and TAT, suggesting that thrombin generation might be an early event in IBD^[8,40,42,43].

Factor XIII

Coagulation factor XIII is a plasma transglutaminase involved in the crosslinking of fibrin, the last step of the coagulation cascade and a connective tissue factor contributing to the wound healing process. It circulates as a heterotetrameric molecule consisting of two identical proenzyme subunits (factor XIIIa) and two carrier protein subunits (factor XIIIs).

A study by Chiarantini *et al.*^[30] reported decreased factor XIII (FXIII) levels, especially in acute phases of the disease, and deposits of FXIII have been detected in both affected and macroscopically normal bowel mucosa^[30,41,43-45]. Those results were confirmed by several other reports, comparing IBD patients to control subjects as well as patients affected by diverticulitis and rheumatoid subjects^[46,47]. As anticipated above for other coagulation factors, this finding does not play an etiopathogenetic role in IBD but may represent only the result of chronic consumption of this enzyme associated to deposition of fibrin at the level of inflamed vessels in enteric mucosa.

The system of natural coagulation inhibitors

The system of coagulation inhibitors is composed of a family of proteins, globally referred to as serpins, a typical example of which is antithrombin (AT), and by the protein C pathway, in which a series of different proteins (such as protein C and protein S) and membrane receptors [thrombomodulin (TM), endothelial protein C receptor (EPCR)] are involved. AT is the physiological inhibitor of thrombin, factor Xa, FIXa, FXIa and FXIIa. There is a growing body of evidence that AT is not only an inhibitor

of blood coagulation, but it is also able, when present at high concentrations, to reduce the inflammatory responses of endothelial and other cells^[48-50]. Thus, AT was shown to reduce the mortality of patients with severe sepsis in a recent clinical trial^[49]. AT-induced attenuation of inflammatory responses might be linked to endothelial production of prostacyclin and inhibition of leukocyte and endothelial cell expression of pro-inflammatory mediators *via* suppression of nuclear factor (NF)- κ B activation^[48,50,51]. Furthermore, AT prevents water-immersion restraint stress-induced gastric mucosal injury in rats by promoting the endothelial release of PGI₂^[52]. In addition, non-uniform information exists on the quantitative expression of these components in IBD. Overall, it seems that no differences in the levels of protein S^[8], protein C^[3,53] and ATIII^[34,41] exist among IBD patients compared to controls. However, in studies comparing the levels of these molecules in the active *vs* inactive form of the disease or in controls, lower levels of protein C, ATIII and protein S were observed^[21,30,34,53,54]. In a single study, higher levels of protein S and C in IBD patients compared to controls were also reported^[30]. These conflicting results indicate that changes in systemic levels of these inhibitors do not necessarily reflect the local loss of inhibition of coagulation occurring within enteric mucosa in IBD. Hence, a new approach has tried to correlate an enhanced production of thrombin in IBD with a possible loss of function in natural anticoagulants mostly occurring on the endothelium of enteric mucosa. This issue will be addressed in the section below.

The fibrinolytic system

In normal hemostasis, the fibrinolytic system allows removal of a fibrin clot when the damaged vessel wall is restored. Activation and regulation of fibrinolysis occurs by multiple proteins and results in the generation of plasmin. Plasminogen may be activated by tissue plasminogen activator (tPA) or urokinase plasminogen activator (uPA). The latter binds to a cellular receptor [urokinase plasminogen activator receptor (uPAR)] resulting in enhanced activation of cell-bound plasminogen and its main role is the induction of pericellular proteolysis^[55]. tPA is the most potent activator of plasminogen in plasma and the main regulator of fibrinolysis. After stimulation, tPA is locally released into the circulation from the endothelial cells where it is produced. tPA-mediated plasminogen activation is facilitated by a fibrin surface, which restricts fibrinolysis to the site of thrombus formation^[56]. Moreover, once bound to fibrin, tPA is protected from inhibition by plasminogen activator inhibitor 1 (PAI-1), its principal inhibitor in plasma^[57]. The level of PAI-1 in blood usually exceeds that of tPA; thus, in general, no active tPA circulates in plasma^[58].

α_2 -Antiplasmin is the primary physiological inhibitor of plasmin, as it can very rapidly inhibit plasmin in plasma^[59]. However, plasmin is partly protected from α_2 -antiplasmin inhibitory activity when the enzyme is bound to fibrin^[60]. During thrombus formation, α_2 -antiplasmin is cross-linked to fibrin by factor XIIIa, facilitating local inhibition of fibrinolysis^[61].

Another important player in the fibrinolytic system is

thrombin-activatable fibrinolysis inhibitor (TAFI), which directly connects coagulation and fibrinolysis. It is activated by thrombin, but its activation is over 1000-fold enhanced by the thrombin-TM complex. Activated TAFI removes carboxyl-terminal lysine residues from partially degraded fibrin. Consequently, the binding of plasminogen and tPA to fibrin clots is decreased, which attenuates clot lysis^[62].

Reduced activity of the fibrinolytic system has been described in IBD^[63-65]. Indeed, a reduction in activators (such as tPA) and an increase in inhibitors (such as PAI and TAFI) of the fibrinolytic system have been described in IBD patients^[40,63-66]. This condition would favor pro-thrombotic mechanisms.

Cellular elements involved in the coagulation pathway

The haemostatic system is composed not only of soluble proteins and enzymes but also of different cell types. Platelets and endothelial cells play a central role in the maintenance of a physiological balance between pro- and anti-coagulant mechanisms. Moreover, accumulating evidence indicates that platelets and endothelial cells, besides their well-known haemostatic functions, play a role in inflammation and its resolution mechanisms^[67].

Platelets

Platelets can release a number of mediators of the inflammatory response, including cytokines, chemokines, nitric oxide (NO) and eicosanoids. Furthermore, they interact with polymorphonuclear cells (PMN) and monocytes, regulating their extravasation and recruitment at sites of inflammation. Along these lines, platelets have the enzymatic machinery to synthesize both pro- and anti-inflammatory eicosanoids. As an example, platelets contain 2-lipoxygenase (12-LO), a key enzyme in the biosynthesis of the lipoxins (LXs), arachidonic acid metabolites with potent anti-inflammatory properties^[68]. LX formation during platelet/PMN interactions occurs *in vivo* and represents a main stop signal of inflammation^[69]. Thus, a sustained inflammatory response, as it occurs in IBD may originate by both increased formation of pro-inflammatory mediators, and reduction in counter-regulatory signals.

Platelet integrin GPIb α is a ligand of P-selectin, a transmembrane adhesion molecule present on endothelial cells, and supports platelet rolling on activated endothelium. P-Selectin binding to P-Selectin Glycoprotein Ligand 1 (PSGL-1) stimulates the release of microparticles bearing tissue factor on their surface by leukocytes^[70]. P-selectin is split as a soluble form (sP-selectin) that stimulates expression and exposition on the monocyte surface of further tissue factor^[71]. Microparticles, together with sPselectin, are considered the main factors responsible for the high procoagulant status of blood in inflammation^[72]. During adhesion to endothelium, platelets release pro-inflammatory cytokine CD40-ligand (CD40L) (CD154, gp39) that can stimulate the endothelium, stabilize platelet aggregates, their binding to blood cells and vascular wall cells and promote stable thrombus formation^[73]. CD40L is expressed on activated platelets and also on immune system cells activated during inflammation (activated

CD4⁺ T cells, basophils, and mast cells)^[74]. This factor is a transmembrane protein related to tumor necrosis factor (TNF)- α . The inducible CD40L on platelets binds to the CD40 receptor on endothelial cells and on monocytes, macrophages, and smooth muscle cells (SMC)^[74]. The CD40/CD40L interaction plays an important role in inflammation and atherothrombosis^[73]. Through binding to the ligand, CD40 induces the inflammatory response independent of cytokines. The pro-inflammatory activity of CD40L also occurs on platelets and other cells by stimulation of the expression of chemokines [monocyte chemoattractant protein 1 (MCP-1)], interleukins (IL-6, IL-8), pro-inflammatory adhesive molecules [vascular cell adhesive molecule-1 (VCAM-1)], intracellular adhesive molecules (ICAM-1, CD54), and P-/E-selectins.

Notably, the activity of CD40L induces the expression of tissue factor, which, as mentioned above, is the major inducer of blood coagulation, and suppresses the expression of TM, which is a thrombin cofactor in activation of the protein C anticoagulant system^[75]. Upon binding of CD40L to the CD40 receptor, intracellular signaling results in activation of the transcriptional factor NF- κ B and its translocation into the nucleus. This event induces the expression of new molecules of CD40L and CD40. The interaction of CD40 expressed by endothelial cells with CD40L exposed on activated platelets stimulates the synthesis of a powerful pro-inflammatory mediator, platelet activating factor (PAF), which induces platelet aggregation with leukocytes and also contributes to remodeling of vessels, stimulating neo-angiogenesis^[76].

Platelet activation is associated with the metalloprotease-mediated split of a soluble fragment of the CD40-ligand (sCD40L)^[76]. Soluble CD40L was shown to promote blood coagulation by two mechanisms: induction of tissue factor expression on monocytes and activation of platelets *via* interaction with integrin α II b/ β 3. The sCD40L binding to integrin α II b/ β 3 activates platelets at high shear stress and stabilizes arterial thrombi^[74]. Increased levels of CD40L on platelets and sCD40L in circulating blood were found in clinical settings characterized by thrombosis associated with inflammation, such as unstable angina, myocardial infarction and other cardiovascular diseases^[77,78].

Thus, a realistic scenario shows that platelet activation during inflammation and expression of adhesive proteins, P-selectin and integrins, leads to their aggregation with leukocytes and the release of contents of intracellular granules. In conclusion, platelet-platelet and platelet-leukocyte aggregates produce a cell surface, which provides activation of both blood coagulation and inflammation.

The association between active IBD and thrombocytosis was first recognized in 1968 and it became clear that patients with IBD also have increased numbers of circulating platelet aggregates and activated platelets compared with healthy controls^[79-81]. More recently, it was demonstrated in studies from different groups that supranormal platelet-leukocyte aggregates are frequently present in patients with IBD compared with both healthy and inflammatory controls^[82]. In other studies, significant changes in platelet volume were also observed^[83,84]. In particular, an

increase in platelet count^[83] and a statistically significant decrease in MPV was noted in patients with colitis compared with healthy controls. Moreover, MPV of active colitis patients was significantly lower than that of the inactive phase of the disease. It is, however, difficult to correlate this finding with the functional alterations that could be responsible for the platelet-mediated thrombotic mechanisms summarized above. It may be hypothesized that in IBD the reduction in MPV may be associated with a peripheral platelet activation responsible for an exalted formation of platelet-platelet, platelet-PMN and platelet-endothelium adducts. This process would mainly involve younger platelets which have a bigger volume. Thus, the overall reduction of MPV could reflect the relative prevalence in circulating blood of less reactive platelets, which are older and smaller^[85]. In a very recent study, an enhanced expression of CD40/CD40L in intestinal epithelial cells was demonstrated^[86]. In particular, endoscopy biopsies taken from CD and UC patients showed a positive immunofluorescence staining for CD40 in intestinal epithelial cells of inflamed ileal or colonic mucosa, while no staining was observed in uninvolved intestinal segments^[86]. These findings provide, for the first time, direct evidence for the epithelial expression and modulation of CD40 in IBD-affected mucosa and indicate its involvement in the pro-inflammatory and platelet-activating function of inflamed intestinal cells.

Finally, another paper from our group showed that *in vitro* activated platelets directly increase CD40L expression by intestinal endothelial cells, leading them to interact with other immune cells and sustain intestinal chronic inflammation. This pathway has been proposed as a new mechanism of chronic inflammation, as a result of the complex interplay among different cell types in the intestinal mucosa^[87].

Endothelium

In a normal artery, endothelium creates a non-thrombogenic surface that acts as a selectively permeable barrier. Endothelium plays a key role in response to vascular injury, regulating leukocyte adhesion, platelet activation and adhesion and blood coagulation. Endothelium expresses and responds to multiple active substances, including cell adhesive molecules, cytokines and chemokines, to accomplish these functions^[88,89]. Injury to a vessel wall results in the triggering and propagation of inflammatory and coagulation events. The cell adhesion molecules (CAM) are expressed onto the surface of activated endothelial cells and attach leukocytes and platelets. Adhesive proteins provide for the binding and spreading of leukocytes, their rolling, and their further transmigration across endothelium. There are three major classes of CAM: selectins, the immunoglobulin superfamily CAM and integrins. Some integrins in turn can be receptors of CAM and the endothelial adhesion molecule, von Willebrand factor (VWF), which binds platelets.

Weibel-Palade bodies in endothelial cells and platelet α -granules contain and release platelet P-selectin (CD62P, GMP140) responsible for adhesion of leukocytes, their

rolling, and for stabilization of platelet aggregates^[90,91]. The lectin-containing N-terminal domain of P-selectin binds to PSGL-1 on monocytes, neutrophils and platelets^[91,92].

E-selectin (CD62E) is another molecule exposed on the endothelial cell surface that can bind to PSGL-1 in response to mechanical injury and inflammatory mediators as IL-1 β , TNF- α , bacterial toxins and oxidants^[89]. P- and E-selectin mediate rolling of activated and quiescent platelets on activated endothelium similar to the mechanism of leukocyte rolling^[93].

The immunoglobulin superfamily CAM includes ICAM-1 (CD54), ICAM-2 and VCAM-1, which are expressed by many cell types including endothelial and SMC. In response to vascular injury, these cells upregulate expression of ICAM-1 and VCAM-1^[89], engaged in leukocyte adhesion. Adhesion of platelets to injured endothelium is controlled by VWF, a multimeric protein, whose molecular weight ranges from 0.5 to 20 million Da^[94] and is stored and released from Weibel-Palade bodies in endothelial cells^[95]. Hence, VWF is considered a marker of endothelial injury. The VWF molecule contains domains responsible for binding blood coagulation factor VIII and platelet integrins such as glycoprotein transmembrane complexes GPIb/IX/V and integrin α IIb β 3 (GP IIb/IIIa), as well as collagen^[94]. VWF binds subendothelial collagens and after immobilization attaches to platelets *via* the membrane complex GPIb α -IX-V^[96]. VWF may be involved in the pathogenesis of acute thrombotic occlusion of stenosed arteries, where high shear stress promotes the formation of "stretched" VWF conformers, which are suitable for binding to platelets and subendothelial components^[88]. P-Selectin could serve as an anchor site for the ultra large VWF multimers on the surface of activated endothelium, to facilitate their cleavage at the Tyr1605-Met1606 peptide bond by the disintegrin and metalloproteinase with thrombospondin motif-13 (ADAMTS-13)^[97]. Microvascular dysfunction has been clearly demonstrated in IBD patients and involved several aspects of endothelium biochemical physiology^[98,99]. In particular, such dysfunction involves an alteration in nitrogen and reactive oxygen species balance, where the microvascular endothelium fails to generate \cdot NO, a potent vasodilator and anti-aggregating agent, forming instead elevated levels of superoxide anion^[54]. However, the mechanism responsible for the loss of endothelial nitrogen oxide in IBD gut microvessels also involves additional biochemical pathways. Previous studies showed an acquired deficient transcription of nitric oxide synthase 2 (NOS2) in chronically inflamed IBD endothelium^[100]. Furthermore, more recently, it was demonstrated that decreased production of nitrogen oxide in IBD endothelial cells can also arise from the induction by many inflammatory cytokines (IL2, TNF- α) of the enzyme arginase (isoform I and II)^[101]. This enzyme converts L-Arg into urea and L-ornithine, precursors for polyamines and L-proline compounds, which are vital to tissue homeostasis and wound repair^[102]. Arginase I and II compete with inducible NOS (iNOS, NOS2), the most relevant inducible pathway for the production of \cdot NO, for L-Arg, which is their common substrate in endothelial cells^[103]. Thus, an

increased arginase activity in IBD may contribute to inhibit the production of a potent antithrombotic agent such as nitric oxide. The increased production of reactive oxygen species in inflamed endothelium may also contribute to oxidative stress in VWF molecules, which become unresponsive to proteolysis by ADAMTS-13 and the accumulation of ultra large VWF multimers^[104]. The latter are the most haemostatically active forms of VWF and, favoring platelet adhesion and aggregation, may contribute to microvascular thrombosis in IBD.

To conclude, endothelium plays an essential role in inflammation due to its central “gatekeeper” function, which controls the quality and quantity of leukocytes that transmigrate from the vasculature into the interstitial space, regulates vascular tone and promotes platelet adhesion and aggregation. The latter function directly affects the haemostatic system and may clearly favor thrombotic phenomena. Several papers reviewed over the last few years suggest an activated status of endothelium in the course of IBD^[98,99].

A COHERENT SCENARIO FOR UNBALANCED HAEMOSTASIS IN IBD

At this point a question arises as to whether the haemostatic and inflammatory alterations briefly described in the above paragraphs could be functionally linked in a coherent framework.

Globally, the coagulation system in IBD patients seems to sustain pro-thrombotic mechanisms, involving both soluble factors and cells, such as platelets, endothelium and leukocytes. This conclusion is supported by results obtained from new laboratory assays. The conventional and global coagulation tests such as PT and APTT both have low sensitivity and specificity and do not contain sufficient amounts of TM or glycosaminoglycans. Thus, these assays do not automatically reflect the coagulation reactions and their inhibition as they occur *in vivo*^[105,106]. In contrast, the latest generation of methods that monitor the tissue factor induced thrombin generation in the presence of TM are credited as better laboratory tools to represent the balance of pro- and anti-coagulant forces operating in plasma^[105-108]. In a recent study from Saibeni *et al*^[105] endogenous thrombin potential, a parameter of the thrombin generation curve, was significantly higher in IBD patients than controls only when the test was performed in the presence of TM. This new assay strongly suggests that in IBD, as anticipated above, the increased generation of thrombin is mainly linked to a partial loss of function of natural anticoagulant pathways, and particularly of the TM-PC system.

Thus, systemic coagulation alterations in IBD may be recognized using more sophisticated techniques, which better reflect the *in vivo* setting. Furthermore, pathogenic considerations suggest that the coagulation imbalance in IBD could be particularly relevant in the vasculature of enteric mucosa, where inflammation shows the majority of destroying effects.

THE INFLAMMATION-COAGULATION INTERPLAY WITHIN THE INTESTINAL MILIEU

In addition to the demonstration that coagulation abnormalities and thromboembolic complications are clinically relevant events in IBD, they have been shown to exert effects at the mucosal level, where a coagulative imbalance exists^[3].

In fact, one of the earliest abnormalities in CD mucosa is the presence of platelet thrombi cross-linked with fibrin in the mucosal microvasculature^[109]. This feature, however, is not specific for CD and can be found in other idiopathic IBD^[110]. The involvement of the microcirculation in IBD pathogenesis is underlined by the analysis of a segment of the small and/or large bowel during active IBD which reveals vasodilatation, venocongestion, edema, infiltration of large inflammatory cells and ulcerations^[111]. This picture is the result of an unregulated intestinal inflammation with a consequent abnormal immune response and production of inflammatory cytokines, which, in turn, sustain the activation of the microvascular endothelium and subsequent recruitment of more leukocytes into the intestinal wall. This uncontrolled inflammatory response produces dramatic alterations in gut microvascular function which contributes greatly to perpetuating the inflammatory damage observed in IBD^[98,112].

Coagulation factors mainly interact with local endothelium, although this interaction is potentially conditioned by many features of the mucosal immunity.

The principal link between endothelium and the coagulation cascade is determined by Protease-activated receptors (PARs)^[113]. PARs, and in particular PAR-1 and PAR-2, are cellular receptors activated after proteolytic cleavage by enzymes^[114], mainly thrombin and activated factor X. Only a single study reports over-expression of PAR1 in patients with IBD^[115], and there are no data available on animal models addressing its role in IBD. The expression of PAR2, which is greatly increased in patients with UC and CD^[116-118], and the functional consequences of its activation in animal models are more widely documented.

Next to expression in the intestine, PAR expression in enteric neurons might be highly relevant for IBD because PARs can mediate gut inflammation *via* neurogenic mechanisms. Interestingly, PAR activation on submucosal and myenteric neurons causes severe edema in rat models. Moreover, the local activation of PAR2 but not PAR1 in the gut causes colitis through a neurogenic mechanism^[116]. Taken together, these results point towards PAR2 expression/cleavage as a cardinal factor in IBD.

The APC-TM system is the natural pathway by which the pro-inflammatory activity of PAR-1 and 2 signaling is contra-balanced. In the following section major findings on how thrombin, factor X and APC contribute to IBD, will be shown and briefly discussed.

Thrombin

Once thrombin is sequentially activated through the in-

trinsic and extrinsic pathway, it not only amplifies the coagulant process but it can also favor inflammation induced by other stimuli, either through ischemia (consequent upon thrombosis), indirectly through the generation of downstream mediators or directly *via* signals through protease-activated receptors (PAR)^[119].

Thrombin activates PARs, thereby establishing a link between activation of coagulation and pathophysiology of IBD. Indeed, thrombin signals through PAR1, PAR3 (in mouse) and PAR4, while tissue factor (TF)/FVIIa activates PAR2, and FXa activates PAR1 and PAR2^[116,120].

In addition to promoting platelet activation, thrombin exerts influence over monocytes, macrophages^[121] and neutrophils in processes related to tissue repair at the site of injury^[122,123]. Thrombin also interacts through an equilibrium high affinity binding with the N-terminus of GpIb α of platelets and endothelial cells^[124,125]. Notably, on platelet membrane, binding of thrombin to GpIb, accelerates cleavage of PAR1 by the enzyme^[126]. Thrombin also affects endothelial cells through various pathways including NF- κ B, early growth response factor-1 and GATA binding proteins^[127]. Thrombin signaling might result in post-transcriptional changes, including calcium influx, cytoskeletal reorganization, and release of soluble mediators, growth factors, and matrix metalloproteinases. In addition, thrombin signaling results in changes in downstream gene transcription, for example increasing the expression of genes involved in cell proliferation, inflammation, leukocyte adhesion, vasomotor tone, and hemostasis^[128-130].

Factor Xa

Borensztajn *et al*^[116] suggested that Factor Xa signaling through PAR2 contributes to the progression of IBD and fibro-proliferative responses. Because FXa is a well-known PAR2 agonist, FXa-induced PAR2 activation is gaining attention in intestinal pathology. Accordingly, in a variety of endothelial *in vitro* systems, FXa induces an array of pro-inflammatory responses and the deposition of connective tissue growth factor^[116,131,132]. It also leads to the activation of NF- κ B, and the release of IL-6, IL-8, and MCP-1 on endothelial cells as well as fibroblasts^[120,133]. Moreover, on endothelial cells, FXa induces the expression of E-selectin and both intracellular ICAM-1 and VCAM-1, resulting in leukocyte adhesion^[116,134,135]. In synergy with tumor necrosis factor, FXa induces TF expression *via* inhibition of its negative regulators I κ Ba and A20^[116,136]. Most of these responses are mediated *via* PAR2 activation, although some studies showed minor involvement of PAR1^[136,137].

Although the potential pro-inflammatory role of FXa on epithelial cells of the gastrointestinal tract is not fully investigated, studies on Hela cells showing that FXa induces activation of the pro-inflammatory transcription factor NF- κ B, suggest that it plays an important role^[116,138]. Finally, FXa also affects immune cells inducing the production of IL-2 by lymphocytes^[139]. Evidence that FXa may mediate inflammatory responses *in vivo* has come from several studies. In particular, Cirino *et al*^[140] demonstrated that FXa induces the formation of edema when

injected subcutaneously in a rat paw inflammation model, *via* local recruitment of mast cells.

The PC pathway

Traditionally described as a major anti-coagulant system, the protein C (PC) pathway, consisting of TM, the EPCR and activated PC (APC), is gaining increasing attention as an important regulator of microvascular inflammation, and in particular intestinal inflammation observed in IBD^[141]. The anticoagulant function of the PC pathway has been reviewed extensively^[142-144]. The main components of the PC system are the cell membrane receptor for PC, referred to as EPCR, the integral membrane glycoprotein TM, and two vitamin K-dependent plasma proteins, the zymogen PC, and the cofactor protein S. Upon cleavage of a dodecapeptide from the N-terminus of the light chain of PC by the thrombin-TM complex, the zymogen PC is activated to PC. Protein C *per se* is a poor substrate for thrombin. Allosteric binding of free thrombin to TM enhances, by several orders of magnitude, the thrombin-PC interaction and subsequent conversion of PC zymogen into its proteolytically active form, APC. The rate of PC activation by the TM-thrombin complex is further enhanced when the substrate PC zymogen is bound to its receptor, EPCR, which is able to reduce the K_m value of the catalytic interaction with thrombin. The extent of *in vivo* PC activation is therefore greatly linked to the bioavailability of PC, thrombin and, critically, by the density of TM and EPCR molecules expressed on endothelial cells. With the exception of disseminated intravascular coagulation, consumptive coagulopathy and defective biosynthesis, thrombin bioavailability in first approximation reflects the intensity of coagulation activation. Within such limits, it was shown that thrombin formation and generation of APC are strongly correlated^[145]. APC is formed mainly within the microcirculation, where endothelial cells express high levels of TM. As a consequence, due to the very small intravascular volume, the concentration of TM may be > 100 nmol/L, greatly exceeding the K_a value of the thrombin-TM interaction. Under these conditions, any amount of formed thrombin is rapidly and completely bound to TM. At variance with this situation, expression of TM is much lower in the endothelium of larger arteries and veins. Notably, EPCR expression is inversely related to that of TM, as it is more abundant in large vessel endothelium than in microcapillary beds. Thus, the efficiency and extent of APC formation differs considerably between different organs. The anticoagulant activity of the PC pathway includes the limited proteolysis by APC of the activated forms of coagulation factors V and VIII (FVa and FVIIIa), thereby limiting active thrombin generation. Protein S, in turn, cooperates with APC in inactivating FVa and FVIIIa, exerting an accelerating effect^[146]. The current model of APC suppression of excessive thrombin generation assumes that the EPCR-bound pool of endothelial cell-associated APC plays a more important role for FV inactivation than the circulating plasma pool of APC. In part, this may be explained by the fact that binding of APC to cell surfaces is

mediated only by EPCR, implying that the site of EPCR expression largely dictates the site of the anticoagulant function of APC. This model is fully consistent with the finding that FVa is highly susceptible to proteolytic degradation by APC when it is associated with the endothelial cell surface. FVa is instead refractory to APC cleavage in the platelet-associated prothrombinase complex^[147]. Other mechanisms can potentially limit the anticoagulant activity of APC on, or close to platelets, i.e. inhibition of APC by the vitronectin-plasminogen activator inhibitor-1 complex, secondary to local release of plasminogen activator inhibitor-1 from activated platelets, and the inhibition of protein S activity by platelet factor 4 released from platelet α -granules^[148-150]. Notably, platelet factor 4 can inhibit the anticoagulant function of APC alone, but not its ability to cleave and activate PAR-1. Thus, the interaction of platelet factor 4 may potentially redirect APC function toward anti-inflammatory and cytoprotective signaling pathways.

Overall, the relatively poor ability of APC to suppress thrombin generation in forming platelet aggregates might support effective and localized platelet-dependent hemostasis while sustaining the systemic anticoagulant potential. Thus, the APC activity in the presence of platelets may be considered another example of the compartmentalized haemostatic system.

Recently, it was demonstrated that surface-immobilized PC supports in a GPIIb α - and apolipoprotein E receptor 2-dependent manner the adhesion and aggregation of platelets under flow conditions^[151]. Thus, the ability of zymogen to engage these receptors raises the question as to whether PC immobilization occurs *in vivo* and whether changes in PC plasma levels are associated with altered platelet adhesion and aggregation.

Protein S circulates in blood in complex with a carrier protein, C4b-binding protein^[152]. The level of C4b-binding protein increases in clinical settings characterized by inflammation. Hence, the amount of bound protein S increases, causing a decrease of free protein S concentration^[152]. It is known that the anticoagulant function of protein S is exerted by its free form. Thus, systemic inflammatory conditions may represent a risk factor for protein-S dependent thrombotic disorders^[152]. Finally, protein S exerts both APC-dependent and APC-independent anticoagulant effects. The APC-dependent mechanism, involving the cofactor function of protein S for the acceleration of APC-mediated degradation of factors VIII and V, is likely the physiologically dominant pathway. The APC-independent anticoagulant activity of protein S is attained by stimulating the inhibition of tissue factor (TF) by tissue factor pathway inhibitor (TFPI)^[153]. The latter blocks the intermediate complex of TF-FVIIa-FXa, thereby preventing substrate exchange of already activated FXa for new FX. Protein S enhances the inhibitory interaction of TFPI with the TF initiation complex, and thereby limits the extent of thrombin generation in plasma. This APC-independent anticoagulant activity of protein S is most pronounced at low TF levels. Due to the anticoagulant effects described above, severe protein S deficiency is

associated with severe thrombotic disorders.

The relevance of the PC system for the prevention of atherothrombotic diseases is further corroborated by studies in animals. Some interesting aspects of *in vivo* PC activation were unraveled by analyzing the role of EPCR in the response of mice to an inflammatory challenge with lipopolysaccharide (LPS)^[154]. In these studies, mice lacking EPCR showed substantially enhanced activation of coagulation, concomitantly with reduced APC formation attributable to the absence of EPCR. Yet, the plasma APC levels in LPS-challenged EPCR-deficient mice were almost identical to that measured in wild-type animals. The authors of this study then showed that in wild-type mice a large fraction (approximately 40%) of APC did not enter the systemic circulation but remained bound to endothelial cell-associated EPCR at its site of activation. It is this sequestered APC pool that is completely missing in EPCR deficient mice, and its absence apparently accounts for all the pro-coagulant and pro-inflammatory effects of EPCR deficiency in mice^[154].

Recent studies have shown that the anti-inflammatory effect of APC, at least in part, is mediated through the EPCR-dependent proteolysis of PAR-1 in endothelial cells^[155,156]. This finding seems paradoxical, as it is known that the cleavage of PAR-1 by thrombin elicits potent prothrombotic and pro-inflammatory responses^[157]. It is well known that thrombin is mainly responsible for the activation of PC in the presence of TM and that the enzyme also cleaves PAR-1 with a high catalytic efficiency, which is 3-4 orders of magnitude higher than that of APC. This finding raises the question as to how APC in the presence of thrombin is able to produce physiologically significant cleavage of PAR1 associated with protective signaling events^[158], as is presented in Figure 1. Notably, both APC and PC bind to EPCR with a similar equilibrium constant, so that it can be hypothesized that thrombin can increase the local concentrations of EPCR-bound APC^[159]. This phenomenon may induce channeling of the protease directly into the signaling pathway.

In a very elegant study, Rezaie and coworkers demonstrated that the critical receptors required for both protein C activation (TM and EPCR) and APC cellular signaling (EPCR and PAR-1) pathways colocalize in the membrane lipid rafts of endothelial cells. The co-localization of EPCR and PAR-1 in lipid rafts of endothelial cells is a fundamental requirement for the cellular signaling activity of APC, which leads to anti-inflammatory and anti-apoptotic cellular effects, such as phosphorylation of mitogen-activated protein kinase^[160] and suppression of NF κ B expression^[161].

TM co-localization with these receptors on the same membrane microdomain can also recruit thrombin to activate the EPCR-bound protein C, therefore eliciting PAR-1 signaling events that are involved in the APC protective pathways^[159] linked to dissociation of caveolin subunits (Figure 1). These findings explain how thrombin effectively channels endogenous APC to the protective signaling pathways, through cleaving the same receptor of thrombin.

Figure 1 Models of protease-activated receptor-1 cleavage and activation by either activated protein C or thrombin when endothelial protein C receptor is occupied by its ligand protein C. A: The unoccupied endothelial protein C receptor (EPCR) is associated with caveolin-1 (Cav-1) within lipid rafts of endothelial cells. Upon thrombin cleavage of protease-activated receptor (PAR)-1, a pro-inflammatory signal is generated through G12/13 and Gq under these conditions; B: The occupancy of EPCR by protein C (PC) results in dissociation of EPCR from Cav-1. This process is linked with the coupling of PAR-1 to Gi. Thrombin cleavage of PAR-1 initiates an antiinflammatory response under these conditions; C: The same as (B) except that the EPCR and PAR-1 dependent protective signaling response is mediated by activated protein C (APC) (adapted from^[159]).

The APC pathway in IBD

TM and EPCR expression is diminished in the colonic mucosal microvasculature of IBD patients^[3,162-164], but is increased in their sera, suggesting increased shedding of TM and EPCR from cells. Inflammatory cytokines also down-regulate TM and EPCR by inhibiting transcription on cultured intestinal endothelial cells (HIMEC)^[162]. These changes in TM and EPCR expression would be expected to affect the conversion of protein C in its activated form, which, in addition to its anticoagulant properties, also has potent anti-inflammatory activity^[165], as described above.

Restoring the function of the PC pathway has anti-inflammatory effects on HIMEC, by decreasing pro-inflammatory cytokines secretion as well as adhesion molecules induced by TNF- α stimulation^[144,162,166]. Furthermore, restoration of APC by supplementation reduces stress-induced gastric mucosal injury in rats by inhibiting the decrease in gastric mucosal blood flow through attenuation of the activated neutrophil-induced endothelial cell injury *via* inhibition of TNF- α production^[167].

Overall, it can be concluded that a homeostatic balance exists between thrombin and APC in coagulation and inflammation. In particular, activated thrombin promotes the generation of APC and the two molecules influence the extent of both fibrin (clot) formation and the inflammatory response. This mechanism is mediated mainly by the cleavage of PAR-1 by either APC or thrombin on endothelial cells. Through binding to EPCR, APC would reverse the pro-inflammatory effects of thrombin on the same PAR^[127,168].

THERAPEUTIC PERSPECTIVES FOR COAGULATION ABNORMALITIES IN IBD

Based on the reported findings from several studies, one can conclude that the PC pathway is strategically located at the crossroads between coagulation and inflammation, where it exerts entirely unexpected roles in the damage that occurs in chronic inflammatory conditions^[169]. Unraveling the pathogenic role of the PC pathway offers a very promising tool in the therapeutic arsenal against IBD as well as many other chronic inflammatory diseases. Inflammation most likely mediates systemic hypercoagulability through various cytokines, which can affect the coagulation cascade at numerous points as well as platelet quantity and function. Unfortunately, perhaps due to this diversity of prothrombotic abnormalities that can exist in IBD patients and their likely multifactorial etiology, no specific therapy has ever been proposed in any clinical randomized trial to correct the cytokine-linked pro-inflammatory unbalance and pro-thrombotic phenomena occurring in IBD. Notably, unfractionated (UFH) and low-molecular-weight heparins (LMWHs), apart from their known anticoagulant/antithrombotic activities, display a broad spectrum of immune modulating and anti-inflammatory properties, such as modulation of cytokine production, T-lymphocyte cytotoxic activity^[170] and inhibition of leukocyte adhesion, activation and trafficking^[171]. Based on these features, these molecules have been proposed for the treatment of IBD. Some open studies suggested the efficacy of UFH^[172,173] and LMWHs^[174] for the treatment of active

UC. Conversely, large controlled studies using UFH and LMWHs did not show a clear efficacy^[175-178]. Moreover, a recent meta-analysis by Shen *et al.*^[179] indicated no significant additive benefit for heparins in the treatment of active UC. However, all studies included in the meta-analysis were very heterogeneous about their clinical, methodological and pharmacological features.

These studies, not only considered different definitions for response and remission, but also used different heparins, with theoretically very different anti-inflammatory activities^[179]. For these reasons, it is still difficult to set the real value of this therapeutic approach in IBD.

Recently, experimental data on animal models of IBD suggested efficacy of LMWHs, when selectively delivered in the site of disease, compared to the other route of administration. The multimatrix oral formulation MMX releasing parnaparin sodium at three different doses was evaluated in a clinical trial in patients with mild-to-moderate UC activity^[180]. This study, carried out on ten UC patients, showed no relevant side effects, including either interference with haemostatic parameters or increased bleeding. After treatment, seven patients were in clinical remission and only one achieved endoscopic healing. However, in a recent meta-analysis it was found that there is no evidence to support the use of UFH or LMWH for the treatment of active UC. In this study no further trials examining these drugs in patients with UC were warranted, except perhaps a trial of UFH in patients with mild disease^[181]. Furthermore, it has to be outlined that any benefit found using heparins in this clinical setting should be weighed against a possible increased risk of rectal bleeding, especially in patients with active UC.

In conclusion, a direct therapeutic approach for controlling inflammation-driven imbalances in the coagulation system in IBD patients is not yet available. The growing body of evidence concerning the molecular and cellular perturbations in this setting should be unraveled to promote a more efficacious, pathogenesis-oriented therapy for these disorders.

CONCLUSION

Overall, this paper was designed to underline the delicate and unstable equilibrium, at the mucosal level, between inflammation and coagulation. This complex equilibrium actively participates in the pathogenesis of several inflammatory disorders, in particular IBD.

Although the majority of available reports have looked at alterations in single coagulation components in IBD patients, no clear evidence of single alterations have been demonstrated to be crucial in IBD development. On the contrary, it is evident that several factors, with diverse relevance, are involved in maintaining chronic inflammation as well as a pro-coagulant profile in IBD. These factors include mainly classical coagulation components as well as inhibitors, and also cells, such as endothelium and platelets, which interact extensively at the mucosal level. Pathways that seem to play a major role in IBD pathogenesis are the APC, thrombin and Factor Xa pathways.

The delicate balance between these pathways, affecting different mucosal cell types, is responsible for controlling endothelium, leukocyte activation and trafficking, cytokines and chemokines secretion as well as the coagulation cascade. Despite a better understanding of the interaction between coagulation and inflammation, very few drugs targeting the coagulation pathways are available or under evaluation for clinical purposes. In conclusion, further studies are required to better characterize the relationship between coagulation and inflammation in different IBD patients and to identify good therapeutic targets.

Abstract

AIM: To evaluate bacteriocinogeny in short-term high-dose indomethacin administration with or without probiotic *Escherichia coli* Nissle 1917 (EcN) in experimental pigs.

METHODS: Twenty-four pigs entered the study: Group A (controls), Group B (probiotics alone), Group C (indomethacin alone) and Group D (probiotics and indomethacin). EcN (3.5×10^{10} bacteria/d for 14 d) and/or indomethacin (15 mg/kg per day for 10 d) were administered orally. Anal smears before and smears from the small and large intestine were taken from all animals. Bacteriocin production was determined with 6 different indicator strains; all strains were polymerase chain reaction tested for the presence of 29 individual bacteriocin-encoding determinants.

RESULTS: The general microbiota profile was rather uniform in all animals but there was a broad diversity in coliform bacteria (parallel genotypes A, B1, B2 and D found). In total, 637 bacterial strains were tested, mostly *Escherichia coli* (*E. coli*). There was a higher incidence of non-*E. coli* strains among samples taken from the jejunum and ileum compared to that of the colon and rectum indicating predominance of *E. coli* strains in the large intestine. Bacteriocinogeny was found in 24/77 (31%) before and in 155/560 (28%) isolated bacteria at the end of the study. Altogether, 13 individual bacteriocin types (out of 29 tested) were identified among investigated strains. Incidence of four *E. coli* genotypes was equally distributed in all groups of *E. coli* strains, with majority of genotype A (ranging from 81% to 88%). The following types of bacteriocins were most commonly revealed: colicins Ia/Ib (44%), microcin V (18%), colicin E1 (16%) and microcin H47 (6%). There was a difference in bacteriocinogeny between control group A (52/149, 35%) and groups with treatment at the end of the study: B: 31/122 (25%, $P = 0.120$); C: 43/155 (28%, $P = 0.222$); D: 29/134 (22%, $P = 0.020$). There was a significantly lower prevalence of colicin Ib, microcins H47 and V (probiotics group, $P < 0.001$), colicin E1 and microcin H47 (indomethacin group, $P < 0.001$) and microcins H47 and V (probiotics and indomethacin group, $P = 0.025$) compared to controls. *Escherichia fergusonii* (*E. fergusonii*) was identi-

fied in 6 animals (6/11 isolates from the rectum). One strain was non-colicinogenic, while all other strains of *E. fergusonii* solely produced colicin E1. All animals started and remained methanogenic despite the fact that EcN is a substantial hydrogen producer. There was an increase in breath methane (after the treatment) in 5/6 pigs from the indomethacin group (C).

CONCLUSION: EcN did not exert long-term liveability in the porcine intestine. All experimental pigs remained methanogenic. Indomethacin and EcN administered together might produce the worst impact on bacteriocinogeny.

INTRODUCTION

Non-steroidal anti-inflammatory drugs (NSAIDs) represent the group of most commonly used drugs worldwide. NSAIDs may cause severe injury to all parts of the gastrointestinal tract. The pathogenesis of NSAID-induced entero- and colopathy is more multifactorial and complex than formerly assumed but is not yet fully understood. A combination of local and systemic effects plays an important role in pathogenesis. NSAID-induced entero- and colopathy is a stepwise process involving direct mucosal toxicity, mitochondrial damage, breakdown of intercellular integrity, enterohepatic recirculation and neutrophil activation by luminal contents including bacteria. Unlike upper gastrointestinal toxicity, cyclo-oxygenase-mediated mechanisms are probably less important^[1-3]. Intestinal bacteria play a significant role in the pathogenesis of NSAID-induced entero- and colopathy. In experimental studies, NSAIDs cannot induce enteropathy in germ-free rats^[4].

Probiotic bacteria are live micro-organisms which, when administered in adequate amounts, confer a health benefit on the host^[5]. Probiotics likely function through enhancement of the barrier function of the gut, immunomodulation, and competitive adherence to the mucus and epithelium^[6]. Probiotic bacteria may exert a systemic anti-inflammatory effect^[7] and modulate apoptosis^[8]. Probiotics have been suggested for amelioration or prevention of

various diseases including antibiotic-associated diarrhoea, irritable bowel syndrome and inflammatory bowel disease. Further possible beneficial effects are being studied (including anti-cancer potential, lowering of serum cholesterol levels and blood pressure reduction, *etc.*)^[9-11]. It has been hypothesised that probiotic bacteria might reduce the adverse effects of NSAIDs on the small and large intestine. However, initial studies provided controversial results, both with ameliorating and deteriorating outcomes^[12-15]. NSAID-induced small intestinal injury is Toll-like receptor 4 dependent^[14]. Probiotic *Escherichia coli* Nissle 1917 (EcN) might ameliorate experimental colitis (induced by dextran sodium sulphate) *via* Toll-like receptor 2 and 4 pathways^[16,17].

Colicins and microcins, members of the bacteriocin family, are produced by bacteriocinogenic strains of *Escherichia coli* (*E. coli*) and some related species of *Enterobacteriaceae*. They are toxic to susceptible bacterial strains of the same family^[18-20]. However, some bacteriocins also exert an inhibitory effect on eukaryotic cells, including observed antineoplastic action *in vitro* and *in vivo*^[21-25]. Bacteriocins might induce apoptosis^[26] as some regulators of apoptosis (e.g. Bcl family with pro- and anti-apoptotic members) share similar structures with pore-forming colicins^[27]. The possible role of bacteriocins was also investigated in clinical studies on bacillary dysentery^[28], inflammatory bowel disease^[29] and colorectal cancer^[30]. Bacteriocins might have a dual role: they may act as both antibiotics and probiotics^[31]. One of the most commonly used probiotic bacterial strains, EcN, is a producer of microcins H47 and M^[32-34].

The aim of this study was to evaluate bacteriocinogeny in short-term high-dose indomethacin administration with or without probiotic bacteria EcN in an experimental porcine model. A small adult pig can be used in experiments as a representative of an omnivore due to its relatively similar gastrointestinal functions in comparison with man^[35-38].

MATERIALS AND METHODS

Ethics

The Project was approved by the Institutional Review Board of Animal Care Committee of the Institute of Experimental Biopharmaceutics, Academy of Sciences of the Czech Republic, Record Number 1492006. Animals were held and treated in accordance with the European Convention for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes^[39].

Animals

Twenty-four healthy mature (4-5 mo old) female pigs (*Sus scrofa* f. *domestica*, hybrids of Czech White and Landrace breeds) weighing 33.0 ± 1.7 kg, were included in our study. The animals were divided into four groups: Group A (controls, 6 animals), Group B (probiotics alone, $n = 6$), Group C (indomethacin alone, $n = 6$) and Group D (probiotics and indomethacin, $n = 6$). All animals were fed twice a day (standard assorted food A1 of equal amounts).

Drug and probiotic bacteria administration

EcN (3.5×10^{10} live bacteria/d for 14 d) and/or indomethacin (Indomethacin suppositories, Berlin-Chemie, Germany; 15 mg/kg per day for 10 d) were administered as one-shot dietary bolus to hungry pigs.

Autopsy

Twenty-four hours after the last drug and/or probiotic bacteria administration (groups B to D) or after 14 d of stabling (Group A), the pigs were sacrificed (after 24 h of fasting) by means of pharmacological euthanasia (iv administration of embutramide, mebezonium iodide and tetracaine hydrochloride - T61, Intervet International BV, Boxmeer, the Netherlands; dose of 2 mL per kg) and exsanguinated. Immediate autopsy was performed and smears for bacterial cultures were taken.

Bacterial culture, isolation and identification

Before the experiment anal smears were taken from all animals. At autopsy, smears from mucosa of the jejunum, ileum, caecum, transverse colon and rectum were taken from each animal and immediately inserted into a transport liver-enriched broth. Standard primary cultures were inoculated on blood and MacConkey agars (24 h at 37°C), followed by standard clone isolation. Up to 9 different colonies of coliform bacteria were isolated from each sample (on blood, MacConkey and deoxycholate agars). Particular bacteria were precisely identified by the Vitek2 system (BioMérieux, Marcy l'Etoile, France). All bacterial strains were frozen in cryotube vials at minus 90°C until bacteriocin genotyping.

Analysis of bacteriocin production

The bacteriocin production of all strains was tested in parallel on 4 different agar plates containing (1) TY medium; (2) nutrient broth; (3) TY medium supplemented with mitomycin C; and (4) TY medium supplemented with trypsin. The TY medium consisted of yeast extract (Hi-Media, Mumbai, India) 5 g/L, tryptone (Hi-Media) 8 g/L, sodium chloride 5 g/L; the TY agar consisted of a base layer (1.5%, w/v, solid agar) and a top layer (0.7%, w/v, soft agar). A Difco™ nutrient broth (Difco Laboratories, Sparks, MD) 8 g/L, NaCl 5 g/L, was used for production of relatively unenriched 1.5% (w/v) agar plates. Mitomycin C (0.01%, w/v) and trypsin (0.1%, w/v) were used for induction of colicin production and for protease sensitivity tests, respectively. The previously described set of *E. coli* indicator strains including *E. coli* K12-Row, C6 (φ), B1, P400, and S40 was used to identify the producer strains together with *Shigella sonnei* 17 indicator^[40,41]. To test bacteriocin production, the agar plates were inoculated by needle stab and the plates were incubated at 37°C for 48 h. The tested macrocolonies were then killed with chloroform vapours and each plate was then overlaid with a thin layer of soft agar containing 10^7 cells/mL of an indicator strain and the plates were incubated at 37°C overnight. All investigated *E. coli* strains were tested on four parallel plates against 6 indicator strains stated.

PCR: Polymerase chain reaction.

Identification of individual colicin types

All investigated strains were tested with colony polymerase chain reaction (PCR). A bacterial colony was resuspended in 100 µL of sterile water and 1 µL of this suspension was added to the PCR reaction. Individual colicin types (colicins A, D, E2-E9, Ia, Ib, Js, K, M, N, S4, U, Y, 5 and 10) were detected using PCR with primers designed using the Primer3 program^[42]. The list of primer pairs and the corresponding length of PCR products are listed in Table 1. Control bacterial producers stemmed from our stock and comprised *E. coli* BZB2101pColA - CA31, BZB2102 pColB - K260, BZB2103 pColD -

Table 2 Bacteriocinogeny of particular strains isolated at the end of experiment

Parameter	Small intestine			Colon and rectum

Small intestine: Bacterial strains isolated from mucosa of the jejunum and ileum; Colon and rectum: Bacterial strains isolated from mucosa of the caecum, transverse colon and rectum; Group A: Control animals with no treatment; Group B: Probiotics alone (see text for details); Group C: Indomethacin alone (see text for details); Group D: Probiotics and indomethacin (see text for details); Bacteriocinogeny: Number of bacteriocinogenic strains out of all tested; Types: Particular bacteriocin types found in single isolates; M: Colicin M, not for microcin M.

CA23, BZB2107 pColE4 - CT9, BZB2108 pColE5 - 099, BZB2150 pColE6 - CT14, BZB2120 pColE7 - K317, BZB2279 pColIa - CA53, BZB2202 ColIb - P9, BZB2116 pColK - K235, PAP1 pCol101M - BZBNC22, BZB2123 pColN - 284, *E. coli* 189BM pColE2 - P9, *E. coli* 385/80 pColE1, pColV, *E. coli* 185M4 pColE3 - CA38, *E. coli* W3110 pColE8, W3110 pColE9, *E. coli* K-12 pColS4, *Shigella boydii* M592 (serovar 8) pColU, *E. coli* K339 pColY, *Sh. sonnei* pColJs, *E. coli* pCol5, *E. coli* pCol10, *E. coli* 449/82 pColX (microcin B17), *E. coli* 313/66 pColG (microcin H47), *E. coli* 363/79 pColV (microcin V), *E. coli* TOP10F⁺ pDS601 (microcin C7), *E. coli* D55/1 (microcin J25), and *E. coli* B1239 (microcin L). Sequentially related colicin genes (colicins E2-E9, Ia-Ib, U-Y, and 5-10, respectively) often yielded PCR products with primer pairs of related colicin types and therefore all these PCR products were sequenced. The PCR detection primers for colicins B and E1 and for 6 microcin types including B17, C7, H47, J25, L, and V, were taken from Gordon *et al.*^[43]. The phylogenetic group of each *E. coli* strain was determined using the triplex PCR protocol according to Clermont *et al.*^[44]. Sequence analysis was performed using Lasergene software (DNASTAR, Inc., Madison, WI, USA).

Hydrogen and methane breath testing

Hydrogen and methane breath tests were performed before and the morning following completion of the treatment, carried out under general anaesthesia in spontaneously breathing animals. Alveolar air was aspirated by means of percutaneous puncture of the trachea. Immediate measurement of hydrogen and methane was accomplished in triplicate by means of gas chromatography (Microlyzer DP Plus Quintron, Milwaukee, WI, USA). Results were expressed as parts per million (ppm).

Statistical analysis

Data were statistically analysed with χ^2 with Yates cor-

rection and by Mann-Whitney rank sum test. Statistical software was used for this analysis (SigmaStat version 3.1, Jandel Co., Erkrath, Germany).

RESULTS

The general microbiota profile was rather uniform in all animals but there was a broad diversity in coliform bacteria (parallel genotypes A, B1, B2 and D found). In total, 637 bacterial strains were tested, mostly *E. coli*. The remaining isolates comprised *Salmonella enterica* ssp *Arizonae* (21 isolates), *Pasteurella aerogenes* (20), *Escherichia fergusonii* (*E. fergusonii*) (11), *Aeromonas hydrophila/caviae* (9), *Klebsiella pneumoniae* (8), *Enterobacter cloacae* (4), *Morganella morganii* (4), *Citrobacter braakii* (2), *Citrobacter youngae* (2), *Citrobacter freundii* (1), *Acinetobacter hvoffii* (1) and *Pseudomonas aeruginosa* (1). There was a higher incidence of non-*E. coli* strains among samples taken from the jejunum and ileum compared to that of the colon and rectum indicating predominance of *E. coli* strains in the large intestine (data not shown).

Bacteriocinogeny was found in 24/77 (31%) before and in 155/560 (28%) isolated bacteria at the end of the study. Altogether, 13 individual bacteriocin types (out of 29 tested) were identified among investigated strains. Incidence of four *E. coli* genotypes was equally distributed in all groups of *E. coli* strains, with majority of genotype A (ranging from 81% to 88%). The following types of bacteriocins were most commonly revealed: colicins Ia/Ib (44%), microcin V (18%), colicin E1 (16%) and microcin H47 (6%). There was a difference in bacteriocinogeny between control group A (52/149, 35%) and groups with treatment at the end of the study: B: 31/122 (25%, $P = 0.120$); C: 43/155 (28%, $P = 0.222$); D: 29/134 (22%, $P = 0.020$). See Table 2 for details. There was a significantly lower prevalence of colicin Ib, microcins H47 and V (probiotics group, $P < 0.001$), colicin E1 and microcin H47 (indomethacin group, $P < 0.001$) and microcins H47 and V (probiotics and indomethacin group, $P = 0.025$) com-

Table 3 Analysis of porcine alveolar breath for hydrogen and methane (in ppm - parts per million) before and after the treatment

Group	Hydrogen before	Hydrogen after	Statistical significance	Methane before	Methane after	Statistical significance
A	N/A	3.50 ± 2.81	N/A	N/A	69.33 ± 56.64	N/A
B	6.0 ± 2.82	2.0 ± 0	NS	106.50 ± 94.05	80.00 ± 48.02	NS
C	1.17 ± 0.41	5.0 ± 3.29	NS	34.67 ± 25.65	66.17 ± 38.83	NS
D	2.0 ± 1.16	6.0 ± 6.0	NS	60.75 ± 34.77	62.00 ± 27.71	NS

Group A (controls with no treatment, $n = 6$), Group B (probiotics alone, $n = 6$), Group C (indomethacin alone, $n = 6$) and Group D (probiotics plus indomethacin, $n = 6$). N/A: Not applicable; NS: Not significant.

pared to controls (Table 2). *E. fergusonii* was identified in 6 animals (6/11 isolates from the rectum). One strain was non-colicinogenic, while all other strains of *E. fergusonii* solely produced colicin E1.

Data on porcine alveolar breath analysis of hydrogen and methane are given in Table 3. All animals started and remained methanogenic. Differences between groups were not statistically significant. There was an increase in breath methane (after the treatment) in 5/6 pigs from the indomethacin group (C).

DISCUSSION

Probiotic bacteria might act in three different ways: they are able to modulate the host's defence mechanisms, they have a direct impact on other micro-organisms and finally probiotic effects may be based on actions affecting microbial products like toxins, host products (e.g. bile salts) and food ingredients^[45].

Our hypothesis for this study was that (1) indomethacin would suppress bacteriocin production of *Enterobacteriaceae*; (2) probiotic bacteria EcN would colonise the porcine gastrointestinal tract permanently; (3) they would protect intestinal microbiota from suppressive action of indomethacin; and (4) EcN would convert the starting methanogenic phenotype of pigs to a hydrogenic one. Surprisingly, most of our presumptions were not proved.

There is no simple way to explain this. The first question that should be addressed is a possible role of human probiotic bacteria in the porcine gastrointestinal tract. It is necessary to consider whether human probiotics can be also assumed to act as probiotic microbiota for domestic pigs. Criteria for probiotics of human origin were proposed^[46], however, potential probiotic bacteria isolated from porcine faeces are usually tested *in vitro* to be active against two or three common porcine pathogens only^[47-50].

Genotype B2 and production of microcin H47 were considered as markers of EcN in our study. None of our 637 isolates comprised these bacteria. Viability and sufficient amount of bacteria were ensured before their administration in our project. According to our results, it is unlikely that EcN could exert long-term viability in the porcine intestinal tract. Other swine studies by several authors^[51-54] were able to identify intestinal colonisation by EcN in pigs and piglets but not by all of them^[55]. There is no final proof of long-term colonisation of the gastroin-

testinal tract by EcN in healthy humans. In an interesting study by Schierack *et al.*^[56], probiotic *Enterococcus faecium* supplementation showed no significant effect on the numbers and diversity of *Enterobacteriaceae* species, or on the total counts, diversity and distribution of virulence gene-positive *E. coli* strains in healthy domestic pigs.

Aspirin and some NSAIDs, including indomethacin, influence intestinal bacteria^[57-60]. Indomethacin might exert some impact on intestinal microbiota in our study, as there was an increase in breath methane after the treatment in 5/6 pigs from the indomethacin group. Another interesting result from our current study showed a marked lower prevalence of colicin Ib, microcins H47 and V (probiotics group), colicin E1 and microcin H47 (indomethacin group) and microcins H47 and V (EcN and indomethacin group) compared to controls. We interpret this difference as a sign of adverse effects of probiotics and/or indomethacin on porcine microbiota. Bacteriocinogeny in controls (35%) was higher compared to the indomethacin (28%), probiotic (25%) and indomethacin and probiotic groups (22%). This evident trend did not reach statistical significance for the probiotic group (B) and indomethacin group (C). However, there was a statistically significant difference between controls and indomethacin and probiotic group (D). We can assume that indomethacin and EcN comprise the worst impact on bacteriocinogeny in the porcine gastrointestinal tract. This would be consistent with other studies showing that other probiotics might deteriorate NSAID-induced injury to the intestine^[13].

Composition of food, especially supplements with probiotics, might influence the probiotic effect of intestinal bacteria^[61,62]. This factor is unlikely to play an important role in our study. All animals received identical assorted food with cereals, animal fat, soya oil and a mix of supplements (lysine, threonine, methionine, lactic acid).

In our current study, the microbiota profile was rather uniform in all animals due to identical breed and feed. However, there was a broad diversity in coliform bacteria; the main four genotypes A, B1, B2 and D were identified in parallel. Similar diversity was also found in other porcine studies, with prevailing group A^[56,63]. Dixit *et al.*^[63] showed that differences among individual pigs accounted for 6% of the observed genetic diversity, whilst 27% of the genetic variation could be explained by clonal composition differences among gut regions (isolates obtained from the duodenum, ileum, colon and faeces of 8 pigs). Finally, the absence of virulence genes in these com-

mensals indicates that they may be suitable as a probiotic consortium, particularly if they also display increased adherence to enterocytes and antagonistic activity against pathogenic strains of *E. coli*^[63].

E. fergusonii was identified as a new species of *Enterobacteriaceae* in 1985^[64]. This is considered to be an opportunistic pathogen of farm animals including domestic pigs^[65]. We identified *E. fergusonii* in 6 animals, all pigs were healthy without any sign of infective disease. Interestingly 10/11 isolated bacteria solely produced colicin E1. Colicins produced by *E. fergusonii* strains closely resemble colicins encoded by *E. coli*^[66]. In a previous series of human isolates, only 6/50 (12%) strains were bacteriocinogenic, 3 of which produced colicin E1^[67].

In humans, all intestinal hydrogen and methane are produced by so called “hydrogenic and methanogenic” bacteria^[68-70]. However, most authors do not usually specify which particular bacteria constitute these producers. Hydrogen is produced by bacterial fermentation of saccharides in the intestinal lumen. Concurrently, hydrogen is consumed by other intestinal bacteria to synthesise methane, acetate and hydrogen sulphide. Methane is synthesised solely by bacteria in the intestine (four mols of hydrogen and one mol of carbon dioxide create one mol of methane and water). This reaction reduces the volume of gas that would otherwise be present in the colon^[71-76]. The question of intestinal methane producers has not been definitely solved yet. We hypothesised that common coliform bacteria could also synthesise methane^[77], however, this assumption was not proved by our further studies^[78,79]. McKay *et al.*^[80] found that several anaerobes (*Bacteroides*, *Clostridium* and others) produced hydrogen but rarely methane. Hydrogen is also produced by *Enterobacteriaceae*^[81]. In adult Caucasians, only 30%-50% of people produce methane while hydrogen is produced by 90%-98% of people^[69]. Kien *et al.*^[82] found low breath hydrogen and higher methane in piglets (even in a subgroup supplemented with lactulose). In our current study, all animals revealed a solely methanogenic phenotype (by the analysis of their alveolar breath). This fact could be explained as they came from an identical breed and received the same assorted food. All animals remained methanogenic despite the fact that EcN is a substantial hydrogen producer^[77]. This further supports our finding that EcN 1917 did not have major impact on porcine intestinal microbiota.

In conclusion, it is unlikely that probiotic EcN could exert long-term liveability in the porcine intestine. All experimental pigs remained methanogenic, despite the fact that EcN is a substantial hydrogen producer. The indomethacin and probiotic group had a significantly lower rate of bacteriocinogeny compared to controls with no treatment. These control pigs revealed higher bacteriocinogeny with simultaneous production of up to five different bacteriocins per single strain. Indomethacin and probiotics administered together might provide the worst impact on bacteriocinogeny in the porcine gastrointestinal tract.

COMMENTS

Background

Non-steroidal anti-inflammatory drugs (NSAIDs) represent the group of most commonly used drugs worldwide. NSAIDs may cause severe injury to all parts of the gastrointestinal tract. The pathogenesis of NSAID-induced entero- and colopathy is more multifactorial and complex than formerly assumed but has still not been fully understood. A combination of local and systemic effects plays an important role in pathogenesis. NSAID-induced entero- and colopathy is a stepwise process involving direct mucosal toxicity, mitochondrial damage, breakdown of intercellular integrity, enterohepatic recirculation and neutrophil activation by luminal contents including bacteria. Unlike upper gastrointestinal toxicity, cyclo-oxygenase-mediated mechanisms are probably less important. Intestinal bacteria play a significant role in the pathogenesis of NSAID-induced entero- and colopathy. In experimental studies, NSAIDs cannot induce enteropathy in germ-free rats.

Research frontiers

Probiotic bacteria are live micro-organisms which, when administered in adequate amounts, confer a health benefit on the host. Probiotics likely function through enhancement of the barrier function of the gut, immunomodulation, and competitive adherence to the mucus and epithelium. Probiotic bacteria might exert a systemic anti-inflammatory effect and modulate apoptosis. Probiotics have been suggested for amelioration or prevention of various diseases including antibiotic-associated diarrhoea, irritable bowel syndrome and inflammatory bowel disease. Further possible beneficial effects are being studied (including anti-cancer potential, lowering serum cholesterol levels and blood pressure reduction, *etc.*). It has been hypothesised that probiotic bacteria might reduce the adverse effects of NSAIDs on the small and large intestine. However, initial studies provided controversial results, both with ameliorating and deteriorating outcomes.

Innovations and breakthroughs

Based on the current study, it is unlikely that probiotic *Escherichia coli* Nissle 1917 (EcN) could exert long-term liveability in the porcine intestine. Genotype B2 and production of microcin H47 were considered as markers of EcN in the study. The authors did not find such bacteria among any of the 637 isolates. All experimental pigs remained methanogenic, despite the fact that EcN is a substantial hydrogen producer. The indomethacin and probiotic group had a significantly lower rate of bacteriocinogeny compared to controls with no treatment. These control pigs revealed higher bacteriocinogeny with simultaneous production of up to five different bacteriocins per single strain. Indomethacin and probiotics administered together might produce the worst impact on bacteriocinogeny in the porcine gastrointestinal tract.

Applications

Bacteriocins might induce apoptosis as some regulators of apoptosis (e.g. Bcl family with pro- and anti-apoptotic members) share similar structures with pore-forming colicins. Bacteriocins might have a dual role: they may act as both antibiotics and probiotics. One of the most commonly used probiotic bacterial strains, EcN, is a producer of microcins H47 and M.

Terminology

Colicins and microcins, members of the bacteriocin family, are produced by bacteriocinogenic strains of *Escherichia coli* and some related species of *Enterobacteriaceae*. They are toxic to susceptible bacterial strains of the same family. However, some bacteriocins also exert an inhibitory effect on eukaryotic cells, including observed antineoplastic action *in vitro* and *in vivo*.

Peer review

This is an innovative manuscript in basic research, which adequately addresses the ethics of the experiment. Its presentation is accurate but very complex in the reading and interpretation of many variables.

DI-TOF MS. By optimizing the parameters of the model, the Genetic Algorithm model had good recognition capability (97%) and positive predictive value (94%). Based on the model, 2 markers with molecular masses of 6788 and 1912 Da were found that differentiated between *H. pylori* positive and negative volunteers. The m/z 1912 sequence was parsed as SKQFTSSTSYN-RGDSTF. The peptide was identified as isoform 1 of the fibrinogen α chain precursor, whose concentration in urine was markedly higher in *H. pylori* infected volunteers than in *H. pylori* non-infected ones.

CONCLUSION: The appearance of urinary fibrinogen degradation products is caused by an active *H. pylori*-induced process.

Abstract

AIM: To investigate the relationship between urinary peptide changes and *Helicobacter pylori* (*H. pylori*) infection using urinary peptidome profiling.

METHODS: The study was performed in volunteers ($n = 137$) who gave informed consent. Urinary peptides were enriched by magnetic beads based weak cation exchange chromatography and spectrums acquired by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry (MS). ClinProTools bioinformatics software was used for statistical analysis and the recognition of peptide patterns. The marker peptides were identified by LTQ Orbitrap XL tandem MS.

RESULTS: Approximately 50 proteins or peptides which loaded onto the magnetic beads were detected by MAL-

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a Gram-negative, micro-aerophilic bacterium adapted for survival in the human stomach, where it can cause chronic gastritis and peptic ulcer disease and is an important risk factor that may lead

to gastric cancer. Great progress has been made in understanding *H. pylori* pathogenicity since its discovery 25 years ago. *H. pylori* infection has been proposed as a risk factor not only for gastrointestinal diseases but also for cardiovascular diseases such as peripheral arterial disease^[1] and atherosclerosis^[2]. In addition, some studies have shown that *H. pylori* infection is associated with Henoch-Schönlein purpura^[3,4] and membranous nephropathy^[5,6]. Purpura nephritis is one of the serious complications of Henoch-Schönlein purpura^[7]. As a result of its long delitescence, rapid growth of drug resistance and the ease of infection, *H. pylori* infection has become a prominent chronic digestive system disease.

Recent progress in proteomic analysis and strategies for the identification of clinically useful biomarkers in biological fluids has shown that urine can be an excellent non-invasive reservoir^[8-10]. By virtue of its noninvasiveness and the availability of specimens, peptidome profiling of human urine is now becoming an important method for detecting novel disease-associated markers^[11,12]. Bruker Daltonics provides the mass spectrometry (MS)-based ClinProt™ system solution for preparation, measurement and visualization of peptides and proteins in body fluid^[13]. The Profiling Kit MB-WCX (Magnetic Beads based Weak Cation Exchange Chromatography) was developed for the enrichment of proteins and peptides from biological samples based on cation exchange chromatography prior to matrix-assisted laser desorption/ionization time-of-flight MS (MALDI-TOF MS) analysis. Successful applications and reproducibility of the MB-WCX beads using serum, plasma and urine samples was demonstrated in various studies^[14-16]. Nanoliquid chromatography coupled to micro-electrospray ionization tandem MS (ESI-MS/MS) has become a powerful tool for identification and quantification in peptide analysis due to its higher sensitivity^[17,18]. In this study, we analyzed the urine peptidome profiles of *H. pylori* infected and non-infected volunteers by the ClinProt™ system, followed by MALDI-TOF MS, and we identified the biomarkers using Aquity nano-ultra-performance liquid chromatography coupled to a Thermo LTQ Orbitrap high resolution/high accuracy ultra-performance liquid chromatography (UPLC)-ESI-MS/MS.

MATERIALS AND METHODS

Protein/peptide marker discovery in urine

Urine specimen collection: Urine samples were collected from healthy volunteers ($n = 137$, 70 male, 67 female) who did not have cardiovascular diseases and had received a health checkup 3 mo prior to the study, and gave written informed consent before participation. The volunteers received ¹³C-urea breath tests to determine whether they were infected with *H. pylori*, and their midstream urine was collected the following morning^[19]. Urine samples were kept at a low temperature with ice and were transferred to the laboratory within 2 h, centrifuged at 3000 *g* for 20 min, aliquotted and stored at -80°C until use.

Urinary peptide enrichment

The urine samples were thawed at room temperature for 30 min, adjusted to pH 7, and centrifuged again. Urinary peptides were separated using MB-WCX kit (Bruker Daltonics, Bremen, Germany; particle size < 1 μm; mean pore size, 40 nm; specific surface area, 100 cm²/g). The magnetic beads were mixed thoroughly on a vortex device for 1 min, then a 30 μL urine sample was diluted in 60 μL MB-WCX binding solution, and 10 μL WCX beads were added. After thorough stirring, sample mixtures were incubated for 1 min at room temperature. The tube was placed into the magnetic separator and the beads at the wall of the tube were collected for 1 min. The supernatant was removed by using a pipette. Wash buffer (100 μL) was added to the tube, which was moved back and forth in the magnetic separator 10 times. The beads were collected at the tube wall for 1 min and the supernatant was removed carefully using a pipette. Elution buffer (5 μL) was added and the beads dissolved at the tube wall by pipetting up and down intensively 10 times. The beads were collected at the tube wall for 2 min and the clear supernatant was transferred into a fresh tube. Stabilization buffer (5 μL) was added to the eluate.

MALDI-TOF data acquisition

Sample solution (1 μL) was dropped onto an AnchorChip™ 600-μm target (Bruker Daltonics) and dried. Next, 1 μL of freshly prepared α-cyano-4-hydroxycinnamic acid [0.4 mg/mL matrix solution in ethanol/acetone (2:1, v/v)] was added onto the sample and crystallized. MALDI-TOF MS analysis of the peptidome profile was performed using an autoflex™ instrument (Bruker Daltonics), equipped with a N₂ laser ($\lambda = 377$ nm), with the ion source voltage as follows: source 1, 120 kV; ion source 2, 18.6 kV; lens 7.6 kV. The pulsed ion extraction delay was 320 ns and operated in positive ion linear mode (LP-ClinProt) with a total of 450 shots (30 shots at each of 15 different spot positions) per sample. All signals with a signal-to-noise ratio > 3 in a *m/z* range of 1000-10 000 Da were collected with the AutoXecute tool of the flexControl™ acquisition software (version 3.0; Bruker Daltonics). Mass calibration was performed with the standard calibration mixture of peptides and proteins (CPS, preparation method in the MB-WCX operation manual, MW range 1000-10 000 Da).

Statistical data analysis

The spectra were analyzed statistically using Clin-Prot™ (version 2.2 β; Bruker Daltonics) bioinformatics software. Parameters were as follows: peak definition: signal to noise ratio > 3; statistical analysis: Wilcoxon/Kruskal-Wallis; area normalization: against total ion count; integration: end point level; mass recalibration: maximal peak shift of 500 ppm; sort mode: *t*-test *P*-value/analysis of variance (ANOVA). The spectra from 90 samples (40 in the *H. pylori* infected group and 50 in *H. pylori* non-infected group) were used to build models and 47 samples (23 in the *H. pylori* infection group and 24 in the *H. pylori*

non-infected group) were used in model verification by the Genetic Algorithm (GA), Quick classifier, and Supervised Neural mathematical algorithms. The parameters k-nearest neighbor classification (KNN), maximal number of generations (MNG) were optimized and the best model was determined. The performance of the models was evaluated by recognition capability (RC) and positive predictive value (PPV): $RC = TP/n$ where TP is the number of true positives (correctly classified) in a data set and n is the number of samples in a data set and $PPV = TP/(TP + FP)$ where FP is the number of false positives (misclassified). The best model (RC and PPV values are a maximum one of 1) was implemented to determine the marker peptides. The *P*-value of the Anderson-Darling test (PAD) which can give information about the normal distribution: < 1 not normally distributed, > 1 normally distributed, the *P*-value of the *t*-test (2 classes) or ANOVA test (> 2 classes) (PTTA, preferable for normal distributed data) or the *P*-value of the Wilcoxon test (2 classes) or Kruskal-Wallis test (> 2 classes) (PWKW, preferable for abnormally distributed data) was used to confirm significant differences. If the PWKW or PTTA value was < 0.05 , the protein/peptide was confirmed to be significantly different.

Identification of significant peptides by nano UPLC-ESI-MS/MS

UPLC: The peptides from urine samples (the differential peptides are relatively abundant) were eluted from the magnetic beads and were analyzed by nano-UPLC-ESI-MS/MS using a nano Aquity UPLC (Waters Corporation, Milford, USA) coupled to a LTQ-Orbitrap mass spectrometer (Thermo Fisher Scientific, Bremen, Germany). Samples of 5 μ L (the sample was diluted by 2 times) were loaded on a C18 precolumn (Symmetry[®]C18, 5 μ m, 180 μ m \times 20 mm, nanoAcquity[™]Column) at 15 μ L/min in 5% acetonitrile (Sigma-Aldrich, St Louis, MO, USA), 0.05% trifluoroacetic acid (Sigma-Aldrich) for 3 min. The precolumn was switched online with the analytical column (Symmetry[®]C18, 3.5 μ m, 75 μ m \times 150 mm, nanoAcquity[™]Column) equilibrated in 95% solvent A (5% acetonitrile, 0.1% formic acid; Sigma-Aldrich) and 5% solvent B (95% acetonitrile, 1.2% formic acid). Peptides were eluted using a 5% to 80% gradient of solvent B over 60 min at a flow rate of 400 nL/min.

UPLC-MS/MS and data analysis

The LTQ Orbitrap XL mass spectrometer was operated in the data-dependent mode to switch automatically between MS and MS/MS acquisition. Full-scan survey MS spectra with 2 microscans (m/z 400–2000) were acquired with the Orbitrap with a mass resolution of 100 000 at m/z 400, followed by 10 sequential LTQ-MS/MS scans. Dynamic exclusion was used with 2 repeat counts, 10 s repeat duration and 60 s exclusion duration. For MS/MS, charge state 1 was rejected and precursor ions were activated using 25% normalized collision energy at the default activation q of 0.25. The mass spectra were searched against

Table 1 Comparison of results for the classification models

2	GA	3	60	10	91.3	85.1
3	GA	7	60	15	96.5	93.6
4	GA	3	60	20	93.3	91.5
5	GA	5	60	25	93.3	87.2
6	SNN			25	78.5	63.8
7	QC			25	78.8	66.0

Model 3 was the best. GA: Genetic Algorithm; QC: Quickclassifier; SNN: Supervised Neural Network; KNN: k-nearest neighbor classification; MNG: Maximal number of generations; RC: Recognition capability; PPV: Positive predictive value.

the human International Protein Index (IPI) database (IPI human v3.45 fasta with 71 983 entries) using Bioworks software (Version 3.3.1; Thermo Electron Co.) based on the SEQUEST algorithm. To reduce false positive identification results, a decoy database containing the reverse sequences was appended to the database. The parameters for the SEQUEST search were as follows: no enzyme, the variable modification was oxidation of methionine, peptide tolerance, 10 ppm, MS/MS tolerance, 1.0 Da. Positive protein identification was accepted for a peptide with Xcorr of greater than or equal to 3.20 for triply and 2.86 for doubly charged ions, and all with $\Delta Cn \geq 0.1$, peptide probability $\leq 2e-3$.

RESULTS

Urinary peptidome profiling

¹³C-urea breath tests showed that 74 volunteers were *H. pylori* negative and 63 volunteers were *H. pylori* positive (delta over baseline > 4). About 50 peaks with signal-to-noise ratios greater than 5 were detected between m/z 1000 and 10 000 in urine from the volunteers (Figure 1). The average intensities of peaks for the negative group and positive group are shown in Figure 2A, and the complete spectra from both the healthy group and the *H. pylori*-infected group are shown in Figure 2C.

Statistical data analysis and classification

When parameter KNN = 7, MNG = 60 and Max.peaks = 15, the GA model was the best fit: RC = 96.5%, PPV = 93.6% (Table 1). All the data PAD were < 1 , so the data were abnormally distributed and PWKW was used to confirm marker peptides. Two markers that differentiated between the *H. pylori* non-infected group and the *H. pylori* infected group (PWKW < 0.05) with molecular masses of 6788 and 1912 Da were found in urine (Table 2). The content of these peptides in urine was markedly higher in *H. pylori* infected volunteers than in non-infected subjects (Figure 2B and D).

Identification of peptides

The peptides from urine were separated using nano-UPLC. Product-ion-spectra of the doubly charged mol-

Figure 1 The mass spectrum of peptides in urine ranging between 1000 and 10000 Da.

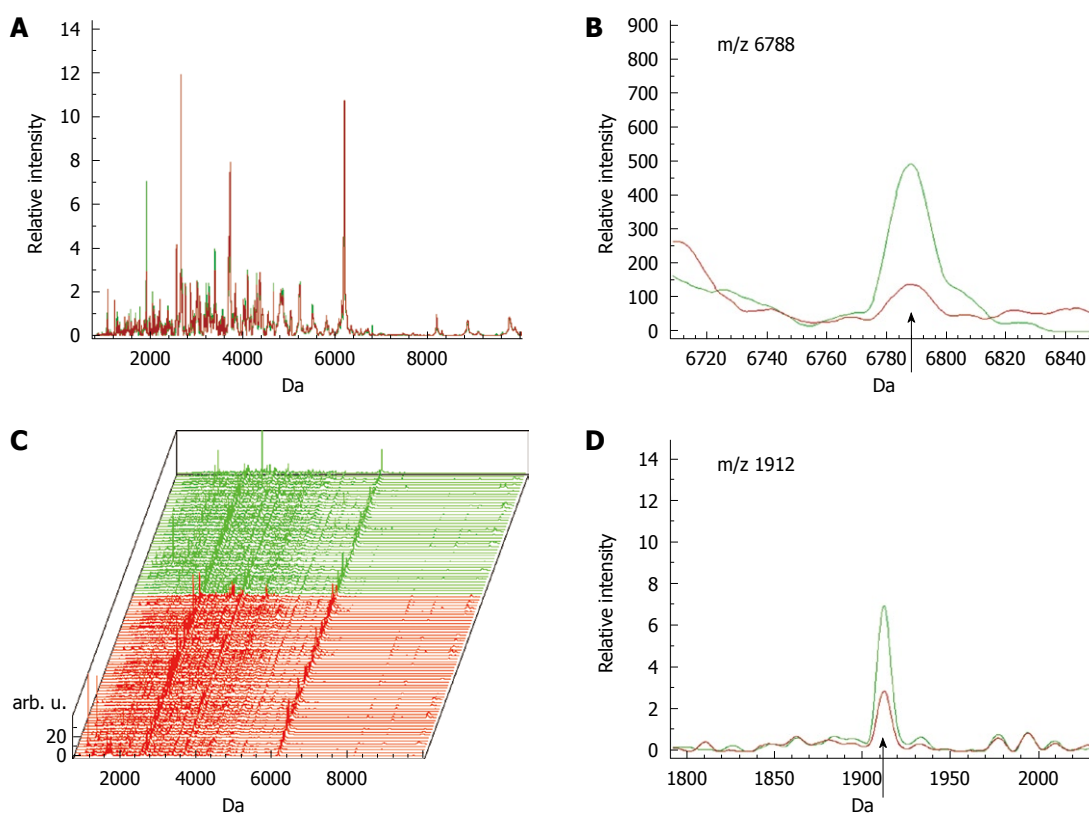

Figure 2 Differentially expressed low-mass peptides in human urine. A: The average intensities of matrix-assisted laser desorption/ionization time-of-flight peaks for the healthy group (red line), and the *H. pylori*-infected group (green line); B, D: The enlarged picture m/z 6788 and m/z 1912, respectively, the healthy group (red line) and the *H. pylori*-infected group (green line); C: The complete spectra from both the healthy group (red line) and the *H. pylori*-infected group (green line).

ecule m/z 957.436 for the 1912 Da peak was recorded with the linear ion trap (Figure 3A) and the sequence was parsed as SKQFTSSTSYNRGDSTF following MS/MS (Figure 3B). The sequence was identified as isoform 1 of fibrinogen α chain precursor (AC: IPI00021885) using the IPI database with Xcorr 3.201 (doubly charged ion), $\Delta C_n = 0.267$, $P = 1.10E-04$ and MS/MS tolerance 0.26 Da. Unfortunately, the m/z 6788 peak sequence was not identified. Because it was possible that the peptide m/z 1912

was from *H. pylori*, the sequence was searched against all the species in the NCBI nr. The fibrinogen was identified again as a fragment of human fibrinogen [gi|4503689|ref|NP_000499.1| fibrinogen, α polypeptide isoform α -E preproprotein (Homo sapiens)].

DISCUSSION

Urine is an especially attractive medium for biomarker

DAve: Difference between the maximal and the minimal average peak area/intensity of all classes; PTTA: *P*-value of *t*-test (2 classes) or ANOVA test (> 2 classes); PWKW: *P*-value of Wilcoxon test (2 classes) or Kruskal-Wallis test (> 2 classes); PAD: *P*-value of Anderson-Darling test.

analysis, because urine can be obtained in large quantities using noninvasive procedures, and ample material is available for analysis and assessment of reproducibility. In addition, repeated sampling from the same individual is simple, facilitating longitudinal studies. Urine generally contains proteins and peptides of lower molecular mass (< 30 kDa) that are highly soluble. These features facilitate analysis of such polypeptides in their natural state, without any need for additional manipulation. Urinary polypeptides are stable and generally do not undergo significant proteolysis for several hours after collection^[20,21]. Urine has been known, or at least has been suspected, to

reflect pathological changes for centuries. Even early pathological changes are thought to be associated with disease-specific changes in the urinary proteome^[22]. In this study, we found 2 specific factors in human urine that were associated with *H. pylori* infection by urinary peptidome profiling. Urinary fibrinogen degradation products (FDP) increased with *H. pylori* infection.

Fibrinogen is a major plasma protein (340 kDa) that consists of pairs of 3 different polypeptide chains, α , β , and γ , joined by disulfide bonds to form a symmetric dimeric structure. The NH₂-terminal regions of all 6 chains form the central E-domain^[23]. Fibrinogen is directly involved in the clotting process as a clotting factor and is synthesized in hepatocytes^[24]. In addition, fibrinogen has a variety of other functions, such as a mediated platelet aggregation response^[25]. Many studies have found that an elevated level of plasma fibrinogen is an important risk factor for cardiovascular and cerebrovascular thrombotic diseases^[26,27] and renal failure^[28].

Fibrinogen can be digested either by plasmin or thrombin. When fibrinogen is cleaved by plasmin, it releases 2 D fragments (the COOH termini of the α , β , and γ chains), one E fragment (the NH₂ termini of the α , β , and γ chains), and several smaller fragments including a small peptide, β 1-42 (the NH₂ terminus of the β -chain). Cleavage by thrombin releases the two fibrinopeptides A and B (FpA and FpB) from the NH₂ termini of the α and β chains, respectively, while exposed polymerization sites form electrostatic bonds between the E-domain of one molecule and the D-domain of an adjacent one. Factor XIIIa, a transglutaminase, then introduces γ -glutamyl- ϵ -amino-lysine isopeptide cross-links between D domains of adjacent fibrin monomers, generating a stable polymer known as fibrin. Then, fibrin can be broken down by plasmin cleavage into the 3-stranded coils found between the D and E domains, yielding a D dimer, D fragment, and fibrin E fragment (which lacks the fibrinopeptides A and B) and smaller fragments^[29]. FDP, such as D-dimer, E-fragment and α , β -chain, have been widely studied in cardiovascular disease and cancer-related research fields^[30,31]. The m/z 1912 peptide is a fragment of an FDP (site 580-596). Our study shows that the peptide m/z 1912 in urine was significantly increased in patients with *H. pylori* infection.

The normal glomerular basement membrane has a filtration function, and the average pore size is 5.5 nm. Therefore, under normal circumstances, some small molecular weight proteins can filter through tiny pores in the glomerular membrane. Because of endocytosis, the major proteins are normally reabsorbed when they pass through the proximal tubule, so there is low protein content in urine, a random urinary protein of 0-80 mg/L. Although there are many kinds of fibrinogen degradation fragments, large fragments are retained by the glomerulus or are taken up by the renal tubule, therefore only small peptides are normally seen in the urine. In this study, the peptides or proteins below 10 kDa in the urine were captured by weak cation beads, so only the marker peptides 1912 and 6788 were detected, while the fragments of FDP that exceeded 10 kDa were not captured.

The reasons why *H. pylori* infection results in an FDP increase in urine are not clear. Our preliminary studies have shown that *H. pylori* will lead to human gastric adenocarcinoma epithelial cell calreticulin phosphorylation, and dephosphorylation of its calcium-binding protein (nucleobindin-2), which affects cell calcium ion channels^[32]. Fibrinogen achieves its biological functions by being degraded by plasmin or thrombin. The activities of plasmin and thrombin are regulated or progressively activated by calcium ions; therefore, the changes in the calcium ion channels will affect the fibrinolytic system. In short, the changes in FDP in urine are important for gaining a comprehensive understanding of the pathogenesis of *H. pylori*.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) infection has been proposed as a risk factor not only for gastrointestinal diseases but also for cardiovascular diseases and nephropathy. The pathogenic mechanisms of *H. pylori* are not yet clear since its discovery 25 years ago.

Research frontiers

The peptidome has been widely used in finding biomarkers with the development of mass spectrometry (MS). As it can be obtained in large quantities using noninvasive procedures, urine is an especially attractive medium for biomarker analysis. In this study, the authors analyzed the urine peptidome profiles of *H. pylori* infected and non-infected volunteers using the ClinProt™ system, followed by matrix-assisted laser desorption/ionization time-of-flight MS, and identified the marker peptides using liquid chromatography coupled to MS.

Innovations and breakthroughs

Cardiovascular diseases and nephropathy have been reported which associated with *H. pylori* infection. To date, the pathogenic mechanism is not clear. This study suggests that the appearance of urinary fibrinogen degradation products is caused by an active *H. pylori*-induced process. The results of this study are important to further the comprehensive understanding of the pathogenesis of *H. pylori*.

Applications

This study suggests that fibrinogen degradation products are associated with *H. pylori* infection. This result can help researchers in this field further understand the potential mechanism associated with *H. pylori* infection and cardiovascular diseases and nephropathy, and provide important information for prevention and control of *H. pylori*-related diseases.

Peer review

It would be of great interest in future experiments to investigate whether the urine fibrinogen peptide correlates with serum fibrinogen levels and *H. pylori* infection, as serum fibrinogen levels have been investigated in *H. pylori* infection in many studies.

Abstract

AIM: To study the influence of CXCR4/stromal cell-derived factor-1 (SDF-1) axis on E-cadherin/ β -catenin complex expression in HT29 colon cancer cells and its underlying mechanisms.

METHODS: Effect of SDF-1 on E-cadherin/ β -catenin expression was detected by immunocytochemistry. E-cadherin and β -catenin mRNA expression levels were measured by reverse transcriptase-polymerase chain reaction. SDF-1-induced phosphorylation of phosphatidylinositol 3-kinase (PI3K)/AKT and β -catenin was detected by Western blotting.

RESULTS: The E-cadherin and β -catenin mRNA ex-

pression levels in HT29 cells were lower 48 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL ($P < 0.05$). SDF-1-induced significant phosphorylation of PI3K/AKT and β -catenin. AMD3100 and LY294002 inhibited the phosphorylation of PI3K/AKT and β -catenin.

CONCLUSION: SDF-1 down-regulates the E-cadherin/ β -catenin complex expression in HT29 cells by decreasing mRNA synthesis and increasing β -catenin phosphorylation.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers and the second leading cause of cancer-related death in the Western world. Death usually results from its uncontrolled metastasis. Although the 5-year survival rate approaches 90% for patients with local CRC, it has decreased to 19% for patients with distant metastasis^[1]. The metastatic process of CRC consists of a series of individ-

ual steps, which are required to establish the diagnosis of metastatic lesions^[2,3]. A number of molecules have been implicated in the metastatic process of CRC.

Chemokines are a group of chemoattractant cytokines that mediate several cellular functions. Stromal cell-derived factor-1 (SDF-1) is expressed in stromal cells, including fibroblasts and endothelial cells^[4,5], and interacts specifically with the seven-transmembrane, G protein-coupled receptor CXCR4^[6]. Recent studies showed that chemotaxis effect of CXCR4/SDF-1 axis is related with lymph node and liver metastasis of CRC^[7-10]. Although there is evidence that the CXCR4/SDF-1 signaling pathway is involved in the metastatic process of CRC, the precise molecular mechanism underlying SDF-1-induced chemotaxis effect has not been completely elucidated.

E-cadherin, a transmembrane glycoprotein located at the adheren junction, mediates calcium-dependent cell-cell adhesion^[11,12]. C terminus of E-cadherin is linked to α -catenin and actin cytoskeleton through the association with β -catenin. Strong cell-cell interactions result in a tight cell cluster as a community, and constrain cells from moving away. It has been shown that dysregulation of E-cadherin/ β -catenin complex expression is responsible for the invasion and metastasis of CRC^[13,14], indicating that the CXCR4/SDF-1 axis is correlated with E-cadherin/ β -catenin complex expression in invasion and metastasis of CRC.

This study was to observe whether SDF-1 can alter E-cadherin/ β -catenin expression in HT29 colon cancer cell line. In addition, the E-cadherin/ β -catenin mRNA expression level was measured and the phosphorylation of phosphatidylinositol 3-kinase (PI3K)/AKT and β -catenin was examined to provide insights into the mechanism underlying the change in E-cadherin/ β -catenin expression.

MATERIALS AND METHODS

Reagents

Antibodies against E-cadherin and β -catenin, and p- β -catenin antibody (Ser33/37) and p-AKT antibody (Ser473) were purchased from Cell Signaling Technology (Beverly, MA, USA). Peroxidase-conjugated goat anti-rabbit IgG and peroxidase-conjugated goat anti-mouse IgG were purchased from Santa Cruz Biotechnology Inc. (Santa Cruz, CA). SDF-1 was bought from Pepro Tech Inc. (Rocky Hill, NJ, USA). AMD3100 was purchased from Sigma Aldrich, USA and LY29400 was bought from Beyotime, China.

Cell culture

Human colon cancer HT29 cell line was obtained from the American Type Culture Collection (ATCC; Manassas, VA, USA). Tumor cells were cultured in RPMI-1640 (Invitrogen product), supplemented with 10% newborn calf serum (Shanghai Mafa Corporation), 100 U/mL penicillin, and 100 mg/mL streptomycin in a humidified incubator containing 5% CO₂ and 95% air at 37°C.

Cell proliferation assay

Exponentially growing HT29 cells were seeded in 96-well plates in RPMI-1640 containing 3% newborn calf serum at a density of 2×10^4 cells/well. After 24 h, either PBS or AMD3100 (100 ng/mL) was added and incubated for 2 h. SDF-1 was added into three wells daily at different concentrations (10, 20 and 40 ng/mL). MTT assay (Amersham Biosciences, USA) was performed after 24, 48 and 72 h. Absorbance was measured at 570 and 630 nm (630 nm as the reference wave length). The results were expressed as a mean of three wells in each group. Proliferation rate of HT29 cells was calculated by the absorbance of experimental groups divided by that of the control group. The results were expressed as a mean of three individual experiments.

Cell chemotaxis and migration assay

Migration of HT29 cells was assessed in a HTS transwell-24 system (Corning, Acton, MA, USA) with 8- μ m membrane pores. After rehydration for 2 h, RPMI-1640 and different SDF-1 concentrations (10, 20 and 40 ng/mL) were added into the lower chamber (0.5 mL per well) and 2×10^4 cells treated with PBS or AMD3100 (100 ng/mL) were added into the upper chamber 30 min before assay. After incubated at 37°C for 24 h, Matrigel and cells on the upper side of the membrane were wiped off with PBS-rinsed cotton swabs and invading cells migrated to the lower surface of the membrane were photographed and counted under an inverted light microscope at 100 \times magnification. Six random fields were counted for each well. Migration of HT29 cells was assayed in triplicate.

Immunocytochemistry

To observe the effect of SDF-1 on E-cadherin/ β -catenin complex expression, HT29 cells were seeded in 24-well plates with glass slides at a density of 2×10^5 cells/well in RPMI-1640 medium in the absence of serum. After incubated overnight, either PBS or CXCR4 antagonist AMD3100 (100 ng/mL) was added and incubated for 2 h. Then, SDF-1 was added at different concentrations (10, 20 and 40 ng/mL). Glass slides were collected after incubated for 24 and 48 h with SDF-1. Cells were washed thrice with PBS prior to fixation with 4% formaldehyde in PBS. Then, the cells were covered with 3% H₂O₂-methanol for 30 min at room temperature to inactivate the endogenous peroxidase. A methanol permeabilisation step was needed for β -catenin, during which cells were covered with ice-cold 100% methanol for 10 min in a freezer. After rinsed thrice with PBS, the cells were covered with 5% normal goat serum for 30 min at room temperature to block the non-specific binding. Primary rabbit anti-E-cadherin antibodies and mouse anti- β -catenin antibodies were applied to the slides and incubated overnight at 4°C. Slides were washed three times with PBS. Secondary antibodies were applied for 1 h at room temperature. Finally, the slides were stained with 0.025% diaminobenzidine tetrahydrochloride containing 4% H₂O₂ for 1-20 min, counterstained with hematoxylin

for an appropriate period of time, and analyzed under a light microscope. The level of nonspecific background staining was established for each measurement using control cells processed in the same way without exposure to primary antibodies.

Reverse transcriptase-polymerase chain reaction analysis

HT29 cells (1×10^6) treated as in immunocytochemistry were collected and washed three times with $1 \times$ PBS. Total RNA was extracted using trizol reagents and quantified by ND-1000 UV-visible spectrophotometry. cDNA was synthesized from 1 μ g of total RNA using Revert Aid™ M-MuLV reverse transcriptase. Reaction mixture contained 4 μ L of $5 \times$ reaction buffer, 2 μ L of 10 mmol/L dNTP mix, 1 μ g of Oligo(dT)18, 1 μ g of total RNA, 0.5 μ L of ribonuclease inhibitor, and 200 U Aid™ M-MuLV reverse transcriptase in a total volume of 20 μ L. PCR contained 2.5 μ L of $10 \times$ PCR buffer, 1.5 μ L of 25 mmol/L $MgCl_2$, 0.5 μ L of 10 mmol/L dNTP mix, 0.8 μ mol/L β -catenin primer, 0.04 μ mol/L GAPDH primer (for β -catenin) and 0.8 μ mol/L E-cadherin primer, 0.1 μ mol/L β -actin primer (for E-cadherin), 3 μ L of cDNA and 25 U *Taq* polymerase in a total volume of 25 μ L. The sequences of gene-specific primers are 5'-TTTGCCTGAGCAGGGTGC-3' (forward) and 5'-GCTGCATATGTCGCCACACC-3' (reverse) for β -catenin, 5'-CCACCCATGGCAAATTCATGGCA-3' (forward) and 5'-TCTAGACGGCAGGTCAGGTCCACC-3' (reverse) for GAPDH, 5'-GATTCTGCTGCTCTTGCTGT-3' (forward) and 5'-CCTGGTCTTTGTCTGACTCTG-3' (reverse) for E-cadherin, 5'-CCTTCCTGGGCATGGAGTCCT-3' (forward) and 5'-GGAGCAATGATCTTGATCTT-3' (reverse) for β -actin, respectively. The PCR conditions for β -catenin were as follows: denaturing at 94°C for 5 min, followed by 35 cycles at 94°C for 30 s, at 63°C for 30 s, at 72°C for 1 min, and a final extension at 72°C for 7 min. The PCR conditions for E-cadherin were as follows: annealing at 58°C for 5 min, followed by 35 cycles at 94°C for 30 s, at 63°C for 30 s, at 72°C for 1 min, and a final extension at 72°C for 7 min. The PCR products were separated on a 2% agarose gel in $1 \times$ TAE, visualized with ethidium bromide staining by BIO-RAD Gel Dos1000, and quantified using the Molecular Analyst software version 1.5 using GAPDH as an internal control for β -catenin, and β -actin as an internal control for E-cadherin. The hue value was calculated as the ratio of each group and the internal control group. Results were expressed as the mean value of three individual experiments.

Western blotting

To study the effect of SDF-1 on phosphorylation of various signaling proteins, HT29 cells were treated with 20 ng/mL SDF-1 for different periods of time (from 1 min to 2 d) or with different concentrations of SDF-1 (5-100 ng/mL) for 30 min after overnight starvation of

growth factors. Cell lysates were analyzed for the presence of phosphorylated AKT and β -catenin by phospho-specific antibodies to the specific phosphorylation sites of AKT (Ser473) and β -catenin (Ser33/37). For experiments using inhibitors, HT29 cells were pretreated with AMD3100 (100 ng/mL) or PI3K/AKT inhibitor LY294002 (20 μ mol/L) for 2 h, followed by stimulation with 20 ng/mL SDF-1. After each treatment, 4×10^6 HT29 cells were collected and washed three times with $1 \times$ PBS. Cytoplasm and membrane extracts were acquired according to the instruction datasheet of Pierce Biotechnology Corporation and quantified by Bradford protein assay. Different extraction proteins were separated by SDS-PAGE and transferred onto the PVDF membrane. Membranes were blocked with 5% BSA for 2 h at room temperature, incubated overnight at 4°C with primary antibodies (p- β -catenin 1:1000, p-AKT 1:1000 and β -actin 1:400) and washed three times prior to incubation with HRP-conjugated secondary antibodies (peroxidase conjugated goat anti rabbit IgG 1:10000) for 1 h at room temperature. Protein expression was visualized by chemiluminescence and quantified using the multigauge software. β -actin was used as a loading control. Data were shown as the ratio of phosphorylation and loading control. Western blotting assay was performed in triplicate.

Statistical analysis

All data were analyzed using the SPSS 16.0 and expressed as mean \pm SD. Statistical significance of differences was determined by Student's *t*-test in two groups and one-way ANOVA among multiple groups. $P < 0.05$ was considered statistically significant.

RESULTS

SDF-1 enhanced viability of HT29 colon cancer cells

The viability of HT29 cells in any experiment groups was not different from that in control group 48 h after incubated with SDF-1. The cells grew much faster with a proliferation rate of 129% and 135%, respectively ($P < 0.05$) 72 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL. AMD3100 plus SDF-1 inhibited the cell growth. AMD3100 alone had no effect on cell proliferation.

SDF-1 promoted migration of HT29 colon cancer cells

MTT assay revealed no significant difference in viability of HT29 colon cancer cells in any experiment groups within 24 h after incubated with SDF-1. Therefore, the migration of HT29 colon cancer cells was assayed 24 h after incubated with SDF-1 to exclude the influence of cell viability. The migration ability of HT29 cells was significantly greater in experiment groups than in control group 24 h after incubated with SDF-1 at the concentration of 10 ng/mL (149 ± 13.3 vs 92.3 ± 12.4 , $P = 0.041$), 20 ng/mL (161 ± 13.5 vs 92.3 ± 12.4 , $P = 0.023$), and 40 g/mL (187.5 ± 14 vs 92.3 ± 12.4 , $P < 0.001$). AMD3100 plus SDF-1 inhibited

Figure 1 Effect of stromal cell-derived factor-1 (20 ng/mL) on E-cadherin expression ($\times 400$). A: E-cadherin expression in HT29 cells; B: Significantly lower E-cadherin expression level 48 h after incubated with stromal cell-derived factor-1 (SDF-1) ($P < 0.05$); C: AMD3100-inhibited E-cadherin expression; D: No effect of AMD3100 alone on E-cadherin expression. Arrows mean the expression of E-cadherin; Bars indicate mean \pm SD of six random fields. ^a $P < 0.05$.

Figure 3 Effect of stromal cell-derived factor-1 (20 ng/mL) on β -catenin expression after 48 h ($\times 400$). A: β -catenin expression in HT29 cells; B: Significantly lower β -catenin expression level 48 h after incubated with stromal cell-derived factor-1 (SDF-1) ($P = 0.031$); C: AMD3100-inhibited β -catenin expression; D: No effect of AMD3100 alone on β -catenin expression. Arrows mean the expression of β -catenin; Bars indicate mean \pm SD of six random fields. ^a $P < 0.05$.

Figure 2 Effect of stromal cell-derived factor-1 (20 ng/mL) on E-cadherin mRNA expression after 24 h (A) and 48 h (B) in different groups. Bars represent mean \pm SD of three individual experiments. ^a $P < 0.05$. SDF-1: Stromal cell-derived factor-1.

the migration of HT29 cells. AMD3100 alone had no effect on cell migration.

SDF-1 down-regulated activation of CXCR4 and E-cadherin expression at protein and mRNA levels

Immunocytochemistry assay showed that E-cadherin was significantly expressed in HT29 cells (Figure 1A). No change was found in E-cadherin expression 24 h after incubated with SDF-1. The E-cadherin expression level was significantly lower 48 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL ($P < 0.05$, Figure 1B). HT29 cells treated with AMD3100 prior to administration of SDF-1 did not decrease the E-cadherin expression level. However, HT29 cells treated SDF-1 decreased the E-cadherin expression level (Figure 1C). AMD3100 alone had no effect on the E-cadherin expression (Figure 1D). The changes of E-cadherin expression in HT29 cells are demonstrated in Figure 1E.

Reverse transcriptase-polymerase chain reaction (RT-PCR) analysis demonstrated that the E-cadherin mRNA expression level was lower 48 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL ($P < 0.05$). AMD3100 plus SDF-1 inhibited the E-cadherin mRNA expression. AMD3100 alone had no influence on E-cadherin mRNA expression (Figure 2A and B).

SDF-1 down-regulated β -catenin expression at protein and mRNA levels

β -catenin was strongly stained in HT29 cells not incubated with SDF-1 (Figure 3A). The β -catenin expression

Figure 4 Effect of stromal cell-derived factor-1 (20 ng/mL) on β -catenin mRNA expression after 24 h (A) and 48 h (B) in different groups. Bars represent mean \pm SD of three individual experiments. ^a $P < 0.05$. SDF-1: Stromal cell-derived factor-1.

Figure 5 Effect of stromal cell-derived factor-1 on the phosphorylation of PI3K/AKT and β -catenin. A: Phosphorylation of PI3K/AKT and β -catenin after incubated with stromal cell-derived factor (SDF) at different periods of time (1, 5, 10, 15, 30, 60, 120 min and on days 1 and 2); B: Phosphorylation of PI3K/AKT and β -catenin after incubated with SDF-1 at different concentrations (5, 10, 20, 40 and 100 ng/mL) for 30 min; C and D: SDF-1 increases phosphorylation of PI3K/AKT and β -catenin in HT29 cells in a time- and dose-dependent manner. Bars represent mean \pm SD of triplicate experiments. ^a $P < 0.05$.

level was lower 24 and 48 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL ($P < 0.05$, Figure 3B). The β -catenin expression level was slightly lower in AMD3100- treated HT29 cells (Figure 3C). AMD3100 alone had no influence on β -catenin expression (Figure 3D). The changes of β -catenin expression in HT29 cells are demonstrated in Figure 3E.

RT-PCR analysis demonstrated that the β -catenin mRNA expression level was lower 24 and 48 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL ($P < 0.05$, Figure 4A and B). AMD3100 plus SDF-1 inhibited the β -catenin mRNA expression. AMD3100 alone did not influence the β -catenin mRNA expression.

Involvement of phosphorylation of PI3K/AKT and β -catenin in SDF-1-induced down-regulation of E-cadherin/ β -catenin expression

The phosphorylation of PI3K/AKT and β -catenin was detected to observe whether phosphorylation is involved in down-regulation of E-cadherin/ β -catenin complex expression, which demonstrated that SDF-1 increased the phosphorylation of AKT and β -catenin. The β -catenin was evidently activated at 5 min and the AKT was significantly phosphorylated at 15 min after incubated with SDF-1. The phosphorylation of β -catenin reached its peak 30 min after incubated with SDF-1. Then, β -catenin was evidently phosphorylated for 2 d (Figure 5A and C). The

Figure 6 AMD3100 and LY294002 inhibit stromal cell-derived factor-1-induced phosphorylation of PI3K/AKT and β -catenin while AMD3100 or LY294002 alone has no effect on phosphorylation of PI3K/AKT and β -catenin. SDF-1: Stromal cell-derived factor-1.

phosphorylation of AKT reached its peak at 15–60 min after incubated with SDF-1, remained there for 2 h, and then slowly declined. To determine the dose-dependent effect of SDF-1 on the phosphorylation of PI3K/AKT and β -catenin, HT29 cells were treated with SDF-1 at different concentrations (0, 5, 10, 20, 40 and 100 ng/mL) for 30 min. Then, cell lysates were analyzed for the phosphorylation of PI3K/AKT and β -catenin. Administration of SDF-1 for 30 min increased the phosphorylation of PI3K/AKT and β -catenin in a dose-dependent manner. PI3K/AKT and β -catenin were phosphorylated after incubated with SDF-1 at the concentration of 5 ng/mL and reached its peak after incubated with SDF-1 at the concentration of 100 ng/mL (Figure 5B and D).

Inhibition of PI3K/AKT prevented phosphorylation of SDF-1-induced β -catenin

To investigate the relation between PI3K/AKT and β -catenin, AMD3100 and LY294002 were used to inhibit the effect of SDF-1 and the signal transmission through PI3K/AKT, which showed that AMD3100 inhibited the phosphorylation of PI3K/AKT and β -catenin (Figure 6). Further study demonstrated that administration of LY294002 prior to SDF-1 also prevented the phosphorylation of PI3K/AKT and β -catenin (Figure 6), suggesting that β -catenin is phosphorylated *via* the PI3K/AKT, and may be the downstream signaling molecule of PI3K/AKT.

DISCUSSION

Although the CXCR4/SDF-1 biological axis contributes to organ-selective metastasis of tumors^[15–17], the mechanism underlying the effect of chemotaxis remains unclear. In this study, the relation between CXCR4/SDF-1 axis and E-cadherin/ β -catenin complex expression was observed. Experiment on HT29 colon cancer cell line was performed because it shows a high expression level of CXCR4^[18]. SDF-1 promoted the proliferation of HT29 cells, thereby contributing to primary tumor formation and down-regulated the E-cadherin/ β -catenin expression by reducing the mRNA expression levels and decomposing their complex formation by phosphorylating the PI3K/AKT and β -catenin. AMD3100 and LY294002

blocked the two processes mediated by SDF-1, suggesting that they may be effective anti-metastatic agents, at least against CRC.

It was reported that CXCR4/SDF-1 axis-induced chemotaxis effect plays a role in the invasion of CRC cells^[16,17]. A number of molecules, such as vascular endothelial growth factor, matrix metalloproteinase (MMP)9, and MMP2, have been implicated in SDF-1-induced CRC invasion^[19]. E-cadherin is not only an adhesion molecule but also a tumor suppressor as well as the most important epithelial marker^[20]. In most cancers of epithelial origin, E-cadherin mediates cell-cell adhesion. Loss of E-cadherin-mediated cell-cell adhesion is implicated in tumor invasion and metastasis^[21,22]. Recent studies showed that Krüppel-like factor 4 inhibits epithelial to mesenchymal transition by regulating E-cadherin gene expression^[23]. In our study, the E-cadherin expression level at protein and mRNA levels was lower 48 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL, suggesting that E-cadherin is involved in SDF-1-induced chemotaxis effect. In this study, the molecular mechanism underlying SDF-1-induced chemotaxis effect was studied. The E-cadherin mRNA expression level was lower after incubated with SDF-1, which may account for the down-regulation of E-cadherin expression.

Tumor invasion is a complex process and loss of E-cadherin-mediated cell adhesion is not sufficient to confer an invasive phenotype to tumor cells. Cell migration requires precise control, which is altered or lost when tumors become invasive and metastatic. It has been shown that decreased β -catenin expression is often related with the absent or reduced E-cadherin, which contributes to the development of several cervical carcinoma cell lines^[24,25]. A recent study revealed that β -catenin membrane/cytosolic expression level is significantly lower in primary tumors than in corresponding matched metastases, suggesting that the low β -catenin expression level may be a prognostic factor for the occurrence of metastasis and a worse outcome^[26]. In this study, the β -catenin protein and mRNA expression levels were significantly lower 48 h after incubated with SDF-1 at the concentrations of 20 and 40 ng/mL, suggesting that β -catenin is involved in SDF-1-induced chemotaxis effect. Changes in β -catenin may also lead to the degradation of E-cadherin/ β -catenin complex and alter cytoskeleton, thus promoting cell migration.

Growth factors, such as epidermal growth factor, induce β -catenin and plakoglobin phosphorylation, resulting in breakage of E-cadherin binding to actin cytoskeleton and contact disassembly^[26]. In this study, the phosphorylation of β -catenin was increased after incubated with SDF-1, indicating that SDF-1 induces phosphorylation of β -catenin. Phosphorylation of β -catenin reduces β -catenin and may lead to decomposition of E-cadherin/ β -catenin complex. G protein-coupled receptor activation results in PI3K and downstream AKT activation^[27]. In this study, SDF-1-induced phosphorylation of PI3K/AKT and β -catenin in a time- and dose-dependent manner. Finally,

whether SDF-1 induces β -catenin phosphorylation *via* PI3K/AKT was also studied. Given that both AMD3100 and LY294002 inhibited the phosphorylation of PI3K/AKT and β -catenin, β -catenin may be the downstream signaling molecule of PI3K/AKT, indicating that the phosphorylation of β -catenin may account for the down-regulation of β -catenin, and the breakage of E-cadherin/ β -catenin complex. The phosphorylation of β -catenin may exert its effect *via* the PI3K/AKT pathway.

In conclusion, down-regulation of E-cadherin/ β -catenin complex expression is involved in SDF-1-induced chemotaxis. The decreased E-cadherin mRNA expression and the down-regulated β -catenin expression may account for the down-regulation of E-cadherin. CXCR4/SDF-1 axis stimulates the phosphorylation of PI3K/AKT and β -catenin. The down-regulation of β -catenin may be induced by the decreased β -catenin mRNA expression and the increased phosphorylation of PI3K/AKT. PI3K inhibitor LY294002 inhibits the SDF-1-induced phosphorylation of PI3K/AKT and β -catenin. β -catenin may be the downstream signaling molecule of PI3K/AKT.

The authors thank Cui-Ling Li and Hai-Peng Yin for their excellent technical support in this study.

COMMENTS

Background

CXCR4/stromal cell-derived factor-1 (SDF-1) axis-mediated chemotaxis effect is crucial in organ-selective metastasis. E-cadherin/ β -catenin complex plays an important role in colorectal tumorigenesis. Relatively little is known about the role of E-cadherin/ β -catenin in CXCR4/SDF-1 axis-mediated chemotaxis effect.

Research frontiers

Recent studies demonstrated that the CXCR4/SDF-1 signaling pathway is involved in the metastatic process of colorectal cancer (CRC). In addition, inhibiting the interaction of SDF-1 and CXCR4 with CXCR4 antagonist AMD3100 prevents the chemotactic migration of CRC cells. However, the underlying molecular mechanism has not been elucidated.

Innovations and breakthroughs

Down-regulation of E-cadherin/ β -catenin complex is involved in SDF-1-induced chemotaxis effect in HT29 colon cancer cells. Moreover, decreased mRNA synthesis and increased β -catenin phosphorylation may down-regulate E-cadherin/ β -catenin. To the best of our knowledge, this is the first study that analyzes the relation between CXCR4/SDF-1 axis and E-cadherin/ β -catenin complex.

Applications

This study demonstrated the relation between E-cadherin/ β -catenin complex and SDF-1-induced chemotaxis effect in HT29 colon cancer cells, thus providing a possible molecular mechanism underlying the SDF-1-induced chemotaxis effect.

Terminology

SDF-1, also known as CXCL12, belongs to the CXC chemokine family and interacts specifically with the seven-transmembrane, G protein-coupled receptor CXCR4. E-cadherin is not only an adhesion molecule but also a tumor suppressor as well as the most important epithelial marker. β -catenin is a key component of adherens junctions, necessary for homophilic cell-cell adhesion. In addition to the membrane-associated pool, β -catenin plays a role in cell-signaling and gene transcription.

Peer review

This is a well designed study, which may explain the development of colorectal metastasis *in vitro*.

Abstract

AIM: To evaluate the natural history of human cytomegalovirus (HCMV) infection in a series of 28 ulcerative colitis patients in whom the search for HCMV was positive.

METHODS: A series of 85 patients with moderate-severe ulcerative colitis flare-up were evaluated for a HCMV search by performing a haematoxylin and eosin stain, immunohistochemical assay and nested polymerase chain reaction on rectal biopsies. Among 85 screened patients (19 of whom were steroid resistant/dependant), 28 were positive for HCMV; after remission the patients were followed up clinically and histologically.

RESULTS: Among the 22 patients with complete follow-up, in 8 (36%) patients HCMV-DNA persisted in the intestinal specimens. Among the HCMV positive patients, 4 (50%) experienced at least one moderate-severe

flare-up of colitis without evidence of peripheral HCMV. Among the 14 HCMV negative patients, 3 with pouches developed pouchitis and 5 out of 11 (45%) experienced a colitis flare-up.

CONCLUSION: Our preliminary results suggest that HCMV may remain in the colon after an acute colitis flare-up despite remission; it seems that the virus is not responsible for the disease relapse.

INTRODUCTION

The etiology of inflammatory bowel disease (IBD) is still unknown. The most current hypothesis is that IBD derives from an unsuitable and exaggerated immune response to normal mucosal resident bacterial microflora, likely induced by an external agent, in genetically predisposed individuals. Among the external agents, environmental factors unquestionably play a major role in the pathogenesis of IBD. Evidence of associations of bacterial factors derives from both human and animal studies. The virus takes an unclear part in the pathogenesis and disease development, but is probably involved.

In recent years several papers have described the link between viral infection and IBD onset, reactivation or steroid resistance^[1-4].

No clear data is available on the natural history of HCMV infection superimposed on IBD. The following questions remain unanswered: (1) does the virus disappear after remission of acute colitis relapse? (2) does the persistence of the virus detected by sensitive assays increase the risk of relapse?

The aim of this study was an attempt to answer the questions raised above and to evaluate the natural history of human cytomegalovirus (HCMV) infection after a severe colitis exacerbation.

MATERIALS AND METHODS

From 1997 to 2007, a prospective study was conducted on 85 patients with ulcerative colitis who were admitted to the Medicine department of V. Cervello Hospital in Palermo due to a severe colitis attack (according to the Truelove-Witts criteria) (Figure 1). All patients were treated with conventional and standardized corticosteroid treatment (1 mg/kg per day) and were endoscopically evaluated with a different approach: from 1997 to 1999 sigmoidoscopy was performed only in steroid resistant patients (17 patients) whereas from 2000 to 2007 sigmoidoscopy was performed in all patients (68 patients) at ward admission, taking systematically rectal biopsies. Therefore a total of 85 patients (Table 1) was investigated for HCMV infection with 3 different techniques.

The rectal biopsies were immediately fixed with 10% buffered formalin for 2 h to obtain tissue fixation; afterwards the preparation was subjected to several processes (lavage, dehydration, clearing, paraffin impregnation and embedding) to prepare sections with a thickness of 3-4 μ m.

The histologic specimens were examined using the following techniques: (1) Light microscopy with hematoxylin and eosin (HE) stain in order to document the microscopic disease activity and allow the detection of cytomegalic cells, markers of infected viral cells. Cytomegalic cells, which are 2- or 4-fold larger (25-35 μ m) than surrounding cells, contain a basophilic intranuclear inclusion (8-10 μ m) eccentrically placed and sometimes surrounded by a clear halo giving it an "owl's eye" appearance, and thickened nuclear membrane, frequently associated with smaller granular intracytoplasmic inclusions. Intranuclear inclusions were observed in epithelial, endothelial, stromal and smooth muscle cells. A biopsy was regarded as positive by light microscopy for HCMV if a single cell showed intranuclear or cytoplasmic inclusions and cytomegalic characteristics (Figure 2); (2) Immunohistochemical (ICH) procedure for HCMV performed on a paraffin-embedded section with monoclonal mouse antibodies anti-Human CMV (clone BM204) and conjugated to a peroxidase-labeled amino acid polymer by peroxidase-antiperoxidase (PAP) method in order to detect viral proteins. Nuclear or cytoplasmic antigen was identified by the typical brown reaction product of the PAP method; and

Table 1 Clinical characteristics of the series *n* (%)

Patient characteristics	Total	HCMV+	HCMV-

Figure 2 Original reproduction of epithelial cytomegalic cells (arrows) in rectal biopsy (hematoxylin and eosin stain, 40 \times).

(3) Nested polymerase chain reaction (nPCR): (a) DNA extraction: DNA was extracted from 10 mm sections of paraffin wax embedded tissues. Five sections were cut with a standard microtome from every paraffin wax block and transferred into a 1.5 mL microtube. To prevent cross

contamination between the samples, the microtome blade was washed with xylene and ethanol after sectioning of each block. DNA extraction was performed using a conventional method. The conventional method consisted of xylene/ethanol dewaxing followed by overnight proteinase K digestion in lysis buffer. The sample was heated at 95°C for 5 min to inactivate the proteinase K. We checked the quality of samples by PCR for the housekeeping gene β -globin (fragment of 268 bp); and (b) Detection of viral DNA: Nested PCR was used to detect the presence of viral DNA in colon tissues. Two pairs of primers annealed to the gB region of HCMV. Primers used for the first-round product and second-round PCRs are as follows (5' to 3'): first-round primer 1, GAGGACAACGAAATC-CTGTTGGGCA; first-round primer 2, GTCGACG-GTGGAGATACTGCTGAGG; second-round primer 3, ACCACCGCACTGAGGAATGTCAG, and second-round primer 4, TCAATCATGCGTTTGAAGAGGTA, to obtain a CMV fragment of 100 bp.

PCR reaction mixture contained 0.5 U *Taq* polymerase, 1 × PCR Buffer (50 mmol/L KCl and 10 mmol/L Tris-HCl (pH 8.4), 0.2 mmol/L of each dNTPs, 1.5 mmol/L MgCl₂, 10 pmol of each primers and 100-200 ng of extracted DNA. The conditions for the first-round PCR were as follows: denaturation at 94°C for 5 min, followed by 35 cycles of denaturation at 94°C for 1 min, annealing at 55°C for 1 min and extension at 72°C for 1 min followed by 5 min final extension at 72°C.

The conditions for second-round PCR were as follows: denaturation at 94°C for 5 min, followed by 25 cycles of denaturation at 94°C for 1 min, annealing at 55°C for 1 min and extension at 72°C for 1 min followed by 5 min final extension at 72°C.

The PCR amplification products were run on 2% agarose gel and stained with ethidium bromide and visualized under ultraviolet light.

HCMV-pp65 antigenemia

All patients were also tested for HCMV-pp65 antigenemia in peripheral leukocytes by CMV-CINAKit (Argene® Biosoft). The samples were considered positive for active HCMV infection using a cut-off value of 5 positive fluorescent nuclei/ 2×10^5 leukocytes^[5]; between 1 to 4 positive cells the result was considered questionable and the blood sample was repeated after 48 h to value a possible increase of cell nuclei positivity. If we detected histopathological examination positive we considered the patient HCMV-infected but not surely with active replication; if both tests (histology and pp65 antigenemia) were positive we judged the patients candidates for antiviral treatment due to a probable active replication. However the last decision about antiviral treatment was related to the disease activity without significant improvement of the disease course after treatment for underlying disease.

Sigmoidoscopy was performed in patients reaching clinical remission in order to control endoscopic activity and the presence of HCMV.

Table 2 Results and outcome of the series *n* (%)

	HCMV+ (HE-ICH/PCR)	HCMV- (HE-ICH/PCR)
Total patients	28	57
Steroid dependent/resistant (%)	68	19
Medical remission	22 (78)	51 (89)
Surgical remission	6 (21)	6 (10.5)
Death	3 (10)	0
Persistence of HCMV DNA+ at follow-up	8 (28.5)	0

HCMV: Human cytomegalovirus; ICH: Immunohistochemical; PCR: Polymerase chain reaction; HE: Hematoxylin and eosin.

The patients were followed clinically as outpatients quarterly to evaluate the remission time, the number of relapses, the immunosuppressive therapies and the need for surgery.

We define as remission a combination of clinical parameters (stool frequency ≤ 3 per day with no bleeding); the term relapse is used to define a flare of symptoms in a patient with established ulcerative colitis (UC) who is in clinical remission, either spontaneously or after medical or surgical treatment.

In the case of clinical relapse, sigmoidoscopy was performed with multiple biopsies and a search for HCMV in rectal biopsies by the 3 methods and peripheral pp65 antigenemia was conducted.

Moreover the asymptomatic patients were examined by colonoscopy every year in order to follow up the natural history of HCMV infection regarding histologic persistence, to understand more clearly the possible role of “bystander” or promoter to the disease relapse.

Oral and written informed consent was obtained from each patient before any procedure.

The rate of surgery and clinical relapse rates in the 2 groups of patients (HCMV positive and negative) were compared using χ^2 test.

RESULTS

The median clinical and endoscopic follow-up was 40 mo.

Among the 85 patients evaluated for HCMV infection from 1997 to 2007, in 28 (12 women and 16 men) the intestinal biopsy resulted positive by routine HE/ICH staining and α PCR assay according to the standard methods previously described. The overall prevalence data was 33% (Table 2). There was no association between HCMV and active immunosuppressive or biologic treatment. Ten patients among a total of 28 also displayed positive pp65 antigenemia (35%). Out of 10 positive patients for both histology and pp65 antigenemia, 7 received antiviral treatment (5 with ganciclovir and 2 with foscarnet) because of steroid resistance and clinical disease worsening, achieving remission in 5 patients. In these 5 treated patients HCMV disappeared at the first endoscopic control. Two patients were operated on because of a rapid clinical disease worsening: 1 patient died due to toxic megacolon. Among the 3 patients not treated with antiviral therapy for a contrain-

Figure 3 Ethidium bromide-stained 2% agarose gel demonstrating detectable second-round human cytomegalovirus products of nested polymerase chain reaction. Lane 1: Molecular size marker; Lanes 2-9: Positive patient samples; Lane 10: Positive control.

dication, 1 achieved remission with therapy for underlying disease, 2 patients were operated on for intractable disease and 1 of these 2 patients died due to post-operative complications.

Among the 18 patients who were histologically positive but pp65 antigenemia negative, 2 were operated on for intractable disease and 1 died; 16 improved with conventional therapy. Among the overall number of 28 patients who tested positive for HCMV, 6 underwent total colectomy (21%), 2 of them treated with antiviral treatment. Among the 57 patients who were negative for HCMV detection, 6 patients were operated on (10.5%).

Among the 25 surviving patients, 22 remained on follow-up (19 on medical remission and 3 with ileoanal pouch anastomosis) because 3 refused to undertake regular clinical and colonoscopic controls.

The 3 patients operated on underwent endoscopic and histological assessment of the ileoanal pouch during follow-up, showing a moderate grade of pouchitis according to PDAI 1 year after surgery, without detection of HCMV in the pouch.

Eighteen patients achieved clinical remission with medical treatment and 1 patient became steroid-dependent; all were followed up for an average period of 46 mo, all were clinically and endoscopically evaluated in accordance with the methods described above.

During the routine endoscopic and biopsy controls 11/19 patients were negative for HCMV detection both by traditional histology with HE and ICH in the intestinal biopsies and by α PCR assay, whereas 8 were positive for HCMV viral DNA detection by α PCR (Figure 3) and negative on light microscopy (HE and ICH) and on pp65 antigenemia.

Among the 8 patients in which positivity for HCMV-DNA persisted in the intestinal biopsies, 3 were treated with antiviral therapy at first detection of HCMV. Four experienced (50%) an early-moderate colitis flare up (within 3 mo) during the follow-up without detection of pp65 antigenemia in the peripheral leukocytes (Figure 4). A patient achieved remission with conventional steroid

Table 3 Clinical course and outcome of ulcerative colitis with persistent human cytomegalovirus at polymerase chain reaction

Patient No.	Age (yr)/sex	Immunomodulators at HCMV diagnosis	Disease relapse	Outcome
1	42/F	Aza	No	Remission with 5-asa
2	71/M	No	Yes	Remission with IFX
3	58/M	Aza	Yes	Procto-colectomy
4	74/M	No	Yes	Remission with IFX
5	65/F	No	No	Remission with 5-asa
6	65/M	No	Yes	Remission with steroid
7	45/M	Aza	No	Leukapheresis-IFX
8	28/M	No	No	Remission with Aza

HCMV: Human cytomegalovirus; Aza: Azathioprine; IFX: Infliximab.

treatment, 2 patients became steroid-dependent and were treated with anti-TNF therapy, both achieving remission. The fourth patient, who was steroid-dependent, intolerant to azathioprine and with a contraindication to anti-TNF therapy, underwent a total colectomy due to severity of disease. None were treated with antiviral treatment due to absence of positive antigenemia (Table 3). Among the 11 HCMV negative patients 5 (45%) experienced a reactivation of colitis and achieved remission with steroid treatment.

After remission, 8 patients (among 22) were treated with azathioprine (in 5 of them HCMV-DNA was present when the treatment was started) and 14 patients were treated with mesalazine (3 HCMV-DNA positive).

The χ^2 test comparing surgical intervention among positive HCMV (21%) and negative HCMV (10.5%) patients was not statistically significant ($P = 0.17$, odds ratio 2.32).

The χ^2 test comparing the relapse rate among HCMV positive (50%) and negative (45%) patients was not statistically significant ($P = 0.36$).

DISCUSSION

Our study was an attempt to answer two recurrent questions about the role of HCMV in IBD. The questions are about HCMV disappearance after remission of acute colitis relapse: we have demonstrated that HCMV persists in the colon after recovery of a colitis flare with a HCMV co-infection in a series of UC patients and remains detectable by sensitive methods such as α PCR without histological/ICH virus detection in a minority of patients. From this small series the persistence of virus in the colon of UC patients does not favour disease relapse because the virus persists in a latent state. The absence of pp65 antigenemia during the follow-up relapse and the response to the conventional corticosteroid treatment do not suggest a remarkable role of HCMV in the re-activation. Furthermore, it is unlikely that immunosuppressive treatment favours relapse of UC when HCMV persists in the colon.

To establish a connection between HCMV and UC

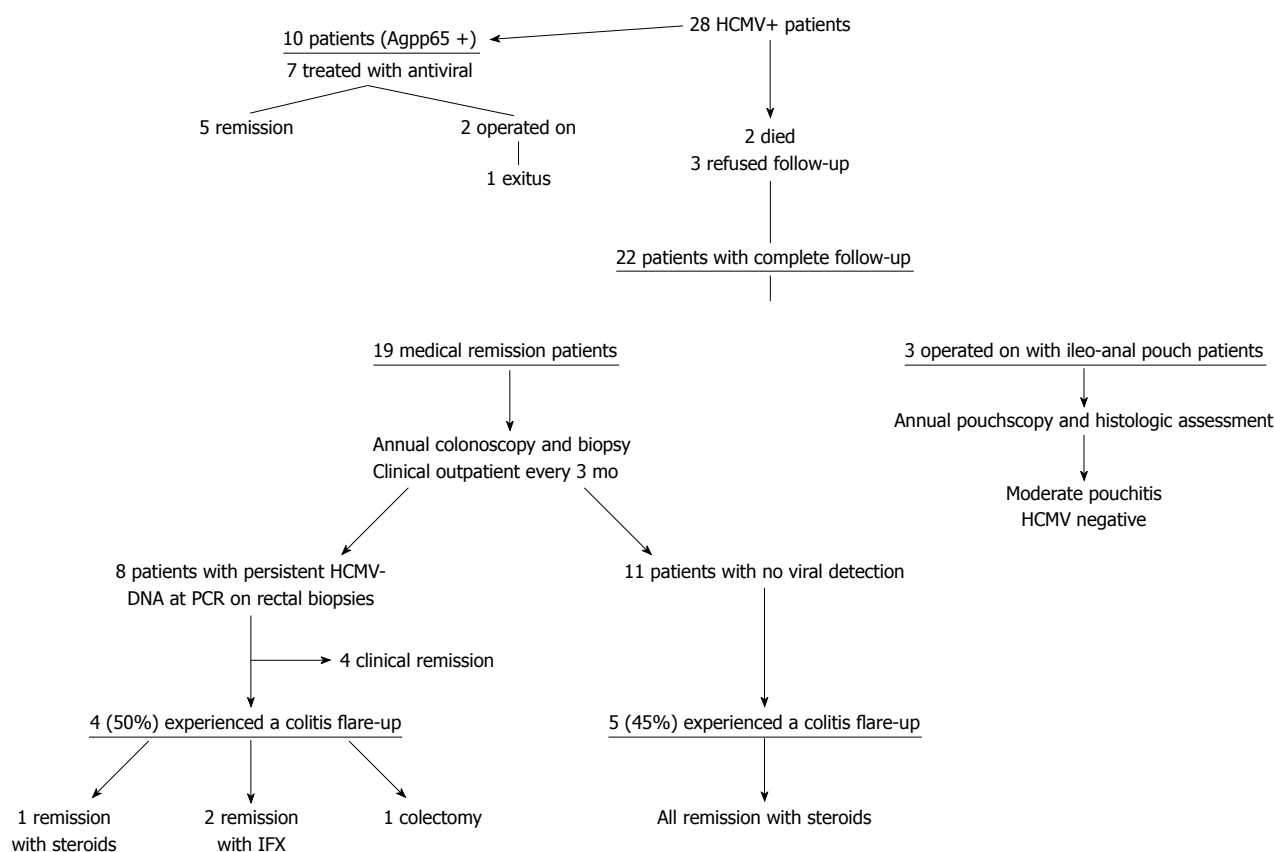

Figure 4 Follow-up human cytomegalovirus+ patients. IFX: Infliximab; HCMV: Human cytomegalovirus; PCR: Polymerase chain reaction.

more reports are needed. The interaction with the immune system plays a key role in the pathogenesis of HCMV disease, and the main determinant is an immunological impairment. As mentioned above, even most primary infections in humans are asymptomatic. No trace of the infection is observable except for seroconversion. In recent years, however, the disease has become more common probably due to the widespread use of immunosuppressants in oncology, in transplantation medicine and in chronic disease^[6].

What happens in intestinal tissue after persistence of HCMV-DNA is not known; maybe the colonic epithelial cells harbour the latent virus that became detectable using the highly sensitive PCR assay. The reactivation of virus from latency may depend on a complex interplay of biological factors with the host that, above all in patients with UC, are not clearly understood. Experimental studies suggest that latent CMV infection in the mouse may modulate mucosal immunity altering the susceptibility to gut microbiota without viral reactivation^[7].

Dimitroulia *et al*^[8] demonstrated that HCMV is frequently detected in IBD patients, showing that the virus genome was detected in intestinal tissue by polymerase chain reaction in 32.9% of the total IBD patients, while the HCMV genome in the blood was detected in 27.1% of these patients. Matsuoka *et al*^[9] showed that HCMV is frequently reactivated in a series of active UC seropositive patients, but that reactivation has little effect on the clinical

course and that most of the colitis reactivation with positive HCMV responds to conventional immunosuppressive therapies.

Kou *et al*^[10] demonstrated that the detected copy number of HCMV-DNA by PCR method is higher in the inflamed colonic tissue than in non inflamed colonic tissue in patients with UC refractory to immunosuppressive therapy. The author strongly supported the hypothesis that HCMV infection is involved in exacerbation of patients with IBD and the early detection of genome in intestinal tissue is important for an eventual change to the therapeutic approach.

We show that patients with HCMV infection were more frequently operated on than those without superimposed HCMV (even though not statistically significant) and this may suggest that the virus is a marker of risk of surgical treatment. This observation is an agreement with Cooper *et al*^[11] that showed in 1977 that HCMV infection might be responsible for acute toxic dilatation with increased colonic resection rate.

In patients who have undergone proctocolectomy we did not detect HCMV in the follow-up biopsies of the ileal pouch. Casadesus *et al*^[12] detected HCMV in a small series of patients with UC who underwent proctocolectomy and hypothesize that the virus may play an etiological role in pouchitis; other case reports^[13,14] demonstrate that HCMV is a rare but possible cause of refractory pouchitis to be considered for antiviral therapy.

In conclusion, our preliminary results suggest that HCMV may remain in the colon despite remission, probably activating a delicate balance with the host immune system in order to avoid its elimination, but the effects are not clear. The variability of genotypes may give an answer to the virulence and cell tropism so that we might be able to understand the different behaviour related to different host conditions.

A multicentre study including a more numerous population (almost 500 patients) with a longer follow-up is warranted to define whether the virus infection causes a disease complication or its presence does not alter the course of disease.

Limitations of the study

A limitation of study is that the assessment is based upon very few patients but it is very difficult to find a large population; possibly a multicentre study would solve this problem.

We performed the «PCR assay that detects only the presence of viral DNA in colon tissues. Maybe a quantitative assay that can distinguish between active and latent disease would give some useful information to correlate the replication of HCMV with bowel disease activity.

ACKNOWLEDGMENTS

The authors thank Professor Florian Mussnug for correcting the English text and Dr. Giuseppe Malizia for providing the photograph of nested PCR.

COMMENTS

Background

Cytomegalovirus (CMV) infection has been described as a cause of relapse of inflammatory bowel disease (IBD), in particular in ulcerative colitis patients, especially those receiving high-dose corticosteroid therapy. No clear data is available on the natural history of human CMV (HCMV) superimposed on IBD.

Research frontiers

The paper aimed to answer two questions concerning HCMV infection in ulcerative colitis patients.

Innovations and breakthroughs

This paper looks at the role of long-term HCMV persistence in patients with moderate to severe ulcerative colitis together with the likelihood this brings of relapse in patients that both cleared and did not clear the infection.

Applications

This is one of the first studies investigating the persistence of HCMV in colonic tissue of ulcerative patients after an acute flare up of disease.

Terminology

Nested polymerase chain reaction is a molecular assay that detects HCMV DNA using specific primers that amplify the gB region of HCMV. HCMV-pp65 antigenemia is an assay for polymorphonuclear leukocytes.

Peer review

I think there are some useful observations in the study, but some clarifications are needed.

Abstract

AIM: To study the natural history and prevalence of heartburn at a 10-year interval, and to study the effect of heartburn on various symptoms and activities.

METHODS: A population-based postal study was carried out. Questionnaires were mailed to the same age- and gender-stratified random sample of the Icelandic population (aged 18-75 years) in 1996 and again in 2006. Subjects were classified with heartburn if they reported heartburn in the preceding year and/or week, based on the definition of heartburn.

RESULTS: Heartburn in the preceding year was reported in 42.8% (1996) and 44.2% (2006) of subjects, with a strong relationship between those who experienced heartburn in both years. Heartburn in the preceding

week was diagnosed in 20.8%. There was a significant relationship between heartburn, dyspepsia and irritable bowel syndrome. Individuals with a body mass index (BMI) below or higher than normal weight were more likely to have heartburn. Heartburn caused by food or beverages was reported very often by 20.0% of subjects.

CONCLUSION: Heartburn is a common and chronic condition. Subjects with a BMI below or higher than normal weight are more likely to experience heartburn. Heartburn has a great impact on daily activities, sleep and quality of life.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is one of the most prevalent diseases worldwide^[1]. GERD is a chronic condition which usually manifests symptomatically, is a great burden for patients, and has significant socioeconomic implications^[2]. The prevalence of predominant gastroesophageal reflux symptoms appears to be stable over time^[3]. Heartburn is the typical GERD symptom and may be induced by various physiological and pathophysiological mechanisms^[4]. Heartburn, coupled with acid regurgitation and odynophagia, are considered to be highly specific for GERD^[1].

Functional heartburn is defined as episodic retrosternal burning in the absence of GERD, histopathology-based motility disorders or structural explanations^[5]. Heartburn alone has a prevalence of 17%-42% in Western populations^[2,3,5-7].

The prevalence of upper gastrointestinal symptoms in the general population is high and symptoms are associated with significant health-care utilization and diminished quality of life^[6]. In contrast, the natural history of heartburn has received limited attention and few epidemiological studies have focused on heartburn. Subjects with upper gastrointestinal symptoms are more likely to use prescription medication and are more likely to have seen a physician about symptoms than those with heartburn^[6]. There has been more focus on GERD than heartburn.

The aim of this present study was therefore to evaluate the natural history of heartburn in the Icelandic population prospectively over a 10-year period, as well as to evaluate different factors which are affected by heartburn both physically and sociodemographically. A parallel publication based on the same database, focusing on functional dyspepsia (FD), has been published^[8] as has another parallel publication regarding irritable bowel syndrome (IBS)^[9].

MATERIALS AND METHODS

Participants and setting

In 1996 an epidemiological study of gastrointestinal diseases was carried out in Iceland^[10], involving 2000 inhabitants in the range of 18-75 years of age. The individuals were randomly selected from the National Registry of Iceland. Equal distribution of sex and age was secured in each age group. In 2006 we attempted to contact all the same individuals as in 1996 as well as adding 300 new individuals in the 18-27 age group who were also randomly selected from the National Registry. A study questionnaire and explanatory letter were mailed to all eligible individuals at baseline. Reminder letters were mailed at 2, 4 and 7 wk, using the Total Method of Dillman^[11]. Individuals who indicated at any point that they did not want to participate in the study were not contacted further.

The questionnaire

The Bowel Disease Questionnaire (BDQ)^[12,13] was translated and modified for this study. The questionnaire was designed as a self-report instrument to measure symptoms experienced over the previous year and to collect the subject's past medical history^[14].

The Icelandic version of the BDQ questionnaire addresses 47 gastrointestinal symptoms and 32 items that measure past illness, health care use, items on sociodemographic and psychosomatic symptoms, together with a valid measure of non-gastrointestinal (non-GI) somatic complaints ascertained through the Somatic Symptom Checklist (SSC)^[15]. The SSC includes questions on 12 non-GI and 5 GI symptoms or illnesses. Individuals are instructed to indicate, on a 5-point scale, how often each symptom has appeared and how bothersome it has been. There were few changes to the later questionnaire (2006)

which addressed 51 gastrointestinal symptoms and 33 items that measure past illness, health care use, and sociodemographic and psychosomatic symptoms items. The 2006 Questionnaire furthermore addressed 17 items to identify heartburn and items related to heartburn.

Criteria for identifying heartburn

Subjects were classified with heartburn if they reported heartburn according to the following definition: Heartburn is a burning sensation in the retrosternal area (behind the breastbone). The pain often rises in the upper abdomen and may radiate to the chest.

Transition between disorders from initial and final surveys

A transition model used by Halder *et al.*^[14] was modified and applied for this study. The responses from the initial (1996) and final (2006) surveys were matched for each subject to examine the changes between disorders at an individual level for the 5 categories (FD, IBS, heartburn, frequent abdominal pain and no symptoms). A 5 × 5 table was used to model these multiple changes and collapsed into 6 groups, as illustrated in Table 1. Those with the most symptoms were prioritized higher. Those who developed more symptoms and those who reported fewer symptoms could be categorized into their respective groups. There were six patterns of symptoms, identified as follows: (1) symptom stability; (2) symptom increase; (3) symptom decrease; (4) symptom onset; (5) became asymptomatic; and (6) none of these symptoms.

Mortality data

For the 2006 survey we identified all deceased individuals with the assistance of the National Registry of Iceland (*Thjodskera*).

Statistical analysis

Tables were constructed to show frequency and percentage. Categorical data were analyzed using the χ^2 test. The type I error protection rate was set at 0.05. The exact *P* is listed in the tables and text. All the research data were imported into SPSS (Statistical Package of Social Science) software.

Ethics

The National Bioethics Committee of Iceland and The Icelandic Data Protection Authority (*Personuvernd*) gave their permission for the research.

RESULTS

Demographic data of involved individuals

In 1996 the response rate was 66.8% (1336/2000). Of the 1336 individuals who participated in 1996, 81 were deceased by 2006, five subjects were unable to answer, mainly because of old age, and 70 could not be traced to a current address. This left 1180 individuals, out of whom 799 responded. Therefore, the response rate in 2006 was 67.7% (799/1180). The mean age of the individuals in

Table 2 Study population: age and sex distribution

	Population 2006 (%)	Respondents 2006 (%)
Gender		
Male	50.3	42.2
Female	49.7	57.8
Age (yr)		
28-35	19.5	14.52
36-45	24.9	20.40
46-55	22.8	22.15
56-65	15.6	19.52
66-75	10.4	15.14
76-85	6.8	8.26
Total number	173859	799

1996 was 42 years, in 2006 it was 43 years, and 41 years for non-respondents in 2006. Women were more likely to respond than men in both years. A larger proportion of women than men responded again in 2006 (57.8%) than had responded in 1996, as is common in similar studies. The responders represented the population in all major factors concerning sex and age distribution. The response rate was also higher for older subjects than for younger ones. The age distribution and demographic details of the study cohort are presented in Tables 2 and 3.

Heartburn 10-year follow-up

At the 10-year follow-up, individuals were asked if they had experienced heartburn in the preceding year; 42.8% in 1996 and 44.2% in 2006 reported heartburn. There was a strong relationship between those who experienced heartburn in 2006 and those who reported heartburn in 1996. Two thirds of those who reported heartburn in 1996 also experienced heartburn in 2006. However, one third of those who reported heartburn in 2006 had not experienced it 10 years earlier.

Almost all who were on medication for heartburn reported relief with the medication. Individuals reported acid reflux once a month or more in 11% of cases in 1996 and 10% of cases in 2006.

There was a significant relationship between heartburn and dyspepsia and between heartburn and IBS, both in 1996 and in 2006.

Individuals of normal weight [body mass index (BMI) 18.5-24.9] were less likely to experience heartburn than individuals with a BMI below or higher than normal weight.

Individuals who smoked were not more likely to have heartburn than those who did not smoke. Individual alcohol consumption within the study group changed during the 10-year period of 1996 to 2006. Alcohol consumption was not associated with heartburn.

Transitions among symptom subgroups between the initial and final surveys

As described in the Methods section, the groups in this analysis were defined as mutually exclusive using a symptom hierarchy so that each subject appears in only one category for both the 1996 and 2006 surveys. There was a “no symptoms” category for those who did not meet any of the criteria applied for functional gastrointestinal disorders. Due to the hierarchical classification only a few participants occurred in some categories.

There was a substantial change in numbers in all the categories over time (Table 1). The group “no symptoms” was the most common (63.3%). Of the heartburn group 39.3% were stable and 31.8% reported “no symptoms”; 24.2% reported increased symptoms and 4.6% decreased symptoms. Of the FD group 52.3% remained stable and 9.9% reported “no symptoms” in 2006. Most of the subjects who were in the IBS group, or 30.3% of the total, were stable over the 10-year period; 20.4% reported “no symptoms” in 2006 and 25.0% showed an increase in symptoms over the 10 years. In 2006, 15.4% of the subjects reported stable frequent abdominal pain, 30.8% reported “no symptoms” and 53.8% reported increased symptoms.

The distribution of the 6 transition groups was: 22.3% symptom stability, 12.6% symptom increase, 10.9% symptom decrease, 14.9% developed symptoms, 13.6% became asymptomatic, and 25.7% had no symptoms in either 1996 or 2006.

Heartburn in subjects in 2006

In the 2006 questionnaire individuals were asked additional questions regarding heartburn during the preceding week. Heartburn during the preceding week was reported by 20.8% of the subjects (19.0% male, 22.1% female). Of these, 60.5% reported taking medicine for heartburn. Increasing age was not a significant factor in prevalence of heartburn/reflux disease. Age was, however, a significant factor associated with the use of medication for heartburn (Figure 1). Most subjects took ranitidine or esomeprazole for their symptoms (Figure 2).

minimal heartburn and 6.3% never. Increased heartburn caused by a specific food was reported as occurring very often by 22.7% and sometimes by 59.7%. A specific food significantly more often provoked considerable heartburn in women than in men (Table 4).

As can be seen in Table 5, heartburn can affect symptoms or activities in many cases. Three out of four heartburn subjects claimed that they felt badly sometimes or seldom. One out of three heartburn subjects felt hopeless, anxious or impatient. And one out of three also reported being worried or scared because of heartburn every week.

Only 1.9% of the subjects reported that heartburn frequently affected their daily activities, whereas one fifth claimed that their daily activities were only sometimes or seldom affected by heartburn. Three out of four subjects reported that heartburn made them irritable. And one out of four heartburn subjects reported that heartburn resulted in less family activities, affected their daily activities and meant they were unable to move in sports, hobbies and

outside of home. Half of the heartburn subjects reported trouble with sleeping because of heartburn.

Many heartburn subjects reported less food and beverage consumption and that they avoided specific food or alcohol because of the heartburn.

DISCUSSION

In this study our main focus was on the natural history of heartburn over a 10-year period in an Icelandic population. The only other long-term study, to our knowledge, that has focused on heartburn is a long-term community study in Sweden covering a maximum of 7 years^[3]. There are strengths and weaknesses in both studies, but taken together they give a reasonably accurate picture of the natural history of heartburn.

The strength of our study is the use of a stable, homogeneous and well-informed population. The sample was randomly selected from the National Registry of Iceland and represented the nation as a whole in selected age groups. The population of Iceland was around 300 thousand inhabitants at the time of the study and the sample was approximately 1% of the whole population from all around the country. The BDQ, the questionnaire used, assesses the whole range of gastrointestinal functional disorders.

The prevalence of heartburn is high in Iceland. More than two out of five subjects reported heartburn in the preceding year. Half of those reported heartburn in the preceding week. Heartburn was reported as still existing after 10 years for 2 out of 3 subjects in the study. The study by Agréus *et al*^[3] showed that the prevalence of predominant gastroesophageal reflux symptoms appears to be stable over time. Results from studies of patients suggest that GERD is a chronic disease in most cases^[3,16,17]. One third of subjects who did not report heartburn in 1996 had developed heartburn 10 years later. So even though the total prevalence of heartburn was almost the same in both 1996 and 2006, there was a change among over one third of subjects reporting heartburn.

Heartburn subjects with a BMI either lower than or higher than normal weight were more likely to experience heartburn than subjects with normal weight. A study by Aro *et al*^[18] found that reflux symptoms are linked to obesity and specifically that the presence of gastroesophageal reflux symptoms was linked to reflux esophagitis in the obese population. Festi *et al*^[19] concluded that it was likely that GERD and obesity are in some way linked and that it was possible to hypothesize that GERD may be a curable condition through the control of body weight. This may also be true for heartburn.

The transition analysis showed a substantial change in numbers in all the categories. The stability of each disease varied. FD subjects were the most stable throughout the 10 years (52.3%). Of the heartburn group 39.3% were stable, as were 30.3% of the IBS group and 15.4% of the frequent abdominal pain group. A quarter of the heartburn group had increased symptoms in 10 years, 4.6% decreased symptoms and one third developed no

symptoms in 10 years. There was a significant relationship between IBS and heartburn as well as FD and heartburn.

Half (45.1%) of the subjects who reported heartburn in the preceding year experienced heartburn in the previous week. Food and beverages play a large part in eliciting heartburn; very often in 20.0% of the cases and sometimes in 73.8% of the cases. Subjects also very often experienced increased heartburn caused by a specific food in 22.7% of the cases. Heartburn did not seem to be the cause for less food and beverage consumption, but one out of five heartburn subjects did avoid a specific food or alcohol because of heartburn. Festi *et al*^[19] report that no definitive data exist regarding the role of diet and specific foods or drinks in GERD clinical manifestations^[19].

Heartburn is associated with feeling tired (61.2%), feeling bad (87.5%) and with irritation (65.5%). One third felt worried or scared for their health because of heartburn symptoms and one third also felt that heartburn caused them to feel hopeless, worried or impatient (33.1%). Every fifth heartburn subject reported that heartburn affected activities such as daily and family activities, as well as that heartburn caused them to be unable to move normally and therefore affected their participation in sports, hobbies and outdoor activities. This effect of heartburn on normal life and activities may have affected the subjects in the manner of a chronic condition throughout the 10 years of the study, and therefore had a great impact on quality of life. This finding is in line with McDougall *et al*^[17] who showed in their study on reflux esophagitis and quality of life that it was not bodily pain and vitality that were impaired, but general health and social function.

Three out of five of all the heartburn subjects in 2006 reported taking medicine for heartburn. Almost all the subjects who were on medication for heartburn reported relief provided by the medication. Age was a significant factor for the use of medication for heartburn. Most subjects took ranitidine or esomeprazole for their symptoms.

Few studies have addressed the impact of nocturnal reflux symptoms in heartburn subjects. A study by Farup *et al*^[20] showed that the prevalence of nighttime heartburn in GERD patients under routine care was high, up to 49% for 1 of 3 years. A population-based survey in the United States claimed that the overall prevalence of nocturnal GERD symptoms was 10%, with 74% of subjects with GERD symptoms fitting the criteria for nocturnal GERD^[21]. In our study, sleep was frequently affected in 5.8% of cases and 45.2% of heartburn subjects were sometimes or seldom troubled with sleeping in the prior week. These numbers can be expected to be higher for the preceding year, since we asked specifically about the preceding week.

There are some limitations to our study. The subjects were not specifically interviewed or examined to evaluate the possibility of organic disease. However, a 10-year (postal) follow-up went some way towards making an organic cause of symptoms unlikely. Furthermore, since the response rate was 66.8% in 1996 and 67.7% in 2006, a dropout bias cannot be excluded.

In summary, heartburn is a common condition in the population of Iceland. The prevalence is slightly higher than reported elsewhere. Heartburn is a chronic condition, affecting every fifth person every week. Heartburn subjects with a BMI lower or higher than normal weight were more likely to experience heartburn than subjects of normal weight. Heartburn did not seem to result in less food and beverage consumption, but one out of five heartburn subjects did avoid a specific food or alcohol because of the heartburn. Heartburn had a great impact on daily activities and quality of life. Half of the heartburn subjects experienced sleep disturbances because of this condition.

COMMENTS

Background

Heartburn is a signature symptom of gastroesophageal reflux disease (GERD), which is a cluster of symptoms and signs associated with regurgitation of stomach acid up to the pharynx and mouth. Patient-based studies of GERD have shown high prevalence and chronicity, particularly in Western societies. GERD is associated with significant health-care utilization and diminished quality of life. Heartburn, coupled with acid regurgitation and painful swallowing are considered to be highly specific for GERD. Very few epidemiological studies have been performed with regard to heartburn, and only one has been population-based. The natural history of GERD or heartburn has received little attention. The pathophysiology of GERD and heartburn is basically unknown.

Research frontiers

The prevalence of upper gastrointestinal symptoms in the general population is high and symptoms are associated with significant socioeconomic consequences. The prevalence and natural history of heartburn is of importance as well as its association with functional dyspepsia and irritable bowel syndrome, and sociodemographic factors such as body mass index (BMI). The aim of the present study was therefore to evaluate the natural history of heartburn in the Icelandic population prospectively over a 10-year period, as well as to evaluate different factors which are associated with heartburn both physically and sociodemographically.

Innovations and breakthroughs

The prevalence of heartburn is high in Iceland. More than two out of five subjects reported heartburn in the preceding year. Half of those reported heartburn in the preceding week. Heartburn was reported as still existing after 10 years for 2 out of 3 subjects in the study. Heartburn subjects with a BMI either lower or higher than normal weight were more likely to experience heartburn than subjects with normal weight. There was an association between heartburn, functional dyspepsia and irritable bowel syndrome and patients floated over time between these categories. This suggests a common etiopathogenesis of these disorders. The quality of life was diminished due to a variety of factors such as worries, irritability, intolerance to specific foods and sleep disturbance.

Applications

The prevalence and natural history of heartburn and its risk factors are important for management and prognosis. Heartburn can be regarded as a reliable surrogate marker of GERD. This study creates a database for future studies and hopefully stimulates studies in other countries. Secular prevalence trends and international comparison can contribute towards understanding of the pathophysiology of the disease.

Terminology

A 10-year follow-up population-based, questionnaire study of the Icelandic population was performed. The primary aim was to study the prevalence and natural history of heartburn. Subjects were classified as having heartburn if they reported heartburn according to the following definition: Heartburn is a burning sensation in the retrosternal area (behind the breastbone). The pain often rises in the upper abdomen and may radiate to the chest.

Peer review

Heartburn alone has a prevalence of 17%-42% in Western populations and is associated with extensive health care expenses and diminished quality of life. Comparative international population-based studies are needed to document secular trends and to elucidate the reasons for the different prevalence in various countries.

Abstract

AIM: To determine the efficacy and success of percutaneous aspiration irrigation and reaspiration (PAIR) in the management of hepatic hydatidosis.

METHODS: Twenty-six patients with 32 hepatic hydatid cysts had PAIR. Twenty-two patients received at least 2 wk of drug therapy before the procedure was carried out to reduce the risk of recurrence from spillage during the procedure. The procedure was performed under local anesthesia with a 19-gauge 20 cm long needle, the cyst was punctured, cystic content (approximately 30 mL) was aspirated by a 12-14 F pigtail catheter and aspirated fluids were sent for analysis. Once the cyst was almost empty, two-thirds of the net amount of ma-

terial aspirated was replaced by hypertonic saline and left in the cavity for about 30 min, with the catheter left in place for reaspiration of most of the fluid. When the amount of fluid drained was less than 10 mL per 24 h, the drainage catheter was removed.

RESULTS: All 32 cysts showed evidence of immediate collapse after completion of the procedure, and before discharge from hospital, ultrasound examination showed fluid reaccumulation in all cysts. Serial follow-up showed a progressive decrease in the size and change in the appearance of cysts. To confirm the sterility of these cystic cavities, seven cysts were reaspirated on average 3 mo after the procedure. Investigations revealed no viable scolices.

CONCLUSION: PAIR using hypertonic saline is very effective and safe with proper precautions.

INTRODUCTION

Until 1980, surgery was the only method of treatment for hepatic hydatidosis. Despite improved surgical techniques

and use of scolical compounds, a high incidence of hydatid cyst recurrence and dissemination is still a major problem. Spillage is known to occur at surgery^[1,2]. On the other hand, medical therapy is associated with side effects and it is effective only in some cases and need several courses to reach a response with albendazole alone^[3], but the outcome is better with combined therapy^[4]. In recent years, percutaneous drainage of hepatic hydatid cysts (HHC) has emerged as a minimally invasive, safe therapy, and a potential alternative to surgery. Different methods have been applied with variable success and healing rates^[5-7].

In this study, we prospectively assessed the value of percutaneous drainage with adjuvant medical therapy in 26 patients with confirmed 32 HHC over an average follow-up period of 10 years.

The Armed Forces Hospital in Riyadh is a well-known tertiary center in the region and is a 1000-bed hospital with facilities for hepatobiliary and liver transplant services. Percutaneous aspiration irrigation and reaspiration (PAIR) was introduced into the hospital in 1993. Between 1985 and 1992 albendazole was used alone in the management of hydatid cysts, and in 1993 praziquantel was added to albendazole as combination therapy.

Previously we reported our first patient with percutaneous drainage of a hydatid cyst of the liver in 1994^[8], and our first patient with a lung hydatid cyst with pleural effusion in 1991^[9].

MATERIALS AND METHODS

The study involved 26 patients (14 males and 12 females; age range 13-53 years) with 32 HHC (Table 1). Eleven patients were recently diagnosed with HHC and had no previous medical or surgical intervention. Seven patients had cyst recurrence following surgical excision. Eight patients had received long-term medical treatment with albendazole and praziquantel for an average of 24 mo with only a partial response of less than 30% reduction in size of the cysts. Nineteen patients had a solitary cyst and four others had multiple liver cysts. Three patients had extra hepatic disease in the lung ($n = 2$) and spleen ($n = 1$). Twenty-six cysts were located in the right lobe of the liver, five in the left, and one in the caudate lobe. All patients were complaining of right upper quadrant pain and/or pressure symptoms and had an abdominal ultrasound (US) examination. The average diameter was 10.2 cm (range, 5.5-18.5 cm). The diagnosis was confirmed by imaging modalities and positive serology (indirect hemagglutination titer $> 1:128$) in all patients. The cysts were classified by US according to the Gharbi *et al.*^[10] classification into Type I ($n = 4$), Type II ($n = 8$), Type III ($n = 2$) and Type IV ($n = 18$) (Table 2). Two of the Type IV cysts had a thin rim at their periphery. Four patients had abnormal liver function tests, 10 had elevated erythrocyte sedimentation rate, and six had high eosinophil count. The 26 patients and their results were evaluated by all relevant staff i.e. surgeons, gastroenterologist and senior

radiologist. Management options i.e. a pharmacological approach, surgical intervention and PAIR were explained and all the above patients chose PAIR. Informed consent prior to the procedure was obtained from all patients. In 22 patients, albendazole 400 mg twice daily and praziquantel 50 mg/kg daily was given orally for at least 2 wk prior to and 4 wk after the procedure to all patients to reduce the risk of possible hydatid cyst fluid spillage and dissemination into the peritoneal cavity. The patient fasted overnight. The procedure was performed under heavy sedation (midazolam 5 mg iv and pethadine 50 mg im) with close monitoring to treat any potential complication including anaphylaxis. Under aseptic conditions, a Teflon sheath needle (19 gauge, 20 cm long; Meditech) was introduced percutaneously through the biopsy port of the 3.5 MHz probe into the cyst under US guidance (Aloka SSD 680). The puncture was made through thick normal liver tissue surrounding the cyst and whenever possible the right intercostal route was used to minimize the risk of hydatid fluid spillage into the peritoneum (Figure 1A). Once the cyst is punctured, a small amount of fluid (10-30 mL) was aspirated for cyst decompression followed by insertion of a 12F or 14F (van Sonnenberg sump drainage, Meditech) catheter, the use of such a large catheter was to prevent catheter clogging by membranes and daughter cysts during aspiration. Once the cyst was almost empty, injection of contrast medium under fluoroscopic control was performed to exclude cyst communication with the biliary system. Two-thirds of the aspirated material was replaced by hypertonic saline (23.4%) and left in the cavity for 20-30 min. The fluid was then reaspirated as much as possible and the catheter was left in place to drain by gravity. Immediately after aspiration, examination of fluid to identify scolices, hooklets, pieces of laminated membranes or daughter cysts were performed in the parasitology laboratory. After the procedure, the patients were closely observed for possible com-

Figure 1 Ultrasound examination. A: Puncture of the hydatid cyst and insertion of a catheter; B: End of percutaneous aspiration irrigation and reaspiration procedure; C: Six months later, aspiration showed only granulation and necrotic tissue without any evidence of hydatidosis.

plications for 48 h. The drainage catheter was left in place for an average period of 3 d (range, 2-6 d) (Figure 1B) and removed when the amount of fluid drained was less than 10 mL/24 h. Follow-up examination in the form of clinical assessment, blood tests, serology and imaging examination with US and/or computed tomography (CT), were performed at 1, 2 and 3 mo after drainage for an average period of 6 mo (range, 2-11 mo), followed by 6-monthly blood tests and yearly imaging for an average period of 10 years.

RESULTS

All 32 cysts were successfully treated by PAIR, with relief of symptoms in all 26 patients with an average hospital stay of 6 d. There was collapse of all cysts immediately

after completion of percutaneous drainage and removal of the drainage catheter. Before discharge from hospital, US examination showed fluid reaccumulation in all cysts within an average of 2 d after catheter withdrawal reaching an average size of 59% (range, 48%-74%) compared to the size of the cysts before drainage. Serial follow-up CT and US examination showed a progressive decrease in the size and change in the appearance of the cysts. Two patterns of healing were observed, the first was a predominantly cystic cavity with detached membranes. All the cystic cavities lost their rounded contour appearance suggestive of being under less tension. The second pattern was a predominantly solid mass.

Asymptomatic fluid reaccumulation following drainage and catheter removal happened in nearly all cysts with an average size of 59% (range, 48%-74%) compared to the predrainage cyst size. However, on regular follow-up examinations, a progressive decrease in the residual cavity with two distinctive healing patterns was observed. A cystic residual cavity with internal membranes was predominantly seen in patients with Type I - II cysts, and a solid mass was predominantly seen in patients with Type IV cysts. The complex large Type IV HHC with a predominantly solid component showed better results following drainage, with an overall reduction in size of 51.5% compared to 29% in patients with Type I and II cysts in whom the cysts had a predominantly fluid component.

To confirm the sterility of the residual cystic cavities, seven out of 32 cysts were reaspirated, three at an average of 3 mo after drainage, and four at an average of 6 mo after drainage. All reaspirated cyst cultures for microorganisms were negative, and microscopy revealed debris of hydatid membranes and hooklets in some cases but no viable scolices (Figure 1C). Serial follow-up serological examination showed a 2-fold elevation in the indirect hemagglutination titer following drainage in 18 patients compared to the titer level before drainage, and it remained elevated at an average follow-up period of 16 mo. No major complications developed during or after the procedure except for a mild anaphylactic reaction which responded very well to immediate treatment (Table 3). Two patients developed urticarial reactions 8 h following drainage, but responded well to antihistamines and steroids. Fever occurred in 10 patients but was mild and transient, and cultures of fluid from the drainage catheters were negative. Minimal right pleural effusion occurred in six patients. The liver cysts in these six patients were rela-

tively large and reached the right hemidiaphragm. However, the pleural effusion was small and resolved completely before the patients were discharged. Two patients developed transient hypernatremia and one patient showed an anaphylactic reaction during the procedure but responded to immediate management. No radiological evidence of reactivation of aspirated cysts was seen during the average of follow-up of 10 years.

DISCUSSION

Surgery is considered as the standard treatment for HHC. However, surgery is not without risks and there is a high incidence of dissemination, infection and recurrence of 2% to 25%, with morbidity of 0.5% to 4%^[11-16]. Furthermore, surgery is not advisable in elderly patients with cardiac or pulmonary disease, nor in recurrent cases. Medical treatment alone in the form of mebendazole, and recently albendazole and praziquantel, have been used as an alternative therapy to surgery, but the success rate in terms of a reduction in size of HHC and the change in echotexture has been variable^[17-19]. Another prospective randomized study compared albendazole, percutaneous drainage and both modalities combined. These studies showed that cyst size reduction was best achieved by the combined therapy when compared to albendazole or percutaneous drainage alone^[20,21]. Percutaneous drainage of HHC was started by Mueller *et al.*^[22], and since then several series of percutaneous drainage have been published with no single fatality related to the procedure has been reported^[23,24]. Reversible anaphylactic shocks, mild to severe allergic reactions, and pleural effusions have been reported in the recent literature^[25,26], and any other complications were minor and infrequent. The reason for the pleural effusion is probably due to diaphragmatic irritation by the sudden collapse of the cyst following drainage and/or catheter manipulation during the procedure. However, pleural effusion was discovered incidentally during follow-up and in US examination, and was small and resolved completely before the patients were discharged. Fever was also a common complication, occurring in 10 patients, but was mild and transient, and cultures of fluid from the draining catheter were negative. Two patients developed an urticarial reaction hours following drainage but the patients responded well to antihistamines and steroid therapy. Only one patient developed an anaphylactic reaction which required immediate intubation and management, but there was a full recovery.

Drainage of complex Type IV cysts have been attempted before. Eighteen cysts in our series belonged to this group, including two patients with a partially calcified wall with multiple daughter cysts, in whom active disease was confirmed by serology and clinical assessment prior to the procedure and microscopy following drainage. It should be remembered that a calcified cyst does not mean always mean an inactive cyst. In our study, a 12F or 14F catheter was used to drain all types of HHC. Such large caliber catheters have not been used before in percutaneous drainage. We used a large catheter in order to

minimize clogging of the catheters by membranes and daughter cysts, and to ensure that all the cyst cavities were completely evacuated, though finer catheters might be safer, despite frequent clogging. Future studies will clarify this and many other issues. Follow-up indirect hemagglutination tests were performed in all patients. There was slight elevation of the indirect hemagglutination titer in 18 patients after the procedure and it remained elevated in comparison to the predrainage value during an average follow-up period of 16 mo. This observation has been reported by others^[27,28], and we believe that a longer follow-up period is needed for the indirect hemagglutination titer to start decreasing.

Our results have shown that percutaneous drainage of all types of HHC with adjuvant medical therapy is minimally invasive, safe and effective therapy with proper precautions. It can be used as an alternative to surgery, and in some cases is superior to surgery. Further evaluation by means of organized multicenter studies and long-term evaluation will answer questions regarding the use of a larger caliber or fine catheter, types of sedation or anesthesia, duration and requirement of adjuvant medical therapy, possible recurrence and many other unanswered questions.

COMMENTS

Background

Human hydatid disease (Echinococcosis) was recognized by Hippocrates over 2000 years ago. Al Razi and Avicenna made references in 900 AD and 11200 respectively and was described as liver cysts filled with water. However, it is still seen all over the world and is endemic and common in many countries i.e. Africa, central Asia, the Mediterranean, South America and Middle East and remains a problem for the World Health Organization. It is a slow growing cyst and may produce no symptoms for up to 10 years. In the most common form of the disease (Echinococcosis granulosis) dogs are the definitive host. Humans and sheep are the intermediate victims. Therefore, human hygiene and dogs' sanitation (removing the tapeworm from the dog) are essential issues in the prevention of this disease.

Research frontiers

Any organ and any part of the body could be affected but the most common sites are the liver and lungs. Over the recent decades substantial improvement has been made in the diagnosis and management of hydatid disease, through diagnostic tools such as imaging procedures including ultrasound (US), computed tomography (CT), magnetic resonance imaging and endoscopic retrograde cholangiopancreatography.

Innovations and breakthroughs

Concerning treatment, until recently the only definitive treatment for hydatid disease had been surgery. Different surgical techniques and procedures have been carried out and even in some cases, a liver transplant has been required. Advances in drug therapy has been influenced by the introduction of albendazole and accelerated by addition of praziquantel, but this requires a long period of treatment i.e. up to a year or more, and is not effective for everyone.

Applications

Percutaneous aspiration irrigation and reaspiration (PAIR) under direct US or CT guidance is a real achievement in the management of hydatid disease. The procedure was associated with reversible complications, no mortality, very short hospitalization and minimal cost. All 32 cysts showed evidence of immediate collapse after completion of the procedure. Serial follow-up showed progressive decrease in the size and change in the appearance of the cysts. At 10 years follow-up, the longest follow-up in the literature, there was no evidence of recurrence. Therefore, the authors confirm and believe that PAIR using hypertonic saline with adjuvant medical therapy has encouraging results and, with appropriate precautions, is very safe.

Peer review

The authors retrospectively analyzed a series of 26 patients whose hydatid liver cysts were treated with percutaneous aspiration and hypertonic solution injection. Albendazole was given prophylactically and after the procedure. The study might provide some confirmation of the efficacy of a non-surgical approach to the treatment of liver hydatidosis.

tween polyethylene glycol (PEG) and acute renal failure (ARF) in elderly patients using a health insurance claims database.

METHODS: We conducted a population-based case-crossover study using information obtained from Korean Health Insurance Review and Assessment Service (HIRA) claims from January 1, 2005 to December 31, 2005 (Seoul, Korea). The study population consisted of elderly patients who received PEG prior to experiencing their first ARF-related hospitalization from April 1, 2005 to December 31, 2005. For each patient, one case and two control periods were matched. PEG use in a 2- or 4-wk window period prior to hospitalization for ARF was compared with PEG use in two earlier 2- or 4-wk control window periods. Conditional logistic regression analysis was used to estimate odds ratios (ORs) and 95% CI, adjusting for concomitant uses of diuretics, angiotensin converting enzyme inhibitors, non-steroidal anti-inflammatory drugs, antibiotics, anti-cancer drugs, and contrast media.

RESULTS: Within the HIRA database which contained 1093262 elderly patients, 1156 hospitalized ARF cases were identified. Among these cases, PEG was prescribed to 17 (1.5%) patients before hospitalization. The adjusted ORs when applying the 2- and 4-wk window periods were 0.4 (95% CI: 0.03-5.24) and 2.1 (95% CI: 0.16-27.78), respectively.

CONCLUSION: No increased risk of ARF was found in elderly PEG users. However, based on the limited number of study subjects, further analysis should be performed to confirm these results.

INTRODUCTION

Colonoscopy is a common diagnostic or therapeutic procedure. As early detection of colorectal cancer can significantly decrease mortality^[1], regular screening is recommended for those aged 50 years or over^[2]. The success and accuracy of colonoscopy are largely dependent on appropriate cleansing of the colon^[3]. Ideally, a colon preparation would provide safe and rapid cleansing with little or no discomfort to patients^[4]. Currently, polyethylene glycol (PEG) bowel preparation and oral sodium phosphate (NaP) are predominantly used as bowel cleansing agents before colonoscopy based on the fact that they are effective and generally well tolerated^[5-7]. PEG is a non-digestible, non-absorbable, osmotically-balanced laxative lavage solution that does not cause physiologic changes and can even be administered to patients in poor general condition^[8-12].

However, several recent studies have raised concerns about the safety of oral NaP preparations due to their reported association with an increased risk of serious electrolyte disturbances and renal failure^[13]. Conversely, although a large volume of PEG produces discomfort to the examinee, it is considered to be a relatively safe agent. Therefore, there has been a tendency to prescribe PEG more than NaP for renally impaired or elderly patients^[14]. Recently, several studies have shown that the risk of renal impairment is similar between PEG and NaP users^[15,16]. In addition, a case report has raised a possible association between the use of PEG and acute renal failure (ARF)^[17]. The patient in that case was a 55-year-old male without pre-existing renal disease who visited the emergency room with severe abdominal pain and frequent diarrhea after ingesting PEG 2 h earlier as pre-treatment for a follow-up colonoscopy. He was diagnosed as having prerenal ARF and improved after intensive fluid administration. Also, a recent cohort study revealed that following colonoscopy, those over 65 years of age without preexisting renal disease were at risk for impaired renal function^[16]. Unfortunately, most of the evidence for PEG risk to date has been based on a limited number of hospital patients or the case report mentioned.

There have been no quantitative epidemiological studies analyzing a relationship between PEG preparation and the development of ARF using a national health insur-

ance database. Therefore, this case-crossover study was performed to evaluate the risk of ARF following the use of PEG among elderly patients using information gathered from a Korean national health insurance database.

MATERIALS AND METHODS

Data source

We used the Korean Health Insurance Review and Assessment Service (HIRA) database that contains information on all claims including prescribed medications for approximately all 50 million Koreans^[18]. We obtained claims data for elderly patients (age 65 years or older) that had been submitted by healthcare providers based in Seoul between January 1, 2005 and December 31, 2005. Seoul is the capital and largest city of South Korea. A megacity with a population of over 12 million, it is one of the largest cities in the world. The study database contained information on 1 093 262 elderly patients with 11 842 586 prescriptions^[19]. This study was exempted from review by the Institutional Review Board of the Seoul National University College of Medicine/Seoul National University Hospital because researchers only accessed a de-identified database which included age, gender, diagnosis, and a list of prescribed drugs.

Study design

We employed a case-crossover approach, using cases at previous time points as their own controls, thereby eliminating time-invariant confounders between subjects through within-subject difference comparisons^[20]. In this design, only patients experiencing an event of interest were included and their exposures were measured during case- and control-time windows. Accordingly, the number having medication available in the case period (which is the period immediately before the event of interest) is compared with the number having medication available in the control period (which is a period prior to but of the same length as the case period)^[21]. Thus this design eliminates the effects of many potential confounders by keeping characteristics such as age, gender, socioeconomic status, and comorbidity fixed^[21,22].

Study subjects

The study population consisted of patients 65 years of age or older who received PEG prior to their first ARF-related hospitalization (ICD-10 code: N17) from April 1, 2005 to December 31, 2005. The index date was defined as the first hospital admission date for ARF. To identify initial ARF admission patients, we excluded those with pre-existing ARF during the preceding 3 mo, from January 1, 2005 to March 30, 2005.

Case and control periods

For each patient, one case and two control periods were matched to increase the study power and improve the precision of the estimates^[23]. The time windows, of 2 and 4 wk, were used to determine the periods over which as-

Figure 1 Definition of hazard and control periods in this case-crossover study. Hazard period was defined as the 2- or 4-wk window before the index date. A 4-wk washout period was chosen between the end of the hazard period and the start of the control period. Two consecutive control periods were defined as 2- or 4-wk windows.

assessment of drug exposure occurred. We defined the case period as a 2- or 4-wk window prior to the index date. A 4-wk washout period was chosen between the end of the case period and the start of the control period. Two consecutive control periods were also defined as 2- and 4-wk windows (Figure 1). Accordingly, for each patient, PEG prescription in each window period prior to hospitalization for ARF was compared with PEG prescription in two earlier control-window periods.

Statistical analyses

Descriptive statistics were used to illustrate the characteristics of the first ARF-hospitalized patients by age and gender. For the study population, the distribution of diagnoses on the day of PEG prescription was analyzed. Diagnoses were constructed from records made at the time of PEG prescription and grouped as colorectal cancer (ICD-10 codes: C18-C21, D12), gastric or duodenal ulcer, gastritis or duodenitis, intestinal disorders (K25-K59), renal disease (N03-N20), fibrosis and cirrhosis of the liver (K74), liver cancer (C22), and pancreatic cancer (C25). Conditional logistic regression analysis was used to estimate odds ratios (ORs) and 95% CI. The date of PEG exposure was regarded as the date of PEG prescription in the database. Use of concomitant medications that could induce ARF^[24,25] was included and evaluated in the model. Concomitant drugs included diuretics, angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), non-steroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, β -lactams, sulfonamides, anti-viral agents, antimycotics, anti-cancer drugs, and contrast media. We assessed PEG prescriptions and uses of concomitant drugs included in the case- or control-window periods. Exposure to PEG and other concomitant drugs was considered as a dichotomous variable in the model (exposed at least once during each specific time window: yes or no). Statistical analysis was performed using the SAS statistical application program (Release 9.1, SAS Institute Inc., Cary, NC, USA).

RESULTS

The total number of elderly patients who had at least one claim for any healthcare service in Seoul between January 1, 2005 and December 31, 2005 was 1 093 262. Their mean age was 71.0 ± 6.1 years and 59.9% were female.

PEG: Polyethylene glycol.

Among them, we identified 1156 patients hospitalized for ARF with a mean age of 75.9 ± 7.3 years. Patient sex was split relatively equally with males accounting for 50.8% of cases (Table 1). Among the cases of ARF, 17 (1.5%) had received PEG prior to their hospitalization. Their mean (SD) age was 70.6 (4.6) years and 82.4% (14 cases) of them were male. The most frequent diagnoses on the day of PEG prescription were colorectal cancer (35.3%), gastric or duodenal ulcer, gastritis or duodenitis, or intestinal disorders (35.3%) (Table 2). Using the 2- and 4-wk windows, the crude ORs for ARF were 0.7 (95% CI: 0.07-6.41) and 1.3 (95% CI: 0.22-7.99), respectively. After adjusting for the use of concomitant drugs the adjusted ORs applying the 2- and 4-wk windows were 0.4 (95% CI: 0.03-5.24) and 2.1 (95% CI: 0.16-27.78), respectively (Table 3).

Table 3 Association between polyethylene glycol and the risk of acute renal failure with respect to time-window periods by matched ratio of case and control period

Time-window period	Case period (<i>n</i> = 17)	Control period (<i>n</i> = 34)	Crude OR (95% CI) ¹	Adjusted OR (95% CI) ²
2 wk				
PEG non-users	16	31	1	1
PEG users	1	3	0.7 (0.07-6.41)	0.4 (0.03-5.24)
4 wk				
PEG non-users	15	31	1	1
PEG users	2	3	1.3 (0.22-7.99)	2.1 (0.16-27.78)

¹Calculated by conditional logistic regression; ²Calculated by conditional logistic regression adjusted for use of nephrotoxic drugs (diuretics, angiotensin converting enzyme inhibitors, angiotensin receptor blockers, non-steroidal anti-inflammatory drugs, aminoglycoside, β -lactams, antiviral agents, antimycotics, anti-cancer drugs, and contrast media). PEG: Polyethylene glycol; OR: Odds ratio.

DISCUSSION

This population-based case-crossover study showed that PEG did not increase the risk of ARF in elderly patients. When several different time-window periods were applied, the use of PEG was not associated with ARF risk. This study supports findings of previous reports which have suggested that PEG does not increase the risk of ARF^[12,26-29]. Known PEG-associated common adverse effects include volume-related symptoms of abdominal fullness, nausea, and bloating, with minimal discomfort^[26]. Also, previous results of a prospective, randomized, multicenter, controlled trial comparing PEG plus ascorbic acid to NaP solution in 352 patients had shown that PEG use was associated with fewer adverse events and no clinically relevant changes in laboratory values^[27]. In a study addressing age, 557 patients were stratified into two groups, > 60 years and \leq 60 years of age, all of whom received either PEG or a cathartic preparation for colonoscopy, barium enema, or elective colon surgery^[28]. Patients in the older age group reported significantly fewer cramps ($P < 0.05$) and no differences in overall discomfort compared to their younger PEG counterparts, confirming the generally accepted understanding that PEG is safe and tolerable^[12,29].

In our study, we excluded patients admitted with a diagnosis of ARF 3 mo before the study starting date; therefore we could infer that PEG did not increase the risk of ARF among patients without recent worsening of renal function. However, because decreased renal function is extremely common in elderly persons^[30], the study population might have asymptotically decreased renal function. Further studies should be performed to examine the possibility that PEG could worsen existing renal impairment and hasten its progression to ARF. Moreover, although the study results did not show a statistically significant risk for ARF in PEG users, it may be desirable to ensure adequate hydration before, during, and after PEG bowel preparation and provide renal function monitoring before and after colonoscopy in high risk patients.

We applied a case-crossover design optimal for evaluating short-term effects after transient exposures, particularly by removing time-invariant between-subject confounding factors^[31]. Results of clinical trials are sometimes difficult to generalize to clinical practice and rarely detect adverse event incidents because they include only small numbers of highly selected patients. Also, the estimates of adverse drug effects derived from observational studies are vulnerable to unmeasured or unknown confounding factors, associated with both the exposure and the outcome^[20]. Actually, a previous cohort study which aimed to compare the risk of renal dysfunction related to the use of PEG and NaP mentioned that its results could be affected by potential selection bias^[11]. The cohort study was conducted using clinical records of patients undergoing colonoscopy in one hospital. Accordingly, the baseline patient characteristics might have affected which drugs were prescribed and the two groups were not comparable^[32,33]. In the present study, using the case-crossover technique, only cases with incident renal failure were considered and their PEG exposures were compared during two different time-windows. Since inherent confounders remain invariant over time, the case-crossover design which is optimal for transient exposures with short-term effects has an advantage in that it can minimize between-subject confounding and assure an optimal sample size^[31].

This study has several strengths. Firstly, we evaluated patients from an entire target population of over one million elderly derived from the national health insurance claims database in Seoul, South Korea, rather than use a sample population. Therefore, our results reflect unbiased real world conditions. Nevertheless, we identified only 17 cases of ARF following PEG use. This means that there is little possibility the PEG would increase the risk of ARF. Secondly, this study included elderly patients who are not usually involved in clinical trials or safety studies, but are at high risk of renal failure related to bowel preparations. Thirdly, although we controlled unmeasured confounders which were stable over time by using a case-crossover design, we further adjusted for other medication use which could affect the development of ARF such as diuretics, ACE inhibitors, ARBs, β -blockers, NSAIDs, aminoglycosides, β -lactams, anti-viral agents, antimycotics, anti-cancer drugs, and contrast media^[24,25].

However, our results should also be interpreted with caution. Although ARF is generally defined as an abrupt and sustained decline in the glomerular filtration rate (GFR)^[34], we defined incident cases of ARF as hospitalization with diagnosis of ARF in the HIRA database. Since the database did not contain laboratory test results such as GFR, a validation study was used to compare the diagnosis derived from the HIRA database with the actual diagnosis in the patients' medical records. The overall positive predictive value of the diagnoses was 81.8% in cases of hospitalized patients^[35]. Also, ARF as defined in this study only included symptomatic and serious events requiring hospitalization. We defined the date of PEG exposure as the prescription date of PEG; however, there could be a

difference of several days or more between the date of prescription and actual administration. Nonetheless, the date of PEG administration followed the prescription, so the period from the actual PEG exposure date to ARF hospitalization might in fact be shorter than calculated.

In this study, PEG was found not to be associated with an increased risk of ARF in elderly patients. However, further studies should be conducted to confirm an association or lack thereof.

COMMENTS

Background

Polyethylene glycol (PEG), a commonly used solution for colonoscopy bowel preparation, is regarded as effective and tolerable. Recent reports have cited an increased risk of acute renal failure (ARF) in the elderly. Until now there have been no quantitative population-based epidemiological studies analyzing a possible relationship between PEG and ARF.

Research frontiers

Colonoscopy is a common diagnostic or therapeutic procedure. The success and accuracy of colonoscopy are largely dependent on appropriate cleansing of the colon. Ideally, a colon preparation would provide safe and rapid cleansing with little or no discomfort to patients. Currently, PEG bowel preparation and oral sodium phosphate (NaP) are predominantly used as bowel cleansing agents before colonoscopy based on the fact that they are effective and generally well tolerated.

Innovations and breakthroughs

Several recent studies have raised concerns about the safety of oral NaP preparations due to their reported association with an increased risk of serious electrolyte disturbances and renal failure. There have been no quantitative epidemiological studies analyzing a relationship between PEG preparation and the development of ARF using a national health insurance database. Therefore, this case-crossover study was performed to evaluate the risk of ARF following the use of PEG among elderly patients using information gathered from the Korean national health insurance database.

Applications

No increased risk of ARF was found in elderly PEG users. However, based on the number of study subjects, further analysis should be performed to confirm an association or lack thereof.

Peer review

This is very well constructed paper regarding the possibility of an association between PEG and ARF in elderly patients.

Abstract

AIM: To investigate the role of intestinal mucosal blood flow (IMBF) and motility in the damage of intestinal mucosal barrier in rats with traumatic brain injury.

METHODS: Sixty-four healthy male Wistar rats were divided randomly into two groups: traumatic brain injury (TBI) group ($n = 32$), rats with traumatic brain injury; and control group ($n = 32$), rats with sham-operation. Each group was divided into four subgroups ($n = 8$) as 6, 12, 24 and 48 h after operation. Intestinal motility was measured by the propulsion ratio of a semi-solid colored marker (carbon-ink). IMBF was measured with the laser-Doppler technique. Endotoxin and D-xylose levels in plasma were measured to evaluate the change of intestinal mucosal barrier function following TBI.

RESULTS: The level of endotoxin was significantly higher in TBI group than in the control group at each time point (0.382 ± 0.014 EU/mL vs 0.102 ± 0.007 EU/mL, 0.466 ± 0.018 EU/mL vs 0.114 ± 0.021 EU/mL, 0.478 ± 0.029 EU/mL vs 0.112 ± 0.018 EU/mL and 0.412 ± 0.036 EU/mL vs 0.108 ± 0.011 EU/mL, $P < 0.05$). D-xylose concentrations in plasma in TBI group were significantly higher than in the control group (6.68 ± 2.37 mmol/L vs $3.66 \pm$

1.07 mmol/L, 8.51 ± 2.69 mmol/L vs 3.15 ± 0.95 mmol/L, 11.68 ± 3.24 mmol/L vs 3.78 ± 1.12 mmol/L and 10.23 ± 2.83 mmol/L vs 3.34 ± 1.23 mmol/L, $P < 0.05$). The IMBF in TBI group was significantly lower than that in the control group (38.5 ± 2.8 PU vs 45.6 ± 4.6 PU, 25.2 ± 3.1 PU vs 48.2 ± 5.3 PU, 21.5 ± 2.7 PU vs 44.9 ± 2.8 PU, 29.4 ± 3.8 PU vs 46.7 ± 3.2 PU) ($P < 0.05$). Significant decelerations of intestinal propulsion ratio in TBI groups were found compared with the control group ($0.48\% \pm 0.06\%$ vs $0.62\% \pm 0.03\%$, $0.37\% \pm 0.05\%$ vs $0.64\% \pm 0.01\%$, $0.39\% \pm 0.07\%$ vs $0.63\% \pm 0.05\%$ and $0.46\% \pm 0.03\%$ vs $0.65\% \pm 0.02\%$) ($P < 0.05$).

CONCLUSION: The intestinal mucosal permeability is increased obviously in TBI rats. Decrease of intestinal motility and IMBF occur early in TBI, both are important pathogenic factors for stress-related damage of the intestinal mucosal barrier in TBI.

INTRODUCTION

Multiple system organ dysfunction syndrome (MODS) often occurs following the stress of severe trauma, burn and acute necrotic pancreatitis^[1-4]. However, its exact mecha-

nism remains unclear. The gut origin hypothesis suggests that damage of intestinal mucosal barriers as a result of these stress permits bacterial and endotoxin translocation, which triggers systemic immunoinflammatory response to release cytokines and inflammatory mediators. All of these might exacerbate systemic inflammatory response syndrome (SIRS) and MODS. Many patients with severe traumatic brain injury (TBI) often die of MODS^[5], but not of the injury itself. So to prevent SIRS and MODS in TBI patients is one of the important factors that affect the prognosis and sequela.

Our previous studies have found the damage of intestinal mucosal morphology and barrier function following TBI^[6]. Although very common, the pathophysiology of this stress-related change is far from understood.

Fortunately, researches over the past decades have provided insight into the potential mechanisms responsible for the pathogenesis of stress-induced gastrointestinal dysfunction. The stressful situation is a multi-factorial disorder involving dysregulation within the brain-gut axis. Upon activation of the brain-gut axis by stress, the release of brain-gut peptides can profoundly affect gastrointestinal physiology and it is frequently associated with gastrointestinal motor, gastrointestinal mucosal blood flow (IMBF), enteric and central nervous system irregularities, and neuroimmune dysregulation^[7].

The aim of this study was to further elucidate the effects of TBI on intestinal motility and IMBF, and to explore the putative mechanism of this stress-induced change in the TBI process.

MATERIALS AND METHODS

Animal model of TBI

Sixty-four healthy male Wistar rats, weighing 200-250 g (provided by Experimental Animal Center of Genetics and Developmental Biology Institute, Chinese Academy of Sciences), were randomly assigned to TBI model group ($n = 32$) and control group ($n = 32$). Each group was divided into four subgroups as 6, 12, 24 and 48 h after operation ($n = 8$). Experimental procedures complied with the ethical requirements for animal care.

Establishment of animal models

TBI group ($n = 32$): RATS with traumatic brain injury by free falling body method^[8]. Rats were deprived of food for 12 h prior to experiment, and then was anesthetized with injection of 10% chloral hydrate (0.4 mL/100 g) and fixed on a stereotaxic apparatus. Scalp was cut along the median line and exposed the skull under sterilized conditions. At the point of 2.0 mm rearward from the coronal suture and 2.0 mm left to the sagittal suture, open a 3.5 mm diameter bone window and maintain the integrity of the duramater. Then 20 g metal bar was released and fallen freely from 50 cm height to strike the meninges to cause the brain injury.

Control group ($n = 32$): rats with sham-operation with skull open operation alone and no brain injury.

Determination of endotoxin

One mL blood was collected from portal vein and placed into an apyrogenic tube (containing heparin) immediately. The levels of endotoxin were measured by chromogenic limulus amebocyte lysate test. The test kit was purchased from Shanghai Yihua Clinical Technology Company (Shanghai, China).

Measurement of D-xylose concentrations in plasma

Intestinal permeability was quantified by D-xylose concentrations in plasma. The 5% D-xylose solution of 1.5 mL was administered into the stomach by gastric tube feeding, and blood samples were collected into chilled tubes containing 100 U heparin 1 h later. The blood was centrifuged at 3000 r/min at 4°C for 10 min. The plasma was stored at -70°C until assayed. Levels of D-xylose in plasma were measured with D-xylose kit.

Measurement of IMBF

IMBF was measured with Laser Doppler Flowmetry (LDF) equipment (PeriFlux System 5000, Perimed, Sweden). The laser probe was inserted through a small enterotomy at the point that 20 cm from pylorus of the jejunal sac and held in a fixed position in the chamber solution at a distance of 1-2 mm above the mucosa. The measurement was taken as the average flow over a 10-min period following an initial 20-min period of stabilization.

Measurement of intestinal transit

Rats were fasted for 24 h prior to experiment, and 0.5 mL carbon-ink was administered into the stomach by gastric tube feeding. Twenty min later, the rats were killed at each time point, their intestines were removed from the pylorus through the ileocecal junction. The distance of carbon-ink from the pylorus to the most distal point of stain was expressed as migration distance. Results were expressed as propulsion ratio (%) of the migration distance to the total length of the small intestine (the distance between the pylorus and the ileocecal junction).

Statistical analysis

Software SPSS 11.0 was used for the statistical analysis. The data were expressed as mean \pm SD. Experimental results were analyzed by unpaired *t* test and $P < 0.05$ was considered as significant difference.

RESULTS

Serum endotoxin levels

There were significant differences of endotoxin levels between the TBI group and control group at each time point (0.382 ± 0.014 EU/mL *vs* 0.102 ± 0.007 EU/mL, 0.466 ± 0.018 EU/mL *vs* 0.114 ± 0.021 EU/mL, 0.478 ± 0.029 EU/mL *vs* 0.112 ± 0.018 EU/mL and 0.412 ± 0.036 EU/mL *vs* 0.108 ± 0.011 EU/mL, $P < 0.05$, respectively). As shown in Table 1, the endotoxin was significantly increased 6 h after TBI, and reached the peak at 24 h, and then declined at 48 h, but was still higher than that of the control group.

Table 1 Changes of endotoxin in plasma (mean \pm SD) (EU/mL)

Groups	6 h	12 h	24 h	48 h
Control	0.102 \pm 0.007	0.114 \pm 0.021	0.112 \pm 0.018	0.108 \pm 0.011
TBI	0.382 \pm 0.014 ^a	0.466 \pm 0.018 ^a	0.478 \pm 0.029 ^a	0.412 \pm 0.036 ^a

^a*P* < 0.05 *vs* control. TBI: Traumatic brain injury.Table 2 Changes of D-xylose in plasma (mean \pm SD) (mmol/L)

Groups	6 h	12 h	24 h	48 h
Control	3.66 \pm 1.07	3.15 \pm 0.95	3.78 \pm 1.12	3.34 \pm 1.23
TBI	6.68 \pm 2.37 ^a	8.51 \pm 2.69 ^a	11.68 \pm 3.24 ^a	10.23 \pm 2.83 ^a

^a*P* < 0.05 *vs* control. TBI: Traumatic brain injury.

D-xylose concentrations in plasma

D-xylose concentrations in plasma in TBI rats were significantly higher than in the control group (6.68 \pm 2.37 mmol/L *vs* 3.66 \pm 1.07 mmol/L, 8.51 \pm 2.69 mmol/L *vs* 3.15 \pm 0.95 mmol/L, 11.68 \pm 3.24 mmol/L *vs* 3.78 \pm 1.12 mmol/L and 10.23 \pm 2.83 mmol/L *vs* 3.34 \pm 1.23 mmol/L, *P* < 0.01, respectively), indicating that the intestinal mucosal barrier was damaged (Table 2).

Changes of IMBF

As shown in Table 3, IMBF was significantly lower in TBI group than that in the control group (38.5 \pm 2.8 PU *vs* 45.6 \pm 4.6 PU, 25.2 \pm 3.1 PU *vs* 48.2 \pm 5.3 PU, 21.5 \pm 2.7 PU *vs* 44.9 \pm 2.8 PU, 29.4 \pm 3.8 PU *vs* 46.7 \pm 3.2 PU) (*P* < 0.05). It began to decrease at 6 h, reached the lowest at 24 h, and did not reach the baseline by 48 h.

Changes of intestinal transit

The overall mean ratio of intestinal propulsion under TBI stress was lower than that of the control group (0.48% \pm 0.06% *vs* 0.62% \pm 0.03%, 0.37% \pm 0.05% *vs* 0.64% \pm 0.01%, 0.39% \pm 0.07% *vs* 0.63% \pm 0.05% and 0.46% \pm 0.03% *vs* 0.65% \pm 0.02%) (*P* < 0.05), indicating that TBI stress could inhibit small intestinal motility (Table 4).

DISCUSSION

Gastrointestinal dysfunction is a common complication of stress. Damage of the gastrointestinal function, especially of the gastrointestinal barrier function, permits translocation of enterogenic bacteria and endotoxins, triggers systemic immunoinflammatory response to release cytokines and inflammatory mediators, which is an important initiator as well as a stimulator for occurrence of SIRS, sepsis and MODS following major stress^[9]. The stress including severe trauma, hemorrhagic shock, severe pancreatitis and burn^[10,11]. So the gastrointestinal barrier function is one of the important factors that affect the prognosis and sequelae.

Intestinal mucosal barrier function could be evaluated by measuring the permeability of saccharide mo-

lecular probe. Lactulose/mannitol and D-xylose have previously been used to assess intestinal mucosal permeability^[12-15]. Shi *et al.*^[16], reported that chronic restraint stress could cause damage of the intestinal barrier function and increased intestinal permeability to D-xylose.

In this study, we used endotoxin and plasma D-xylose to evaluate the intestinal mucosa barrier function. We found that the endotoxin and plasma D-xylose levels in the TBI group were significantly higher than in the control group at 6 h following TBI, and reached its peak at 24 h, and then declined at 48 h, but still markedly higher than that in the control group. All of these demonstrated that TBI stress could be an initiating factor to increase the permeability of intestinal mucosa, suggesting that the intestinal mucosal barrier dysfunction initiated at the early stage of TBI.

At present, the specific pathogenesis and progress of the intestinal mucosal barrier damage still remain unclear. Stress is known to alter ingestive behaviors and associated physiological events such as gastric acid secretion and gastrointestinal motility. Mast cells translate the stress signal that has been transmitted through brain-gut axis to release a wide range of neurotransmitters and proinflammatory mediators, some of them are brain-gut peptides, such as 5-HT, SP, CGRP, CRP, CCK, NO, NE and VIP. Evidences implicated that the brain-gut peptides are involved in these physiological effects which can change the intestinal motility, modulate tight junction proteins and increase the intestinal permeability^[7,17]. Animal studies suggest that cholecystokinin (CCK) acts *via* a vagal afferent pathway to decrease gastrointestinal motility^[18] and substance P can stimulate a contractile function of smooth muscle^[19]. Studies in animal models showed that burn injury and cardiopulmonary bypass markedly down-regulated the expression of occludin and tight junction associated protein ZO-1 in intestinal mucosa of rats. The close correlation between expression of tight junctions and plasma levels of diamine oxidase or *D*-lactate supports the hypothesis that intestinal permeability increases during and after stress events because of decreases in the expression of tight junctions^[20,21].

IMBF plays a vital role in intestinal mucosal defense system. Sufficient IMBF brings oxygen and nutrients to the mucosal cells, maintains the normal structure and function of intestinal mucosa and is closely associated with the pathogenesis and healing of intestinal mucosal lesions^[22]. Our results revealed that IMBF decreased significantly at the early stage of TBI, and the intestinal mucosal permeability increase occurred at the same time. As intestinal mucosa is very sensitive to the shortage of blood and oxygen, ischemia/reperfusion (I/R) is the main pathogenesis of intestinal mucosal damage. The physiopathology of intestinal mucosal damage by I/R is not fully understood. But, it is believed that cytotoxic substances such as free radicals, nitric oxide, pro-inflammatory cytokines, leukotrienes, serotonin and other related products, play important roles^[23,24]. I/R not only damages the intestinal mucosal barrier function but also alters the gastrointestinal motility^[25].

It is widely believed that delayed intestinal motility could cause small intestinal bacterial overgrowth (SIBO). Gangarosa^[26] demonstrated that intestinal motility served as a normal cleansing mechanism of the intestine. Leveau *et al.*^[27] noticed a delay in intestinal transit time, appearing as an early event in acute pancreatitis, preceding SIBO, and suggested that impairment in intestinal motility may play a role in the development of SIBO. Tsukada *et al.*^[28-30] demonstrated that the small intestinal transit was significantly inhibited by restraint stress. Our results revealed that, at the early stage of TBI, the intestinal propulsion ratio decreased significantly as compared with control group ($P < 0.05$). Damage of intestinal mucosal barrier function occurred at the same time, indicating that the inhibition of intestinal motility might be another vital factor of gastrointestinal barrier dysfunction.

The mechanism may be explained by the fact that the prolonged small intestinal transit makes it possible that the small intestinal content remains in the intestinal tract for a long time, preceding SIBO, increasing the chance of bacterial and endotoxin translocation and producing a great deal of gas. The defect of intestinal barrier and the above factors of small intestinal dysfunction may enhance each other.

In summary, the damage of intestinal mucosal barrier function following TBI is caused by multiple factors, the close correlation between decrease of intestinal blood flow and motility and increase of intestinal permeability supports the hypothesis that both of them might play a very important role in the regulation of intestinal epithelial barrier dysfunction during and after TBI. Therefore, maintaining intestinal barrier function is a systematic engineering project. Further research that more precisely characterizes the role of intestinal mucosal blood flow and intestinal motility in these diseases could put new insights into the new therapies for stress-induced injury of intestinal mucosal barrier function.

COMMENTS

Background

Multiple system organ dysfunction syndrome (MODS) often occurs following

the stress of traumatic brain injury (TBI). Although being very common, the pathophysiology of this stress-related change is far from understood. The gut origin hypothesis suggests that damage of intestinal mucosa barriers as a result of these stress permits bacterial and endotoxin translocation, which triggers systemic immunoinflammatory response to release cytokines and inflammatory mediators. All of these might exacerbate the systemic inflammatory response syndrome (SIRS) and MODS.

Research frontiers

Gastrointestinal dysfunction is a common complication of stress. Damage of gastrointestinal function, especially of the gastrointestinal barrier function is an important initiator as well as a stimulator for occurrence of SIRS, sepsis and MODS following major stress, including severe trauma, hemorrhagic shock, severe pancreatitis and burn. Studies in animal models showed that brain-gut axis/ brain-gut peptides are involved in these physiological effects which can change the intestinal motility, modulate tight junction proteins and increase intestinal permeability.

Innovations and breakthroughs

The specific pathogenesis and progress of stress-induced damage of intestinal barrier function remain unclear. But, disruption of the intestinal mucosal protection is certainly involved. Intestinal blood flow plays a vital role in intestinal mucosal defense system and intestinal motility served as a normal cleansing mechanism of the intestine. This study revealed that the intestinal blood flow and motility decreased significantly at the early stage of TBI, and the intestinal mucosal permeability increase occurred at the same time. The results suggested that both might be important pathogenic factors for intestinal barrier function damage during and after TBI.

Applications

Many patients with severe TBI often die of MODS, but not of the injury itself. So to protect the mucosal barrier function at the early stage of TBI will be of significance for reducing the stress-related SIRS and MODS.

Terminology

Brain-gut axis is composed of main regulatory cores in the central nervous system that are connected to peripheral (enteric and autonomic) nervous systems through a series of networks of afferent and efferent nerves. Brain-gut peptide is named because of its distribution in both nervous system and gastrointestinal tract. Intestinal mucosal barrier function include mechanical barrier, chemical barrier, immunologic barrier and biological barrier, any damage of these barriers will damage the intestinal mucosal barrier function.

Peer review

This is a well conducted randomized controlled trial on animal models. The authors presented the results of their study that decreased intestinal blood flow and motility occur early in TBI, which supports the hypothesis that both are important pathogenic factors for increasing the intestinal permeability. So resuming the intestinal blood flow and motility might be a useful method for maintaining intestinal barrier function during and after TBI.

SM. Each treatment lasted for 30 min. Rats undergoing treatment with SM were not anesthetized. Untreated CVH rats and normal rats were used as controls. The abdominal withdrawal reflex was determined 30-90 min after the seven treatments. The hypothalamic corticotropin-releasing hormone (CRH) mRNA level was measured using real-time quantitative reverse transcription-polymerase chain reaction.

RESULTS: We found that SM treatment significantly decreased visceral sensitivity to colorectal distention in this rat model. In treated animals, SM also decreased the relative hypothalamic CRH mRNA expression level to control levels.

CONCLUSION: Lower hypothalamic CRH levels may mediate the beneficial effects of SM in this rat irritable bowel syndrome model.

Abstract

AIM: To evaluate the effect of suspended moxibustion (SM) on rectal sensory thresholds and to analyze the possible mechanisms involved in SM treatment of chronic visceral hypersensitivity (CVH) in rats.

METHODS: SM was administered once daily to 37-d-old CVH rats for 7 d. The two pairs of acupoints (ST25 and ST37, bilateral) were simultaneously treated with

INTRODUCTION

Irritable bowel syndrome (IBS) is a functional disorder

characterized by chronic recurring abdominal pain or discomfort and altered bowel habits^[3]. Several recent studies have demonstrated that electro-acupuncture (EA) can decrease chronic visceral hypersensitivity (CVH) in a rat IBS model induced by mechanical colorectal irritation in the postnatal period^[2-6]. Previously, we reported that EA in this model can decrease hypothalamic corticotropin-releasing hormone (CRH) levels^[7]. CRH, a 41 amino acid peptide produced mainly in the paraventricular nucleus of the hypothalamus, is regarded as a major mediator of the stress response^[8]. IBS patients are reported to be hypersensitive to routine stress^[9], and stressful life events are known to contribute to the clinical course of IBS^[10].

Moxibustion is an alternative or complementary therapy that is also used to treat IBS. Methods of moxibustion include suspended moxibustion (SM, also known as warming moxibustion), scarring moxibustion and herb-partition moxibustion. Previously, we reported that both SM^[11] and herb-partition moxibustion^[12] could decrease CVH in a rat IBS model induced by mechanical colorectal irritation in the postnatal period. Moreover, we found that rats were relaxed or asleep during SM, indicating that the procedure was not stressful to the animals^[11]. Therefore, in the present study, we focused on whether SM could decrease hypothalamic CRH levels in rats.

MATERIALS AND METHODS

Animals

We used a rat model of CVH^[13] induced by mechanical colorectal irritation during postnatal development. Neonatal male Sprague-Dawley rats (5 d old) were obtained from the Experiment Animal Center, Shanghai University of Traditional Chinese Medicine. The animals were maintained in a plastic cage containing corn chip bedding at a controlled temperature (21°C) in a light-dark cycle (12 h:12 h). The maximum number of rats per cage was five. All rats were used strictly in accordance with the National Institutions of Health Guide for the Care and Use of Laboratory Animals.

Neonatal rats were subjected to daily mechanical colorectal distention (CRD) from the age of 8 d to the age of 21 d. Neonatal rats received CRD twice daily, at 30-min intervals using a procedure modified from previous studies^[6,13]. A balloon constructed from a condom (length 20.0 mm and diameter 3.0 mm) was inserted rectally into the descending colon. The balloon was distended with 0.5 mL air for 1 min. It was then deflated and withdrawn. The rats were reared until they reached adulthood (at least 6 wk old), and behavioral responses to visceral pain induced by acute CRD were then examined. SM was administered to CVH rats ($n = 8$) for 7 d. CVH rats without SM ($n = 8$) and normal rats ($n = 8$) were used as controls. After seven treatments, the abdominal withdrawal reflex (AWR) was monitored over a period of 30-90 min. The animals were then sacrificed by intraperitoneal anesthesia using sodium pentobarbital (80 mg/kg), and the hypothalamus was isolated immediately and frozen in liquid nitrogen.

SM treatment

In the CVH + SM group, one ignited moxa stick was suspended perpendicularly 2 cm above Tianshu (ST25)^[11] and Shangjuxu (ST37) (5 mm lateral to the anterior tubercle of the tibia and 20 mm below the knee joint). ST25 and ST37 were the two key acupoints chosen in this study based on our clinical treatment of patients with IBS since the 1980s. The two pairs of acupoints (ST25 and ST37) were simultaneously treated with SM. Each treatment consisted of 30 min of moxibustion (15 min for each pair of acupoints). SM was administered once daily to CVH rats for 7 d. The animals were not anesthetized before SM, but were held in the supine position in one gloved hand. Rats from both the normal group and CVH group were also held in one gloved hand in the supine position, but not treated with SM^[11], these were used as controls.

Colon stimulation and testing of the AWR

Behavioral responses to CRD in young adult rats were assessed by recording AWR scores, using a procedure modified from previous studies^[5,13]. After anesthesia with diethyl ether, a balloon (3 cm in length, made using one finger of a latex glove) was inserted into the descending colon. The rats were then housed in small lucite cubicles (20 cm × 8 cm × 8 cm) on a platform and allowed to wake up and adapt for 20 min. CRD was induced by rapidly inflating the balloon at pressures of 20, 40, 60 and 80 mmHg for a duration of 10 s. AWR scores were observed by two blinded observers using the scale developed by Al-Chaer *et al.*^[13].

Real-time quantitative reverse transcription-polymerase chain reaction

Total RNA was isolated from the hypothalamus using TRIZOL Reagent (TAKARA Biotechnology Co., Ltd., China), and quantified using a UV-3000 spectrophotometer (UNICO, USA). First-strand cDNA was synthesized using oligo(dT)15 primer, Moloney murine leukemia virus reverse transcriptase (TAKARA Biotechnology Co., Ltd., China), and 4 µL RNA. CRH and GAPDH (housekeeping gene) primers were designed in different exons to amplify cDNA using ABI Prism 7500 SDS Software (Applied Biosystems Co., Ltd., USA). CRH primers were: sense 5'-TGGCCTGCAGTGCAATGC-3' and antisense 5'-CCTGGCACTCAGAATAATTACAC-3'. Real-time quantitative polymerase chain reaction (qPCR) was performed with 5 µL of first-strand cDNA reaction in the presence of 0.5 µL dNTP, 10 µL specific buffer, 1 µL *Taq* polymerase, SYBR green fluorescent dye and the appropriate sense and antisense primers (0.5 µL) in a final volume of 50 µL (qPCR™ Core Kit, Shanghai DaWei'K Biology Technology Co., Ltd., China). PCR was carried out using the 7500 Sequence Detection System (Applied Biosystems). The reaction conditions were as follow: initial denaturation for 5 min at 95°C followed by 40 cycles with denaturation at 95°C for 15 s and annealing and extension at 60°C for 45 s. Three SYBR cycle threshold values were

Table 1 Abdominal withdrawal reflex scores in response to graded colorectal distention at 20, 40, 60 and 80 mmHg

Group	n	AWR score			
		20 mmHg	40 mmHg	60 mmHg	80 mmHg
Normal	8	0.13 ± 0.13	0.38 ± 0.18	0.75 ± 0.25	1.50 ± 0.33
CVH	8	1.38 ± 0.18 ^{b,d}	1.80 ± 0.25 ^{b,d}	2.75 ± 0.25 ^{b,d}	3.50 ± 0.27 ^{b,d}
CVH + SM	8	0.25 ± 0.16	0.50 ± 0.19	1.13 ± 0.30	1.63 ± 0.18

AWR: Abdominal withdrawal reflex; SM: Suspended moxibustion; CVH: Chronic visceral hypersensitivity. ^b*P* < 0.01 *vs* normal group; ^d*P* < 0.01 *vs* CVH + SM group.

averaged for each sample, and the RNA input for the target gene was calculated from the standard curve.

Statistical analysis

All values are expressed as mean ± SE. Statistical analyses were performed using one-way ANOVA followed by Fisher's PLSD procedure using SPSS 10.0 (SPSS Inc., USA). Dunnett's T3 test was used if variances were unequal. *P* < 0.05 was considered to be significant.

RESULTS

AWR scores in response to graded CRD at 20, 40, 60 and 80 mmHg

As shown in Table 1, the AWR scores in response to graded CRD (20, 40, 60, and 80 mmHg) in the normal control group were lower than in the CVH group (*P* < 0.01). SM treatment significantly reduced AWR scores in the CVH rats in response to CRD (20, 40, 60 and 80 mmHg).

Relative hypothalamic CRH mRNA expression

The relative CRH mRNA expression level was significantly higher in the CVH group than in the normal control group (*P* < 0.01). However, the relative CRH mRNA expression level was markedly lower in the CVH + SM group than in the normal control group (*P* < 0.01) (Table 2).

DISCUSSION

In our previous study, we found that SM depressed AWR scores following CRD stimulation at 20 mmHg. However, in this study SM depressed AWR scores following CRD stimulation at 20, 40, 60 and 80 mmHg, which may be due to the increased number of treatments (1 treatment *vs* 7 treatments), and acupoints (1 pair of acupoints *vs* 2 pairs of acupoints). Overall, the results of this experiment demonstrated the efficacy of SM in decreasing CVH in a rat IBS model induced by mechanical colorectal irritation in the postnatal period.

We previously reported that EA can decrease the hypothalamic CRH levels in a rat IBS model^[7]. Moreover, the rats were relaxed or asleep during SM, indicating that the procedure was not stressful to the animals^[11]. Stress is known to lead to central CRH release, and we have confirmed that hypothalamic CRH levels are elevated in IBS rats. In the present study, we focused on whether SM

Table 2 Relative hypothalamic corticotropin-releasing hormone mRNA expression

Group	n	CRH mRNA (relative expression)
Normal	8	0.29 ± 0.03
CVH	8	3.62 ± 0.23 ^{b,d}
CVH + SM	8	0.47 ± 0.06

CRH: Corticotropin-releasing hormone; SM: Suspended moxibustion; CVH: Chronic visceral hypersensitivity. ^b*P* < 0.01 *vs* normal group; ^d*P* < 0.01 *vs* CVH + SM group.

could decrease hypothalamic CRH expression level in rats. Our results showed that the relative hypothalamic CRH mRNA expression level also decreased in IBS rats, suggesting that the modulation of hypothalamic CRH may mediate the decreased visceral sensitivity arising from SM.

The effects of CRH on different tissues are mediated *via* CRH receptors on the cell membrane^[14]. CRH receptors are expressed in different brain regions^[15,16] and in several peripheral organs^[17]. Both central CRH receptor 1 (CRH-R1) and peripheral CRH-R1 are believed to be responsible for colorectal distension-induced sensitization^[18]. Moreover, the activation of CRH-R2 reduces visceral sensitivity induced by colorectal distension in conscious rats.

We hope that this study will pave the way for further studies on the relationship between CRH, CRH receptors, and SM. It will be necessary to determine whether SM can regulate the expression or activity of CRH receptors in IBS rats. Further experiments with CRH receptor antagonists would shed light on the functional relationship between SM and changes in CRH levels.

In conclusion, SM increased pain thresholds in a rat model of IBS and decreased relative hypothalamic CRH mRNA expression level. We suggest that reduced hypothalamic CRH levels may mediate the beneficial effects of SM in a rat IBS model induced by mechanical colorectal irritation in the postnatal period.

COMMENTS

Background

The authors previously reported that electro-acupuncture can decrease hypothalamic corticotropin-releasing hormone (CRH) levels in a rat model of irritable bowel syndrome (IBS). However, it is still not known whether suspended moxibustion (SM) can decrease hypothalamic CRH levels. Previously, the authors reported that both SM and herb-partition moxibustion can decrease chronic visceral hypersensitivity (CVH) in a rat IBS model induced by mechanical colorectal irritation in the postnatal period. Moreover, the authors found that rats were relaxed or asleep during SM, indicating that the procedure was not stressful to the animals.

Research frontiers

The effects of CRH on different tissues are mediated *via* CRH receptors on the cell membrane. CRH receptors are expressed in different brain regions and in several peripheral organs. Both central CRH receptor 1 (CRH-R1) and peripheral CRH-R1 are believed to be responsible for colorectal distension-induced sensitization. Moreover, the activation of CRH-R2 reduces visceral sensitivity induced by colorectal distension in conscious rats.

Innovations and breakthroughs

This study is the first to report on the effects of SM on hypothalamic CRH levels in CVH rats.

Terminology

Moxibustion is an alternative or complementary therapy and is also used to treat IBS. Methods of moxibustion include SM (also named warming moxibustion), scarring moxibustion and herb-partition moxibustion. In the SM treatment, one ignited moxa-stick was suspended perpendicularly above the acupoints.

Peer review

The paper is very interesting. But there are some questions to be addressed before publication.

Abstract

AIM: To evaluate the diagnostic efficacies of narrow-band imaging (NBI) endoscopy with and without high magnification in distinguishing neoplasia from non-neoplasia colorectal lesions.

METHODS: A total of 118 patients with 123 colorectal lesions examined by NBI endoscopy in the Zhejiang Provincial People's Hospital from September 2008 to April 2010 were enrolled in this study. These lesions were classified by pit pattern and capillary pattern, and then assessed by histopathology.

RESULTS: Ten lesions not meeting the diagnostic criteria were excluded, the overall diagnostic accuracy of NBI endoscopy in distinguishing neoplasia from non-neoplasia colorectal lesions was 91.2% (103/113), and that of NBI endoscopy with and without high magnification was 93.0% (40/43) and 90.0% (63/70), respectively. Both were significantly higher than that of conventional colonoscopy reported in the literature ($P < 0.05$), but there was no significant difference between the two groups ($P > 0.05$).

CONCLUSION: Besides NBI magnifying endoscopy,

Narrow-band imaging endoscopy with and without magnification in diagnosis of colorectal neoplasia. *World J Gastroenterol* 2011; 17(5): 666-670 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i5/666.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i5.666>

INTRODUCTION

Colorectal cancer is a common gastrointestinal malignancy with a slow process in occurrence and development involving multi-steps, multi-stages and multiple genes, and most of them arise from preexisting adenomas and have an adenoma-carcinoma sequence^[1,2]. Early detection and removal of colorectal adenomas may greatly reduce both the incidence of colorectal cancer and cancer-related death^[3].

Electronic colonoscopy is considered to be an effective examination for the detection of colorectal neoplastic lesions^[4]. However, it is difficult to assess pre-malignant and early neoplastic lesions precisely using conventional white light endoscopy. In chromoendoscopy, a biocompatible dye, such as indigo carmine, can strengthen the surface structure of epithelial lesions^[5], but the operation

is relatively cumbersome, time-consuming and costly, not conducive to observe the vascular structure, and may damage the DNA of epithelial cells.

Narrow-band imaging (NBI) is a novel technology that emerged in endoscopic diagnosis of early cancer, and it has better targeting for biopsy and higher diagnostic accuracy than conventional videoendoscopy by enhancing the visualization of surface mucosal and vascular patterns on the polyp surface^[6]. Our study aimed to verify the diagnostic accuracy of NBI endoscopy in distinguishing neoplasia from non-neoplasia colorectal lesions, and evaluate the diagnostic efficacies of NBI endoscopy with and without high magnification.

MATERIALS AND METHODS

Patients

The patients who have poor bowel preparation, familial adenomatous polyposis, infectious bowel disease, inflammatory bowel disease and colorectal cancer were excluded. A total of 118 patients with 123 colorectal lesions examined by NBI endoscopy in the Zhejiang Provincial People's Hospital from September 2008 to April 2010 were enrolled in this study. Forty-six and 77 lesions were examined by NBI endoscopy with and without high magnification.

NBI and colonoscopy

A standard videoendoscopy system with two light sources was used for examination. One light source was for the standard optical filter (broadband) and the other was for the NBI system. The control knob on the grip of the endoscope allows single touch exchange of the standard filter for the NBI filter. Olympus CV-260SL, CLV-260SL, CF240I, H260AZI and SONY LMD-2140MD were used respectively for the endoscopic host, source, conventional endoscopy, magnifying endoscopy and monitor.

Methods

Researching methods, observation tables and patient's informed consent were obtained before the study. Polyethylene glycol lavage solution and diprivan propofol were used for bowel preparation and intravenous anesthesia, respectively, and the whole examination process was managed by an experienced endoscopist (the second author). The scope was entered to the ileocecal part using conventional observation mode, and back with white light and NBI. The lesions were classified by pit pattern and capillary pattern with NBI immediately when they were detected, and then biopsied or resected for pathological diagnosis by an experienced pathologist. The endoscopist and pathologist were unaware of each other's diagnosis, and finally the NBI endoscopic diagnosis was assessed based on the pathological diagnosis.

The NBI endoscopic diagnostic criteria followed Kudo's^[7] classification of mucosal pit pattern and Sano's^[8] classification of capillary pattern. We developed the comprehensive diagnostic criteria: Pit II + CP1 as hyperplastic polyp, Pit III L + CP2 or Pit IV + CP2 as adenoma, and Pit V + CP3 as adenocarcinoma.

Table 1 Comparison of narrow-band imaging endoscopy and pathological diagnosis

	Narrow-band imaging diagnosis	Pathological diagnosis				Total
		Hyper-plastic polyp	Tubular adenoma	Villous adenoma	Adenocarcinoma	
Pit pattern	II	38	9	0	0	47
	III s	0	0	0	1	1
	III L	4	51	1	0	56
	IV	0	0	6	0	6
	V	0	0	0	13	13
Capillary pattern	CP1	35	4	0	0	39
	CP2	7	56	7	0	70
	CP3	0	0	0	14	14

Statistical analysis

Statistical differences of diagnostic accuracies were analyzed by the Mann-Whitney *U* test and χ^2 test. $P < 0.05$ was considered significantly different.

RESULTS

Among the 118 patients, 73 were males and 45 were females, with a mean age of 57.54 ± 14.01 years (range, 19-86 years). The location of the lesions was as follows: 53 in rectum, 22 in sigmoid colon, 14 in descending colon, 21 transverse colon and 13 in ascending colon, with a mean size of 10.13 ± 7.79 mm (range, 3-40 mm).

Pathologically, lesions were divided into non-neoplastic lesions, including hyperplastic and inflammatory lesions (42) and neoplastic lesions, including tubular adenoma (60), villous adenoma (7) and adenocarcinoma (14).

Based on the Kudo's classification of mucosal pit pattern and Sano's classification of capillary pattern, the lesions were classified with NBI and assessed by histopathology. The diagnostic accuracy, sensitivity and specificity to distinguish between non-neoplastic and neoplastic colorectal lesions were 94.7% (72/76), 88.9% (72/81) and 90.5% (38/42) for pit pattern delineation; and 91.7% (77/84), 95.1% (77/81) and 83.3% (35/42) for capillary pattern delineation, respectively (Table 1). According to the comprehensive diagnostic criteria, Pit II + CP1 (Figure 1A and B) was defined as hyperplastic polyp, Pit III L + CP2 (Figure 1C and D) or Pit IV + CP2 (Figure 1E and F) as adenoma, and Pit V + CP3 (Figure 1G and H) as adenocarcinoma. Ten lesions failed to meet the diagnostic criteria. The overall diagnostic accuracy of NBI endoscopy in distinguishing neoplastic from non-neoplastic colorectal lesions was 91.2% (103/113) and that of NBI endoscopy with and without high magnification was 93.0% (40/43) and 90.0% (63/70), respectively (Table 2). Both were significantly higher than that of conventional colonoscopy reported in the literature^[9] ($P < 0.05$), but there was no significant difference between the two groups ($P > 0.05$).

DISCUSSION

NBI is a novel imaging technology that uses special nar-

Figure 1 Narrow-band imaging endoscopic evaluation and the corresponding pathological images. row-band filters in the endoscopic system, which allow for a more detailed visualization of the mucosal architecture and vascular pattern. Current NBI technology limits

the mucosal surface light penetration, thereby enhancing the visualization of the fine capillary vessel structure on the surface layer^[10]. According to a previous pilot study by

NBI: Narrow-band imaging.

Machida *et al*^[9], NBI with magnifying endoscopy achieved better visualization of the mucosal vascular network pattern than conventional white light imaging, and the diagnostic accuracy was higher than that of conventional colonoscopy and equivalent to chromoendoscopy. Furthermore, compared with chromoendoscopy, the NBI observation has the advantage of convenient application without the necessity of dye spraying, thus the procedure can be shortened in time and an overlooked lesion with accumulation of dark-blue dye at the dependent portion of colon can also be avoided^[11].

According to previous pathological studies, most of the colorectal cancers arise from preexisting adenomas and such an adenoma-carcinoma sequence, and the adenoma shares many architectural features with the carcinoma in terms of vascular architecture including vessel diameter and spatial distribution which is considerably different from that in the non-neoplastic portion of colonic mucosa^[12]. Therefore, NBI endoscopy has a significant advantage in the diagnosis of colorectal dysplasia accompanied with microvascular changes. In recent years, a number of researches^[9,13-15] have shown that the diagnostic accuracy of NBI endoscopy in distinguishing neoplastic from non-neoplastic colorectal lesions was higher than that of conventional colonoscopy and equivalent to chromoendoscopy. In our study, we used Kudo's classification of mucosal pit pattern and Sano's classification of capillary pattern, and the diagnostic accuracy, sensitivity and specificity to distinguish between non-neoplastic and neoplastic colorectal lesions were 94.7% (72/76), 88.9% (72/81) and 90.5% (38/42) for pit pattern delineation, which is similar to the data reported in the literature (92.7%, 95.7% and 87.5%), significantly higher than that of conventional endoscopy (82.9%, 80.0% and 81.8%)^[14]; and 91.7% (77/84), 95.1% (77/81), 83.3% (35/42) for capillary pattern delineation, which is slightly lower than the data reported in the literature (96.6%, 97.1% and 91.8%)^[16], but there was no significant difference. It may be related to the relatively small number of the cases in this study. In addition, it is possible that endoscopists who are familiar with NBI endoscopy may also improve the diagnostic accuracy, but this requires further investigation.

In recent years, as NBI combined with magnifying endoscopy could enhance the contrast detailed morphological changes in the mucosal surface and clearly visualize

the microvascular structures, most studies described the use of NBI endoscopy with magnification^[13,17-22], but few data about diagnostic accuracy of NBI endoscopy without magnification were reported. However, magnifying endoscopy is not clinically used as standard endoscopic equipment in most institutions, not only in China but also in Japan and some Western countries, because magnifying endoscopy is much more expensive. This greatly restricted the wide application of NBI magnifying endoscopy. In order to evaluate the diagnostic efficacies of NBI conventional endoscopy in distinguishing neoplastic from non-neoplastic colorectal lesions, we compared the diagnostic accuracy of NBI with and without high magnification. The results showed that the overall diagnostic accuracy of NBI endoscopy in distinguishing neoplastic from non-neoplastic colorectal lesions was 91.2% (103/113), and that of NBI endoscopy with and without high magnification was 93.0% (40/43) and 90.0% (63/70), respectively. Both were significantly higher than that of conventional colonoscopy reported in the literature, but there was no significant difference between the two groups. Therefore, we believe that NBI endoscopy without high magnification could also greatly improve the diagnostic accuracy and may also be used to distinguish neoplastic from non-neoplastic colorectal lesions instead of NBI magnifying endoscopy. However, as the sample was relatively small in our study, it was not clear whether NBI without high magnification could improve the detection rate in the mass population screening; this requires further study and investigation.

As a new non-invasive endoscopic method, the diagnostic efficacies of NBI combined with magnifying endoscopy in distinguishing neoplastic from non-neoplastic colorectal lesions has been confirmed by extensive literatures^[13,14,23-25]. We found in our study that the endoscopic system installed with the NBI system enables the clinicians to significantly improve the diagnostic accuracy. Therefore, even the institutions without the expensive magnifying endoscopy equipment can also use conventional NBI endoscopy to get an accurate diagnosis. Although these findings need to be confirmed in large prospective trials, this initial experience with conventional NBI endoscopy is encouraging and holds promise for future application in prospective studies. In addition, endoscopists, through training in NBI endoscopic practice, may also improve their own diagnostic accuracy and raise the detection rate of colorectal neoplasia^[26].

COMMENTS

Background

Narrow-band imaging (NBI) is a novel technology developed for endoscopic diagnosis of early cancer, and it has a higher diagnostic accuracy than conventional endoscopy by enhancing the visualization of surface mucosal and vascular patterns on the lesion surface.

Research frontiers

In recent years, as NBI combined with magnifying endoscopy could enhance the contrast detailed morphological changes in the mucosal surface and clearly visualize the microvascular structures, most studies described the use of NBI endoscopy with magnification, but few data about diagnostic accuracy of NBI endoscopy without magnification were reported.

Innovations and breakthroughs

Compared with NBI magnifying endoscopy, NBI endoscopy without magnification may be used in distinguishing neoplasia from non-neoplasia colorectal lesions.

Applications

NBI endoscopy enables clinicians to significantly improve their diagnostic accuracy. Even those institutions equipped without magnifying endoscope can also use NBI conventional endoscopy to get an accurate diagnosis.

Terminology

NBI is a novel imaging technology that uses special narrow-band filters in the endoscopic system, which allow for a more detailed visualization of the mucosal architecture and vascular pattern.

Peer review

This paper compares narrow band imaging with and without high magnification in 100 patient with colorectal lesions over an 18 mo period. The authors show that both of these techniques are more accurate than conventional colonoscopy in distinguishing between neoplastic and non-neoplastic lesions with similar sensitivity. A larger study would have had more value.

Abstract

AIM: To compare the fast-track rehabilitation program and conventional care for patients after resection of colorectal cancer.

METHODS: One hundred and six consecutive patients who underwent fast-track rehabilitation program were encouraged to have early oral feeding and movement for early discharge, while 104 consecutive patients underwent conventional care after resection of colorectal cancer. Their gastrointestinal functions, postoperative complications and hospital stay time were recorded.

RESULTS: The restoration time of gastrointestinal functions in the patients was significantly faster after fast-track rehabilitation program than after conventional care (2.1 d vs 3.2 d, $P < 0.01$). The percentage of patients who developed complications was significantly lower 30 d after fast-track rehabilitation program than after

conventional care (13.2% vs 26.9%, $P < 0.05$). Also, the percentage of patients who had general complications was significantly lower 30 d after fast-track rehabilitation program than after conventional care (6.6% vs 15.4%, $P < 0.05$). The postoperative hospital stay time of the patients was shorter after fast-track rehabilitation program than after conventional care (5 d vs 7 d, $P < 0.01$). No significant difference was observed in the re-admission rate 30 d after fast-track rehabilitation program and conventional care (3.8% vs 8.7%).

CONCLUSION: The fast-track rehabilitation program can significantly decrease the complications and shorten the time of postoperative hospital stay of patients after resection colorectal cancer.

INTRODUCTION

The concept of fast track rehabilitation program has been recently introduced with the intent to improve the management, stress, complications, shorten hospital stay time and reduce cost of patients after resection of colorectal cancer^[1-7]. Fast track rehabilitation program is basically a

multidisciplinary perioperative care strategy for patients after resection of colorectal cancer, including preoperative education, effective anesthesia, postoperative analgesia techniques, early oral nutrition and ambulation^[8-11]. However, the previous researches were mainly focused on the postoperative complications after conventional care rather than on the general complications after fast-track rehabilitation program. This study was to compare the complications, restoration of gastrointestinal functions, and hospital stay time of postoperative colorectal cancer patients after fast-track rehabilitation program and conventional care.

MATERIALS AND METHODS

Patients and procedures

Two hundred and thirty patients who underwent resection colorectal cancer in the Research Institute of General Surgery, Jinling Hospital (Nanjing, China) in July 2007 to August 2009 were enrolled in this study. Of the 230 patients, 115 who underwent resection of colorectal neoplastic disease served as a fast-track rehabilitation program group, and 115 who underwent resection of colorectal cancer served as a conventional care group. Nine patients with non-selective admission, preoperative distant metastasis, stoma, emergency situations, scheduled total colectomy or abdominoperineal resection, contraindications for epidural anesthesia or early ambulation were excluded from the fast-track rehabilitation program group, and 11 from the conventional care group. Finally, 106 patients in the fast-track rehabilitation program group and 104 patients in the conventional care group were analyzed in this study.

The contents of fast-track rehabilitation program include preoperative education of patients with no bowel preparation and fasting but with carbohydrate containing liquids 2 h before surgery, analgesia with routine oral non-steroidal anti-inflammatory medications and minimization of opioid pain management, avoidance of perioperative fluid overload, no routine use of nasogastric tubes, early removal of bladder catheters, early feeding and enforced ambulation on the day of surgery. In the fast track rehabilitation program group, minimal-access surgery or transverse curved incision used included right-sided hemicolectomy through a right horizontal incision above the umbilicus, sigmoid resection through a curved incision in the left iliac fossa and low anterior rectal resection through a mini-laparotomy in the subumbilicus which was extended toward the curvature if necessary. Principles of the perioperative care are shown in Table 1.

Discharge criteria for patients in both groups were the same, including tolerance to fluids and solid diet, adequate oral analgesia, passage of flatus or stool, and no surgical complication, basic self-care ability, and acceptance of discharge.

Clinical outcome

The intestinal function was defined as passage of flatus, morbidity requiring treatment during the first 30 postoperative days, postoperative hospital stay time, and readmis-

sion rate. No patient was lost during the follow-up. General complications were defined as those occurred in the cardiovascular, pulmonary, thromboembolic, urinary systems, while surgical complications were defined as wound complication, anastomotic leak, and bowel obstruction requiring reoperation as previously described^[12].

Statistical analysis

Statistical analysis, based on an intention-to-treat analysis, was performed with the SPSS version 16.0 (Chicago, IL, USA). Mann-Whitney test was used to compare the continuous variables. χ^2 test and Fisher's exact test were used to compare the discrete variables. $P < 0.05$ was considered statistically significant.

RESULTS

Of the 230 enrolled patients (115 in the fast track rehabilitation program group and 115 in the conventional care group), 210 were analyzed (106 in the fast track rehabilitation program group and 104 in the conventional care group). The relevant characteristics of patients and the types of surgery are shown in Table 2. No significant difference was observed in age, ASA status, types of surgery and tumor stages between the two groups.

The intestinal function of patients in the fast track rehabilitation program group and conventional care group became normal 2 d (range, 1-6 d) and 3 d (range, 1-8 d), respectively, after resection of colorectal cancer ($P < 0.01$). The median postoperative hospital stay time was 5 d (range, 2-41 d) and 7 d (range, 3-55 d), respectively, for the patients in the fast track rehabilitation program group and conventional care group ($P < 0.01$). The postoperative rehabilitation was also faster in patients of the fast track rehabilitation program group than in those of conventional care group. On the day of surgery, 11 patients (35%) in the fast track rehabilitation program group and no patient in the conventional care group were able to walk. On postoperative day 1, 56 patients (53%) in the fast track rehabilitation program group and 24 patients (23%) in the conventional care program group were able to walk. On postoperative day 2, 90 patients (85%) in the fast track rehabilitation program group and 61 patients (59%) in the conventional care group were able to walk ($P < 0.01$) (Table 3).

The urethral catheter in 81 patients (81%) of the fast track rehabilitation program group and in 21 patients (20%) of the conventional care group was removed on day 1 after resection of colorectal cancer ($P < 0.05$), and in 97 patients (92%) of the fast track rehabilitation program group and in 47 patients (45%) of the conventional care group on day 2 after resection of colorectal cancer ($P < 0.05$). Urinary retention occurred in 5 patients (5%) of the fast track rehabilitation program group and in 16 patients (15%) of the conventional care group. Urethral catheter was inserted again in 4 patients of the fast track rehabilitation program group and in 12 patients of the conventional care group.

Table 1 Principles of fast track rehabilitation program and conventional care

	Fast track rehabilitation program	Conventional care
Preoperative	Patients and their relatives were informed about the surgical procedure and postoperative course	Patient were educated in the standard manner
Day before surgery		
Bowel preparation	No bowel preparation was performed	Two oral sachets of fleet® bowel preparation
Carbohydrate load	4 units (preOp®)	No
Diet	Last meal 6 h before operation	Last meal at midnight
Day of surgery		
Pre-operative fasting	No, 2 units (preOp®) 2 h before surgery	Yes
Nasogastric tubes	No unless nausea and vomit	Routine placement
Pre-anesthetic medication	No	Oral diazepam 10 mg
Anesthesia	General anesthesia Remifentanyl 1 µg/kg per minute Propofol 2-4 mg/kg per hour Cisatracium 0.15 mg/kg Ondansetron 4 mg Bupivacaine 0.25% 20 mL (incision) Epidural catheter T10-T12 Test: 3 mL 2% lidocaine with epinephrine Bupivacaine 0.5% (6 + 6) mL	General anesthesia Remifentanyl 1 µg/kg per minute Propofol 2-4 mg/kg per hour Cisatracium 0.15 mg/kg Ondansetron 4 mg
Surgical management	Minimal invasive incision Infiltration of surgical wounds with Bupivacaine	Median laparotomy approach No infiltration of surgical wounds with local anesthetic drugs
Surgical drains	No, unless required in circumstances and discarded in early time (usually on postoperative day 1)	Routine placement usually discarded the day before discharge
Early post-operative care	Use of epidural catheter (0.125% Bupivacaine with 2.5 µg/mL Fentanyl) First oral drink 2 h after surgery IV infusion of Ringers lactate 1.5 L/d Mobilization in the evening (> 2 h out of bed)	Analgesia by bolus administration of diclofenac or morphine No oral application scheme IV infusion of Ringers lactate 2.5 L/d No mobilization scheme
Postoperative care		
Day 1 after surgery	Oral intake > 2 L (including 4 units CHL liquids) Semi-solid food intake Stop IV fluid administration Remove urine catheter Expand mobilization (> 6 h out of bed)	Diet increased on daily basis IV fluid administration (2.5 L/d) till adequate oral fluid intake Mobilization according to attending surgeon
Day 2 after surgery	Remove epidural add Diclofenac 3 × 50 mg/d Normal diet Expand mobilization (> 8 h) Plan discharge	Continue as on day 1 till discharge criteria fulfilled
Day 3 after surgery	Continue as on day 2 till discharge criteria fulfilled	Continue as on day 2 till discharge criteria fulfilled

Table 2 Characteristics of patients and their diagnosis

	Fast track rehabilitation group (n = 106)	Conventional care group (n = 104)	P value
Median age (range, yr)	57 (38-69)	55 (40-67)	0.462
Male/female	65/41	60/44	0.393

Death	2	1	0.572

care group ($P < 0.01$). The nasogastric tube was reinserted in 4 patients (4%) of the fast track rehabilitation program group and in 12 patients (11%) of the conventional care group due to nausea and vomit ($P < 0.05$).

No significant difference was observed in re-admission rate between the two groups within 30 d after resection of colorectal cancer. Four patients (4%) in the fast track rehabilitation program group were readmitted due to wound infection, and 9 patients (9%) in the conventional care group were readmitted due to bowel obstruction, vomit and wound infection.

The incidence of complications was 19% in patients of the fast track rehabilitation program group and 38% in those of the conventional care group ($P < 0.05$) during the first 30 postoperative days. One or more complications occurred in 14 patients (13%) of the fast track rehabilitation program group and in 28 patients (27%) of the conventional care group ($P < 0.05$). The overall incidence of general complications was lower in patients of the fast track rehabilitation program group than in those of the conventional care group ($P < 0.05$). The incidence of complications in the cardiac and pulmonary system was also significantly lower in patients of the fast track rehabilitation program group than in those of the conventional care group ($P < 0.05$). A significant difference was observed in surgical complications between the two groups. Two patients died in the fast track rehabilitation program group due to cardiovascular failure and multiple organ failure, respectively. One patient died in the conventional care group due to cardiovascular failure. The types of complications are listed in Table 4.

DISCUSSION

The results of the present study indicate that fast-track rehabilitation program can significantly accelerate the

restoration of gastrointestinal function and reduce the postoperative complications as well as hospital stay time of patients after resection of colorectal cancer. The results of this study show that preoperative education of patients, epidural anesthesia or regional anesthesia^[13], early ambulation and early postoperative oral nutrition are the important predictors for the rehabilitation of patients after resection of colorectal cancer.

Preoperative education of patients is regarded as one of the crucial factors for fast-track rehabilitation. It is necessary to explain the detailed treatment plan, different stages of fast-track rehabilitation program and relevant measures for recovery for the patients in order to make them better understand the importance of fast-track rehabilitation program. Better cooperation of patients can bring better outcomes of fast track rehabilitation program. Generally, since the gastric emptying time of solid meal and fluid is 6 and 2 h, respectively^[14], the patients should be encouraged to have liquid meal 2 h before operation instead of fasting. It has been shown that preoperative oral carbohydrate is safe and can efficiently reduce complications^[15-17].

The role of epidural anesthesia or regional anesthesia in fast-track rehabilitation program should be stressed. Postoperative epidural analgesia can avoid stress-induced neurological, endocrinological and homeostatic changes or the blocking of sympathetic nerve-related surgical stress response, reduce complications such as nausea, vomiting and enteroparalysis after operation, early ambulation, improve the intestinal function and shorten the hospital stay time of patients after resection of colorectal cancer^[18-24]. In this study, epidural analgesia significantly shortened the bedridden time and potentially reduced the cardiopulmonary and thromboembolic complications. The rate of cardiopulmonary and thromboembolic complications was much lower in patients of the fast track rehabilitation program group than in those of the conventional care group ($P < 0.05$).

Early postoperative oral nutrition also plays an essential part in fast-track rehabilitation program. Food intake can stimulate gastrointestinal peristalsis, and early feeding during the first 24 h after surgery promotes the recovery of ileus. It has been illustrated that early postoperative oral nutrition attenuates catabolism and potentially decreases infectious complications^[25,26]. Consistent with this, early postoperative oral nutrition has been suggested as a routine procedure of abdominal surgery^[26]. Enforced postoperative mobilization of patients can reduce protein loss due to long-term bedridden, pulmonary infection and venous thrombosis. In this study, complete analgesia, control of nausea and vomiting, early postoperative oral nutrition and early ambulation efficiently reduced the postoperative complication of ileus and improved the recovery of intestinal function.

In this study, the early removal of gastric tube and urethral catheter decreased not only the infectious complications in cardiopulmonary and urinary systems but also the symptoms of patients. The shortened fasting

time, preoperative carbohydrate load and intraoperative fluid restriction effectively protected against homeostasis in patients after resection of colorectal cancer. The outcome of fast-track rehabilitation program was better than that of conventional care.

Fast track rehabilitation program can improve the symptoms of patients after resection of colorectal cancer better than conventional care, thus benefiting their surgery, anesthesia, pain management, physical therapy and social work. The primary work of fast track rehabilitation program is the preoperative education of patients to make them understand the whole plan and the aim of each stage. Therefore, it is necessary to get the cooperation from nurses, because they need to work professionally and nicely. Although there must be lots of difficulties in fast track rehabilitation program, it is an inevitable stage to test a new set of rules and guidelines.

Recently, laparoscopic surgery, applied in treatment of colorectal and early gastric cancer, can significantly reduce trauma and speed up the rehabilitation of patients after surgery. It was reported that the hospital stay time is shorter and the morbidity and readmission rate are lower after laparoscopic surgery^[27,28]. However, these studies only compared open surgery with laparoscopic surgery rather than laparoscopic surgery with fast-track rehabilitation program^[27,28]. Therefore, further studies are needed to focus on the potential influence of laparoscopy-assisted surgery with or without fast-track rehabilitation program on the recovery of patients after resection of colorectal cancer. Laparoscopic surgery and fast-track rehabilitation program can effectively promote the recovery of patients after resection of colorectal cancer. We believe that laparoscopic surgery in combination with fast track rehabilitation program is significantly advantageous over other procedures for patients after resection of colorectal cancer.

In conclusion, fast track rehabilitation program plays an important role in the recovery of patients after resection of colorectal cancer, which can accelerate the restoration of their gastrointestinal function, decrease their postoperative complications, and shorten their hospital stay time.

COMMENTS

Background

Fast-track rehabilitation program, first reported by Kehlet *et al.*, can reduce the postoperative complications and hospital stay time of patients after resection of colorectal cancer without compromising the surgical outcome. The concept of fast track rehabilitation program has been recently introduced in colorectal surgery. It is basically a multidisciplinary perioperative care strategy for patients after resection of colorectal cancer.

Research frontiers

The previous studies seemed to compare the postoperative complications rather than the general complications of fast track rehabilitation program and conventional care.

Innovations and breakthroughs

The gastrointestinal function, postoperative complications, and hospital stay time of patients after resection of colorectal cancer were studied during their fast track rehabilitation program. The accelerated restoration of gastrointestinal

function and decreased postoperative complications may shorten the hospital stay time of patients after resection of colorectal cancer.

Applications

Surgical care has changed dramatically over the past half century and will continue to improve with the time. Extensive studies on the optimized care will allow us to develop more appropriate perioperative surgical care programs for patients after resection of colorectal cancer.

Terminology

Fast track rehabilitation program, basically a multidisciplinary strategy for patients after resection of colorectal cancer, is to optimize the preoperative, perioperative and postoperative factors for reducing their physiological and psychological stress surgery.

Peer review

This manuscript describes a prospective randomized trial comparing fast track rehabilitation program and conventional care for patients after resection of colorectal cancer. The data are sound support the hypothesis of the authors.

Abstract

Recently, the use of confocal laser endomicroscopy (CLE) in the diagnosis of chronic ulcerative colitis (CUC) was reported. In this brief report we aimed to assess the application of probe-based CLE to characterize colonic mucosa and dysplasia in CUC. The study involved a patient presenting long-standing CUC. Confocal imaging of both the inflamed mucosa, a circumscribed lesion (dysplasia-associated lesional mass), and adjacent colonic mucosa are demonstrated and the correlation between the CLE and histological images. Inflamed mucosa and dysplasia

INTRODUCTION

The term dysplasia-associated lesional mass (DALM) has been adopted to describe the group of endoscopically visible lesions, within the colitic colon (in the course of IBD), that refers to a heterogeneous population of lesions that demonstrate plaque-like, mass, stricture, sessile, or pedunculated morphology, that have an associated dysplasia in the surrounding mucosa^[1-3].

With recent rapid advances in videoendoscopic instrument systems, improved endoscopic skills, and improved detection techniques such as pan-colonic dye spraying, the proportion of lesions that are discovered macroscopically is likely to increase^[4].

Recently, the use of confocal laser endomicroscopy

(CLE) in the diagnosis of chronic ulcerative colitis (CUC) was reported^[5,6].

This report describes the CLE findings in a case of DALM in CUC in correlation with histopathology diagnosis.

CASE REPORT

A 48-year-old woman with a 23 years history of left-sided ulcerative colitis underwent a surveillance colonoscopy.

A mild anemia (hemoglobin level, 110 g/L) with low serum iron levels (210 µg/L; normal value, 53-167 µg/L) and a high erythrocyte sedimentation rate (37 mm/L per hour; normal value, 1-10 mm/L per hour) were the only blood chemistry abnormalities identified.

Colonoscopy revealed a left-sided Mayo CU-1 CUC with a 2 cm plaque-like lesion at the sigmoid colon (Figure 1A and B). A morphological characterization of the lesion with CLE was undertaken.

Probe-based CLE procedure

The procedure was performed using the Cellvizio® Endomicroscopy System (Mauna Kea Technologies, Paris, France) by a Coloflex UHD-type probe (1 µm lateral resolution; 12 frames/s).

This system uses a 2.5-mm catheter probe (Coloflex UHD-type probe) that is inserted through the endoscope-working channel to obtain dynamic imaging of the mucosa. This probe has a field of view of 240 µm × 200 µm, with a lateral resolution of 1 µm. Probe-based CLE (pCLE) imaging data were collected at a scan rate of 12 frames/s with a scanning field of 30 000 pixels. Single video frames were reconstructed into 1 larger static image (4 mm × 2 mm) by a special computer software ("mosaicing" Mauna Kea Technologies).

Five milliliters of 10% sodium fluorescein were injected intravenously before CLE image acquisition as a contrast agent.

Confocal imaging of both the inflamed mucosa, the circumscribed lesion (DALM), and adjacent colorectal mucosa was performed by placing the tip of the probe in direct contact with the target tissue site.

Mucosal biopsy specimens were collected from the observation sites using biopsy forceps. Fixed samples were embedded in paraffin and sectioned transversely, and stained with hematoxylin-eosin to facilitate the comparison between confocal images and histology.

pCLE Images

pCLE imaging of inflamed mucosa showed dilation of crypt openings, more irregular arrangement of crypts, and enlarged spaces between crypt, crypt destruction, and/or crypt fusion and crypt abscess. Microvascular alterations with fluorescein leaks into the crypt lumen (therefore making the lumen brighter than the surrounding epithelium) were observed (Figure 2A and B).

DALM was characterized by "dark" cells, with mucin depletion and goblet cell/crypt density attenuation; the

Figure 1 Conventional "white light" imaging of a plaque-like lesion of sigmoid colon in ulcerative colitis (A) and 0.5% indigo carmine chromoscopy of the lesion (B). The lesion is "unmasked" and clearly delineated.

Figure 2 Confocal (A) and histological (B) images of colonic mucosa showing the switch from normal mucosa to inflamed mucosa. Normal crypt architecture is classically represented by ordered and regular crypt orifices covered by a homogeneous epithelial layer with visible "black-hole" goblet cells within the subcellular matrix (long thin arrows). Inflamed mucosa showing irregular arrangement of crypts, crypt fusion (red circles) and capillaries alterations (short arrows) and inflammatory cells (lymphocytes: long thick arrows). Magnification, × 200.

architectural pattern was irregular, as well as the epithelial thickness, with villiform structures and "dark" epithelial border. The blood vessels were dilated and irregularly-branching, with poor orientation to adjunct tissue, and fluorescein extravasation (Figure 3A and B).

pCLE imaging of colorectal mucosa adjacent to lesion (1 to 2 cm around DALM) showed the switch from the inflamed mucosa, to the neoplastic mucosa as evidenced by DALM (Figure 4).

Figure 3 Confocal images of colonic mucosa evidencing the switch from the inflamed mucosa, to the neoplastic mucosa. Inflamed mucosa (green rectangle) is characterized by dilation of crypt openings, enlarged spaces between crypt, and microvascular alterations with fluorescein leaks into the crypt lumen (white arrow) therefore making the lumen brighter than the surrounding epithelium. Dysplastic mucosa (red rectangle) is characterized by “dark” cells, irregular architectural patterns with villiform structures and a “dark” epithelial border. Histology images show high-power hematoxylin and eosin stain of the tissue sampled, evidencing respectively inflamed area with features suggestive of chronic ulcerative colitis (green rectangle) and low grade dysplasia (red rectangle). Magnification, $\times 200$.

Figure 4 Confocal (A) and histological (B) images of dysplasia-associated lesion mass showing “dark” cells, with mucin depletion and goblet cell/crypt density attenuation; the architectural pattern is irregular, as well as the epithelial thickness, with villiform structures and “dark” epithelial border (red rectangles). There is gross distortion of the vascular architecture with tortuous and dilated vessels (white arrows). The hematoxylin and eosin stain histology shows a low grade dysplasia (red rectangle; hematoxylin and eosin staining; original magnification, $\times 200$).

DISCUSSION

CLE is a new technology that has enabled endoscopists to collect real-time *in vivo* histological images or “virtual biopsies” of the gastrointestinal mucosa during endoscopy.

CLE can be performed currently with 2 devices: one integrated into an endoscope (Pentax, Japan, herein termed

eCLE) and one as a stand-alone probe (herein termed pCLE) capable of passage through the accessory channel of most endoscopes (Cellvizio, Mauna Kea Technologies, Paris, France)^[7-9]. There are no data, at present, comparing pCLE with eCLE to demonstrate the superiority of any one system. pCLE has several advantages and disadvantages compared with eCLE. Advantages include the greater versatility of pCLE probes, which can be used in conjunction with virtually any endoscope (high-resolution endoscopes, NBI, cholangioscope, *etc.*), ad hoc usage (such as when a lesion is detected with a normal endoscope) and acquisition at video frame rate of 12 frames/s. allowing *in vivo* imaging of capillary flow. Disadvantages include a slightly lower resolution (approximately 1 μm compared with 0.7 μm for eCLE) and smaller field of view (240-600 μm).

Recently, the use of eCLE in the diagnosis of CUC was reported. Watanabe *et al.*^[5] and Li *et al.*^[6] reported on real-time inflammation activity assessment by CLE. The inflammation activity assessment includes crypt architecture, cellular infiltration, and vessel architecture. These studies evidenced that images taken with the CLE provided information that was equivalent to conventional histology, differentiating between active and non-active CUC patients during ongoing endoscopy.

Hurlstone *et al.*^[10] assessed the clinical applicability and predictive power of the CLE for the *in vivo* differentiation of ALM and DALM in CUC. The study evidenced that ALM and DALM can be differentiated with a high overall accuracy, enabling the safe selection of patients suitable for endoluminal resection *vs* immediate referral for surgery.

To the best of our knowledge, this is the first report that addressed the application of pCLE for the *in vivo* characterization of colonic mucosa and DALM in a patient with CUC during ongoing videocolonoscopy.

Our study showed that the pCLE system permits high-quality cellular, subsurface vascular and stromal imaging *in vivo*, with an excellent correlation between CLE and standard histopathologic examination for both inflammation and dysplasia in ulcerative colitis.

Post-acquisition specifically-developed software (“mosaicing”, Mauna Kea Technologies) was used to reconstitute the dynamic high-resolution pictures into a larger static image. By the use of mosaicing, the image area could be increased 2- to 4-fold, and image definition could be further enhanced to allow finer detail visualization. As a result of the large static image comprising of many single pictures of a video sequence, evaluation of the examination is easier and more efficient. Thereby, these features lead to an excellent correlation between CLE and standard histopathologic examination (Figures 1-4).

The main aspect of inflamed mucosa consisted of dilation of crypt openings, enlarged spaces between crypt, and microvascular alterations with fluorescein leaks into the crypt lumen (therefore making the lumen brighter than the surrounding epithelium); DALM showed typical neoplastic features of Mainz CLE criteria for prediction of intraepithelial neoplasia^[11] (Figure 4).

In conclusion, this is the first study to address the novel applicability of pCLE for the *in vivo* characterization of mucosal inflammation and dysplasia in CUC. With appropriate training and careful patient selection, CLE imaging may become a suitable imaging modality in patients with CUC. The ability to target biopsies to areas suggestive of dysplasia *in vivo* allows rapid, highly accurate diagnosis “on table”, reducing inappropriate, non-significant histopathology.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organizations]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1144 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 60 countries, including Albania (1), Argentina (8), Australia (29), Austria (14), Belgium (12), Brazil (10), Brunei Darussalam (1), Bulgaria (2), Canada (20), Chile (3), China (69), Colombia (1), Croatia (2), Cuba (1), Czech (4), Denmark (8), Ecuador (1), Egypt (2), Estonia (2), Finland (8), France (24), Germany (75), Greece (14), Hungary (10), India (26), Iran (6), Ireland (7), Israel (12), Italy (101), Japan (112), Jordan (1), Kuwait (1), Lebanon (3), Lithuania (2), Malaysia (1), Mexico (10), Moldova (1), Netherlands (29), New Zealand (2), Norway (11), Pakistan (2), Poland (11), Portugal (4), Romania (3), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (10), South Africa (2), South Korea (32), Spain (38), Sweden (18), Switzerland (11), Thailand (1), Trinidad and Tobago (1), Turkey (24), United Arab Emirates (2), United Kingdom (82), United States (249), and Uruguay (1).

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Membrane microdomains or lipid rafts are known to be highly dynamic and to act as selective signal transduction mediators that facilitate interactions between the cell's external and internal environments. Lipid rafts play an important mediating role in the biology of cancer: they have been found in almost all existing experimental cancer models, including colorectal cancer (CRC), and play key regulatory roles in cell migration, metastasis, cell survival and tumor progression. This paper explores the current state of knowledge in this field by highlighting some of the pioneering and recent lipid raft studies performed on different CRC cell lines and human tissue samples. From this literature review, it becomes clear that membrane microdomains appear to be implicated in all key intracellular signaling pathways for lipid metabolism, drug resistance, cell adhesion, cell death, cell proliferation and many other processes in CRC. All signal transduction pathways seem to originate directly from those peculiar lipid islands, thereby orchestrating the colon cancer cells' state and fate. As confirmed by recent animal and preclinical studies in different CRC

models, continuing to unravel the structure and function of lipid rafts - including their associated complex signaling pathways - will likely bring us one step closer to better monitoring and treating of colon cancer patients.

INTRODUCTION

In recent years, high-speed multidimensional live-cell confocal laser imaging^[1], often combined with combinatorial labeling approaches^[2] and/or subsequent correlative electron microscopy studies^[3], has allowed high-throughput studies that add missing pieces of temporal and spatial resolution and detail to the cell membrane puzzle. At the nanometer length scale, semi-automated transmission electron tomography (TET) has enabled generation of accurate three-dimensional models of the fine architecture of the cell membrane and its associated proteins^[4,5]. Meanwhile, advances in the high-throughput analyses of chemical and molecular biology have allowed researchers to catalogue the lipidomics of the cell with hitherto unseen sensitivity^[6,7], complementing recent computer simulations of lipid membranes^[8,9]. Over the last decade, this

progress in analytical chemistry and in rapid microscopy-based imaging has underpinned the exponential growth in our understanding of the dynamic and multifaceted role of the cell membrane in various physiological processes.

The cell membrane is unquestionably one of the most studied subcellular components in the modern era of cell biology^[10-12]. This is not simply because it is an attractive target for drug designers^[13], but also because it acts as a selective protector of the interior of the cell^[14]. Key regulatory roles for the cell membrane have been demonstrated in cell homeostasis and differentiation, cell death and cell survival pathways, inter- and intracellular signaling, cell development and movement, and trans- and intercellular transport mechanisms^[15,16]. Of special interest are unique lipid domains within the cell membrane that have been shown to be involved, directly or indirectly, in such lipid-mediated cell regulation. These small domains, also known as lipid rafts, were initially described by Palade through the use of electron microscopy^[17] and later carefully identified by Simons *et al.*^[18] through a combined biochemistry and imaging approach. These rafts lie as discrete patches, known as detergent-resistant membrane structures, in the plasma membrane of cells and are rich in sphingolipids and cholesterol^[18,19]. The fatty acid chains of lipids within these rafts tend to be tightly packed, creating ordered lipid domains that float in a sea of poorly-ordered lipids within the membrane^[20]. Lipid rafts are highly dynamic and temperature sensitive, are able to form large clusters and to interact with the cell's internal molecular and structural compartments^[21,22]. From recent studies, it is becoming ever more evident that rafts act as highly dynamic and selective guardians between the cell's external and internal worlds, which makes researchers view them as important structural and molecular targets for altering cell function and behavior (for a review^[23]).

With regard to the biology of cancer, it has been demonstrated that lipid rafts play important mediating roles in cell migration, metastasis, cell survival and tumor progression^[24,25]. The literature of the past five years contains over one thousand original research papers that have studied the role of these peculiar lipid islets in cancer. This illustrates their importance and their perceived potential in future cancer cures and/or as markers for tumor staging and, hence, diagnosis and prognosis. This literature also shows the presence of lipid rafts in almost all existing experimental cancer models, *in vitro* and *in vivo*. The presence and role of rafts have also been highlighted within relevant human and clinical settings^[26,27], including in colorectal cancer (CRC)^[28,29]. Lipid rafts in CRC cells were observed initially in 1998 by Orlandi and Fishman^[30] and studied extensively by many others subsequently (see next section). So far, however, no dedicated paper has addressed "raft biology and pathobiology" in CRC. Here, therefore, we carefully review the current state of knowledge by highlighting some of the pioneering and recent raft studies carried out on different CRC cells and tissue samples.

MEMBRANE MICRODOMAINS IN COLORECTAL CANCER CELLS

Researchers have shown, for example, that lipid rafts in CRC cells act as go-betweens for cell death-mediated signaling^[31,32], as portals for bioactive compounds^[33], and as congregation regions for adhesion proteins and major histocompatibility complex class 1 (MHC-1) molecules^[34]. However, despite the abundance of literature available on the biology and pathobiology of lipid rafts in cancer^[35], only a few dedicated papers presently address the importance of these membrane domains in the process of CRC. While lipid rafts have been thoroughly described in other malignant tumor models such as cancers of the breast, lung and prostate, this does not imply that we should overlook their important role in the onset and development of CRC (see below). Unraveling their structure and function - including their associated complex signaling pathways - could eventually form the basis for future therapeutic interventions.

Labeling and morphometric imaging approaches

Although lipid rafts have been studied extensively through dedicated labeling and microscopy techniques^[36], relatively little is known about their fine structure in CRC cells or tissue at the nanometer scale^[37]. The majority of CRC membrane raft studies use immunofluorescence microscopy, often in conjunction with protein blotting and/or flow cytometry. Microscopic identification of lipid rafts in CRC cells is frequently performed by direct labeling against specific molecular components of membrane rafts^[32,38]; the classic example is the use of fluorescently-labeled cholera toxin against ganglioside II3-N-acetylneuraminosyl-gangliotetraosylceramide (GM1)^[39-41]. Indirect identification approaches are frequently used as well, such as staining against molecular targets or proteins that are supposed to associate with CRC lipid microdomains^[42]. However, combinatorial protein blotting studies on isolated raft protein fractions must be an essential part of this approach to unambiguously identify the association of raft-specific proteins with lipid rafts. The different caveolin (Cav) isoforms - predominantly Cav-1 and Cav-2 - are also popular protein targets for raft detection^[43,44], but should be used with caution because the degree of Cav expression in cancer cells depends on the differentiation status of the cells and the cancer model studied^[35].

Depending on the imaging approach applied, lipid rafts have been reported to range from between 30 and 100 nanometers up to almost one micrometer in size^[20,45,46]. We have applied correlative fluorescence and electron microscopy (CFEM) to confirm that the same holds true for CRC cells^[37]. CFEM analysis of Caco-2 cells labeled for GM1 allowed the direct observation of fluorescently-labeled lipid rafts by light-optical microscopy and by electron microscopy (Figure 1A). We observed that the smaller lipid rafts could be easily resolved under electron microscopy, but could not be clearly seen by confocal imaging. In some

Figure 1 High-resolution imaging of membrane domains in human Caco-2 colorectal cancer cells. These data come from high-resolution correlative fluorescence and transmission electron microscopy (CFEM) studies on whole mounts. Human colorectal cancer (CRC) cells (Caco-2) were cultured on formvar-coated nickel grids and then treated with Triton X-100 in cytoskeleton stabilization buffer, leaving detergent-resistant membranes behind^[37]. These membrane fractions were labeled with the membrane raft marker GM1 CTxB-594 (red) and the actin cytoskeleton was stained with phalloidin-488 (green)^[48]. A: Low-magnification overview of the peripheral cytoskeleton reveals actin-rich lamellipodia and associated filopodial extensions. Note the numerous GM1-positive lipid rafts interspersed throughout the extracted cytoplasm. The corresponding high-magnification CFEM analysis (a1-a3) of one of these lamellipodium-filopodial regions reveals the complex architectural nature of the leading edge, showing an intricate cytoskeleton-rich matrix and the close structural relationship with the lipid rafts (a1). Subsequent TEM analysis of exactly the same region not only allowed us to determine the exact size and shape of lipid rafts, but also provided an accurate idea of whether the rafts were located on top or beneath the lamellipodium: i.e. apical or basal (a2). The corresponding merged information (a3) clearly shows the additional value of applying different imaging techniques on the same cell: the electron-microscope data reveals small detergent-resistant membrane islands that could not be resolved by advanced confocal microscopy. Scale bar, 2 μ m; For the electron tomographic analysis of a detergent-resistant membrane island and the surrounding cytoskeletal matrix (shown in B and C), whole mounts of Caco-2 cells were prepared as outlined under A. Then we performed transmission electron tomography imaging at 1.5° incremental steps under dual-axis tilting (B) and then carried out subsequent segmenting (b1-b4) of the XYZ-tilting series. The single-image slices obtained via the IMOD tomography software show the sample at different heights from bottom to top (b1-b4) spanning a height of about 300 nm; C: An area of the entire tomogram was next selected (c) and a three-dimensional model generated of the membrane raft-cytoskeleton interface (c), showing the close interaction of fine cytoskeletal fibers at the rim of the detergent-resistant membrane.

cases, no fluorescent label could be detected at all, supporting earlier observations regarding the heterogeneous size and composition of lipid rafts^[46,47]. The samples prepared

for CFEM investigation were also readily used for subsequent TET^[48], which generated a stack of virtual XYZ sections through the structure of interest (Figure 1B). When

combined with computer modeling, we obtained a three-dimensional view of the structure at a typical resolution of approximately 5-8 nm (Figure 1C). From these tomographic data, it became apparent that a web of fine cytoskeletal fibers, derived from the surrounding cytoskeletal matrix, accumulates at the circumference of rafts. These cytoskeleton-raft interactions probably indicate that membrane rafts require an intact cytoskeleton lattice for proper functioning of raft-associated subcellular processes^[49].

Raft-mediated cell death

There has been an extraordinary increase in research activity aimed at understanding the mechanisms and processes that underlie cell death, which occurs in different forms. The best-studied cell death mechanisms are apoptosis and necrosis (for a recent review^[50]). Whether by apoptosis or necrosis, cell death is initiated, triggered and regulated by a cascade of signaling pathways that involve different molecules. As we continue to unravel the pathways of cell death, novel findings emerge concerning the complex role that the cell membrane - and in particular rafts and their associated molecules - play in the tightly coordinated process of programmed cell death and cell survival^[25]. A few reports unambiguously illustrate that rafts are key signal transducers when it comes to death of CRC cells. Remacle-Bonnet *et al.*^[51] showed that lipid rafts segregate pro- from anti-apoptotic insulin-like growth factor-I (IGF- I) receptor signaling in various human colon adenocarcinoma cell lines (HT29-D4, HRT-18, HCT-116, HCT-15, COLO-205, SW480, SW620, HCT-8/E11 and HCT-8/E11R1) when exposed to tumor necrosis factor- α (TNF- α). However, the pro-apoptotic effect of IGF-1 was not observed in all CRC cell lines tested, and SW480, SW620, HRT-18 and COLO-205 cells seem to be exceptions. The authors found that the paradoxical pro-apoptotic action of IGF- I is conveyed *via* the phosphoinositide 3-kinase (PI3K)/Akt pathway and that integrity of lipid rafts is necessary for proper anti-apoptotic cell signaling (Figure 2). In contrast, the activation of the Erk 1/2 and p38 MAPK pathways that transmit the IGF- I anti-apoptotic signaling is independent of lipid rafts.

These unexpected findings, obtained by incubating the different cell lines with the cholesterol-depleting agent methyl- β -cyclodextrin (Me- β -CD), showed the complicated functions that lipid rafts can display, depending on the molecules they are exposed to in the tumor microenvironment. Here, lipid rafts acted to precisely regulate whether CRC cells would survive or die. This might also partially explain the different and conflicting data reported in CRC cell death studies.

Another groundbreaking finding comes from a careful comparative *in vitro* and *in vivo* study in which sugar-cholestanol derivatives provoked cell death in COLO-201, HT29 and Colon-26 cells, including Balb/c mice that contain Colon-26 tumors^[38]. In this study, Hahimoto *et al.* showed that chemically-synthesized sugar-cholestanols, with mono-, di- and tri-saccharides attached to cholestanol, are transported into the cell's interior *via* membrane microdomains; however, cholestanol without sugar moi-

eties was not taken up. Biochemical analysis revealed that all N-acetyl-D-glucosamine-based sugar-cholestanols accumulate quite rapidly within the mitochondria of CRC cells, gradually increasing the release of cytochrome C from these organelles within the cytoplasm. Subsequent studies performed with time-pulse DNA ladder fragmentation assays and Western blotting demonstrated that cell death occurred *via* the caspase-9/caspase-3 apoptotic pathway (Figure 2). In their animal studies, the authors validated the potential anti-cancer effect of sugar-cholestanol derivatives when administered intraperitoneally at different time intervals: Balb/c mice showed a significant reduction in tumor growth and had prolonged survival. This is one of the first CRC *in vivo* studies that unambiguously demonstrated the importance of membrane microdomains as a molecular target for cancer therapy (see also next section).

Other studies have shown that food-derived biochemical compounds can induce substantial cell death in CRC. In 2003, resveratrol - a polyphenol found in various food products - was reported to trigger apoptosis in SW480 human CRC cells^[42]. By combining microscopy, cell sorting and protein blotting, the authors established the direct involvement of the caspase-8/caspase-3-mediated apoptotic cascade (Figure 2). Furthermore, resveratrol exposure induced a specific redistribution of the cell death receptor Fas (i.e. CD95) within membrane microdomains, and caused formation of the death-inducing signaling complex. Intriguingly, no interaction between the cell death receptor ligand (i.e. FasL) and Fas was required for the resveratrol-induced cell death. The authors, therefore, postulated that resveratrol, which is abundantly found in grape skin, holds strong potential as a chemoprotective and therapeutic agent for CRC and other malignant tumors. In another study, quercetin - a plant-derived flavonoid, plentiful in apples and red onions - was reported to induce apoptosis in HT-29 and SW-620 cells, although by a different apoptosis signaling pathway^[40]. It was found that quercetin enhanced apoptosis caused by the TNF-related apoptosis-inducing ligand (TRAIL) through redistributing the death receptors (DR) DR4 and DR5 into membrane microdomains (Figure 2). The application of nystatin, a cholesterol-sequestering agent, prevented (1) quercetin-induced clustering of death receptors; and (2) sensitization to TRAIL-induced apoptosis in CRC cells. The involvement of the mitochondrial-dependent death pathway was demonstrated by the activation of related pro-apoptotic molecules and the subsequent release of cytochrome C to the cytosol. These data suggest that membrane microdomain localization of death receptors is probably required for optimal cytotoxicity of quercetin and/or TRAIL.

Cisplatin or cisplatin is a well-known chemotherapeutic drug, widely used to treat various types of cancers. Rebillard *et al.*^[32] demonstrated that cisplatin-induced apoptosis in human CRC cells involves cell membrane fluidification *via* the inhibition of the Na⁺/H⁺ membrane exchanger-1. Inhibition leads to an overall intracellular acidification and the subsequent activation of acidic sphingomyelinase, which generate ceramides that finally affect membrane fluidity. The team also found that this

Figure 2 Scheme outlining the various membrane microdomain-mediated intracellular signaling pathways in colorectal cancer. This diagram summarizes what has been reported to date in the literature about the different intracellular signaling pathways that are mediated by lipid rafts and the implications of these paths for the colon cancer cells' state and fate. Briefly, the different observations of colorectal cancer (CRC) lipid rafts can be generally categorized under the following main topics of investigation: cell death-mediated mechanisms, caveolae in cancer cell growth and function, unique structure-function molecular associations, and intervention studies with bioactive compounds. Note that the text and connector arrows as shown in black are confirmed observations, whereas the gray denotes postulated signaling pathways and/or unknown molecular targets. The lipid bilayer of the cell membrane is depicted in light blue, membrane microdomains or lipid rafts in light purple, and the pear-shaped caveolae associated with these rafts in dark purple. For detailed descriptions of each of the individual cell signaling pathways, refer to the corresponding sections in this paper. The numbers in superscript refer directly to the original published papers. MRP: Multidrug-resistance protein; GlcCer: Glucosylceramide; FADD: Fas-associated protein with death domain; TRADD: Tumor necrosis factor receptor type 1-associated DEATH domain protein; PI3K: Phosphoinositide 3-kinase; AKT: Serine/threonine protein kinase; ERK: Extracellular signal-regulated kinase; MAPK: Mitogen-activated protein kinase; IRS1: Insulin receptor substrate 1; ASK1: Apoptosis signal-regulating kinase 1; SHC: Src homology 2 domain; TNF- α : Tumor necrosis factor- α ; IGF-I: Insulin-like growth factor-1; VDR: Vitamin D receptor; Vit D: Vitamin D; RAF: Proto-oncogene serine/threonine-protein kinase; RAS: Rat sarcoma; Tfr2: The second transferrin receptor; Tf: Transferrin; JNKs: c-Jun N-terminal kinases; ICAM-1: Intercellular adhesion molecule 1; IFN- γ : Interferon- γ ; MHC-I: Major histocompatibility complex 1; FAK: Focal adhesion kinase; ECM: Extracellular matrix; FASE: Fatty acid synthase; SCD-1: Stearoyl-coenzyme A desaturase 1; ACC1: Acetyl-CoA carboxylase; Cav: Caveolin.

rapid increase in membrane fluidity after cisplatin treatment was inhibited by membrane stabilizing agents, such as excess cholesterol or monosialoganglioside-1 treatment. Furthermore, these lipid-interfering compounds prevented the early aggregation of the Fas receptor and of membrane microdomains on the cell surface of HT-29 cells. As a result, significant inhibition of cisplatin-induced apoptosis was observed, without altering the intracellular drug uptake or the formation of cisplatin-DNA adducts. Hence, cisplatin-induced cell death in CRC cells seems to be mediated, in part, *via* the Fas-signaling pathway, the cell death receptors of which reside within lipid rafts (Figure 2). This concept was elegantly demonstrated through a variety of analytical tools, including GM1 labeling studies, in the course of lipid fluidity studies on isolated lipid rafts, and biochemical assays to detect caspase-3 activity and determine the extent of apoptosis.

Caveolin at the raft interface

There is widespread evidence that caveolin proteins associate structurally and functionally with membrane microdomains, interacting closely with numerous microdomain-associated molecules and thereby regulating cell signaling pathways that control cell function and cell fate^[23]. Although all types of caveolins (Cav-1, Cav-2 and Cav-3) are structurally similar and associate with cholesterol and sphingolipids in parts of the cell membrane to form caveolae, Cav-1 and Cav-2 are most prominently upregulated and/or downregulated in oncogene-transformed cells^[35]. However, a certain degree of variability in Cav-1 and Cav-2 expression seems to occur within various classes of cancer and across different types of cells or tissues. Furthermore, the amount of Cav-1 and Cav-2, together with the ultrastructural presence of caveolae, not only depends on the tumor model studied, but also on the stage and grade of

the cancer. This is particularly relevant for CRC in which the expression of Cav-1 mRNA is four to five times lower or two times lower, respectively, for Cav-2 mRNA in HT-29 or in COLO-205 CRC cell lines. These data were obtained by directly comparing the relative expression of caveolins in more than 55 commonly-used human cancer cell lines from different tissues (for an overview^[35]). However, others have demonstrated, *via* classical immunocytochemical staining^[52] and reverse transcriptase-polymerase chain reaction (RT-PCR)^[53] in human colon tumor tissue, that Cav-1 was significantly enhanced compared to normal colon epithelium. In addition, caveolin-mediated raft signaling has been demonstrated to be pivotal in various experimental CRC models, especially in the strong anti-proliferative action of Cav-1. Bender *et al.*^[54] showed that Cav-1 possesses a strong tumor suppression activity in CRC cells, but the exact signaling mechanism responsible is not yet clear (Figure 2). Experiments involving immunoblotting, RT-PCR and microarrays disclosed that expression of Cav-1 in HT-29 and DLD-1 cells delayed or blocked tumor formation in nude mice. Likewise, Cav-1 levels were significantly reduced in colon tumors from human patients. Another interesting finding was that increased levels of Cav-1 were observed in multidrug-resistant HT-29 cells. The authors concluded from their studies that Cav-1 modulates a variety of signaling pathways, but that we still require a better understanding of target molecules affected by the expression of this all-round protein in malignant cells.

Henkhaus *et al.*^[55] demonstrated a direct link between Cav-1-mediated expression and secretion of kallikrein 6 (KLK6) in HCT116 human CRC cells. Sucrose-gradient subcellular fraction analysis revealed that Cav-1 and KLK6 co-localize to lipid rafts. Deactivation of Cav-1 - through interference in the Src-mediated phosphorylation pathway - decreases KLK6. In addition, immunoblotting, ELISA and RT-PCR studies revealed that Cav-1 controls KLK6 expression *via* the Src, Akt and phosphatases (i.e. PP1/PP2A) signaling pathway (Figure 2). Kallikreins are serine proteases, and the various subtypes of kallikreins are considered to hold promise as specific biomarkers for different cancers. Furthermore, once secreted by the cell, these serine proteinases have the ability to degrade the surrounding extracellular matrix (ECM). The authors postulated that KLK6-mediated degradation of the ECM enhances CRC cell invasiveness.

Raft-associated molecular expression

Besides the presence of cell death receptors and caveolar proteins within membrane microdomains, other key molecules have been shown to have close structure-function associations with rafts, thereby controlling a variety of other vital cellular processes in CRC, such as cell adhesion and motility, intracellular transport and cellular exchange, immune tolerance, and numerous hormone-mediated cellular responses^[23]. For example, Baillat *et al.*^[56] demonstrated how focal adhesion kinase (FAK) and Src family protein tyrosine kinases (SFKs) work together in lipid rafts during the initial stage of CRC cell adhesion. It is well known that elevated expression and activity of SFKs in CRC often ac-

company disease progression. In cancer development, tumor cells acquire migration capability and effective homing ability in the body's host environment. Cell adhesion molecules, such as integrins that link components of the ECM with the cytoskeleton, are pivotal during this process. By applying a combination of cell transfection methods, protein-blotting assays and membrane raft ultracentrifugation to Me- β -CD-treated and/or cholesterol-treated SW480 cells, the team found that the formation of raft-associated FAK/Fyn complexes and the activation of Akt-1 *via* PI3K occur simultaneously during early contact with the ECM (Figure 2). Fyn is a tyrosine-specific phospho-transferase and member of the SFKs. Akt-1 is a serine threonine kinase that is considered to be an oncogene and is often activated in human cancers, thereby contributing to tumor progression and metastasis. The team concluded that, during the very early stage of cell adhesion, FAK is transiently co-located with Fyn thereby inducing raft-dependent Akt-1 signaling. This study also showed, for the first time, that FAK in membrane microdomains can act as a signaling intermediate to control various aspects of tumor cell behavior during cell adhesion.

Major histocompatibility complex I (MHC- I) and intercellular adhesion molecule I (ICAM- I) are crucially involved in the functioning of the immune system and are implicated in inflammatory bowel diseases and CRC. Cytokines used in therapy, such as interferon γ (IFN- γ), are known to modulate the expression of MHC- I and/or ICAM- I, so it is no surprise that these cell surface receptors are under investigation in an attempt to cure various gastrointestinal diseases. Bacsó *et al.*^[34] showed that exposing LS-174-T colon carcinoma cells to IFN- γ significantly increased the cell surface density of MHC- I and ICAM- I. Flow cytometric fluorescence energy-transfer measurements of immunolabeled LS-174-T cells and confocal microscopy of GM1-labeled LS-174-T cells revealed that both receptor types cluster in the nanometer range and that amounts of both substantially increase, within GM1-positive membrane microdomains, upon IFN- γ treatment (Figure 2). Moreover, the team found that the relative size of the lipid rafts increased, while the total cell size and membrane surface remained unchanged. Another interesting observation was that MHC- I and ICAM- I form sterically tight hetero-associates such that ICAM-1, with its long protrusion above the cell membrane, can readily bind to a cytotoxic lymphocyte (CTL) and simultaneously MHC- I can favorably present its peptide directly to the CTL. As both receptors are co-localized in lipid rafts, which are considered as pre-formed cell-signaling sites, all steric conditions are present for rapid trans-membrane signal transduction. These data imply that IFN- γ treatment can alter the surfaces of CRC cells to make them better target for CTLs.

Examination of resected tumor tissue has demonstrated that expression of the second transferrin receptor (TfR2) occurs in human colon carcinomas^[41]. These authors also showed the presence of TfR2 in three different CRC cell lines (HT29, HCT116 and SKCO1) as assessed by immunolabeling, flow cytometry and Western blot analysis. This is intriguing given that TfR2 expression in

normal tissues is restricted to the liver, where it mediates cellular uptake of transferrin (Tf)-bound iron. The authors also found evidence that TfR2 expression induces a rapid and pronounced ERK1/ERK2 phosphorylation, indicating involvement of the Ras-dependent ERK1/ERK2 MAP-kinase signaling pathway (Figure 2). This pathway has a central role in controlling cell proliferation and is frequently activated in cancers, including CRC. It was concluded that TfR2 present within lipid rafts of CRC cells might contribute to the growth advantage of these cells.

Recently, Taïeb *et al.*^[57] demonstrated the presence of prominin 1 (CD133) within Caco-2 and HT-29-D4 cells. CD133 is a trans-membrane protein that has been shown, in different experimental tumor models, to make cancer cells transplantable, resistant against radiation therapy, and highly likely to initiate tumors. Researchers also believe CD133-ganglioside interactions are crucial for the recruitment and/or the phenotype of cancer stem cells. For this reason, there is obvious interest in understanding the molecular biology of CD133⁺ cancer cells. With the aid of a novel anti-CD133 antibody, Taïeb *et al.*^[57] demonstrated that CD133-immunolabeling progressively decreased to undetectable levels in postconfluent CRC cell cultures, possibly through ganglioside-mediated epitope masking, because the staining was partially recovered after chemical disruption of lipid rafts. It is noteworthy that the N-terminal epitope of CD133 belongs to a ganglioside-binding domain and that blocking experiments with various gangliosides, including purified GM1, resulted in negative labeling. The authors proposed that synthetic soluble ganglioside analogues, which act as competitors and specifically affect CD133⁺-mediated signaling pathways, deserve thorough evaluation in the development of new therapeutic approaches to CRC.

Bioactive compounds and raft function

Since the mid-1990s, hundreds of papers have examined the interference of drugs, pharmacological agents and other chemical or natural compounds with membrane microdomains^[26]. Recent headway in animal disease models has provided knowledge as to how compounds affect membrane raft function, which might help to cure diseases such as ischemic heart impairment^[58], keratitis^[59] and colitis^[60]. In colorectal studies, findings are limited so far to experimental *in vitro* models (see below). However, despite the limited data, the results all indicate that CRC membrane microdomains appear to be an important entryway for anti-cancer drugs, hormone(-like) molecules and dietary components. As reviewed above (see “Raft-Mediated Cell Death”), the bioactive compounds cisplatin^[32], sugar cholestanol^[38], flavonoids^[40] and resveratrol^[42] have all been shown to possess a strong adverse cellular effect that is mediated *via* membrane raft signaling. Besides these classes of cell death-inducing compounds, other molecules have been described that control CRC cell function and fate.

For instance, in a study of the estrogen-induced vitamin D receptor (VDR) expression model, Gilad *et al.*^[61] elegantly illustrated how vitamin D (Vit D) controls CRC cell proliferation. By combining agents that interfere with lipid

and intracellular signaling with subsequent protein immunoblotting studies, the authors unraveled that the estrogen 17 β -estradiol (E2) binds to estrogen receptors (ERs) confined to lipid rafts or caveolae in HT29 cells, thereby activating the mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK) signaling pathway *via* the protein kinases Ras/Raf. This affected transcriptional activity and finally resulted in upregulation of expression of the VDR gene. The MAPK/ERK pathway links intracellular responses to the binding of hormones and/or cell growth factors to cell membrane receptors (Figure 2). A direct functional association of ERs with lipid rafts was shown by using the cholesterol-binding agent Me- β -CD that blocked ERK phosphorylation concomitantly with VDR upregulation. E2 treatment did not affect proliferation of HT29 cells, while Vit D exposure significantly inhibited cell proliferation, and the combined treatment resulted in potentiation of Vit D activity. This anti-proliferative effect of Vit D, mediated *via* membrane microdomain receptor signaling, again illustrates the significance of lipid rafts in the regulation of tumor growth. It also emphasizes the importance of a well-balanced diet, including the daily intake of essential vitamins such as Vit D abundant in dairy products and fish oils, for controlling health.

Multidrug resistance (MRD) is a major challenge for drug designers and cancer cell biologists. When continuously exposed to chemotherapeutic compounds over long periods, cancer cells tend to acquire MDR by overexpressing proteins that belong to the superfamily of ATP-binding cassette (ABC) transporter proteins. Klappe *et al.*^[62] generated a new HT29^{col} cell line that, during colchicine-induced acquisition of MDR, increases their glucosylceramide (GlcCer) content and upregulates multidrug-resistance protein 1 (MRP-1). The overexpression of sphingolipids, such as GlcCer, appears to be a rather general aspect of MDR cancers and has even been proposed as a candidate marker for MDR⁺ malignant tumor cells. Furthermore, the tightly coordinated upregulation of MRP-1 - a member of the ABC transporter proteins that displays strong drug-efflux properties - and GlcCer were both enriched in lipid rafts (Figure 2). The authors also demonstrated that GlcCer upregulation did not appear to be necessary for MRP-1 function, given the absence of effects of inhibition of GlcCer biosynthesis on MRP-1-mediated drug efflux and cell survival. They, therefore, concluded that GlcCer appears to play a structural role in membrane microdomain organization instead and, as such, might help to accommodate the excess MRP-1 expressed in membrane lipid islets in CRC cells.

The enzyme fatty acid synthase (FAS) synthesizes only saturated fatty acids and overexpression has been shown to be involved in numerous human malignancies, including CRC. Rakheja *et al.*^[28] demonstrated, through gas chromatography and mass spectrometry, a statistically significant increase in saturated C18:0 fatty acid (stearic acid) in colonic adenocarcinoma, compared to adjacent normal colonic mucosa tissue. None of the thirteen patients investigated had received any pre-operative chemotherapy and/or radiotherapy, thereby excluding artifactual read-

ings or false-positive measurements caused by treatment. Although the authors did not present any immunohistochemical data on normal or cancerous tissues, they postulated that the increase in the proportion of saturated fatty acids will most likely affect the functional properties of lipid rafts in CRC cells (Figure 2), and particularly might impair intracellular signaling mechanisms as discussed earlier (i.e. cell growth and cell death). In support of this proposal, it is known that the relative abundance of saturated fatty acids is a principle reason for the liquid-ordered state of lipid rafts and that the inhibition of FASE mainly affects the synthesis of raft-associated lipids. The authors concluded that dietary intervention to normalize the balance between saturated and unsaturated lipids within the cell membranes of colonic mucosa might be seen as a preventive or even therapeutic cure (see next section).

POTENTIAL DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS OF MEMBRANE MICRODOMAINS IN CRC

Many benign and malignant tumors synthesize and secrete compounds (i.e. tumor-associated proteins) that can be detected histopathologically on tissue sections or biochemically by chemical pathology analysis of blood or other bodily fluids. As the majority of these compounds are produced within tumors, they are said to be tumor-derived and so provide direct evidence of the tumor's existence (i.e. they are tumor-associated markers). It is highly probable that determination of raft composition or the detection of raft-associated markers, *via* proteomic and/or lipidomic approaches, could be extremely helpful in diagnosing malignancy in a patient with symptoms, preferably during the early stages of tumor formation^[63,64]. The measured marker concentration or a combination of markers should directly correlate with the mass and/or activity of the tumor, and ideally might even help to fine-tune the formulation and dosages of anti-cancer drugs. Taking the currently available information on CRC rafts into account, the ratio of Cav-1/GM⁺ and/or the presence of other molecules - such as TfR2, CD133 or KLK6 - have proven to be extremely useful candidate cancer markers that could aid in the diagnosis, staging and prognosis of CRC. However, despite initially high enthusiasm when the first experimental tumor marker-based assays appeared, only rarely does a marker exhibit sufficient specificity and sensitivity to be of any practical use in the clinic. While one single marker will not be sufficient to make a reliable diagnosis and prognosis, mass-spectrometry-based lipidomics^[64] seems to hold great promise as a novel diagnostic approach to detect the unique "lipid fingerprint" of cancer cells. When combined with existing biomarker assays, lipidomics brings us one step closer to better monitoring and treating of cancer patients.

As it stands, we still have a long way to go when it comes to implementing our practical knowledge of lipid rafts to treat patients. Although the first animal studies showed much promise - as briefly mentioned before - in helping find a cure for diverse diseases, we still await the

first full translational (pre-)clinical studies for curing diseases by targeting lipid rafts and their associated molecules. This, however, does not mean that raft-mediated therapy is entirely impossible or merely wishful thinking. It is just a reflection of the early days of membrane raft biology. When it comes to cancer and membrane raft-mediated therapeutic intervention, commonalities in proposed therapeutic approaches can be found that are independent of the cancer model studied. The majority of work targets trans-membrane proteins present in lipid rafts that control cell death *via* the programmed pathway (i.e. apoptosis; for a review^[65]). However, this enthusiasm must be tempered by caution, because cancer cells have the ability to change the expression pattern of membrane-associated cell death receptors, depending on their cellular environment and/or progression stage. CRC cells have the ability, for example, to switch between the cell death receptor Fas and its corresponding ligand (i.e. FasL), depending on their microenvironment or the chemokines they meet^[66,67]. A therapeutic intervention that uses smart drug complexes to target several different cell death molecules, including membrane raft-disrupting compounds, therefore is the approach most likely to result in successful outcomes.

Another interesting field concerns the modulation of membrane raft composition *via* dietary intake, or altering lipid synthesis *via* pharmacologic intervention within malignant cells^[68]. Both are meant to change the cholesterol content within the lipid membranes in the hope of impairing the membrane raft signaling that controls tumor development and growth. Altered levels of membrane cholesterol and cholesterol-rich membranes have been shown to influence the aggressiveness and progression of cancers^[69]. In CRC, this approach has a considerable chance of success because of the cancer's position within the digestive tract, which allows clinicians to directly expose the cancer cells to significant amounts of dietary or pharmacological compounds. In animal studies of various tumor models, dietary supplementation with long-chain polyunsaturated fatty acids combined with anti-cancer drugs significantly decreased tumor size and resulted in prolonged survival (for a review^[70]). These fatty acids have been shown to be beneficial in various colon-related diseases, so an important role has been postulated for membrane microdomains in controlling tumor growth; this is currently a topic of active investigation^[29,71]. Other examples of potential dietary therapies, as previously discussed, include the reduction of CRC tumor growth mediated by sugar-cholestanols^[38], or the beneficial effects of polyphenols, found in grape skin and various other food products^[42], or of quercetin, which is present in apples and red onions^[40]. Whatever the ultimate therapeutic approach will be, it is most likely that a combination of drugs, combining classic anti-cancer pharmacological agents with anti-membrane raft compounds, has the best chance for success against the cancer cells' unfortunate ability to change their cell membrane composition to resist anti-cancer drugs. Indeed, it is not inconceivable that the same molecular drift will occur in membrane microdomains of cancer cells after continuous exposure to a certain class of drugs. The quest to identify

stable membrane raft molecular markers and/or target molecules within the different stages of tumor development and progression is the greatest challenge that faces cancer membrane biologists today.

CONCLUSION

Membrane microdomains or lipid rafts in CRC cells appear to be involved in all key cellular regulatory processes that control tumor development, growth, progression and regression. Signaling pathways for lipid metabolism, drug resistance, cell death, cell division and many other processes all seem to diverge from those peculiar lipid islands, thereby orchestrating the cancer cells' state and fate. This demonstrates once more the multifaceted nature of lipid rafts. In the near future, we foresee that manipulating the structural and functional integrity of lipid rafts with anti-cancer drugs might result in the direct inhibition of CRC cell adhesion, the arrest of cancer cell division, or might even totally eliminate cancer cells. One can only dream.

Abstract

Endoscopic ultrasound (EUS) has recently evolved through technological improvement of equipment, with a major clinical impact in digestive and mediastinal diseases. State-of-the-art EUS equipment now includes real-time sono-elastography, which might be useful for a better characterization of lesions and increased accuracy of differential diagnosis (for e.g. lymph nodes or focal pancreatic lesions). Contrast-enhanced EUS imaging is also available, and is already being used for the differential diagnosis of focal pancreatic masses. The recent development of low mechanical index contrast harmonic EUS imaging offers hope for improved diagnosis, staging and monitoring of anti-angiogenic treatment. Tridimensional EUS (3D-EUS) techniques can be applied to enhance the spatial understanding of EUS anatomy, especially for improved staging of tumors, obtained through a better assessment of the relationship with major surrounding vessels. Despite the progress gained through all these imaging techniques, they cannot replace cytological or histological diagnosis. However, real-time optical his-

tological diagnosis can be achieved through the use of single-fiber confocal laser endomicroscopy techniques placed under real-time EUS-guidance through a 22G needle. Last, but not least, EUS-assisted natural orifice transluminal endoscopic surgery (NOTES) procedures offer a whole new area of imaging applications, used either for combination of NOTES peritoneoscopy and intraperitoneal EUS, but also for access of retroperitoneal organs through posterior EUS guidance.

INTRODUCTION

Endoscopic ultrasound (EUS) has evolved in recent years into a technique with a major clinical impact in digestive and mediastinal diseases. Thus, EUS determines a change in the diagnosis in approximately a quarter of patients, as well as a change in management in half of the patients examined^[1]. A major step in the development of the EUS imaging techniques (Table 1) was represented by the appearance of electronic linear EUS scopes, which allowed a significant improvement in image quality, as well as the

development of several EUS-guided or EUS-assisted procedures, which start with the real-time targeted placement of a fine-needle aspiration needle under direct imaging by ultrasound guidance^[2].

REAL-TIME SONO-ELASTOGRAPHY

Technique

Real-time sono-elastography (RTSE) represents a technique which allows the calculation and visualization of tissue strain and hardness based on the average tissue strain in a selected region of interest^[3]. The technique allows the real-time visualization of the calculated strain values (Figure 1A), displayed in a transparent layout over the gray-scale images, in a similar fashion with color Doppler imaging^[4]. Several generations of software led to the improvement of image quality, reduced artifacts, but more important to the possibility of averaging through several cycles and calculation of semi-quantitative values of tissue strain inside a defined region of interest (for e.g. a lymph node or a focal pancreatic mass). By obtaining average hue histogram values inside a region of interest, the system displays the average strain inside a defined region of interest, as a semi-quantitative value that estimates tissue elasticity at that level.

Applications

Several applications were described for RTSE, as a technique that offers additional information as compared with gray-scale EUS images^[5]. The technique allows the selection of the most probable lymph nodes to be malignant, as well as the identification of lymph nodes that are most probable to be benign^[5-7]. This was suggested to be helpful for the selection and guidance of EUS-guided fine needle aspiration (FNA) for staging purposes in lung cancer or other digestive and mediastinal cancers (including esophageal, gastric or pancreatic cancer). EUS elastography was also reported to be useful for the differentiation of focal pancreatic masses, especially in pseudotumoral chronic pancreatitis and pancreatic cancer, in the presence of negative (false-negative) EUS-guided FNA and a strong suspicion of pancreatic cancer^[8-11]. The results of initial studies were recently validated in two multicentre studies^[12,13]. Both studies indicated similar values for sensitivity, specificity, negative predictive value, positive predictive value and overall accuracy (92.6% *vs* 92.3%, 71.7% *vs* 80%, 76% *vs* 77.4%, 90.9% *vs* 93.3% and 87.4% *vs* 89.2%, respectively). It was thus suggested that the overall accuracy of 85-90% of EUS elastography might change current clinical decision making algorithms for the patients with focal pancreatic masses, especially in false-negative cases of EUS-FNA, when the suspicion of pancreatic cancer is still strong^[12]. This warrants a more aggressive approach in negative EUS-FNA cases where EUS elastography suggests a hard mass, with the patients referred directly to surgery or to repeat EUS-guided FNA.

The method was also tested in initial feasibility studies in diffuse pancreatic diseases like early chronic pancreatitis or autoimmune pancreatitis^[14,15].

Future usage of RTSE as a technique that simulates virtual palpation might include distant transmission of information and simulation of tele-palpation by using haptic devices and systems. This could lead to a better educational tool in order to simulate intra-operative palpation, and could also help provide guidance for remote surgical laparoscopic and robotic techniques.

CONTRAST-ENHANCEMENT

Technique

The development and subsequent approval of blood-pool contrast agents was a major step forward for the development of contrast specific ultrasound techniques^[16]. Several contrast agents are clinically available, including Albunex, Levovist and Echovist (first generation), as well as SonoVue, Sonazoid and Optison (second generation), *etc.* All of them are quite safe, without severe complications or long-lasting side-effects. The usage of second-generation microbubble contrast agents further improved the diagnostic capabilities, through a strong increase in ultrasound backscatter and enhancement of echogenicity during the dynamic assessment of small volume and slow velocity blood flow. The advantage of second generation microbubble contrast agents is that they are able to pass through the lungs, thus remaining confined to the intravascular space for a longer time. Also, because of the low solubility they are more stable with favorable resonance at low acoustic pressures, hence longer specific imaging in real-time.

Initial applications used spectral (pulsed) Doppler, color or power Doppler imaging, with contrast agents used as vascular signal enhancers^[17]. Contrast agents can thus rescue non-diagnostic Doppler examinations by increasing the intensity of weak flow signals to detectable levels. The appearance of contrast specific ultrasound modes further allowed the cancellation of tissue signals and utilization of the non-linear response of microbubbles (especially the second generation harmonic). The development of low-mechanical index techniques consequently led to a significant improvement consisting of visualization of the dynamic enhancement pattern in real-time. The main advantage is the absence of motion artifacts caused by cardiac or respiratory movements, including also flash and blooming (overpainting) artifacts.

Conventional imaging applications

One specific use of contrast-enhancement techniques in EUS was to detect low-velocity, low-volume flow of pancreatic tumors, with emphasis on the differential diagnosis between focal pancreatitis and pancreatic cancer^[18-23]. An initial feasibility study in a pig model showed that the use of contrast agents is possible during EUS, leading to improved visualisation of the splanchnic vasculature^[18]. Several studies further showed that contrast-enhanced power Doppler EUS can be successfully used for the differential diagnosis of chronic pseudotumoral pancreatitis and pancreatic cancer, with a sensitivity and specificity higher than 90%, in the presence of hypovascular malignant tumors^[19-23]. An initial study that used Optison in combina-

Table 1 Comparative assessment of new endoscopic ultrasound imaging techniques

EUS technique	Advantage	Disadvantage	Cost	Invasiveness
Real-time sono-elastography	Improved diagnosis of focal pancreatic masses	Assessment in large RCTs needed	Average	Minimal
Contrast-enhanced EUS	Improved diagnosis and staging of focal pancreatic masses	Assessment in large RCTs needed	Average	Minimal
3D-EUS	Moderate improvement of staging in pancreatic area	Limited assessment in clinical applications	Average	Minimal
Optical diagnosis	Improvement of real-time diagnosis	Limited assessment in clinical applications	High	Average
EUS-NOTES	Improvement of therapeutic options	Limited assessment in clinical applications	High	High

EUS: Endoscopic ultrasound; RCTs: Randomized clinical trials; 3D-EUS: Tridimensional EUS; NOTES: Natural orifice transluminal endoscopic surgery.

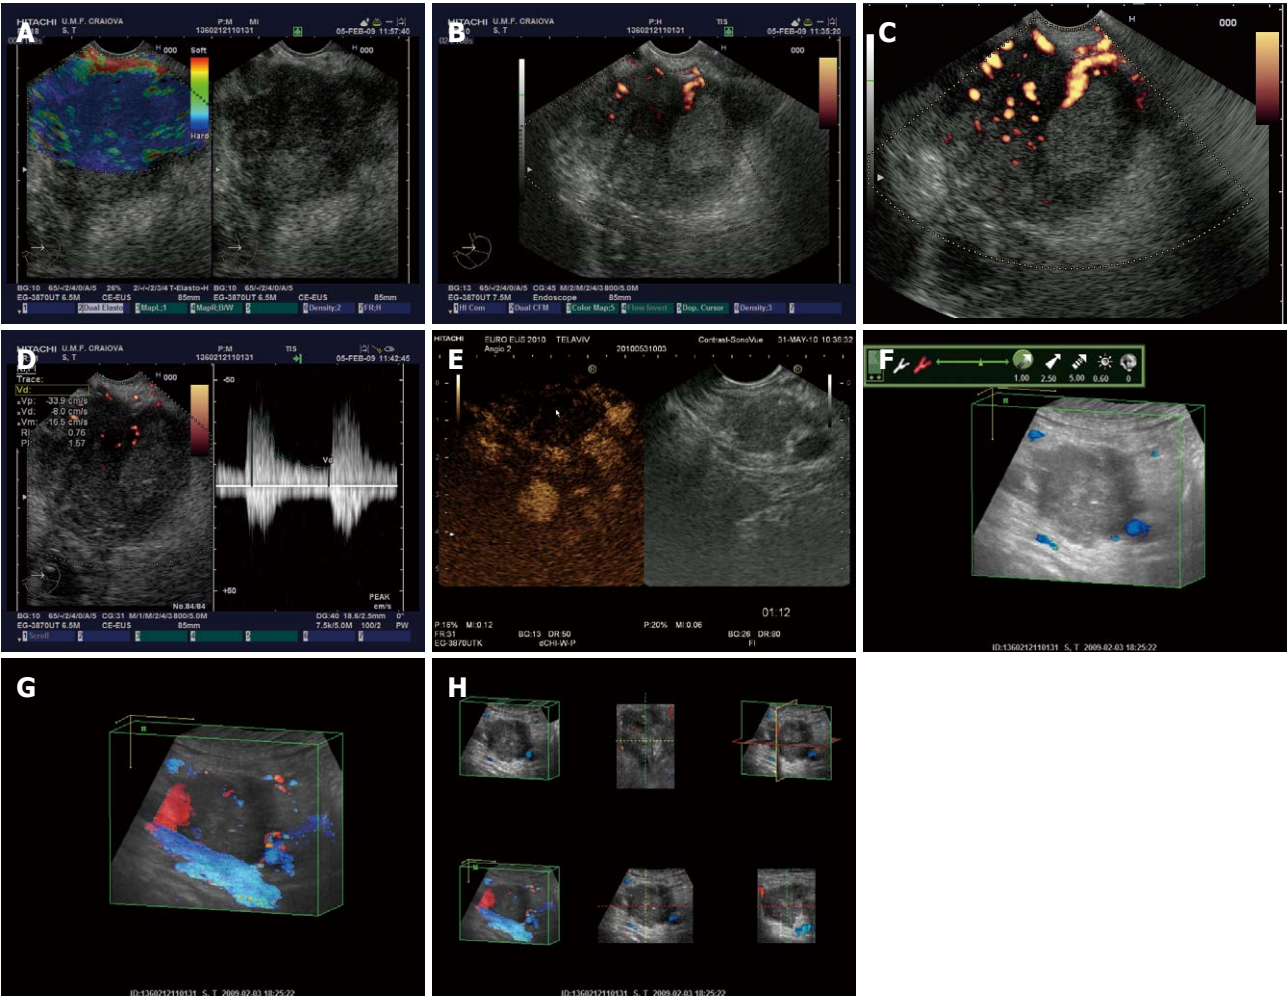

Figure 1 Pancreatic carcinoma at the level of pancreatic head depicted by different endoscopic ultrasound imaging techniques. A: Real-time elastography showing an in-homogenous hard mass; B: Power Doppler endoscopic ultrasound (EUS) without contrast-enhancement; C: Power Doppler EUS after contrast-enhancement with Sono-Vue, showing a hypovascular mass; D: Pulsed Doppler (triplex mode) after contrast-enhancement, with high resistivity and pulsatility indexes of intratumoral arteries; E: Contrast-enhanced low-mechanical index EUS harmonic imaging, showing a hypovascular appearance in the late (venous) phase; F: Tridimensional EUS showing an enhanced image in the opacity mode; G: Transparency mode obtained after contrast-enhancement with Sono-Vue; H: Multiview tridimensional (3D)-EUS display of the pancreatic tumor.

tion with power Doppler contrast-enhanced EUS showed a sensitivity, specificity, positive predictive value, negative predictive value and overall accuracy of 94%, 100%, 100%, 88% and 96%, respectively^[19]. Another study used different criteria for benign and malignant lesions, after contrast-enhancement with Sono-Vue and power Doppler EUS examinations, in combination with pulsed (spectral) Doppler. Malignant lesions were defined by the presence

of irregular arterial vessels over a short distance and no detectable venous vessels inside the lesion, while benign lesions included regular appearance of vessels over a distance of at least 20 mm after injection of SonoVue and detection of both arterial and venous vessels^[20]. By using this methodology, the sensitivity and specificity for the detection of pancreatic cancer were 91.1% and 93.3%, with an overall accuracy of 91.9%. Two other studies con-

firmed these results, although they used Levovist, a first generation contrast agent, in combination with color or power Doppler^[21,22]. By using power Doppler vascularity index values calculated by special software (Figure 1B-D), a recent study also depicted values of sensitivity and specificity of 90.5% and 90.1% for the characterization and differentiation of focal pancreatic masses after contrast-enhancement with Sono-Vue^[23].

Harmonic imaging applications

Contrast harmonic imaging based on the second harmonic, in combination with microbubble specific software, allows an improved visualization of vascular and parenchymal phases, in a similar approach with computer tomography (CT) or magnetic resonance (MR) techniques. However, contrast harmonic imaging has several advantages and differences as compared with contrast-enhanced CT or MR, due to the different pharmacokinetics and containment inside the intra-vascular space of the ultrasound contrast agents^[16]. The most important advantage is that contrast-enhancement patterns can be followed in real-time, with a very good temporal resolution (Figure 1E), while the administration can be easily repeated. Because the technology has recently become available for use during EUS examinations, a few studies have already assessed the value of contrast-enhanced harmonic EUS, based on second-generation contrast agents (mostly Sono-Vue)^[24,25]. An initial feasibility study showed that harmonic EUS with low mechanical index can be used for the differential diagnosis of pancreatic cancer and chronic pancreatitis^[24]. By using a mechanical index of 0.4 in conjunction with harmonic EUS with a low mechanical index, both real-time visualization of finely branching vessels of the pancreas, as well as intermittent parenchymal perfusion images could be obtained^[25]. The method showed irregular “network like” structures inside the pancreatic carcinoma masses, with hypovascular heterogeneous perfusion images in the intermittent mode. This contrasted with focal masses in chronic pancreatitis that were homogenous iso- or hypervascular, thus allowing a correct differential diagnosis.

The use of microbubble contrast agents has already been recommended for the monitoring of the response to anti-angiogenic treatment, because the conventional criteria [Response Evaluation Criteria in Solid Tumors (RECIST) and World Health Organization size criteria] do not show changes in the tumor parenchymal perfusion, hence they cannot predict response in the presence of tumor necrosis without volume changes^[16]. Thus, a clear correlation has been proven between histological intratumoral microvessel density, vascular endothelial growth factor (VEGF) and microvessels visualized by contrast-enhanced ultrasound in pancreatic ductal carcinoma^[26]. By using a similar approach, contrast-enhanced EUS might prove very useful for the real-time monitoring of the efficacy of antiangiogenic treatments. Contrast-enhanced harmonic EUS would certainly have the advantage of an improved resolution and decreased artifacts induced by bowel air and obesity.

Targeted imaging and targeted treatment

Microbubbles used as ultrasound contrast agents can be targeted *in vivo* to specific endothelial cell surface receptors^[27]. Thus, different ligands can be conjugated to the outer surface of microbubbles and directed selectively towards endothelial cells. Microbubbles can be linked with monoclonal antibodies directed against VEGF receptor 2 (VEGFR2), thus allowing the binding to tumor-associated epithelium *in vivo*^[28]. This allows *in vivo* quantification of VEGFR2 expression in tumor vessels, permitting both the selection of antiangiogenic drugs (e.g. bevacizumab which blocks specifically the VEGF-VEGFR2 pathway), as well as monitoring of treatment response. Multitarget quantification and visualization of targeted contrast-enhanced ultrasound microbubbles conjugated with either VEGFR2 and/or $\alpha(v)\beta(3)$ integrin were tested in initial experimental designs^[29]. Targeted treatment during targeted contrast-enhanced ultrasound has been recently proven interesting due to the enhanced cellular uptake of drugs and genes in the presence of ultrasound and especially contrast-enhanced ultrasound, a process called sonoporation^[30]. New microbubbles incorporating chemotherapeutic or gene vectors can be delivered at a cellular level through the formation of transient porosities in the cell membrane.

3D-EUS

Tridimensional EUS was recently reviewed in a separate paper^[31]. The method enhances the spatial understanding of EUS anatomy, especially for the pancreatobiliary area. The method can better depict the relationship with major surrounding vessels, consequently improving staging and resectability, mainly for pancreatic tumors (Figure 1F-H). Contrast-enhanced 3D-EUS can also be performed, allowing a better calculation of the vascular index that might offer important prognostic information, linked with the status before and after antiangiogenic treatment.

REAL-TIME OPTICAL DIAGNOSIS

Real-time optical pathological diagnosis might be achieved based on recent advances in single fiber-based optical techniques, the best example being confocal laser endomicroscopy^[32]. Miniaturization of a confocal laser endomicroscopy miniprobe allowed the EUS-guided placement of a miniprobe through a 22G needle, inside different organs/lesions located in the vicinity of the digestive tract, e.g. pancreas, spleen, adrenal, liver, *etc.* The method has been shown to be feasible, yielding high quality confocal laser endoscopy images, equivalent of real-time histopathology images.

EUS-NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY

The combination of EUS and natural orifice transluminal endoscopic surgery (NOTES) has already been described as a combination of NOTES peritoneoscopy and intra-peritoneal EUS through transgastric and transcolonic ap-

proaches^[33]. Thus, intraperitoneal EUS is considered safe and feasible, allowing adequate visualization of 4 sections of liver. Although objective landmarks for EUS were absent, intraperitoneal EUS could replace laparoscopic US, while NOTES peritoneoscopy can successfully replace laparoscopy. EUS-guided NOTES procedures were proven to be useful in a comparative sequential study which assessed mediastinoscopy/thoracoscopy, gastrojejunostomy and adrenalectomy^[34]. EUS-guided access was useful mainly to obtain initial access or to identify structures in difficult areas, especially in the mediastinal or retroperitoneal regions. Furthermore, both an anterior and a posterior approach of the pancreas are possible through EUS-NOTES procedures, indicating a possible role for these combined techniques^[35]. The aim was to improve pancreatic cancer staging of borderline cases and minimal invasive therapy of pancreatic diseases. Peritoneoscopy based on a EUS-assisted anterior transgastric approach, as well as EUS-guided posterior transgastric access to the pancreas, were both shown to be possible in this small non-survival animal study. Different therapeutic procedures like gastrojejunostomies and cholecysto-gastrostomies were also shown to be possible after initial EUS-assisted procedures. Future survival studies with randomized design should establish clearly the clinical role of these procedures.

CONCLUSION

EUS reached maturity as an imaging technique, as compared with the initial description in 1980. With a superior resolution as compared with cross-sectional imaging and with the addition of recent techniques like real-time sonoelastography, contrast-enhancement and 3D reconstructions, EUS seems likely to represent the technique of choice for early diagnosis, staging and stratification of prognosis. EUS-guided FNA or EUS-assisted procedures are also considered procedures of choice for the pathological confirmation of advanced cases, as well as for targeted treatment procedures. All of these procedures lead to a significant clinical impact of EUS, especially due to the improved clinical decision making algorithms, which nowadays incorporate routine EUS-guided or EUS-assisted procedures. The transition of these procedures to real-time optical diagnosis might offer additional value, allowing the immediate initiation of minimal invasive therapeutic procedures. Also, the appearance of combined EUS-NOTES procedures might enhance the safety and success of recent NOTES applications.

Abstract

Gastrointestinal tract is the most common extranodal site involved by lymphoma with the majority being non-Hodgkin type. Although lymphoma can involve any part of the gastrointestinal tract, the most frequent sites in order of its occurrence are the stomach followed by small intestine and ileocecal region. Gastrointestinal tract lymphoma is usually secondary to the widespread nodal diseases and primary gastrointestinal tract lymphoma is relatively rare. Gastrointestinal lymphomas are usually not clinically specific and indistinguishable from other benign and malignant conditions. Diffuse large B-cell lymphoma is the most common pathological type of gastrointestinal lymphoma in essentially all sites of the gastrointestinal tract, although recently the frequency of other forms has also increased in certain regions of the world. Although some radiological features such as bulky lymph nodes and maintenance of fat plane are more suggestive of lymphoma, they are not specific, thus mandating histopathological analysis for its definitive diagnosis. There has been a tremendous leap in the diagnosis, staging and management of gastrointestinal lymphoma in the last two decades attributed to a better insight into its etiology and molecular aspect as well as the knowledge about its critical signaling pathways.

INTRODUCTION

Gastrointestinal tract is the most common extranodal site involved by lymphoma accounting for 5%-20% of all cases^[1]. Primary gastrointestinal lymphoma, however, is very rare, constituting only about 1%-4% of all gastrointestinal malignancies. Gastrointestinal lymphoma is usually secondary to the widespread nodal diseases. Although virtually lymphoma can arise from any region of the gastrointestinal tract, the most commonly involved sites in term of its occurrence are the stomach followed by small intestine and ileocecal region^[2]. Histopathologically, almost 90% of the primary gastrointestinal lymphomas are of B cell lineage with very few T-cell lymphomas and Hodgkin lymphoma. Certain histological subtypes have been noted to have a relative predilection site as mucosa-associated lymphoid tissue (MALT) lymphoma in stomach, mantle cell lymphoma (MCL) in terminal ileum, jejunum and colon, as well as enteropathy-associated T-cell lymphoma (EATL) in jejunum, and follicular lymphoma (FL) in duodenum with a geographic variation in its distribution^[3]. Multifocality, however, has been noticed particularly in MALT lymphoma and follicular lymphoma. Certain risk factors have been implicated in the pathogenesis of gastrointestinal lymphoma including *Helicobacter pylori* (*H. pylori*) infection, human immunodeficiency

virus (HIV), celiac disease, *Campylobacter jejuni* (*C. jejuni*), Epstein-Barr virus (EBV), hepatitis B virus (HBV), human T-cell lymphotropic virus-1 (HTLV-1), inflammatory bowel disease and immunosuppression^[4,5]. Marker expression and translocations of common histological types of gastrointestinal lymphoma are depicted in Table 1.

Dawson's criteria are used for labeling primary gastrointestinal lymphoma, that include (1) absence of peripheral lymphadenopathy at the time of presentation; (2) lack of enlarged mediastinal lymph nodes; (3) normal total and differential white blood cell count; (4) predominance of bowel lesion at the time of laparotomy with only lymph nodes obviously affected in the immediate vicinity; and (5) no lymphomatous involvement of liver and spleen^[6]. Ann Arbor staging with Musshoff modification is commonly employed to stage gastrointestinal lymphoma and the international prognostic index has been used to define the prognostic subgroups and Paris staging has increasingly gained its significance. Accurate diagnosis and staging of gastrointestinal lymphoma are detrimental for the stratification of treatment in this heterogeneous group of malignancies. The different procedures employed for the pre-treatment staging include endoscopic ultrasound (EUS), endoscopic biopsies, computed tomography (CT), magnetic resonance imaging (MRI), 18F-fluorodeoxyglucose positron emission tomography (FDG-PET) or molecular markers^[7,8]. Contrast-enhanced techniques and functional imaging such as perfusion CT can also help the monitoring, assessment, and prediction of response. New promising techniques such as hybrid PET-CT imaging and new PET tracers like 18F-fluoro-thymidine may significantly benefit the overall management of lymphomas^[9].

In the following sections, the commonly involved sites of gastrointestinal lymphoma and its clinical, pathological and radiologic features are discussed with stress laid on the different histological subtypes based on the predilection. The characteristic features of gastrointestinal lymphoma in different regions of gastrointestinal tract are shown in Table 2.

CLINICAL/PATHOLOGICAL/IMAGING CHARACTERISTICS

Oropharyngeal lymphoma

The head and neck region is the second most common site for extra-nodal lymphoma accounting for 10%-15% of all cancers in this region. Approximately 2.5% of all malignant lymphomas originate from the oral and paraoral region, and the majority of them in the Waldeyer's ring include adenoids, palatine tonsils, base of tongue and oropharyngeal walls. Tonsil is the most frequently involved site (> 50%) of tumors, followed by nasopharynx and base of tongue^[10]. Several factors are known to increase the risk of oropharyngeal lymphoma including EBV. The affected patients are usually at the age of over 50 years with a predilection of males. The most common clinical presentations of oropharyngeal lymphoma include airway obstruction, hearing pain, progressive enlarging painless local mass, dysphagia and foreign body sensation in the

throat. Cervical lymphadenopathy is present in over 50% patients with tonsillar lymphoma^[11].

More than 80%-90% of oropharyngeal lymphomas belong to the B-cell lineage of non-Hodgkin lymphoma (NHL)^[12]. Diffuse large B-cell lymphoma (DLBCL) is the most common type of primary oral and paraoral NHL with a small percentage of thymic T-cell type. Histologically, DLBCL, composed of intermediate-large cells which may be noncleaved, cleaved and immunoblastic, shows B-cell lineage with expression of pan-B-cell antigens (CD19, CD20, CD22, CD79A, and PAX5/BSAP), and is less commonly positive for germinal centre cell markers (CD10 and BCL6) and negative for T-cell antigens. A small number of cases show a translocation between the *BCL-2* gene on chromosome 18 and the *IgH* gene on chromosome 14, t (14;18)^[13]. Other lymphomas involving the Waldeyer's ring include 15% B-cell lymphomas in extranodal marginal zone of MALT, 8% peripheral T-cell lymphomas, 6% follicular lymphomas, and 3% MCLs. Hodgkin lymphoma (HL) involving the oropharynx is very rare accounting for about 1%-5% of all Hodgkin diseases. The majority of oropharyngeal HL are of lymphocyte predominant and nodular sclerosis type on histopathology with a common immunophenotype of Reed Sternberg cells positive for CD15, CD30 and negative for CD45, CD20, and EMA, which can rule out the diagnosis of NHL^[14].

Radiologically, oropharyngeal lymphoma typically appears in barium studies as a lobular mass near the base of tongue in the palatine fossa with the overlying mucosa usually being nodular. The appearance of oropharyngeal lymphoma can be hard to differentiate from more common pharyngeal carcinomas. Because the signal intensity of lymphoma is similar to that of normal tissue, the MR signal characteristics cannot reliably show the early lymphomatous involvement at these sites. CT or PET with FDG and CT (PET/CT) has proved their usefulness both in diagnosis and staging of the disease and in assessment of its response to therapies^[15]. Certain features that may favor the diagnosis of NHL on imaging are the short clinical history and a large homogeneous mass which displaces rather than invades local structures and large homogeneous non-necrotic cervical nodes^[16].

Esophageal lymphoma

The esophagus is a rarely involved site, accounting for < 1% of all gastrointestinal lymphomas. Esophageal involvement usually results from metastasis from cervical or mediastinal lymph nodes or extension from gastric lymphoma. Primary esophageal lymphoma is extremely rare, with less than 30 cases reported in the literature^[17-19]. The majority are the DLBCL type of NHL. Only few cases of MALT lymphoma, MCL, T-cell lymphoma and HL involving the esophagus have been reported^[19-22]. The etiology of esophageal lymphoma is unknown and the role of EBV in its pathogenesis is controversial. It has been shown that esophageal lymphoma is most common in immunocompromised patients, with HIV infection as a probable risk factor^[17]. The age of presentation is variable. The common symptoms

+: ≥ 90% positive; +(-): > 50% positive; -(+): < 50% positive; -: < 10% positive cases. MALT: Mucosa-associated lymphoid tissue; EATL: Enteropathy-associated T-cell lymphoma; EBV: Epstein-Barr virus.

of patients with esophageal lymphoma include dysphagia, odynophagia, weight loss, chest pain or present as a result of complications such as hemorrhage, obstruction or perforation with a tracheoesophageal fistula. Constitutional B symptoms (fever, night sweats) are not typically present.

Almost all cases of primary esophageal lymphoma are DLBCLs with positive surface markers of tumor cells on immunofluorescent staining for immunoglobulin G and κ light chain. MALT lymphoma of the esophagus, however, unlike that of stomach, is not associated with *H. pylori*. HL of the esophagus is extremely rare. Follicular lymphoma affecting the esophagus is a part of multifocal presentation in the gastrointestinal tract.

Radiological and endoscopic findings in esophageal lymphoma vary greatly and are nonspecific, which poses diagnostic challenges when it is differentiated from other benign and malignant lesions. Radiographic patterns of esophageal lymphoma, described in the literature^[18-20], include stricture, ulcerated mass, multiple submucosal nodules, varicoid pattern, achalasia-like pattern, progressive aneurysmal dilatation, and tracheoesophageal fistula formation, and none of them is diagnostic. The morphological features seen at endoscopy are nodular, polypoidal, ulcerated or stenotic^[21]. EUS has gained clinical acceptance for the assessment of lymphoma and preoperative staging, because it can accurately depict the structural abnormalities and depth of invasion of the lesions. EUS findings, however, are not pathognomonic, with presentation varied as anechoic, hypoechoic or even hyperechoic masses^[22]. CT findings in esophageal lymphoma are nonspecific and not diagnostic, with features such as thickening of the wall mimicking other common tumors, such as esophageal carcinoma. CT, however, they are valuable for the evalua-

tion of the extraluminal component of esophageal mass, its mediastinal extension, fistula formation, and status of lymph nodes, thus playing a role in staging disease, assisting in stratification of available treatment modalities, evaluating treatment responses, monitoring disease progression, and detecting relapses^[23]. Recently, incorporation of PET/CT has emerged as an indispensable tool in staging the disease and following up the patients with extranodal involvement of Hodgkin's and non-Hodgkin's lymphoma, with an increased sensitivity and specificity. Diffuse large B-cell non-Hodgkin lymphoma of the esophagus is manifested as circumferential thickening of the wall, with diffuse increased FDG uptake. However, the intensity of FDG uptake in lymphoma is influenced by various intrinsic tumor factors such as histological features and grade, as well as various extrinsic factors. FDG PET/CT can also detect the indolent lesions that are undetectable on conventional cross-sectional imaging^[24].

Gastric lymphoma

Stomach is the most commonly involved site (60%-75%) in gastrointestinal tract followed by small bowel, ileocecal region and rectum^[25]. Gastric lymphoma accounts for 3%-5% of all malignant tumors of the stomach^[26]. Although the incidence of gastric carcinoma has been reduced, the incidence of primary gastric lymphoma is increasing^[27]. *H. pylori* play a role in the development of most MALT lymphomas. However, its exact mechanism has not been fully understood, although a chronic inflammation may enhance the probability of malignant transformation via B cell proliferation in response to *H. pylori* mediated by tumor-infiltrating T cells^[28]. *H. pylori* may play a similar role in development of DLBCL and few studies have shown

Table 2 Characteristic features of gastrointestinal lymphomas

Region	Age (yr)	GIL (%)	Sex	Predilection site	Etiological/risk factors	Presenting symptoms	Common pathological subtypes	Radiographic features
Oropharyngeal	> 50	-	M > F	Tonsil, nasopharynx ¹ , base of tongue	EBV	Dysphagia, dyspnea, painless mass, ulcer, oral/hearing pain, B symptoms rare	DLBCL, EMZL/MALT, PTCL, FL, MCL, ENKL, HD	Lobular mass, ulcers
Esophagus	Variable	< 1	-	Mid and lower third	EBV, HIV	Dysphagia, odynophagia, weight loss, epigastric/chest pain, pneumonia, bleeding rare, B symptoms rare	DLBCL, MALT lymphoma, HD, MCL, T-cell lymphoma	Stricture, ulcerated mass, submucosal nodules, varicoid-like, achalasia-like, aneurysmal, fistula formation
Stomach	> 50	60-75	M > F	Antrum	<i>H. pylori</i> (MALT lymphoma), HTLV-1, HBV (DLBCL), EBV, HCV	Epigastric pain, dysphagia, nausea, vomiting, weight loss, abdominal mass, gastrointestinal bleeding, obstruction, perforation, B symptoms rare	DLBCL, MALT, PTCL	Ulcers, polypoid mass, thickened fold, mucosal nodularity, linitis plastica-like
Small intestine	Variable	20-30	Usually, M > F	Ileum, jejunum, duodenum, multiple sites	Celiac disease (EATL), <i>C. jejuni</i> (IPSID), EBV, HIV/AIDS	Abdominal pain, nausea, vomiting, weight loss, GI bleeding, obstructive symptoms, intussusceptions, perforation, diarrhea (in IPSID), B symptoms rare	DLBCL, MALT, EATL, MCL, Burkitt lymphoma, FL, IPSID, PTCL, ENKL	Polypoid mass, multiple nodules, infiltrative form, ulcer, excavation, fistulization, extraluminal mass, mucosal thickening, strictures
Colon/rectum	50-70	6-12	M > F	Caecum, ascending colon, rectum	Celiac disease (EATL), EBV, <i>H. pylori</i> (MALT lymphoma)	Abdominal pain, weight loss, abdominal mass, lower GI bleeding, obstruction, perforation	DLBCL, MALT, EATL, MCL, PTCL, Burkitt lymphoma	Polypoid mass, ulcers, mucosal nodularity, cavitory mass, mucosal thickening, strictures, aneurysmal

¹Included here though usually not applicable. GIL: Gastrointestinal lymphoma; EBV: Epstein Barr virus; DLBCL: Diffuse large B cell lymphoma; EMZL: Extranodal marginal-zone lymphoma; PTCL: Peripheral T cell lymphoma; FL: Follicular lymphoma; EATL: Enteropathy-associated T-cell lymphoma; MCL: Mantle cell lymphoma; IPSID: Immunoproliferative small intestinal disease; HD: Hodgkin's disease; HTLV-1: Human T-cell lymphotropic virus-1; HCV: Hepatitis C virus; HBV: Hepatitis B virus; *H. pylori*: *Helicobacter pylori*; *C. jejuni*: *Campylobacter jejuni*; HIV: Human immunodeficiency virus; AIDS: Acquired immune deficiency syndrome; ENKL: Extranodal NK/T-cell lymphoma.

complete remission after eradication therapy alone^[28]. It has been shown that individuals with positive HBsAg have an increased risk of developing NHL^[29]. It was reported that HBV plays a role in the development of B-cell NHL^[30]. In contrast, primary gastric lymphoma with a T-cell phenotype is relatively rare, accounting for only 7% of primary gastric lymphomas in HTLV-1 infected endemic areas and a relatively large number of such cases are secondary gastric involvement of adult T-cell leukemia. Primary gastric T-cell lymphoma without HTLV-1 infection is rare, and sporadic cases have been reported^[31]. The age of most gastric lymphoma patients is over 50 years with a relative predilection in males. Clinical symptoms of gastric lymphoma are nonspecific and indistinguishable from other benign and malignant conditions. The most common complaints of gastric lymphoma patients are epigastric pain, weight loss, nausea and vomiting. Occasionally, an abdominal mass is palpable. Lymphadenopathy is rare and its patients often have no physical signs. Perforation, bleeding, or obstruction is very uncommon. Unlike nodal lymphoma, B constitutional symptom is not common.

Although all histological kinds of nodal lymphoma can arise from the stomach, the majority of them are of the B-cell origin, and MALT lymphoma and DLBCL ac-

count for over 90%. MALT lymphoma comprises up to 50% of all primary lymphomas involving the stomach. Histologically, the most significant finding is the presence of a variable number of lymphoepithelial lesions defined by evident invasion and partial destruction of mucosal glands by the tumor cells. MALT lymphoma shows the immunophenotype of B cells in the normal marginal zone of spleen, Peyer's patches and lymph nodes. The tumor B-cells can express the surface immunoglobulin and pan-B antigens (CD19, CD 20, and CD79a), the marginal zone-associated antigens (CD35 and CD21, and lack CD5, CD10, CD23) and cyclin D1. MALT lymphoma can be divided into *H. pylori* positive or negative based on the presence of *H. pylori*. *H. pylori* negative MALT lymphoma tends to have a higher positive rate for t (11;18) (q21;q21) translocation than *H. pylori* positive MALT lymphoma^[32]. DLBCL, a heterogeneous group of tumors which are clinically, histologically, immunophenotypically, cytogenetically variable, can be divided into 3 subgroups, namely germinal-center B-cell-like, activated B-cell-like, and primary mediastinal DLBCL according to the gene expression patterns with each having a different prognostication. The most commonly seen translocations as mentioned earlier include t (14;18) (q32;q21) with BCL2-rearrange-

ment, t (3;14) (p27;q32) with BCL6-rearrangement and t (8;14) (q24;q32) with MYC rearrangement, respectively. Variability has been observed in CD45, CD5 and CD10 expression, with the CD10 expression in particular referred as a prognostic indicator^[33].

Endoscopy cannot distinguish gastric lymphoma from the more common gastric carcinoma. The three main patterns that can be recognized at endoscopy include ulceration, diffuse infiltration, and polypoid mass, which are, however, not specific^[34]. Endoscopy, however, is an indispensable tool for the initial diagnosis and follow-up of cases as well as for obtaining biopsy specimens. EUS can assess the extent of lesion and its invasion. Lesions are usually hypoechoic although few hyperechoic cases have been reported^[34]. Infiltrative carcinoma tends to have a vertical growth in gastric wall, while lymphoma tends to show mainly a horizontal extension and more involvement of perigastric lymph nodes^[35]. EUS is highly accurate in detecting the depth of lymphomatous infiltration and the presence of perigastric lymph nodes, thus providing additional information for treatment planning, and can differentiate lymphoma from carcinoma both in early stage and in advanced stage^[36].

Radiographic patterns of gastric lymphoma observed in double-contrast UGI studies include ulcers, polypoid mass, thickened fold, mucosal nodularities or infiltrating lesions, which are not conclusive, thus posing a diagnostic challenge while differentiating from other malignant and benign lesions, hence requiring pathological confirmation. Preservation of gastric distensibility and pliability, despite the extensive infiltration with gastric fold thickening, is a finding more suggestive of lymphoma. Gastric wall thickening is much less severe in low-grade lymphoma than in high-grade lymphoma on CT images, and abdominal lymphadenopathy is less common in low-grade lymphoma. Preservation of the fat plane with no invasion of surrounding structures may be suggestive of lymphoma, although it is, however, not specific. Transpyloric spread and extension of lymphadenopathy below the renal hilum and the presence of bulky lymph nodes are more suggestive of lymphoma than carcinoma^[37]. The patterns of gastric involvement observed can be segmental or diffuse infiltration, or localized polypoid. Tumor infiltration is usually homogeneous although areas of low attenuation may be present in larger tumors. Diffuse infiltration involving more than 50% of the stomach and segmental infiltration are the most common features of gastric NHL on CT images^[38]. The MRI features include irregularly thickened mucosal folds, irregular submucosal infiltration, annular constricting lesion, exophytic tumor growth, mesenteric masses and mesenteric/retroperitoneal lymphadenopathy. The tumors are usually homogeneous and intermediate in signal intensity on T1-weighted images. Heterogeneously increased signal intensities are noted on T2-weighted images. The enhancement is usually mild-moderate after intravenous administration of gadolinium dimeglumine^[39]. Application of 18F-FDG PET/CT in diagnosis of gastric lymphoma is challenging due to the physiologic FDG activity in the stomach and variability

in the degree of uptake in various histologic subtypes. It was reported that aggressive gastric lymphoma has more intense uptake than low grade MALT lymphoma^[40].

Small intestine lymphoma

Primary malignant tumors of the small intestine are very rare, accounting for less than 2% of all gastrointestinal malignancies. Lymphoma constitutes 15%-20% of all small intestine neoplasms and 20%-30% of all primary gastrointestinal lymphomas. Ileum is the most common site (60%-65%) involving small intestine lymphoma followed by jejunum (20%-25%), duodenum (6%-8%) and other sites (8%-9%)^[41]. The age of presentation varies with the histological subtype of lymphoma. The clinical presentation of small intestinal lymphoma is non specific and the patients have symptoms, such as colicky abdominal pain, nausea, vomiting, weight loss and rarely acute obstructive symptoms, intussusceptions, perforation or diarrhea^[42].

Primary small intestine lymphomas that are more heterogeneous than those in stomach include MALT lymphoma, DLBCL, EATL, MCL, follicular lymphoma and immunoproliferative lymphoma, and can be divided into immunoproliferative small intestinal disease (IPSID)^[43]. IPSID, also known as alpha chain disease, is a MALT-associated lymphoma due to *C. jejuni* infection and characterized by "centrocyte like" mucosal infiltration with plasma cells that secrete monotypic and truncated immunoglobulin, a heavy chain lacking of an associated light chain. IPSID mainly affects older children and younger adults with a predominant involvement of proximal small intestine, the symptoms of its patients are diarrhea and abdominal pain^[44]. MCL primarily affects individuals at the age of over 50 years, and involves terminal ileum and jejunum appearing as numerous polyps, hence called multiple lymphomatous polyposis^[45]. The prototype MCL is positive for pan B-cell antigens, although few cases of CD5-MCL have been reported^[44]. Cytogenetic analysis of MCL has shown the rearrangement of bcl-1 locus on chromosome11 due to t (11;14) (q13;q32) translocation, accompanying cyclin D1 antigen overexpression. Few cases of cyclin D1-negative MCL, however, have been reported with up-regulated cyclin D2 or D3^[46]. Burkitt's lymphoma mainly affects children and is associated with EBV and HIV/AIDS^[47]. T cell lymphoma of the small intestine accounts for approximately 10%-25% of all primary intestinal lymphomas primarily occurring as enteropathy-associated T cell lymphoma, and most of them are often complicated by Crohn's disease^[48,49]. Although follicular lymphoma is very rare, it expresses SIg (frequently IgM) and pan B-cell antigens with CD10 and bcl-2 expressed in almost 90% of cases. It is negative for CD5 and cyclin D1 differentiating it from MCL. IgH/BCL2 rearrangement with t (14;18) (q32;q21) can be demonstrated by FISH or PCR analysis in the majority of cases^[50]. Lymphocytic lymphoma (chronic lymphocytic leukemia) rarely arises primarily from the gastrointestinal tract.

Evaluation of the small intestinal lymphoma has been revolutionized since the introduction of capsule endoscopy (CE) and double-balloon technique of push-and-

pull enteroscopy which is capable of enabling biopsies as well as performing interventions, and limiting major surgical interventions. Small intestine lymphoma appears as a mass, polyp and ulcer on CE which cannot be distinguished from other lesions^[51]. Radiologic findings of small intestinal lymphoma are not specific, thus posing a difficulty in distinguishing it from other benign and malignant lesions. The common features of small intestine lymphoma seen in barium studies and CT include polypoid form, multiple nodules, infiltrative form, endoexoenteric form with excavation and fistulization, and mesenteric invasive form with an extraluminal mass. The radiological findings usually do not correlate to its pathological subtypes. Certain features are, however, peculiarly noted. MCL, follicular lymphoma and MALT lymphoma rarely present with multiple polyps (multiple lymphomatous polyposis)^[52]. Burkitt lymphoma usually presents as a bulky mass in the right lower quadrant. IPSID tends to affect proximally with a disseminated nodular pattern leading to mucosal fold thickening, irregularity and speculation. EATL, usually proximal or diffuse, shows nodules, ulcers or strictures^[53]. PTCL preferentially involves the jejunum with an increased tendency to perforate^[54].

Colorectal lymphoma

Colorectal lymphoma constitutes 6%-12% of all gastrointestinal lymphomas. Most colorectal lymphomas are secondary involvement of the wide spread diseases. Primary colorectal lymphoma is very rare, constituting only 0.2% of all malignant tumors arising from the colorectal region with caecum, ascending colon and rectum more often affected^[55]. The disease predominantly affects males in the fifth-seventh decade of life with abdominal pain, loss of weight, palpable abdominal mass or lower gastrointestinal bleeding. Obstruction and perforation are relatively rare in patients with colorectal lymphoma^[56].

Lymphoma of the colorectal region is mostly the B-cell lineage as other sites of the gastrointestinal tract. Primary colorectal lymphoma comprises low grade B-cell lymphoma arising from MALT, MCL and T-cell lymphoma besides large B cell lymphoma. The role of *H. pylori* in the pathogenesis of colorectal lymphoma has not been fully established^[57]. Colorectal MALT-lymphoma is less common in colon and rectum than in small intestine. MCL in the colorectal region presents usually in the setting of diffuse systemic diseases. Peripheral T-cell lymphoma is rare in Western countries with an increasing frequency in many Asian countries, and is more aggressive in nature than other types with perforation as its common feature, and its prognosis is poor^[58].

Endoscopically, lymphoma appears to be fungating, ulcerative, infiltrative, ulcerofungating, and ulceroinfiltrative types, with fungating and ulcerofungating types being more common^[59]. The radiologic appearances of colorectal lymphoma are variable and significantly overlapped with other benign and malignant condition of the colorectal region. The imaging findings during double-contrast barium enema can be divided into focal and diffuse lesions. The observed focal lesions include polypoid mass,

circumferential infiltration with smooth mucosal surface or extensive ulceration, cavitary mass, mucosal nodularity, and mucosal fold thickening. Diffuse lesions encompass diffuse ulcerative and nodular lesions. Peripheral T-cell lymphoma presents as a diffuse or focal segmental lesion with extensive mucosal ulceration similar to that observed in granulomatous conditions as Crohn's disease or tuberculosis. MALT lymphoma is manifested as multiple mucosal nodularity^[60,61].

TREATMENT

The treatment strategy for gastrointestinal lymphoma is dependent on the age of patients, clinical scenario, histological subtype, extent and burden of the disease, and comorbidity, besides other factors. Surgery, chemotherapy, radiotherapy and radioimmunotherapy are the different modalities for its management and can be applied in different combinations. A detailed discussion on the treatment of all subtypes is beyond the scope of this article, thus the most common treatment modalities are highlighted in brief based on the region of presentation.

Oropharyngeal lymphoma

The definite management protocol for oropharyngeal lymphoma has not yet been established. Unlike the majority of other malignancies in this region, surgery does not play a primary role in the management of oropharyngeal lymphoma^[62]. Combined chemotherapy and radiotherapy for localized oropharyngeal lymphoma is recommended in most studies^[14]. Advanced oropharyngeal lymphoma is usually treated with aggressive chemotherapy with or without radiotherapy.

Esophageal lymphoma

Due to the rarity of esophageal lymphoma, no standardized approaches to its management have been formulated. Secondary lymphoma involving the esophagus can be treated with chemotherapy, while primary esophageal lymphoma can be managed with surgery, chemotherapy and radiotherapy or their combination. Treatment protocols vary depending on its histological subtypes and extent. Although surgery is the initial treatment modality, it has been recently reserved for cases with their diagnosis not possibly made at endoscopic biopsy or for those who warrant surgical intervention due to complications such as perforations. Esophageal lymphoma can be treated with local resection and chemotherapy with or without radiotherapy as its initial therapy. However, chemotherapy or radiotherapy alone can be also used as its initial therapy. The commonly employed chemotherapy regimen is CHOP in combination with Rituximab. It was reported that external beam radiation at the dose of 40 Gy can also be used^[63].

Gastric lymphoma

Treatment strategies for gastric lymphoma have changed dramatically over the last two decades. However, they are still very controversial. The most widely recommended

strategy for the management of early stage *H. pylori* positive MALT type of gastric lymphoma is to eradicate *H. pylori* with antibiotics and proton pump inhibitors. Antibiotic therapy can achieve a long-term remission in 60%-100% patients with localized *H. pylori*-positive MALT lymphoma without t (11;18) chromosomal translocation. Histological assessment of treatment response, however, faces the problem of standardization, thus mandating serial follow-up. The GELA histologic evaluation system is commonly employed at certain centers. It has been shown that monoclonal B-cells still exist in almost half of the patients despite histological and endoscopic remission following antibiotic therapy^[64].

No definite guidelines have been advocated for the treatment of advanced or *H. pylori* negative MALT-type of gastric lymphoma. Although surgery has been used as its initial treatment, recent studies showed that radiotherapy alone can achieve a complete remission with a 5-year disease free period^[20]. Thus, "involved-field" irradiation at the total dose of 30 Gy for over 4 wk has become the treatment of choice for stages I and II MALT lymphoma without *H. pylori* or with persistent lymphoma following therapy. Surgery is, at present, reserved only for those with complications such as perforation, hemorrhage or obstruction that cannot be treated with other alternative therapies. Systemic therapy similar to that for indolent and advanced lymphoma must be taken into consideration in patients with their disease spread. Treatment options include chemotherapy and use of monoclonal antibodies. Diffuse large B-cell lymphoma of the stomach is treated with aggressive poly-chemotherapy, which is usually combined with Rituximab. Thus, gastric lymphoma should be treated with the front-line chemioimmunotherapy with 3-4 cycles of standard R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisone) followed by "involved-field" radiotherapy. A complete remission can be achieved in advanced gastric lymphoma patients after 6-8 cycles of R-CHOP as their nodal counterparts. Recent studies have demonstrated that anti-*H. pylori* therapy can achieve the remission of indolent lymphoma, *H. pylori* negative MALT lymphoma and DLBCL^[26,65].

Intestinal lymphoma

The treatment outcome of intestinal lymphoma is relatively poorer than that of gastric lymphoma depending on their histologic subtypes. Lymphoma primarily located in the small intestine usually warrants laparotomy with the affected segment removed both for its diagnosis and for its treatment. Low-grade B-cell lymphoma of the small intestine (stage IE) only requires surgical resection. Although few studies have reported its benefit for localized intestinal lymphoma particularly that of the duodenum and rectum^[66], radiotherapy in particular is not beneficial for intestinal lymphoma due to the multifocal involvement and its spread. No therapeutic guidelines are available for MALT lymphoma involving the small intestine with various modalities depending on the disease burden and other clinical parameters. Local intestinal lymphoma can be managed with surgical or endoscopic resection, while

some cases of colonic MALT lymphoma can benefit from *H. pylori* therapy alone. Multi-agent chemotherapeutic strategy is warranted for advanced stage intestinal lymphoma with multifocal presentation of MALT lymphoma. A wait and watch policy for indolent FL at stage IE is advocated by some authors until they are symptomatic or show evidence of its progression due to a comparable relapse rate in treated patients and the progression of FL in untreated patients^[50,66]. Symptomatic cases, or advanced disease of FL necessitates surgery, chemotherapy (CHOP) and/or irradiation intervention. Although Rituximab is beneficial for FL, its true value has not been well ascertained^[66]. MCL treatment response and prognosis are poor with a short unmaintained remission after chemotherapy. Treatment is stratified based on the eligibility of patients for stem cell transplantation (SCT). Those who are eligible for grafting are previously induced with R-CHOP or R-HyperCVAD (Rituximab, cyclophosphamide, vincristine, doxorubicin and dexamethasone). Chemotherapy regimen, consisting of Rituximab alone or purine nucleoside analogs with Rituximab, can be applied to those ineligible for stem cell transplantation. The mammalian target of rapamycin inhibitors, antibodies, bendamustine or radioimmuno conjugates, can achieve a promising outcome in patients with relapse or refractory setting single-agent bortezomib, temsirolimus and ibritumomab tiuxetan^[67,68]. IPSID in early stage responds to antibiotics such as tetracycline or combined metronidazole and ampicillin, with a remission occurring within 6-12 mo. IPSID at intermediate or advanced stage responds to anthracycline-based chemotherapy, with added antibiotics such as tetracycline. Surgery plays a limited role in the majority of cases due to diffuse involvement, although it may be required for accurate diagnosis. It has been reported that radiotherapy as an adjuvant or palliative treatment is beneficial for some cases^[66]. High grade lymphoma frequently presents with complications, thus mandating surgical intervention. No optimized therapeutic protocol is available for Burkitt lymphoma which usually requires an aggressive approach. High intensity chemotherapeutic agents for a short duration, such as cyclophosphamide, vincristine, doxorubicin, methotrexate and cytarabine, can significantly improve the treatment outcome. High dose chemoradiotherapy and hematopoietic SCT are beneficial for almost 50% of Burkitt lymphoma patients^[69]. Radiotherapy is not beneficial for DLBCL involving the small intestine^[70]. Systemic treatment with anthracycline-based chemotherapy followed by radiotherapy is proposed for wide spread advanced intestinal lymphoma which cannot be removed. Some studies have shown that post surgery chemotherapy is beneficial for some patients^[68]. The overall response of non surgical patients with intestinal B cell lymphoma to chemotherapy is better than that of those with the intestinal T cell subtype^[71]. No guidelines are available for the management of EATL although anthracyclin-based chemotherapy is a mainstay treatment modality for overt EATL with a poor response. In view of the poor performance and complications related to chemotherapy, such as perforation, multimodal approaches including curative or debulking surgery

Table 3 Paris staging system for primary gastrointestinal lymphomas

Stage	Gastrointestinal lymphomas
TX	Lymphoma extent not specified
T0	No evidence of lymphoma
T1	Lymphoma confined to the mucosa/submucosa
T1m	Lymphoma confined to mucosa
T1sm	Lymphoma confined to submucosa
T2	Lymphoma infiltrates muscularis propria or subserosa
T3	Lymphoma penetrates serosa (visceral peritoneum) without invasion of adjacent structures
T4	Lymphoma invades adjacent structures or organs
NX	Involvement of lymph nodes not assessed
N0	No evidence of lymph node involvement
N1	Involvement of regional lymph nodes
N2	Involvement of intra-abdominal lymph nodes beyond the regional area
N3	Spread to extra-abdominal lymph nodes
MX	Dissemination of lymphoma not assessed
M0	No evidence of extranodal dissemination
M1	Non-continuous involvement of separate site in gastrointestinal tract (e.g. stomach and rectum)
M2	Non-continuous involvement of other tissues (e.g. peritoneum, pleura) or organs (e.g. tonsils, parotid gland, ocular, adnexa, lung, liver, spleen, kidney, breast, <i>etc.</i>)
BX	Involvement of bone marrow not assessed
B0	No evidence of bone marrow involvement
B1	Lymphomatous infiltration of bone marrow
TNM	Clinical staging: status of tumor, node, metastasis, bone marrow
pTNMB	Histopathological staging: status of tumor, node metastasis, bone marrow
pN	The histological examination will ordinarily include six or more lymph nodes

are recommended to remove the gross EATL in all cases, if it is tolerable prior to chemotherapy^[72]. It was reported that 66% of EATL patients undergoing surgical resection followed by combination chemotherapy and autologous stem cell transplantation can achieve a sustained complete response^[73].

STAGING, PROGNOSTICATION AND RESTAGING

Staging of gastrointestinal lymphoma is a matter of debate due to various available staging systems. Although the modified Ann Arbor classification is feasible and relevant for prognosis, certain demerits in terms of disseminated and incurable infiltration of the gastrointestinal tract prompted development of the Paris staging system, which can differentiate distant lymphoma manifestations depending on the involved organ, and further subdivide lymph node involvement (Table 3)^[74]. In general, comprehensive history taking and physical examination may reveal the possible etiologies of some specific lymphoma types and provide information for their further assessment and management. Minimal laboratory investigations performed include complete blood count, liver and renal function test, measurement of lactate dehydrogenase, blood glucose, serum uric acid, potassium, calcium, and phosphorus levels. Bone marrow aspirate with a biopsy is

Table 4 International prognostic index

Adverse risk factors
Age > 60 yr
≥ 2 extranodal sites
Ann arbor stage III-IV
Performance status ≥ 2 (ECOG)
High lactate dehydrogenase
Risk
Low (<i>n</i> = 0-1)
Low-intermediate (<i>n</i> = 2)
High-intermediate (<i>n</i> = 3)
High (<i>n</i> = 4-5)

performed for involvement of lymphoma cells and monitoring of treatment response. Other investigations include serum protein electrophoresis and identification of paraprotein in certain types of lymphoma. Additional serological tests are often employed for etiological recognition in various types of lymphoma. CT scan of the chest, abdomen and pelvis is employed to stage gastrointestinal lymphomas with a marked sensitivity and specificity. Incorporation of FDG-PET has a significant advantage in staging of DLBCL, follicular lymphoma and MCL with a sensitivity of 80% and a specificity of 90%, although it has no added benefit for MALT lymphomas. EUS has gained momentum as an integral tool in the diagnosis, locoregional staging, and monitoring response of gastrointestinal lymphoma to treatment. EUS is superior to CT scan for the T- and N-staging by providing vivid details for any invasion to the mucosa, submucosa, muscularis propria or beyond serosa. The value of EUS and CT, however, is a matter of debate in the follow-up of patients as it is well established that histological remission precedes the normalization of wall changes in patients with lymphoma^[74,75], thus precluding the necessity for endoscopic biopsy follow-up. Gastric MALT lymphoma, though indolent, often warrants a more meticulous staging procedure because it is usually multifocal, transforms to the DLBCL variant, and is difficult to diagnose due to normal endoscopic findings in the majority of cases as well as involvement of multiple organs. Endoscopic biopsies are therefore usually taken from multiple sites of the stomach and duodenum encompassing both normal and abnormal regions^[75].

The international prognostic index (IPI) developed for DLBCL is, at present, the most valuable and widely used for the stratification of almost all subtypes of NHL (Table 4). However, the IPI does not hold the same predictive value for patients treated with immunochemotherapy. Moreover, the IPI is less useful for follicular lymphoma because a significant number of patients with a poor prognosis are not recognized, thus warranting development of follicular lymphoma IPI^[76]. Reevaluation of patients who have completed the whole planned treatment is an integral part in the management of lymphoma patients. The most important prognostic factor for the management is the assessment of complete remission of the disease because salvage treatment with a high dose and autologous or allogeneic bone marrow transplantation may be contem-

plated in those who fail to initial therapy. The different parameters are compared with the prior treatment values and evaluated. A possible necessity of histopathological assessment by follow-up biopsy may be required in certain atypical situations. Nuclear studies and PET in particular have been recommended for the evaluation of recurrence of various lymphomas^[77].

FUTURE PERSPECTIVE

There has been a tremendous leap in the diagnosis, staging and management of gastrointestinal lymphoma in the last two decades. With a better insight into its etiology and molecular aspect, various critical signaling pathways provide an impetus with greater benefits. Identification of the cell surface antigens has led to the introduction of monoclonal antibodies like Rituximab and radioimmunotherapy that can result in a more targeted approach with a significant impact for the overall management of lymphoma. A deep understanding of the role of monoclonal antibodies in the pathogenesis of gastrointestinal lymphoma has led to development of the second and third generations of anti CD-20 antibodies (ofatumumab, veltuzumab, ocrelizumab), anti CD-22 antibodies such as Epratuzumab, anti CD-30 antibodies such as SGN-30, anti CD-40 antibody SGN-40, and anti vascular endothelial growth factor (VEGF) antibody bevacizumab^[78]. Furthermore, addition of cytokines and other immune modulators has a boon resulting from a better understanding of the antibody activities at targeted tissues. Agents targeting the Bcl-2, Syk and the PI3K/AKT/mTOR pathways have emerged as a more biologically- focused management with further development in this field^[79].

Another important aspect to be considered is the increasing sensitivity and specificity of imaging techniques like EUS and PET-CT in the diagnosis of lymphomas. An emerging field is the molecular imaging with a variety of new radiopharmaceutical agents that target the up-regulated specific receptors in cancer cells^[80].

CONCLUSION

The epidemiology, clinical presentation, histopathologic subtypes, as well as radiological presentation of gastrointestinal lymphomas are highlighted in this review, with emphasis laid on the need for accurate diagnosis, staging, treatment of the disease with the promising novel techniques.
