Abstract

AIM: To identify the prevalence of hepatitis B e antigen (HBeAg) and to assess the association of hepatitis B virus (HBV) core promoter mutations and viral load in Indonesian patients.

METHODS: Sixty-four patients with chronic hepatitis, 65 with liver cirrhosis and 50 with hepatocellular carcinoma were included in this study. HBeAg and hepatitis B e antibody (HBeAb) tests were performed using enzyme-linked immunosorbent assay and the mutations were analyzed by sequencing. Viral load was measured by real-time polymerase chain reaction.

RESULTS: Of 179 patients, 108 (60.3%) were HBeAg(-) and 86 (79.6%) of these HBeAg(-) patients had been seroconverted. The A1896 mutation was not found in HBeAg(+) patients, however, this mutation was detected in 70.7% of HBeAg(-) patients. This mutation was frequently found when HBeAg was not expressed (87.7%), compared to that found in HBeAg seroconverted patients (65.1%). The A1899 mutation was also more prevalent in HBeAg(-) than in HBeAg(+) patients ($P = 0.004$). The T1762/A1764 mutation was frequently found in both HBeAg(+) and HBeAg(-) patients, however, the prevalence of this mutation did not significantly differ among the two groups ($P = 0.054$). In HBeAg(+) patients, the T1762/A1764 mutation was correlated with lower HBV DNA ($P < 0.001$). The A1899 mutation did not correlate with HBV DNA ($P = 0.609$). In HBeAg(-) patients, the T1762/A1764 mutation alone was not correlated with HBV DNA ($P = 0.095$), however, the presence of either the T1762/A1764 or A1896 mutations was associated with increased HBV DNA ($P < 0.001$).

CONCLUSION: The percentage of HBeAg(-) patients is high in Indonesia, and most of the HBeAg(-) patients

had been seroconverted. The A1896 mutation was most likely the major cause of HBeAg loss. The T1762/A1764 mutation alone was associated with lower viral loads in HBeAg(+) patients, but not in HBeAg(-) patients.

INTRODUCTION

More than 2 billion people are infected with hepatitis B virus (HBV) and 350 million of them are chronic carriers of the virus^[1]. Indonesia has a moderate to high endemicity of HBV infection, which is perhaps due to the lack of proper health facilities, poor economical status and less public awareness^[2]. HBV infection is associated with a diverse clinical spectrum of liver damage ranging from asymptomatic carriers, chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma (HCC)^[3]. Patients with chronic hepatitis B are typically hepatitis B e antigen positive [HBeAg(+)] with detectable HBV DNA in serum. Generally, seroconversion from HBeAg to hepatitis B e antibody (HBeAb) positive correlates with reduced HBV replication in the liver and low infectivity during the natural course of infection^[4,5]. In some patients, however, the immune pressure associated with seroconversion selects for HBV variants that express little or no HBeAg. Although the patient may develop HBeAb, active HBV DNA replication continues with associated liver damage^[6].

Most infected patients that are HBeAg(-) harbor HBV variants with mutations in the precore or core promoter region^[7]. The predominant precore variation is a G-to-A change at A1896, which creates a premature stop codon and which abolishes the synthesis of HBeAg^[8-10]. The most common core promoter mutations involve a two-nucleotide substitution at T1762 and A1764 (T1762/A1764 mutation)^[7,11]. Several transfection studies showed that the T1762/A1764 mutation decreased the level of precore mRNA by 50% to 70% and led to reduced HBeAg synthesis^[12-14]. A previous study has also demonstrated that HBeAg may be a target antigen on HBV-infected hepatocytes^[15].

Failure to produce a target antigen may allow the infected cell to evade immune clearance.

The prevalence of HBeAg(-) patients is likely to vary across geographic areas. The total number of HBeAg(-) chronic hepatitis B patients is higher in the Mediterranean region and is estimated to be up to 33%. However, the prevalence of HBeAg(-) patients who achieved HBeAg seroclearance was higher in Asian patients (36%) than in Mediterranean patients (24%)^[16]. Furthermore, HBeAg(-) patients have a higher rate of active liver disease in Asian patients, however, no data from Indonesia is available at present. In a recent study, we analyzed the genotype and core promoter mutations of HBV isolates in Indonesian carriers and patients^[17]. The present study identifies the prevalence of HBeAg and assesses the association of HBV core promoter mutations and viral load in Indonesian patients.

MATERIALS AND METHODS

Patients

Serum samples were obtained from 179 HBV-associated liver disease patients, comprising 64 patients with chronic hepatitis B (CH), 65 patients with liver cirrhosis (LC), and 50 patients with HCC. Sera from CH, LC, and HCC patients were collected from Cipto Mangunkusumo Hospital, Gatot Soebroto Hospital, Klinik Hati "Professor Ali Sulaiman", Jakarta, Siloam Hospital Lippo Karawaci, Tangerang, Moewardi Hospital, Surakarta, Mataram General Hospital, Mataram, and M. Jamil Hospital, Padang, Indonesia, during the period of May 2006 to March 2010. All sera were persistently seropositive for HBsAg for at least 6 mo. The study was approved by the Institutional Ethics Committee and informed consent was obtained from each patient.

HBeAg and HBeAb tests

HBeAg and HBeAb from all plasma were tested using the MicroLISA™-HBeAg Test and MicroLISA™-HBeAb Test kits (Amgenix, San Jose, CA, USA), according to the manufacturer's instructions.

Analysis of HBV genotype and precore/core promoter mutations

HBV DNA was extracted from 200 µL serum using the QIAamp DNA blood mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions, and 80 µL eluted DNA was stored at -70°C until use. HBV genotype was identified based on S gene sequence or genotype-specific polymerase chain reaction (PCR)^[17,18]. Precore and core promoter mutations were analyzed by direct sequencing of the corresponding regions, as described previously^[17]. However, for samples in which the precore sequence appeared inconsistent with the HBeAg test, amplification products were inserted into pBluescript II SK(+), and at least ten independent clones of each were sequenced.

HBV viral load measurement

HBV DNA was first extracted from 200 µL serum with

CH: Chronic hepatitis; LC: Liver cirrhosis; HCC: Hepatocellular carcinoma; AFP: α -fetoprotein; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen; HBeAb: Hepatitis B e antibody.

the QIAmp DNA blood mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions with the addition of internal control (1 μ L/10 μ L sample) from ARTUS HBV (Qiagen, Hilden, Germany). From 50 μ L of eluted DNA, 20 μ L was then quantified by ARTUS real-time PCR assay according to the manufacturer's instructions (Qiagen, Hilden, Germany). The range of HBV DNA detection was 10^1 to 10^5 IU/mL.

Statistical analysis

All statistical analyses were performed using SPSS 15.0 software for Windows (SPSS Inc., Chicago, IL, USA). Significance differentiations for continuous variables were analyzed using *t*-test analysis. The categorical variables were analyzed using the Fisher's exact test and χ^2 test. *P*-values of < 0.05 were considered significant.

RESULTS

Characteristics of patients

Patients' characteristics are summarized in Table 1. Of the 179 patients, 129 (72.1%) were male and the male/female ratio was significantly increased from CH to HCC and from LC to HCC, but not from CH to LC. The mean age of all patients was 45.8 ± 12.3 years, and significantly increased from CH to LC and to HCC, but not from LC to HCC. The median level of AST and ALT were 66.0 and 50.0 IU/mL, respectively. The level of AST, but not ALT, was significantly increased according to the severity of liver disease. The mean level of HBV DNA was 5.6 ± 2.0 log₁₀ IU/mL, and was significantly lower in HCC (4.6 ± 2.2) than in LC (5.8 ± 1.4) and CH (6.1 ± 2.1). Seventy-one (39.7%) and 108 (60.3%) of patients were HBeAg(+) and HBeAg(-), respectively. The percentage of HBeAg(+) samples was significantly higher in CH (56.3%) than in

LC (29.2%) or HCC (32.0). Eighty-six of 179 patients (48.0%) were HBeAg seroconverted, and the percentage of HBeAg seroconversion was higher in LC (61.5%) than HCC (48.0%) and CH (34.4%). There was no difference in HBV genotype prevalence between samples of different clinical diagnosis.

Comparison between HBeAg(+) and HBeAg(-)

Table 2 demonstrates the comparison between HBeAg(+) and HBeAg(-) groups. The mean age of patients was significantly higher in the HBeAg(-) group (49.2 ± 11.7) than in the HBeAg(+) group (40.7 ± 11.5) ($P < 0.001$), indicating a longer period of disease in the HBeAg(-) group. No significant difference in the male/female ratio between the two groups was observed ($P = 0.106$). Surprisingly, there was also no significant difference in ALT levels between the two groups ($P = 0.535$). As shown in Table 3, 79.6% (86/108) of HBeAg(-) patients were HBeAg seroconverted [HBeAb(+)]. There was no significant difference in ALT levels in the samples prior to HBeAg seroconversion [i.e. HBeAg(+), HBeAb(-)] vs after HBeAg seroconversion [i.e. HBeAg(-), HBeAb(+)] ($P = 0.200$). However, ALT levels in the HBeAg seroconverted group were significantly higher than those in the group that did not express HBeAg (60.0 IU/L vs 43.0 IU/L, $P = 0.023$). The AST/ALT ratio was significantly higher in HBeAg(-) than in HBeAg(+) patients (1.4 vs 1.1, $P = 0.022$), suggesting the presence of other factors involved in HBeAg(-) patients. HBV DNA was significantly higher in the HBeAg(+) (6.5 ± 1.8 log₁₀ IU/mL) group compared to the HBeAg(-) (5.0 ± 1.9 log₁₀ IU/mL) group ($P < 0.001$) (Table 2). The percentage of samples with HBV DNA load ≥ 20000 IU/mL was much higher in HBeAg(+) patients (91.5%) than in HBeAg(-) patients (68.5%). There was no significant difference in levels of HBV DNA between the HBeAg sero-

Table 2 Comparison of hepatitis B e antigen (+) and hepatitis B e antigen (-) patients

Characteristics	Total	HBeAg(+)	HBeAg(-)	P-value

converted and non-expressing groups ($P = 0.146$) (Table 3), suggesting that HBeAg expression did not affect HBV replication. The percentage of HBeAg(+) samples was high in CH (50.7%) and was less in LC (26.8%) and HCC (22.5%).

Precore/core promoter mutations and HBeAg status

The prevalence of mutations in the precore and core promoter regions was compared between HBeAg(+) and HBeAg(-) patients (Table 4). As expected, the precore A1896 mutation, which is associated with HBeAg expression, was absent in HBeAg(+) patients, but was found in 70.7% of HBeAg(-) patients. Interestingly, the A1896

mutation was frequently found not only in HBeAg non-expressing patients (87.7%), but also in HBeAg seroconverted patients (65.1%). The A1899 precore mutation was found to be more common in HBeAg(-) than in HBeAg(+) patients (34.5% *vs* 10.4%, $P = 0.004$), but there was no significant difference between the HBeAg seroconverted group and the HBeAg non-expressing group (37.2% *vs* 26.7%, $P = 0.116$), suggesting that this mutation contributes to the expression of HBeAg. On the other hand, the T1762/A1764 core promoter mutation was found both in HBeAg(+) (40.8%) and HBeAg(-) (55.6%) patients, and the prevalence of this mutation was not significantly different between the two groups ($P = 0.054$).

¹Total samples *n* = 179; Hepatitis B e antigen (HBeAg) (+) and hepatitis B e antibody (HBeAb) (-) *n* = 71; HBeAg(-) and HBeAb(+), *n* = 86; HBeAg(-) and HBeAb(-), *n* = 22; ²Total samples *n* = 106; HBeAg(+) and HBeAb(-) *n* = 48; HBeAg(-) and HBeAb(+), *n* = 43; HBeAg(-) and HBeAb(-), *n* = 15; ³Three samples had a mixed population of precore stop codon mutation (A1896) and its wild type (G1896); ⁴Two samples with a mixed population of basal core promoter mutation (T1762/A1764) and its wild type (A1762/G1764).

However, the presence of either the T1762/A1764 mutation or the A1896 mutation was very high in the HBeAg(-) group (98.1%), [including patients that had seroconverted (HBeAb(+)) (95.3%) and HBeAg non-expressing patients (100.0%), compared to the HBeAg(+) group (35.4% of which had the mutations), indicating these mutations are associated with HBeAg status.

We further analyzed the effect of precore and core promoter mutations on HBeAg expression and viral replication in twenty two HBeAg non-expressed samples. Enough DNA was recovered so that the T1762/A1764 core promoter mutation could be analyzed in all samples, however, the A1896 and A1899 precore mutations could only be analyzed in fifteen samples (Table 5). Either core promoter (T1762/A1764) or precore (A1896 or A1899) mutations were found in all samples, with the exception of three samples from which we were unable to obtain the DNA sequence. Almost all samples demonstrated relatively high HBV DNA, although in some samples the HBV DNA was low, but still detectable. Taken together, these results suggest that precore or core promoter mutations were associated with reduced HBeAg expression, but did not affect HBV replication in groups that did not express HBeAg.

HBV: Hepatitis B virus.

Precore/core promoter mutations and HBV viral load and ALT

Precore and core promoter mutations correlated with different levels of HBV DNA in HBeAg(+) and HBeAg(-) patients. In HBeAg(+) patients, the T1762/A1764 core promoter mutation correlated with lower HBV DNA levels ($P < 0.001$) (Table 6). The A1899 mutation was not associated with HBV DNA level ($P = 0.609$) and, as expected, no A1896 mutations were detected in the samples. The

presence of either the T1762/A1764 or A1896 mutations also correlated with lower HBV DNA levels ($P = 0.011$). On the other hand, in HBeAg(-) patients, T1762/A1764 core promoter, as well as A1896 and A1899 precore mutations were not individually correlated with higher or lower HBV DNA level ($P = 0.095, 0.231, 0.382$, respectively), however, the presence of either the T1762/A1764 muta-

tion or the A1896 mutation was associated with increased HBV DNA levels (*P* < 0.001) (Table 7). In addition, no correlations between precore and core mutations and serum ALT levels were observed in either the HBeAg(+) or HBeAg(-) patients (Tables 6 and 7).

DISCUSSION

The present study was an epidemiological investigation of the precore and core promoter mutations and their relationship to HBeAg expression levels in Indonesian patients. The majority of patients enrolled in this study were infected with HBV genotype B (73.7%), while the rest were genotype C (26.3%) (Table 1), which is consistent with previous reports^[17,19-21]. The prevalence of HBeAg(-) chronic hepatitis B patients was 60.3%, which is similar to other Asian countries^[16]. Among the HBeAg(-) patients, 79.6% were HBeAb(+), which meant that they were HBeAg seroconverted (Table 3). Studies in Europe, Asia, and the United States have all reported an increased prevalence of HBeAg(-) chronic hepatitis among HBeAg(+) patients^[16]. Our results support previous studies which reported that HBeAg(-) chronic hepatitis B is the most common form of chronic HBV infection in Asia. However, in our study, most of the HBeAg(-) patients had been seroconverted, and the percentage of HBeAg(-) due to abolition of HBeAg synthesis was relatively low (20.4%).

Analysis of the A1896 mutation by direct sequencing demonstrated that all HBeAg(+) samples were wild type (i.e. did not bear the A1896 mutation) (Table 4), however, in our initial sequencing the A1896 mutation was found in three HBeAg(+) samples. The PCR fragments from

these samples were cloned into pBluescript II SK(+), and sequence analysis of ten clones showed that wild type virus was also present in some isolates. Thus, the presence of these wild type viruses was presumably responsible for HBeAg synthesis. On the other hand, a high percentage of the HBeAg(-) patients bore the A1896 precore mutation. As expected, in HBeAg(-) patients, this mutation was more prevalent in HBeAg non-expressing patients (87.7%) compared to seroconverted patients (65.1%) (Table 4). Nevertheless, the percentage of this mutation in seroconverted patients was relatively high. Since the A1896 mutation creates a premature stop codon which results in abolition of HBeAg synthesis^[8-10], seroconverted patients cannot have always had virus with the A1896 mutation. It is believed that precore mutants emerge as a result of selection under immune pressure during the process of HBeAg seroconversion^[22-24]. Therefore, at the early stage of infection, the virus might be a wild-type and the A1896 mutation occurs during the process of HBeAg seroconversion. In this study, because the mutation analysis was carried out after HBeAg seroconversion, it is also possible that the A1896 mutation detected in the samples occurred during the process of HBeAg seroconversion. In addition, the prevalence of the A1899 precore mutation was significantly higher in HBeAg(-) than in HBeAg(+) patients (*P* = 0.004), and was also higher in samples before HBeAg seroconversion compared to that after HBeAg seroconversion (*P* = 0.003) (Table 4). These results suggest that the A1899 mutation is associated with expression and seroconversion of HBeAg, which is in accordance with previous studies in Taiwanese patients^[25]. Another study from Korea also reported that the A1899 mutation

was frequently found in HBeAg(-) patients, however, the authors found that the A1899 mutation was always accompanied by A1896 mutation^[26], which was different to our results.

The frequency of the T1762/A1764 mutation was relatively high both in HBeAg(+) and HBeAg(-) patients, and there was no significant difference between the two groups or between patients before and after HBeAg seroconversion. These results suggest that there is no independent association between the T1762/A1764 mutation on HBeAg expression and seroconversion. The presence of both the T1762/A1764 and A1896 mutations correlated with HBeAg expression and seroconversion, but was likely due to the effect of A1896 mutation alone. Although previous studies demonstrated that the core promoter region regulates transcription of the pregenomic and precore RNA and T1762/A1764 mutation suppression, it does not abolish the synthesis of HBeAg, leading to a reduction in HBeAg expression^[12,27-29], and we did not observe this phenomenon in our study. Moreover, by measuring HBeAg titer quantitatively, a recent study also reported that the T1762/A1764 mutation reduced the expression of HBeAg^[30]. In this study, however, HBeAg analysis was performed qualitatively, which perhaps explains the different results from those of previous studies.

Further analysis of precore and core promoter mutations in HBeAg non-expressed patients revealed that the A1896 mutation alone did not abolish HBeAg synthesis. Theoretically, A1896 mutation creates a premature stop codon which results in abolishment of HBeAg synthesis, however, A1896 was not found in all HBeAg non-expressed patients. Among twenty-two patients with HBeAg(-) and HBeAb(-), we identified the A1896 mutation in fifteen patients of which two did not show the A1896 mutation, but showed the T1762/A1764 mutation (Table 5). To confirm the A1896 mutation in these two samples, we cloned the amplified fragments into the plasmid, and sequenced eighteen clones, and no mutations were found in any of the clones. Furthermore, the A1899 mutation was not found in these samples. These results suggest that the expression of HBeAg might not be affected by the A1896 mutation alone, however, further study is needed to investigate other factors involved in HBeAg expression.

In addition to precore and core promoter mutation, HBV variants with point mutations around the Kozak sequence (nucleotides 1809-1812) were also analyzed. Mutations at the Kozak sequence were less common in our samples and were not associated with HBeAg expression (data not shown), which is similar to the results from Korea^[31]. Some studies have found that mutations in the Kozak sequence are correlated with HBeAg expression^[32-34]. Our study demonstrated that these mutations do not play an important role in the clinical outcome of chronic hepatitis B patients. The differences may be attributable to genetic differences.

Another interesting finding of this study is that the effect of precore and core promoter mutation on HBV viral

load was different in HBeAg(+) and HBeAg(-) patients. In HBeAg(+) patients, T1762/A1764 mutation was associated with lower viral load. On the other hand, this mutation was associated with higher viral load in HBeAg(-) patients, including HBeAg seroconverted patients. These results are in accordance with a previous study in Chinese patients^[35,36]. It may be postulated that, among individuals who are HBeAg(+), those with both wild-type and mutant viruses have them in different phases of the infection, the former being in the first phase and the latter, at the end of the second phase. These patients experience different immune pressures, resulting in different levels of virus replication. However, those who are HBeAg(-), regardless of core promoter sequence, are in the same phase (the third phase) and experience similar immune pressures, resulting in similar levels of virus replication. If this is the case, it is not difficult to understand why T1762/A1764 core promoter mutations are associated with lower viral loads in HBeAg(+) patients, but have no effect in HBeAg(-) patients.

In conclusion, the percentage of HBV infected HBeAg(-) patients is relatively high in Indonesia. Most of the HBeAg(-) patients had been seroconverted and the remaining patients did not express HBeAg. A1896 mutation in the precore region was the major cause of the loss of HBeAg expression. T1762/A1764 core promoter mutations are associated with lower viral loads in HBeAg(+) patients, but are associated with higher viral loads in HBeAg(-) patients.

COMMENTS

Background

Seroconversion from hepatitis B e antigen (HBeAg)-positive to hepatitis B e antibody (HBeAb)-positive correlates with reduced hepatitis B virus (HBV) replication in the liver and low infectivity during the natural course of infection. However, the immune pressure associated with HBeAg seroconversion selects for HBV variants that express little or no HBeAg. Although the patient may develop HBeAb, active HBV DNA replication continues with associated liver damage and is known as HBeAg-negative chronic hepatitis B. The aims of the study were to identify the prevalence of HBeAg-negative patients and to assess the association between HBV core promoter mutations and viral load in Indonesian patients.

Research frontiers

To date, there have been no reports on the prevalence of HBeAg-negative chronic hepatitis B in Indonesia. Therefore, it is important to obtain information on the HBeAg status of liver disease patients in Indonesia, and its association with precore and core promoter mutations. In addition, the correlation between precore and core promoter mutations and HBV replication is crucial.

Innovations and breakthroughs

The present study showed that the prevalence of HBeAg-negative chronic hepatitis B in Indonesia is high and most patients had seroconverted. The A1896 mutation was most likely to be the major cause of HBeAg loss. A1899 mutation is also associated with HBeAg-negative and is not always accompa-

nied by A1896 mutation. Furthermore, A1896 was not found in all HBeAg non-expressing patients, two HBeAg(-) and HBeAb(-) patients did not show either the A1896 or A1899 mutation, but had the T1762/A1764 mutation, suggesting that the expression of HBeAg might not be affected by the A1896 mutation alone. Interestingly, the T1762/A1764 mutation was associated with lower viral loads in HBeAg-positive, but not in HBeAg-negative patients.

Applications

The A1896 mutation can be used to predict HBeAg-negative variants in patients who achieve HBeAg seroconversion during disease progression or anti-viral therapy. In addition, the A1899 and T1762/A1764 mutations can be used to predict HBeAg-negative chronic hepatitis B, although there is no A1896 mutation.

Terminology

Core promoter: Part of the HBx gene that regulate the HBe and core gene expression. HBeAg seroconversion: The clearance of HBeAg by the production of HBeAb.

Peer review

The reported work is very intriguing and represents a large undertaking.

Abstract

AIM: To investigate the possible biological outcome and effect of glutamine depletion in neonatal mice and rodent intestinal epithelial cells.

METHODS: We developed three kinds of artificial milk with different amounts of glutamine; Complete amino acid milk (CAM), which is based on maternal mouse milk, glutamine-depleted milk (GDM), and glutamine-rich milk (GRM). GRM contains three-fold more glutamine than CAM. Eighty-seven newborn mice were divided into three groups and were fed with either of CAM, GDM, or GRM *via* a recently improved nipple-bottle system for seven days. After the feeding period, the mice were subjected to macroscopic and microscopic observations by immunohistochemistry for 5-bromo-2'-deoxyuridine (BrdU) and Ki-67 as markers of cell proliferation, and for cleaved-caspase-3 as a marker of apoptosis. Moreover, IEC6 rat intestinal epithelial cells were cultured in different concentrations of glutamine and were subject to a 4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolio]-1,3-benzene disulfonate cell proliferation assay, flow cytometry, and western blotting to examine the biological effect of glutamine on cell growth and apoptosis.

RESULTS: During the feeding period, we found colonic hemorrhage in six of 28 GDM-fed mice (21.4%), but not in the GRM-fed mice, with no differences in body weight gain between each group. Microscopic examination showed destruction of microvilli and the disappearance of glycocalyx of the intestinal wall in the colon epithelial tissues taken from GDM-fed mice. Intake of GDM reduced BrdU incorporation (the average percentage of BrdU-positive staining; GRM: 13.8%, CAM: 10.7%, GDM: 1.14%, GRM *vs* GDM: $P < 0.001$, CAM *vs* GDM: $P < 0.001$) and Ki-67 labeling index (the average percentage of Ki-67-positive staining; GRM: 24.5%, CAM: 22.4% GDM: 19.4%, GRM *vs* GDM: $P = 0.001$, CAM *vs* GDM: $P =$

0.049), suggesting that glutamine depletion inhibited cell proliferation of intestinal epithelial cells. Glutamine deprivation further caused the deformation of the nuclear membrane and the plasma membrane, accompanied by chromatin degeneration and an absence of fat droplets from the colonic epithelia, indicating that the cells underwent apoptosis. Moreover, immunohistochemical analysis revealed the appearance of cleaved caspase-3 in colonic epithelial cells of GDM-fed mice. Finally, when IEC6 rat intestinal epithelial cells were cultured without glutamine, cell proliferation was significantly suppressed after 24 h (relative cell growth; 4 mmol/L: 100.0% \pm 36.1%, 0 mmol/L: 25.3% \pm 25.0%, $P < 0.05$), with severe cellular damage. The cells underwent apoptosis, accompanied by increased cell population in sub-G0 phase (4 mmol/L: 1.68%, 0.4 mmol/L: 1.35%, 0 mmol/L: 5.21%), where dying cells are supposed to accumulate.

CONCLUSION: Glutamine is an important alimentary component for the maintenance of intestinal mucosa. Glutamine deprivation can cause instability of the intestinal epithelial alignment by increased apoptosis.

INTRODUCTION

Amino acids have various roles in the living body; however, their cytobiological functions associated with cell proliferation or immune responses have not been fully elucidated. Among them, glutamine, which is the most abundant amino acid in the human body, has been recognized as a conditional essential amino acid in critical illness, stress, and injury^[1-4]. Glutamine also has a key role in intermediary metabolism for rapidly dividing cells, such as enterocytes and cells of the immune system^[1,5]. Indeed, the small intestine accounts for the largest uptake of glutamine of any organ, absorbing this amino acid from the lumen of the gut, as well as from the bloodstream^[6]. Illness or injury can lead to a significant decrease in plasma levels of glutamine, and when this decrease is severe, it correlates with increased mortality^[7,8]. Several studies have demonstrated the efficacy of either enteral or parenteral

glutamine in adults and infants with a variety of conditions, such as bone marrow transplantation, critical illness, burns, trauma, surgically treated patients, and very low birth weight infants^[9,10]. Thus, glutamine appears especially important for susceptible individuals who are in high stress conditions.

In the past, it was difficult to identify the roles played by these amino acids *in vivo*. Past studies involved the evaluation of immunological effects of amino acids by the administration of a diet rich or deficient in each amino acid (glutamine, arginine, *etc.*) by means of total parenteral nutrition or stomach tubing^[11]. However, no such study in newborn mice has yet been reported. The lack of such a study in newborn mice is attributable to the fact that it is quite difficult to develop a method of alimentation or to prepare a diet for neonatal mice. To overcome these issues, Yajima *et al.*^[12] have recently developed artificial milk for mice with a composition very close to that of mouse maternal milk. Subsequently, artificial milk for mice with all of the proteins broken down into amino acids was developed. We expected that the use of this milk would make it possible for us to feed newborn mice with milk either deficient or enriched in certain amino acids. In addition, Hoshiba established and reported a new system for the artificial alimentation of rats and mice immediately after birth^[13]. With this system, it is possible to administer certain nutrients orally to newborn mice and rats and to evaluate the effects of these nutrients directly.

In this study, we utilized the above improved special milk and feeding device to achieve the following scientific aims: (1) to explore what happens when newborn mice are fed with glutamine-devoid milk; and (2) to dissect the physiological mechanism of glutamine deprivation-oriented events.

MATERIALS AND METHODS

Bottle-nipple system

The nursing bottle and nipple, which were made by Hoshiba^[13], were used to feed the newborn mice. The nursing bottle has three tubes (a filling tube, an outlet tube, and a ventilation tube) and the nipples are made of a silicone rubber. The nipple consists of inner and outer parts, and a stopper devised to control the pressure as well as to avoid milk leakage.

Animals and study design

Specific-pathogen-free Jcl:ICR pregnant mice were purchased from Charles River Laboratories (Yokohama, Japan). They were maintained under the following environmental conditions: lighting, 12:12-h light:dark cycle; temperature, 22 to 25°C; air changes, 12 to 14 times per hour; and humidity, 40% to 50%. Newborn pups were separated from each dam immediately after birth. They were reared with artificial milk from the nursing bottle four times per day (09:00, 12:30, 16:00, and 20:00) for seven days and sacrificed on day eight. Body weights of the pups were measured before and after feeding, and the difference between them was represented the quantity of feeding.

Table 1 Amino acid components of complete amino acid milk

Serine	0.53 ± 0.01

¹The amount of each amino acid is presented as average ± SE (mg/100 mL of milk).

Milk formula

Artificial milk was purchased from Meiji Dairies Corporation (Odawara, Japan). The amino acid composition of the milk is shown in Table 1. The composition of the milk was made as similar as possible to mouse maternal milk. Table 2 shows the composition of mouse milk and artificial amino acid milk. The artificial amino acid milk showed an extremely high osmotic pressure compared to that of mouse maternal milk, because the proteins in the milk used in this study were in the form of amino acids with a low amount of fat. Thus, 10% lipid microsphere Intralipid (Nihon Pharmaceutical Co. Ltd., Tokyo, Japan) was added to this artificial amino acid milk at a ratio of 1:1 to yield the complete amino acid milk, thus the amount of amino acid contained in this milk was 50% of the initial amount with 16% fat, similar with that of mouse milk (22%). We named this milk complete amino acid milk (CAM). Furthermore, glutamine rich milk (GRM) had three-fold more glutamine than CAM, whereas glutamine-depleted milk (GDM) contained no glutamine.

Histological study

Resected tissues from the mice were fixed in 10% formalin, embedded in paraffin, and cut at a thickness of 5 µm. Sections were deparaffinized, rehydrated, and stained with hematoxylin and eosin. On day eight, the animals were perfused with 2% glutaraldehyde (5 mL) and fixed, followed by the removal of each organ for subsequent thin slicing and observation under an electron microscope.

Immunohistochemistry

To detect cells synthesizing DNA, 5-bromo-2'-deoxyuridine (BrdU) was injected (100 mg/kg i.p.) 1 h before sacrificing the animals. The organs were then placed in 4% paraformaldehyde for 48 h prior to paraffin embedding. BrdU incorporation in colon sections was determined by immunohistochemical staining. Briefly, sections were

deparaffinized with xylene (Mallinckrodt Baker, Paris, Kentucky) and taken through a graded series of alcohol/water mixtures to rehydrate the tissue. To retrieve the antigen, sections were incubated with 2 mol/L HCl for 30 min and then incubated with 0.1 mol/L Na₂VO₄O₇ at room temperature for 30 s. Sections were exposed to rat anti-BrdU monoclonal antibodies (OBT, Oxford, UK) for 60 min at room temperature. Peroxidase-conjugated anti-mouse IgG₁ antibody (DAKO, Carpinteria, CA) was then applied, and 3,3'-diaminobenzidine chromogen was added as the peroxidase substrate. A light counterstain of modified Mayer's hematoxylin (Muto Pure Chemicals, Tokyo, Japan) was then applied so that unlabeled nuclei could be easily identified. Immunostaining for Ki-67 and cleaved caspase-3, the biological markers for cell proliferation and apoptosis, respectively, used a rabbit anti-Ki-67 monoclonal antibody (Ylem, Rome, Italy) and a rabbit anti-cleaved caspase-3 polyclonal antibody (Cell Signaling Technology, Beverly, MA, USA), respectively.

Cell culture and treatments

There was no commercially available mouse intestinal epithelial cell line; therefore, we used IEC6 rat intestinal epithelial cells, which were obtained from Dainippon Pharmaceutical Co. Ltd. (Tokyo, Japan), and maintained in dulbecco's modified eagle medium (DMEM) with 10% FBS and 4 mmol/L L-glutamine for 24 h. Cells were incubated in DMEM with 0, 0.4, or 4 mmol/L L-glutamine without FBS for the indicated time periods (0, 3, 6, 12, 24 and 48 h).

Proliferation assay

The number of surviving cells was measured by the 4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolol]-1,3-benzene disulfonate (WST-1) assay (Roche, Indianapolis, USA) for the indicated time periods after plating.

Immunoblot analysis of caspase-3

Cells were lysed in 1 × sodium dodecyl sulfate (SDS) sample buffer (62.5 mmol/L Tris-HCl (pH 6.8 at 25°C), 2% w/v SDS, 10% glycerol, 50 mmol/L dithiothreitol, and 0.01% w/v bromophenol blue or phenol red) and centrifuged at 4°C. The sample viscosity was reduced by pipetting. The samples were then boiled for 5 min and cooled on ice. The samples were separated by SDS-poly-acrylamide gel electrophoresis on 12% polyacrylamide gels, transferred onto a polyvinylidene difluoride membrane, immunoblotted with Rabbit anti-caspase-3 polyclonal antibody (Upstate Cell Signaling Solutions, Charlottesville, VA) and Rabbit anti-cleaved caspase-3 polyclonal antibody (Millipore corporation, Bedford, MA) followed by anti-rabbit immunoglobulin G-horseradish peroxidase (GE, Piscataway, NJ). Immuno-reactive proteins were visualized using an Enhanced Chemi-Luminescence kit according to the manufacturer's protocol (GE, Piscataway, NJ).

Cell cycle analysis

Cell cycle analysis was performed by propidium iodide (PI) staining. Briefly, IEC6 cells were first seeded into 10-cm

Table 2 Nutrient composition of mouse milk and artificial amino acid milk

	Mouse milk	Artificial amino acid milk	CAM ¹	GDM	GRM
Osmotic pressure (mOsm/kg)	300	1800	1161	ND	ND
Glutamine (g/L)	ND	24.23	12.12	0	36.35
Fat (%)	22	10	16	16	16

¹Emulsified fat was added to artificial amino acid milk at a ratio of 1:1 to yield complete amino acid milk (CAM), because the proteins in the milk used in this study were in the form of amino acids, resulting in a very high osmotic pressure with a low amount of fat. As a result, the amount of amino acid contained in the CAM is 50% of the initial amount. GDM: Glutamine-deleted milk; GRM: Glutamine-rich milk; ND: Not determined.

Figure 1 Macroscopic views of milk-fed mice with colonic hemorrhage. Representative macroscopic views of newborn mice that were fed with glutamine-rich milk (GRM) (A), complete amino acid milk (CAM) (B), and glutamine-deleted milk (GDM) (C) are shown. Compared to the colons of GRM-mice and CAM-mice (asterisks), those of the GDM-mice appeared distended and edematous, with a pool of blood (arrow); D: Close-up views of the resected intestines from a CAM-mouse and a GDM-mouse, shown for comparison; E: Bar chart of the number of mice with melena on each day.

dishes at a cell density of 5×10^5 . After further culture for 48 h and 96 h, the cells were trypsinized and harvested in phosphate buffered saline (PBS) followed by resuspension in PBS at $1-2 \times 10^6$ /mL. Finally, the cells were stained with 0.5 mL of PI staining solution (3.8 mmol/L sodium citrate, 50 mg/mL PI in PBS) for 1 h at room temperature to analyze cell cycle distribution by FACSCalibur (Becton Dickinson Immunocytometry Systems, San Jose, CA) excitation at 488-nm. The DNA-linked red fluorescence (PI) was measured through a 600-nm wavelength filter. This experiment was performed three times.

Statistical analysis

For *in vivo* experiments, the significance of differences between the control and test values was determined by Tukey's test using JMP 6.0.3 software (SAS Institute, Cary, NC). $P < 0.05$ was considered statistically significant.

RESULTS

Mice fed with GDM display colonic hemorrhage

Newborn mice were assigned to three groups (GRM, CAM, and GDM) and were fed four times a day according to the above-mentioned schedule. During the observation periods, the mice gained weight regardless of the amount of glutamine, and there were no significant differences between the groups (data not shown).

We measured the glutamine concentration in serum taken from each mouse fed with different types of milk. As expected, the GRM-mouse serum contained the highest amount of glutamine (7.53% of total amino acids), while the GDM-mouse serum had the lowest amount of glutamine (4.92% of total amino acids) in circulation. The CAM-mice maintained less glutamine in serum (5.74% of total amino acids) than the dam-reared mice (6.44%).

Figure 2 Glutamine depletion induces severe damage of the colonic epithelial structure with reduced epithelial cell growth. A: Representative pictures of H-E staining (left panels) and immunohistochemical staining for BrdU (middle panels) and Ki-67 (right panels). Each colonic epithelium was taken from infant mice fed with glutamine-rich milk (GRM), complete amino acid milk (CAM), or glutamine-deleted milk (GDM). Magnification, $\times 200$. Positive stained epithelial cells with BrdU (B) and Ki-67 (C) were counted and compared with each group in a histogram. $^bP \leq 0.001$; $^cP < 0.05$.

These data suggested that the amount of glutamine in the milk fed to the pups did affect the concentration of glutamine circulating in the animal body.

When the mice were sacrificed on day eight, we found a pool of blood in the colons of the GDM-fed mice accompanied by melena (Figure 1A-C). In addition, the entire bowel of these mice showed a massive edematous change, accompanied by wall thickening, redness, and dilatation of the small intestine (Figure 1D). No macroscopic changes were observed in mice fed with glutamine-containing milk, except for one mouse fed with CAM (Figure 1A-D). These events were observed in six of 28 GDM-fed mice (21.4%) and one CAM-fed mouse (3.3%), and started on days five to seven (one mouse on day five, four mice including the mouse fed with CAM, on day six, and two mice on day seven) (Figure 1E). No mice fed with GRM developed

melena during the observation period. The incidence of melena was significantly higher in the GDM group compared to the other groups (Figure 1E), suggesting that glutamine depletion must affect the maintenance of the neonatal gastrointestinal tract.

Glutamine depletion reduces cell proliferation and increases apoptosis in the colonic epithelium

Histological observation by hematoxylin-eosin staining revealed the destruction of the villous structure, wall thickening with edematous dilatation of the submucosal layer, and inflammatory cell infiltration around the hemorrhage site of the colons in the mice fed without glutamine (Figure 2A). In addition, a reduction of goblet cells was noted in this group, suggesting a disorder of cell maturation. Interestingly, the intestinal mucosa of the GRM-fed mice were

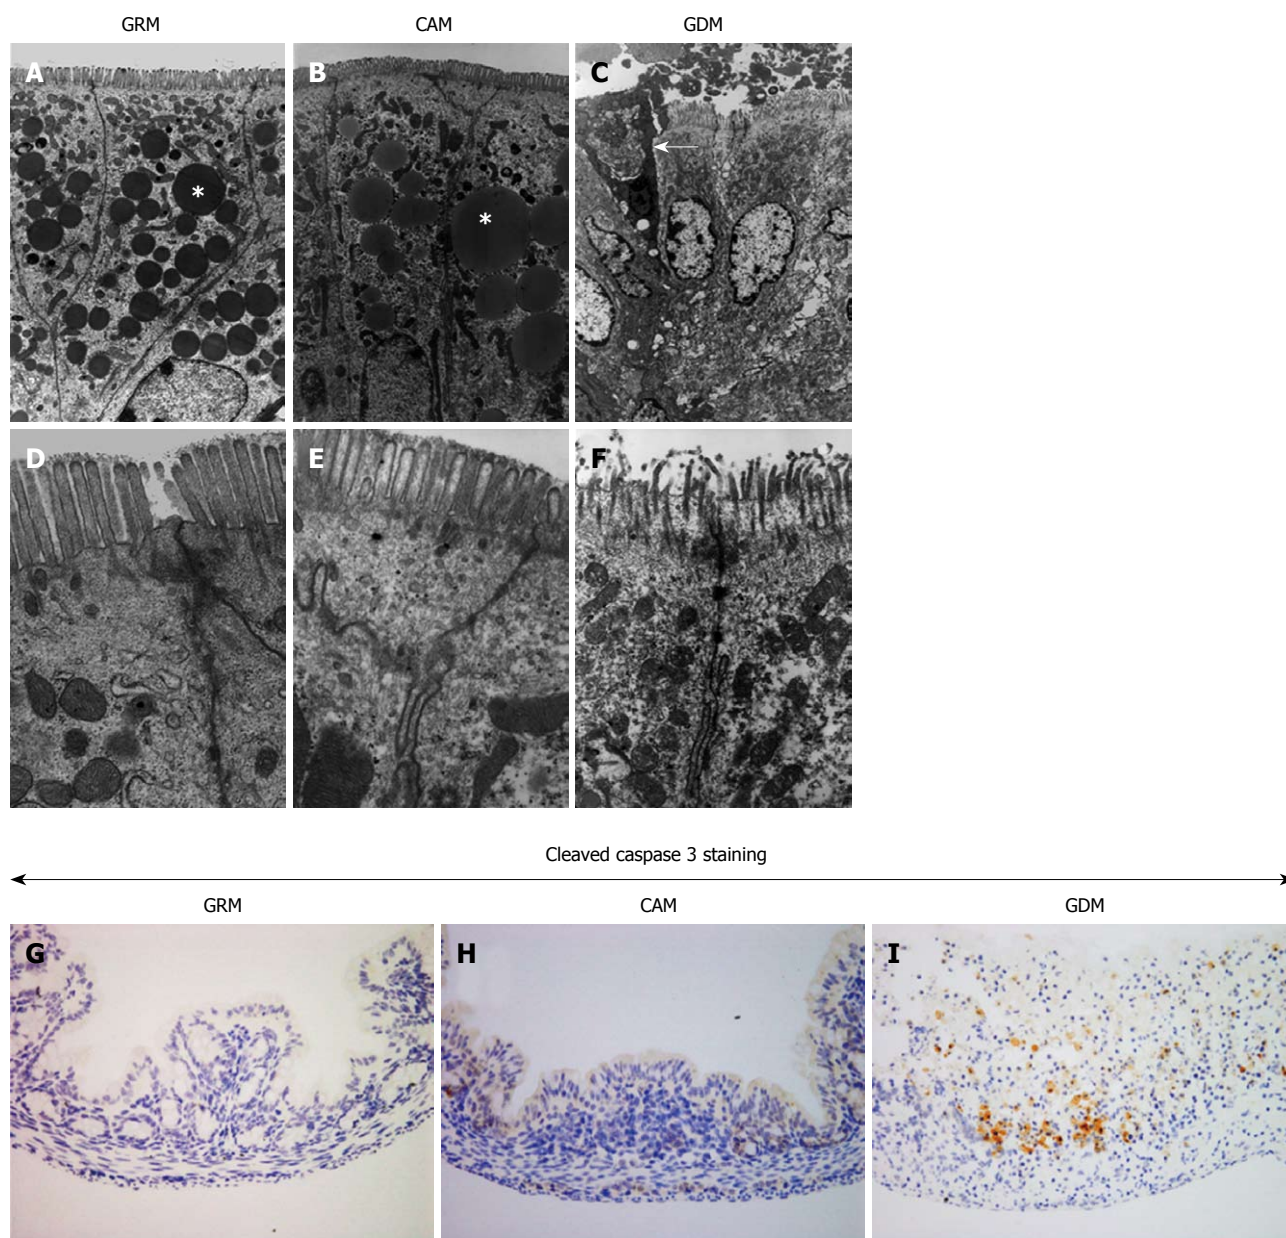

Figure 3 Apoptotic changes observed in the damaged colonic epithelium. Electron micrographs of colonic epithelia obtained from infant mice with glutamine-rich milk (GRM) (A, D), complete amino acid milk (CAM) (B, E), and glutamine-deleted milk (GDM) (C, F) at low magnification (A-C) and high magnification (D-F). Asterisks (*) represent lipid droplets and the arrow shows an apoptotic cell. G-I: Optical microscopic views (magnification, $\times 200$) of immunohistochemistry for cleaved caspase-3 as a marker of apoptosis using resected tissues from the same mice (G: GRM, H: CAM, I: GDM).

higher than those of the CAM-fed mice (Figure 2A).

We then assessed cell proliferation in colonic epithelial cells by immunostaining for BrdU and Ki-67, which are markers for DNA synthesis and cell proliferation, respectively (Figure 2A). BrdU incorporation was significantly decreased in colonic epithelial cells of the GDM-fed mice compared to those of CAM-mice and GRM-mice (average percentage of BrdU-positive staining per 1000 cells; GRM: 13.8%, CAM: 10.7%, GDM: 1.14%, Tukey test; GRM *vs* GDM, $P < 0.001$; CAM *vs* GDM, $P < 0.001$) (Figure 2B). Ki-67-positive staining was also significantly decreased in the colonic epithelia of the GDM-fed mice (average percentage of Ki-67-positive staining; GRM: 24.5%, CAM: 22.4%, GDM: 19.4%, Tukey test; GRM *vs* GDM, $P = 0.001$; CAM *vs* GDM, $P = 0.049$) (Figure 2C). These data indi-

cated that glutamine deprivation strongly diminished cell growth of the intestinal epithelium.

We further examined the damaged colonic mucosa under the electron microscope. Figure 3A-F shows representative pictures of colonic epithelia from each group. Glutamine deprivation caused deformation of the nuclear membrane and the plasma membrane, accompanied by the destruction of microvilli and the disappearance of glycocalyx, resulting in nuclear deformation and chromatin degeneration. Fat droplets, which were seen in the colons of the mice fed with the glutamine-containing milk, were absent in the GDM Group. Furthermore, a partial loss of colonic epithelial cells was noted in the GDM Group, indicating that glutamine deprivation promotes cell death. To confirm glutamine deprivation-induced cell death,

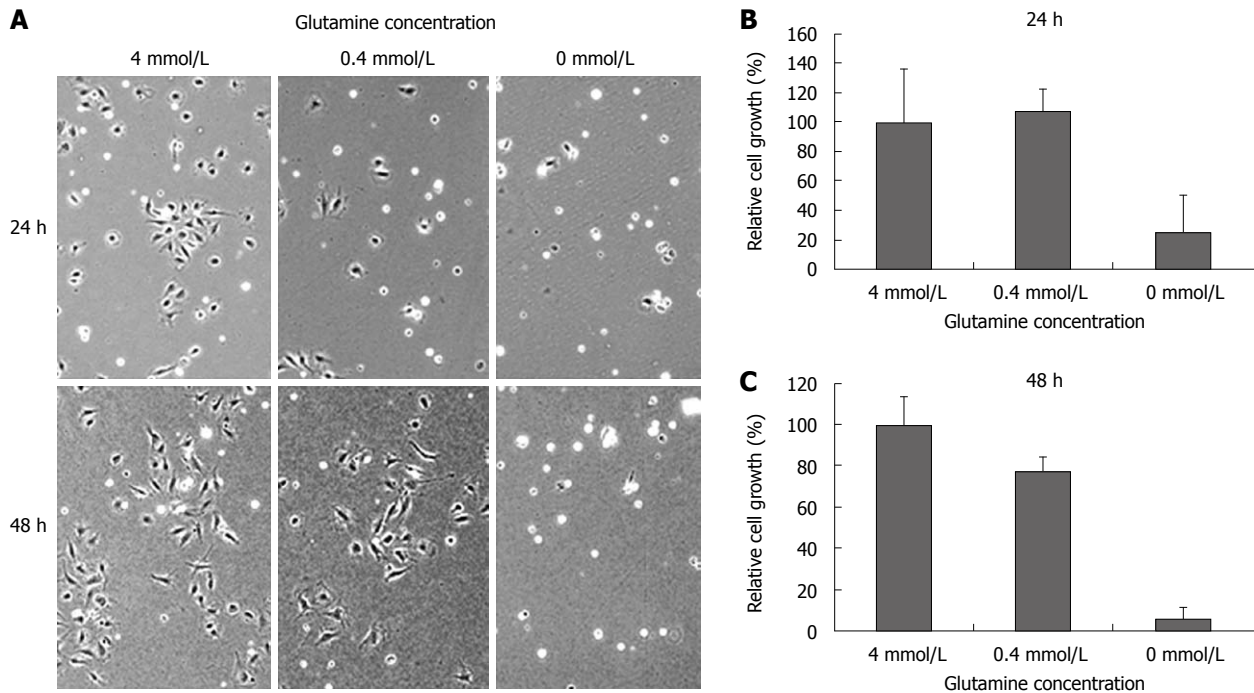

Figure 4 Glutamine depletion suppresses cell proliferation of cultured intestinal epithelial cells. A: IEC6 rat intestinal epithelial cells were treated with media containing different amounts of glutamine (0, 0.4 and 4 mmol/L); Cell morphology and cell number were observed at the indicated time points (B: 24 h, C: 48 h).

cleavage of caspase-3 was assessed by immunohistochemistry. As shown in Figure 3G-I, there was a remarkable number of cleaved caspase-3-positive stained cells in the glutamine-deprived mucosa, suggesting that a lack of glutamine induces colonic epithelial cell death, possibly through the process of apoptosis.

Glutamine depletion reduces cell proliferation in IEC6 rat intestinal cells

To clarify the effect of glutamine depletion on intestinal epithelial cell growth, IEC6 rat intestinal epithelial cells were cultured in the presence of varying concentrations of glutamine. Microscopic observation showed that glutamine depletion damaged cell morphology and reduced cell density (Figure 4A). As shown in Figure 4B and C, glutamine depleted conditions significantly suppressed IEC6 cell growth after 24 h (4 mmol/L: 100.0 ± 36.1 , 0 mmol/L: 25.3 ± 25.0 , $P < 0.05$), while there was no apparent difference between 4 mmol/L and 0.4 mmol/L after 24 h (4 mmol/L: 100.0 ± 36.1 , 0.4 mmol/L: 107.4 ± 15.4 , $P = 0.7614$), or after 48 h (4 mmol/L: 100.0 ± 14.0 , 0.4 mmol/L: 77.4 ± 6.9 , $P = 0.0659$). We further assessed the inhibitory effect on cell proliferation by cell cycle analysis, using flow cytometry (Figure 5A and B). We did not observe significant cell growth arrest at the G1 or G2 phase; however, an increased cell population at the sub-G0 phase was observed within 48 h of glutamine depletion (4 mmol/L: 1.68%, 0.4 mmol/L: 1.35%, 0 mmol/L: 5.21%, Figure 5B), which is consistent with the observation in the animal model that glutamine-depletion seemed to be lethal to intestinal epithelial cells.

Finally, we determined whether glutamine depletion-mediated cell death in cultured IEC6 cells occurs due to

induction of apoptosis. Cells cultured with a complete depletion of glutamine showed a time-dependent decrease in caspase-3 expression, accompanied by cleavage of caspase-3 within 24 h (Figure 5C). These data support our finding in the animal study that a lack of glutamine affects the maintenance of intestinal epithelial cells, suppresses cell growth and induces apoptosis, resulting in melena.

DISCUSSION

Until recently, it was quite difficult to study the physiological and cytobiological effects of amino acids *in vivo*, especially for neonatal animals, because of the lack of methods of alimentation or of preparing a diet for neonatal mice. In this study, using a totally new milk feeding system and amino acid milk, we successfully observed the physiological effects of glutamine depletion in newborn mice. Interestingly, a significantly high incidence of colonic hemorrhage occurred in mice fed with GDM, compared to the CAM or GRM groups. We had one CAM-fed mouse that had a similar colonic hemorrhage on day six. This mouse might have had a genetic/physiological susceptibility to the event. It could also have been caused by the fact that the amount of amino acid contained in the CAM was 50% of the ordinary amount because emulsified fat was added to the artificial amino acid milk at a ratio of 1:1 to yield CAM. The proteins in the milk used in this study were in the form of amino acids, resulting in a very high osmotic pressure with a low amount of fat (Table 2). If the artificial amino acid milk is applied directly to newborn mice without adding fat, which is a major nutrient for them, a fat deficiency might occur. Therefore, the melena that occurred in the CAM-

Figure 5 Potent antiproliferative effect of glutamine depletion results in increased cleavage of caspase-3. Cell cycle distribution under culture condition with different concentrations of glutamine was analyzed by flow cytometry (A) and cell populations at the sub-G0 phase were compared with each other (B); C: Immunoblotting for caspase-3 and cleaved caspase-3 revealed the induction of apoptosis in IEC6 cells after 24 h of culture without glutamine. Each experiment was independently repeated three times and the representative data among the similar results are shown.

fed mouse may be explained by an insufficient intake of glutamine. Meanwhile, no animal developed colonic hemorrhage in the GRM Group; thus, we assume that the glutamine level in this milk was high enough to maintain the intestinal epithelium.

Other macroscopic findings in the hemorrhagic intestines of the GDM-fed mice were the apparent inflammatory changes of the entire intestine, with intestinal wall thickening by edema. Microscopic observations supported these findings, with infiltration of inflammatory cells in and around destroyed colonic mucosa at the site of the hemorrhage. On the other hand, the height of the colonic mucosa of GRM-fed mice was well conserved and was higher than that of the CAM mice. In addition, as more glutamine was administered, more positive-staining cells for BrdU and Ki-67 appeared, suggesting that glutamine is a critical nutrient for the proliferation of intestinal cells. Moreover, both electron microscopic observations and immunohistochemistry for cleaved caspase-3

reflected an increased incidence of apoptosis induced by glutamine depletion. However, no exact intracellular mechanism has been identified for the destruction of the nuclear membrane and microvilli, or the disappearance of glycocalyx, which were induced by GDM. Clarifying the molecular/biophysical mechanism of this glutamine depletion-mediated event will be crucial to understanding the intrinsic functions of glutamine or other amino acids.

Experimental data from cultured IEC6 cells supported the findings of the animal experiments, with the reduced cell proliferation, accumulation of a cell population in the sub-G0 phase, and the cleavage of caspase-3 under glutamine-depleted culture conditions. According to these results, glutamine depletion induces cell death of colonic mucosa, presumably due to an acute induction of apoptosis, followed by the destruction of mucosa maintenance, which eventually leads to colonic hemorrhage.

In the present study, it was remarkable that colonic hemorrhage could be induced simply by removing one

amino acid, glutamine. Glutamine has attracted close attention as an amino acid nutrient and as an immunopotentiating factor for intestinal cells^[14-16]. However, no case of intestinal hemorrhage induced by glutamine deficiency has been reported to date. Although glutamine is a non-essential amino acid and can be produced in the living body, neonatal mice are actively growing and are very dependent on external alimentation due to a heavier consumption of nutrients, including glutamine, compared to adults^[17]. It seems likely that the consumption of glutamine by these neonatal mice might exceed the amount of glutamine pooled and formed in the living body, leading to the emergent status of glutamine deficiency.

In terms of molecular/biological effects of glutamine, there are outstanding several issues that remain to be clarified. One of our interests is to explore the possible involvement of certain signaling pathways. It has recently been unveiled that amino acids are involved in the control of the mTOR signaling pathway^[18]. We have also demonstrated previously that leucine activates the mTOR signaling pathway in a hepatocellular carcinoma cell line^[19]. It has also been shown that leucine and arginine activate the mTOR signaling pathway in a small bowel epithelial cell line derived from rats^[20]. We also found that glutamine regulates the activation of this pathway in the same cell line^[21]. Therefore, future studies should focus on the mechanism for the induction of colonic hemorrhage and how glutamine is involved in the intracellular signaling pathway, such as in mTOR^[22-24].

In conclusion, we found that feeding neonatal mice with GDM induced a high incidence of colonic hemorrhage within a week, and that this was due to an induction of epithelial cell death. Further investigation is necessary to explore the biological mechanism.

COMMENTS

Background

Glutamine, the most abundant amino acid in the human body, is conditionally essential, especially for susceptible individuals who are in high stress conditions. A lack of glutamine correlates with increased mortality.

Research frontiers

The small intestine accounts for the largest uptake of glutamine of any organ, absorbing this amino acid from the lumen of the gut, as well as from the bloodstream. Past studies involved the evaluation of immunological effects of amino acids by the administration of a diet rich or deficient in each amino acid (glutamine, arginine, etc.) by means of total parenteral nutrition or stomach tubing. However, no such study in newborn mice has yet been reported. The lack of such a study in newborn mice is attributable to the difficulty in developing a method of alimentation or preparing a diet for neonatal mice.

Innovations and breakthroughs

The authors developed three kinds of artificial milk with different amounts of glutamine. Using these amino acid milks and a recently improved nipple-bottle feeding system, they successfully fed the newborn mice with the new amino acid milk and observed colonic hemorrhage in mice fed without glutamine. It was remarkable that colonic hemorrhage could be induced simply by removing one amino acid, glutamine. In addition, glutamine deprivation can cause instability of intestinal epithelial alignment by increased apoptosis.

Applications

No exact intracellular mechanism has been identified for the destruction of the nuclear membrane and microvilli or the disappearance of glycocalyx, which were induced by glutamine depletion. Thus, we must explore the mechanism of the induction of colonic hemorrhage and investigate glutamine's involvement in the intracellular signaling pathway, to better understand the intrinsic functions of glutamine and other amino acids.

Peer review

The authors have described that glutamine depletion induces neonatal mice melena and apoptosis of intestinal epithelium *in vivo* and *in vitro*. The authors obtained good data allowing the conclusion that glutamine depletion induces neonatal mice melena and apoptosis of intestinal epithelium, using appropriate methods. An animal model was established for glutamine deprivation-induced destruction of the intestinal epithelium. It would also be meaningful to study the effects of glutamine-deprivation on human intestinal function.

selected metabolites were different between normal and cancer groups (non-metastasis and metastasis groups), and seven metabolites were also different between non-metastasis and metastasis groups. Two diagnostic models for gastric cancer and metastasis were constructed respectively by the principal component analysis (PCA). These PCA models were confirmed by corresponding receiver operating characteristic analysis (area under the curve = 1.00).

CONCLUSION: The urinary metabolomic profile is different, and the selected metabolites might be instructive to clinical diagnosis or screening metastasis for gastric cancer.

Abstract

AIM: To gain new insights into tumor metabolism and to identify possible biomarkers with potential diagnostic values to predict tumor metastasis.

METHODS: Human gastric cancer SGC-7901 cells were implanted into 24 severe combined immune deficiency (SCID) mice, which were randomly divided into metastasis group ($n = 8$), non-metastasis group ($n = 8$), and normal group ($n = 8$). Urinary metabolomic information was obtained by gas chromatography/mass spectrometry (GC/MS).

RESULTS: There were significant metabolic differences among the three groups (t test, $P < 0.05$). Ten

INTRODUCTION

Gastric cancer is the second leading cause of cancer death worldwide, and in many Asian countries, such as China^[1,2]. Until now, there has been no effective treatment for gastric cancer. Even among patients undergoing gastrectomy,

because of locoregional relapse and distant metastases, the 5-year survival rates remain disappointing^[3]. Early dissemination of the disease through the lymphatic system, blood and peritoneum has limited the therapeutic effects of optimal surgery, except in patients with relatively early-stage tumors^[4]. Therefore, it is significant to establish an accurate early diagnosis of gastric cancer. Currently, the diagnosis or screening of gastric cancer or tumor recurrence mainly depends on endoscopy and pathological examinations. The ratio for identifying early gastric cancer with endoscopy is higher than that with X-ray^[5], and the diagnosis of gastric cancer using endoscopy is more accurate^[6]. Nevertheless, the results of endoscopy are easily affected by artificial factors (e.g. the experience of the endoscopist). Over the past years, epidemiological data have shown that *Helicobacter pylori* (*H. pylori*) infection is strongly associated with the development of gastric cancer^[1], and *H. pylori* eradication may be considered as a strategy to prevent gastric cancer^[7]. In addition, investigation of gastric cancer tissues and some biomarkers have been used for screening gastric cancer^[8-13]. However, compared with tissues and serum, the markers acquired from urine are noninvasive and convenient, especially in the patients with recurrent gastric cancer. The urinary metabolic profiling could be used to get urinary metabolites as gastric cancer or tumor recurrence biomarkers.

Metabolomics is a post-genomic research field for analysis of low molecular weight compounds in biological systems^[14], and offers an analysis of metabolite level changes in biological samples^[15]. In recent years, studies of metabolomics used in various diseases have been conducted, such as stomach cancer^[16], lung cancer^[17], renal cancer^[18,19], brain tumors^[20], and colorectal cancer^[21-24]. Nuclear magnetic resonance spectroscopy (NMR) and mass spectrometry (MS) are the most commonly employed techniques for measuring the metabolome^[14]. MS-based techniques, including gas chromatography/mass spectrometry (GC/MS), GC-MS/MS, liquid chromatography/mass spectrometry (LC-MS) and LC-MS/MS, are among the most efficient and versatile for quantitative analysis of endogenous and exogenous substances in biological samples^[25]. Because of its peak resolution, high sensitivity and reproducibility, GC/MS has been well established and widely utilized in metabolomics^[26-28].

In this study, we have established a human gastric cancer non-metastasis model and a metastasis model using severe combined immune deficiency (SCID) mice, and deployed GC/MS following chemical derivatization to profile the mouse model urinary specimens and their matched urine. The metabolic differences among the three groups were characterized by principal components analysis (PCA). On the basis of its results, we expected that the potential metabolic biomarkers could be found in mice for early diagnosis and screening the metastasis or the recurrence of gastric cancer.

MATERIALS AND METHODS

Chemicals and materials

Tetrahydrofuran (THF) and bis-(trimethylsilyl)-trifluoroacetamide (BSTFA) were obtained from Sigma Chemical

Co. (St Louis, MO, USA). Vacuum dryer was purchased from Shanghai NOTED Technologies. All other reagents were obtained from Sinopharm Chemical Reagent Co. Ltd.

Animal models

Male SCID mice were acquired from Shanghai Experimental Animal Center of Chinese Academy of Sciences. Animals used were 6-wk old and weighed 20-25 g. Animal and experimental procedures were performed according to the relative ethical regulations for the care and use of laboratory animals of our university. Human gastric cancer SGC-7901 (Shanghai Cancer Institute), a poorly-differentiated adenocarcinoma line, was originally derived from a primary tumor and maintained by passage in the subcutis of nude mice. Tumors were cut out aseptically. Necrotic tissues were cut and the reserved healthy tumor tissues were scissor minced into pieces (about 3 mm × 4 mm in diameter) in Hank's balanced salt solution. Each tumor piece was weighed and adjusted to be approximately 100 mg. All animals were randomly divided into metastasis group ($n = 8$), non-metastasis group ($n = 8$), and normal group ($n = 8$). Animal models were made using orthotopic implantation of histologically intact tissue of human gastric cancer^[29]. Mice were anesthetized with 4.3% trichloraldehyde hydrate. An incision of the metastatic group and the normal group was made through the left upper abdominal pararectal line. Then peritoneal cavity was carefully exposed and a part of serosal membrane in the middle of the greater curvature of stomach was mechanically injured by scissors. A tumor piece of 100 mg was fixed on each injured site of the serosal surface of the metastatic group, while normal control mice received no tumor implantation. The stomach was then returned to the peritoneal cavity, and the abdominal wall and skin were closed. An incision of the non-metastatic group was made at the left outer. A tumor piece of 100 mg was fixed under the skin. All animals were sent to the breeding room after becoming conscious.

Specimen collection and pathological examination

Six weeks after implantation, all mice were housed in metabolic cages and maintained in an air conditioned room ($24 \pm 2^\circ\text{C}$). They were only allowed free access to water during urine sample collection (8:00 pm that day to 8:00 am the next day). All animal urine was collected in frozen tubes at the sixth week after implantation, and immediately stored at -80°C until processing. The specimens were collected at the same time. Then all mice were killed, tumors growing on the stomach wall were resected and fixed in 4% formalin, and processed for routine paraffin embedding after careful macroscopic examination. In order to evaluate histologically for liver metastasis or lymph node metastasis or other organ metastasis under microscope, four-micron-thick sections were stained with hematoxylin and eosin, then observed by a blinded pathologist.

Sample pretreatment and derivatization

Each urinary specimen was transferred to a glass cen-

trifuge tube, subsequently centrifuged at $18000 \times g$ for 3 min and 50 μL of the supernatant was collected from each sample into a 1-mL EP tube, respectively. The collected supernatant was evaporated to dryness at 60°C for 24 h, using a vacuum dryer. Then 100 μL THF was added to each of the dried urine extracts and vortex-mixed for 2 min, and 50 μL BSTFA was added to the mixture and vortex-mixed for 2 min. The mixture was incubated at 60°C and derivatized for 30 min. After returning to the ambient temperature, samples were prepared for GC/MS analysis.

GC/MS analysis

Each derivatized sample of 1 μL was injected splitless into an Agilent 6980 GC system equipped with an HP5MS capillary column (30 m \times 0.25 mm i.d., 0.25 μm), electron impact ionization at 70 eV, and a quadrupole mass spectrometric detector (Agilent Technologies, Palo Alto, CA, USA). The column temperature was initially held at 100°C for 3 min, $10^\circ\text{C}/\text{min}$ up to 220°C , then $10^\circ\text{C}/\text{min}$ to 280°C , and remained there for 5 min. The injector temperature was 280°C . Carrier gas flow was helium at a constant flow rate of 1.0 mL/min. The interface temperature and the ion source temperature were set at 200°C . Masses were obtained from 100–600 m/z . GC total ion chromatograms (TICs) and fragmentation patterns were acquired using GC/MSD ChemStation Software (Agilent Technologies, Palo Alto, CA, USA). Compound identification was performed by comparing the mass spectrum with a standard mass spectrum in the national institute of standards and technology (NIST) mass spectra library. Peaks with similarity index more than 70% were assigned compound names, while those having less than 70% similarity were listed as unknown metabolites^[30]. The chromatograms were subjected to noise reduction prior to peak area integration. Any known artificial peaks, such as peaks due to noise, column bleed and BSTFA derivatization procedure, were excluded from the data set. Integrated peak areas of multiple derivative peaks belonging to the same compound were summed and considered as a single compound. The resulting three dimensional matrix included sample information, peak intensities and peak retention time, and was applied to correlation analysis and pattern recognition.

Data processing and pattern recognition

The relative peak area of each compound would be calculated as the response after the peak areas of compounds were integrated. Each sample was represented by a GC/MS TIC. *t* test was employed for statistical analysis. Data were expressed as mean \pm SD. The differentially expressed compounds with $P < 0.05$ were considered statistically significant. PCA was used to differentiate the samples and performed using the SPSS 16.0 for Windows.

RESULTS

General state of mice and pathological results

The mean weight of mice was 23.81 ± 0.16 g, 23.87 ± 0.19 g and 23.98 ± 0.19 g for normal group, non-metastasis group and metastasis group, respectively ($P > 0.05$).

Figure 1 Gastric cancer pathological photographs. A: Gastric cancer cells in mice of the non-metastatic group (HE stain, $\times 200$); B: Gastric cancer metastasis in the liver (HE stain, $\times 200$).

All animals from the three groups were alive at the sixth week. The normal group mice had no tumor and metastasis. The non-metastasis group and metastasis group developed localized tumors at the implanted site, which were poorly-differentiated adenocarcinomas under microscope (Figure 1A). The non-metastasis group tumor tissues (4.28 ± 0.20 g) were located at the left oter, and have no metastasis in regional lymph nodes, liver and other organs. The metastasis group mice had cancer tissues (4.3 ± 0.3 g *vs* non-metastasis group, $P > 0.05$) in the stomach, while metastatic tumors were also found in liver (Figure 1B), regional lymph nodes, and other organs. Six mice developed metastatic tumors in regional lymph nodes, four in liver, and two in other organs.

Metabolomic profiling of samples

GC/MS TIC chromatograms of urine samples derived from the normal group, the non-metastatic group and the metastatic group are presented in Figure 2. In the GC/MS TICs of urinary samples from the three groups, some peaks were identified based on NIST mass spectra library, and several examples of peaks had statistical significance (Figure 2).

With GC/MS, around 120 signals were detected per sample using mass spectral deconvolution software for peak detection. However, many of them were not consistently found in other samples or were of too low abundance or too poor spectral quality to be obviously assigned to unique metabolites. Several choline, amino acids, and fatty acids could not be found, which may be

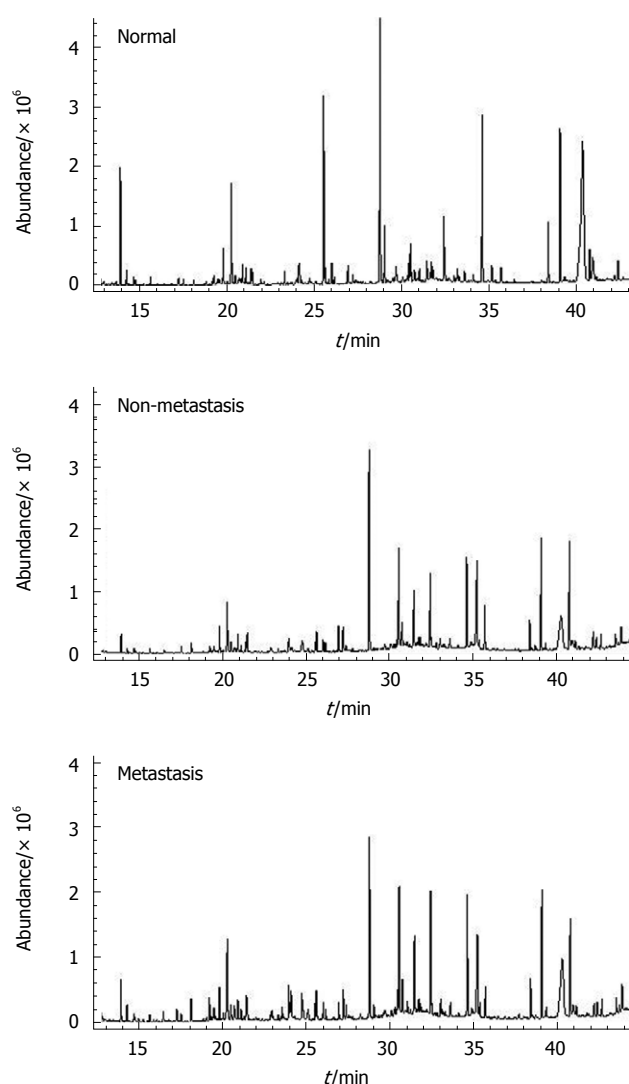

Figure 2 Representative gas chromatography/mass spectrometry total ion chromatograms of the samples from the three groups (normal group, non-metastasis group and metastasis group) after chemical derivatization.

associated with the efficiency of chemical derivatization. Table 1 shows that 46 signals could be auto-identified by the NIST library through comparing with a standard mass chromatogram. The remaining peaks which could not be identified were not listed. In addition, the retention time of metabolites and the match percentage to the NIST library are also listed in Table 1.

Three TIC profiles of consecutively injected samples of the same aliquot are presented in Figure 3, which showed stable retention time with no drift in all of the peaks. The stable TICs reflected the stability of GC/MS analysis and reliability of the metabolomic data.

Urine GC/MS data from the three groups were analyzed. Metabolites selected by *t* test are listed in Tables 2 and 3 after normalization of data. Lactic acid, butanoic acid, propanoic acid, glycerol, pyrimidine, butanedioic acid, malic acid, citric acid, hexadecanoic acid and uric acid were found at higher levels in the urine of cancer group (non-metastasis group and metastasis group) than in normal control group (Table 2). Furthermore, the de-

Table 1 Urine metabolites of mice in the three groups (normal, non-metastasis and metastasis)

Peak No.	Retention time	Metabolites	Match percent (%)

45	38.388	Retinoic acid, methyl ester	95
46	39.065	Octadecanoic acid	99

Peaks in the total ion chromatograms are numbered according to their retention time. The identification of metabolite is based on national institute of standards and technology mass spectra database according to the match of masses (*m/z*) between the interested peak's fragmentation pattern and that from the standard database.

creased levels of alanine, butanoic acid, glycerol, L-proline and L-threonic acid were found in the metastasis group as compared with the non-metastasis group. However, the levels of butanedioic acid and myo-inositol were significantly higher in the metastasis group than in the non-metastasis group (Table 3).

Pattern recognition and function analysis

A PCA model for gastric cancer was constructed using

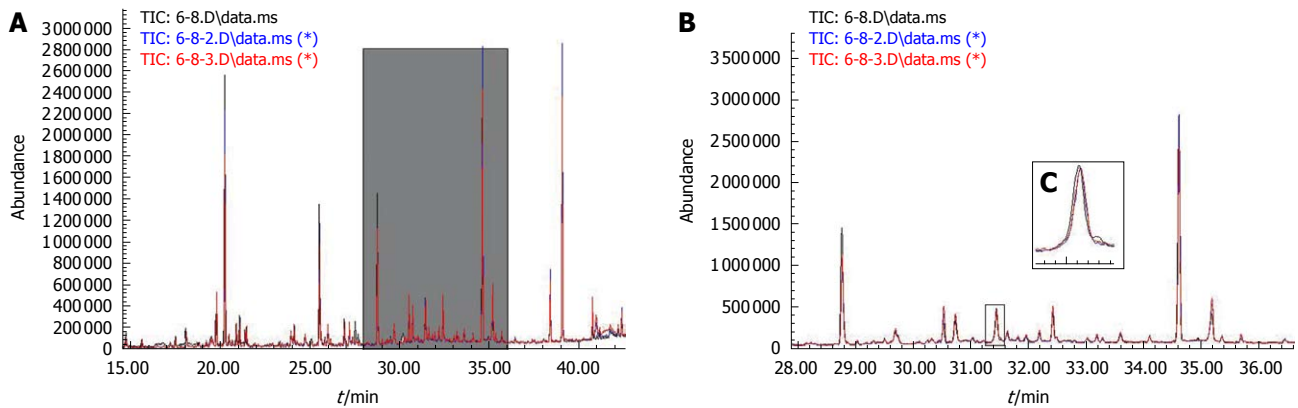

Figure 3 The overlay chromatograms of three parallel samples. A: The total ion chromatograms (TICs) of gas chromatography/mass spectrometry analysis; B: Enlarged part of TIC from 28 to 36 min; C: One peak enlarged.

Table 2 Marker metabolites found in normal and cancer groups

Metabolites	Retention time	P value ¹	A (normal)	B (cancer ²)	R ³
Lactic acid	7.196	2.4×10^{-5}	79.24 ± 6.1	187.04 ± 71.99	1.36
Butanoic acid	9.412	0.000	16.79 ± 0.52	27.33 ± 4.98	0.63
Propanoic acid	14.293	0.000	60.58 ± 9.79	147.77 ± 15.3	1.43
Glycerol	12.511	0.000	147 ± 8.98	269.13 ± 50.31	0.83
Pyrimidine	14.705	0.000	61.68 ± 8.05	163.11 ± 12.23	1.64
Butanedioic acid	13.933	0.1×10^{-5}	161.51 ± 5.85	267.89 ± 54.64	0.66
Malic acid	19.301	0.000	10.7 ± 1.91	32.15 ± 1.16	2.00
Citric acid	28.768	1.4×10^{-4}	1291.89 ± 364.74	2164.74 ± 529.58	0.68
Hexadecanoic acid	34.612	4.17×10^{-4}	1347.84 ± 304.67	2066.57 ± 437.28	0.53
Uric acid	35.691	0.000	172.2 ± 17.03	214.52 ± 7.74	0.25

¹P values were calculated based on Student *t* test (significance at $P < 0.05$); ²Cancer group included the non-metastasis group and the metastasis group; ³R value was calculated from the arithmetic mean values of each group. $R = (B-A)/A$. R with a positive value indicates a relatively higher concentration in cancer group while a negative value means a relatively lower concentration as compared with the normal group.

Table 3 Metabolic differences in the two groups

Metabolites	Retention time	P value ¹	A (non-metastasis)	B (metastasis)	R ²
Alanine	8.105	0.000	173.75 ± 39.59	19.28 ± 10.63	-0.89
Butanoic acid	9.412	0.000	32.09 ± 1.00	22.58 ± 0.72	-0.30
Glycerol	12.511	0.003	303.23 ± 26.16	235.04 ± 45.64	-0.22
Butanedioic acid	13.933	0.1×10^{-5}	216.36 ± 2.63	319.43 ± 17.89	0.48
L-proline	20.497	0.000	184.99 ± 10.26	117.78 ± 7.05	-0.36
L-threonic acid	20.909	2.28×10^{-4}	284.94 ± 46.47	181.48 ± 37.25	-0.36
Myo-inositol	29.032	0.000	33.08 ± 3.58	114.8 ± 2.20	2.47

¹P values were calculated based on Student *t* test (significance at $P < 0.05$); ²R value was calculated from the arithmetic mean values of each group. $R = (B-A)/A$. R with a positive value indicates a relatively higher concentration in metastasis group while a negative value means a relatively lower concentration as compared with the non-metastasis group.

the marker metabolite intensities as variables (lactic acid, butanoic acid, propanoic acid, glycerol, pyrimidine, butanedioic acid, malic acid, citric acid, hexadecanoic acid and uric acid). The PCA scores plot showed that the normal group and cancer group (non-metastasis group and metastasis group) samples were scattered into different regions (Figure 4A). ROC analysis, which was performed using the values determined by the first two components of the PCA model, confirmed the robustness of the PCA model. These first two components could present the ma-

jority of all significantly different metabolites among the groups (the percentage is 82.7%). Area under the curve (AUC) value of this PCA model was 1.00 (Figure 4B), which demonstrated a good diagnostic value for gastric cancer. In addition, another PCA model for gastric cancer metastasis constructed by seven marker metabolites (alanine, butanoic acid, glycerol, L-threonic acid, L-proline, butanedioic acid and myo-inositol) could differentiate between the non-metastasis group and the metastasis group (Figure 5A). This PCA model was also validated by

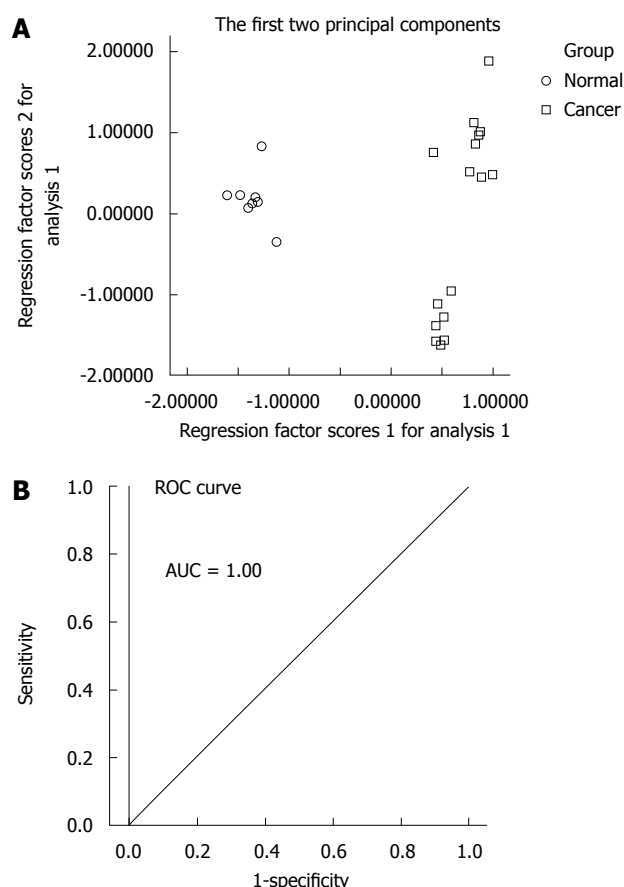

Figure 4 Principal component analysis model and receiver operating characteristic curve for gastric cancer. A: Principal component analysis (PCA) scores plot of gastric tumor specimens from control specimens based on 10 marker metabolites. The PCA scores plot showed different samples (normal group, cancer group including non-metastasis group and metastasis group) were scattered into different regions; B: Receiver operating characteristic (ROC) analysis was performed using the values determined by the first two components. Area under the curve (AUC) = 1.00.

receiver operating characteristic (ROC) analysis (AUC = 1.00, Figure 5B).

DISCUSSION

In this study, we investigated urinary metabolite profiling using GC/MS. This was assessed non-invasively by measuring two voxels (tumor and healthy controls). We have discriminated the gastric cancer model mice from their healthy controls in a PCA analysis of GC-MS urinary metabolite spectra. Moreover, we could also discriminate the gastric cancer metastasis model mice from the non-metastasis model mice by GC-MS and PCA of urinary metabolites. Some marker metabolites were worth investigating in the future. Compared with the normal group, the level of lactic acid was higher in the cancer group urine. It could be explained that glucose is often converted into lactic acid in cancer cells, which is known as the “Warburg effect”, and cancer cells have a higher rate of aerobic glycolysis^[31]. The levels of butanedioic acid, malic acid and citric acid, intermediates of tricarboxylic acid (TCA) cycle, were also found to be higher in the gastric cancer mice. The abnormalities

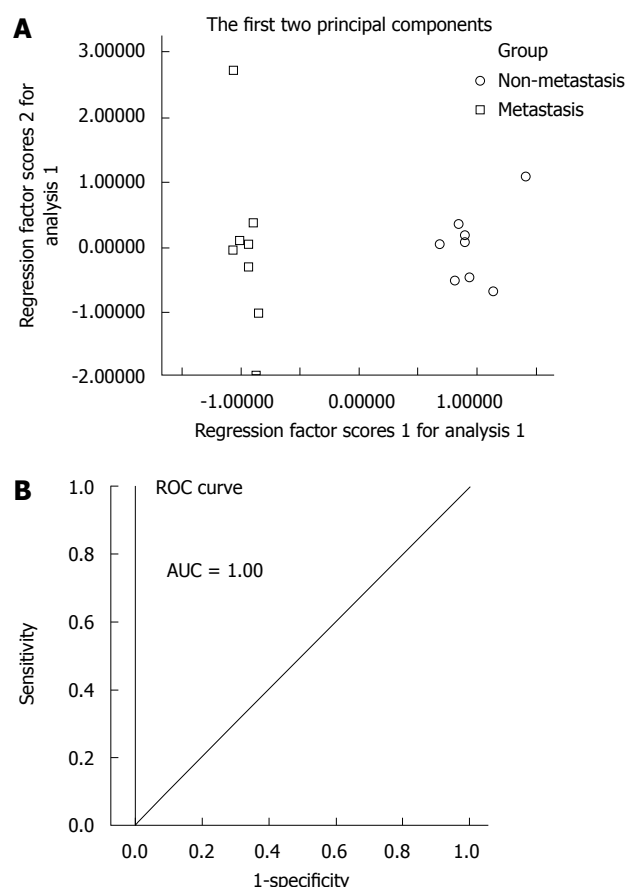

Figure 5 Principal component analysis model and receiver operating characteristic curve for gastric cancer metastasis. A: Principal component analysis (PCA) scores plot of non-metastasis group and metastasis group based on 7 marker metabolites. The PCA scores plot showed the samples from non-metastasis group and metastasis group were scattered into two different regions; B: Receiver operating characteristic (ROC) analysis was performed using the values determined by the first two components. Area under the curve (AUC) = 1.00.

of these metabolite expressions demonstrated a close correlation of TCA cycle with gastric cancer morbidity along with disordered aerobic respiration and mitochondrial functions. The disorder of aerobic respiration (mainly TCA cycle) and the impairment of mitochondrial enzymes have been reported in other malignancies including colorectal cancer, pheochromocytoma and paraganglioma^[22,32,33]. Uric acid, the final metabolite of purines, at enhanced level in cancer mice urine, suggests the abnormalities of purine metabolism in gastric cancer^[34]. In our study, the significantly higher levels of glycerol and hexadecanoic acid in cancer than in normal groups were interpreted as increased adipocyte lipolysis in cancer and enhanced expression and function of adipocyte hormone-sensitive lipase (HSL)^[35].

Cancer metastasis could be considered as an essential prognostic factor^[36]. Figure 5A shows the new constructed tumor metastatic model by seven marker metabolites for the non-metastasis group and the metastasis group. This PCA model was also validated by ROC analysis (AUC = 1.00, Figure 5B). Seven metabolites in this model are capable of predicting the gastric cancer metastasis. Compared with the non-metastasis group, levels of alanine

and glycerol were found to be lower in the metastasis group. Alanine and glycerol could get into the glycolytic pathway through gluconeogenesis, which produced more energy for the tumor progression and metastasis. The decreased level of L-proline in the metastasis group may be interpreted as increased demand for structural proteins synthesis. These proteins, including receptors, membrane channels and enzymes, play an important role in tumor progression and metastasis^[37-39]. Moreover, the higher level of myo-inositol in metastasis group urine, was consistent with the reduction of myo-inositol in lung cancer tissues^[40]. The amount of myo-inositol may be a potential indicator for gastric cancer metastasis, as it has been reported that the Gly:Myo-inositol ratio may be a useful index for brain tumor classification^[41].

What the difference of metabolite changes of butanoic acid and pyrimidine between the normal and the cancer groups, and the decreased levels of butanoic acid and L-threonic acid in the metastasis group indicates remains unclear.

In conclusion, GC/MS revealed detailed information on the metabolic profile of normal and cancer urine and was found to be suitable, in tandem with the PCA model, for the identification of metabolic variations characteristic of the gastric cancer. Furthermore, seven metabolites have been selected, which constructed a diagnostic model for distinguishing the non-metastatic and the metastatic gastric cancer. To our knowledge, this is the first report on urinary metabolomic investigation of gastric cancer metastasis by GC/MS. On the basis of this research, we believe that urinary metabolomic information obtained by GC/MS might play a significant role in the early diagnosis and screening metastasis or recurrence of gastric cancer.

COMMENTS

Background

Gastric cancer is the second leading cause of cancer death worldwide, and in many Asian countries. Tumor metastasis is one of the leading causes of cancer death. Metabolic alterations play a role in the biology of cancer. The urinary metabolites as gastric cancer or tumor recurrence biomarkers can be obtained by investigating the urinary metabolic profiling.

Research frontiers

Metabolomics is a post-genomic research field for analysis of low molecular weight compounds in biological systems, and its approaches offer an analysis of metabolite level changes in biological samples. Recently, metabolomic method has shown great potentials in identifying the new diagnostic markers and therapeutic targets for cancers. However, metabolomic studies on cancer metastasis remain scarce.

Innovations and breakthroughs

Recently, metabolomic studies on gastric cancer and colon cancer tissues have been conducted. Compared with tissues and serum, markers acquired from urine are noninvasive and convenient, especially in the patients with recurrent gastric cancer. This is the first report on urinary metabolomic investigation in gastric cancer using gas chromatography/mass spectrometry (GC/MS).

Applications

Potential metabolic biomarkers in urine could be used for early diagnosis and screening the metastasis or the recurrence of gastric cancer.

Terminology

Metabolomics is a post-genomic research field for analysis of low molecular weight compounds in biological systems, and its approaches offer an analysis of metabolite level changes in biological samples. Because of its peak resolu-

tion, high sensitivity and reproducibility, GC/MS has been widely utilized in metabolomics.

Peer review

This manuscript evaluates tumor metabolism with a goal to identify possible biomarkers with potential diagnostic value and the potential for prediction of tumor metastasis. The authors concluded that the urinary metabolomic profiling of each group is different, and the selected metabolites might be instructive to clinical diagnosis or screening metastasis for gastric cancer. This is a relevant randomized control trial using an animal model to evaluate a non-invasive method for surveillance of gastric cancer.

We measured the body mass index, waist and hip circumference, blood pressure, fasting blood glucose, insulin, homeostasis model assessment of insulin resistance (HOMA-IR), whole-body insulin sensitivity index (WBISI), lipid profile and transaminases in all the participants. The risk of developing metabolic syndrome (MS) was assessed according to the degree of liver fatty infiltration based on the B-ultrasound examination.

RESULTS: Among the 861 obese children, 587 (68.18%) were classified as having NAFLD, and 221 (25.67%) as having MS. The prevalence of MS in NAFLD children (groups 1 and 2) was 37.64% (221/587), which was much higher than that in non-NAFLD group (group 0, 12.04%) ($P < 0.01$). There were significantly higher incidences concerning every component of MS in group 2 compared with group 0 ($P < 0.05$). The incidence of NAFLD in MS patients was 84.61% (187/221), which was significantly higher than that of hypertension (57.46%, 127/221) and glucose metabolic anomalies (22.62%, 50/221), and almost equal to the prevalence of dyslipidemia (89.14%, 197/221). Based on the B-ultrasound scales, the presence of moderate and severe liver fatty infiltration carried a high risk of hypertension [odds ratio (OR): 2.18, 95% confidence interval (95% CI): 1.27-3.75], dyslipidemia (OR: 7.99, 95% CI: 4.34-14.73), impaired fasting glucose (OR: 3.65, 95% CI: 1.04-12.85), and whole MS (OR: 3.77; 95% CI: 1.90-7.47, $P < 0.01$). The state of insulin resistance (calculated by HOMA-IR and WBISI) deteriorated as the degree of fatty infiltration increased.

CONCLUSION: NAFLD is not only a liver disease, but also an early mediator that reflects metabolic disorder, and liver B-ultrasound can be a useful tool for MS screening.

Key words: Childhood obesity; Non-alcoholic fatty liver disease; Metabolic syndrome; Liver B ultrasonography

Abstract

AIM: To investigate if non-alcoholic fatty liver disease (NAFLD) is an early mediator for prediction of metabolic syndrome, and if liver B-ultrasound can be used for its diagnosis.

METHODS: We classified 861 obese children (6-16 years old) into three subgroups: group 0 (normal liver in ultrasound and normal transaminases); group 1 (fatty liver in ultrasound and normal transaminases); and group 2 (fatty liver in ultrasound and elevated transaminases).

INTRODUCTION

There is a growing concern for non-alcoholic fatty liver disease (NAFLD) and metabolic syndrome (MS) in obese children^[1-3]. NAFLD is a clinicopathological syndrome that ranges from simple steatosis to steatohepatitis, fibrosis or cirrhosis of the liver^[4]. It is associated with dyslipidemia, obesity, and insulin resistance, which are the main features of MS. NAFLD and MS often are seen in the same individual^[5-8], whereas insulin resistance probably is a key event that links them together. The mortality of patients with NAFLD has increased significantly among the general population, and cardiovascular risk competes with liver-related risk in dictating the final outcome^[9,10]. Several prospective studies in adults have demonstrated that NAFLD is associated with an increased incidence of MS and type 2 diabetes mellitus in elderly patients, and independent patients with obesity^[11-14]. Thus, NAFLD may be not only a liver disease, but also an early mediator of type 2 diabetes mellitus and MS in adults. However, the impact of NAFLD on MS among the young population is still not clear. The debate remains as to whether NAFLD should be included as one of the components of the MS. This study aimed to assess idiopathic NAFLD among Chinese obese children, to verify the prevalence of MS in NAFLD patients based on B-ultrasound scan, and to investigate whether NAFLD is associated with MS and MS profile, and whether it is an important risk factor for MS as well.

MATERIALS AND METHODS

Study design and population

A total of 861 obese children and adolescents, aged between 6 and 16 years, who were referred to our endocrinology department with the complaint of obesity from January 2004 to September 2009, were enrolled in this study. Based on an accepted criteria for obesity diagnosis in Chinese children^[15], all the participants had a body mass index (BMI) that was above the 95th percentile for their age and sex, based on the national reference data in 2004^[16]. Exclusion criteria were the known presence of endocrine metabolic or kidney diseases, and the use of medication that altered blood pressure, liver function, and glucose or lipid metabolism. The demographic distribution of subjects is displayed in Table 1. Participants underwent a routine clinical examination, including physical examination, biochemical tests, oral glucose tolerance

test (OGTT) and liver ultrasonographic scanning. There was no difference in age and Tanner stages between boys and girls. However, significant differences existed in clinical, anthropometric and laboratory data in relation to sex (Table 1).

The protocol was approved by the Medical Ethics Committee of The Children's Hospital of Zhejiang University School of Medicine. Written informed consent from parents (or guardians) and children (where appropriate) were obtained.

Definition of disease, syndrome and disorders

NAFLD: NAFLD was defined according to the revised definition and treatment guidelines for NAFLD by the Chinese Hepatology Association in February 2006^[17], and was diagnosed by means of a protocol using clinical, laboratory and ultrasound examinations in combination. In this study, NAFLD was diagnosed as a diffusely echogenic change on liver B-ultrasonography (fatty infiltration in liver), with or without elevated serum aminotransferase levels and other factors that can cause liver fatty infiltration or aminotransferase elevation, such as hepatitis virus infection, drug-induced injury, and other metabolic diseases, such as Wilson's disease, were excluded. There was no history of current or past alcohol drinking. Two subgroups were classified in NAFLD obese children: group 1 (fatty liver in ultrasound and normal transaminases) and group 2 (fatty liver in ultrasound and elevated transaminases). Group 0 was diagnosed as obese children without liver disorder (normal liver in ultrasound and normal transaminases).

MS: The diagnosis criteria have been described in our previous study^[18], which followed the suggestions of the Chinese Diabetes Association and the definition modified from the National Cholesterol Education Program's Adult Treatment Panel III (NCEP-ATPIII). MS was diagnosed if patients met three or more of the following criteria for age and sex: (1) central obesity; (2) hyperglycemia (fasting glucose ≥ 6.1 mmol/L, or random glucose ≥ 7.8 mmol/L) or impaired glucose tolerance (IGT) or type 2 diabetes; (3) systolic or diastolic blood pressure above the 95th percentile for age and sex; and (4) hypertriglyceridemia (triglyceride concentration > 1.7 mmol/L) or low high-density lipoprotein-cholesterol (HDL-C) (< 1.03 mmol/L). In this study, high blood pressure was based on the percentile data of the 7th edition of Practical Pediatric Text Book by Zhu Fu-Tang^[15]. IGT was defined as a glucose level > 7.8 mmol/L but < 11.1 mmol/L at 2 h. Type 2 diabetes was diagnosed according to the criteria of American Diabetes Association in 1997 and World health Organization in 1999.

Laboratory assessment

Height was measured without socks and shoes, and weight was measured in children who were wearing only under-clothing. Waist was measured at the midpoint between the lower border of the rib cage and the iliac crest. Hip circumference was determined at the widest circle of the bottom. Pubertal development stages were assessed using Tanner stage criteria. Blood pressure was taken twice using the right arm, with the subject in a quiet sitting position, and the average level was recorded.

Subjects underwent routine biochemical evaluation in the morning before 09:00 h after an overnight fast for at least 8 h. Fasting glucose, insulin, lipids total triglyceride (TG), total cholesterol (TCHO), HDL-C and low-density lipoprotein-cholesterol (LDL-C), liver function [alanine aminotransferase (ALT) and aspartate aminotransferase (AST)] and uric acid were detected. Hepatitis serial serological tests (antibodies for hepatitis A-E) and glucose and insulin levels were also recorded during a standard (75 g) OGTT. Blood glucose was determined using a glucose oxidase method (North Biotechnology Company, Beijing, China) with intra-assay and inter-assay coefficient of variation (CVs) of 2.1% and 4.4%. Insulin serum levels were determined by radioimmunoassay (North Biotechnology Company) with intra-assay and inter-assay CVs of 6.4% and 9.7%, respectively. The serum concentrations of TCHO, TG, HDL-C, LDL-C, ALT, AST and uric acid were measured by routine enzymatic methods in our clinical laboratory.

The homeostasis model assessment of insulin resistance (HOMA-IR), based on serum fasting glucose and insulin levels, was used to measure insulin resistance. The whole body insulin sensitive index (WBISI) and the ratio of early insulin increment to early glucose increment (I30-0/G30-0) following oral glucose loading (75 g) were also obtained. $HOMA-IR = [FIN \text{ (mU/L)} \times FBG \text{ (mg/dL)}] / 22.5$; $WBISI = 10000 / [FIN \text{ (mU/L)} \times FBG \text{ (mg/dL)} \times \text{average insulin (mU/L)} \times \text{average glucose (mg/dL)}]^{1/2}$; $BMI = \text{weight (kg)} / [\text{height (m)}]^2$ (FIN: Free insulin; FBG: Free blood glucose).

Liver ultrasound examination

Liver ultrasound examination was carried out by one specialist who was unaware of the aims of the study and blinded to laboratory values on the same equipment (GE, LOGIC 500), using a convex 3.5-5.0 MHz probe. Sagittal hepatic sections that encompassed longitudinal images of the right liver lobe and the ipsilateral kidney were obtained. Liver-kidney contrast with two other well-known ultrasonographical findings of fatty liver, vascular blurring and deep attenuation, enabled us to grade fatty change semi-quantitatively. Fatty infiltration was graded semi-quantitatively into four classes^[19,20]: no steatosis (class 0), mild steatosis (class 1), moderate steatosis (class 2) and severe steatosis (class 3) (Figure 1).

Statistical analysis

Data were collected using an MS-Excel spreadsheet. Data were analyzed using the JMP Statistical Discovery Software version 7.0 (SAS Institute, Cary, NC, USA). Group comparisons for continuous data were performed using *t* tests for independent means or one-way analysis of variance. A non-parametric test was used to evaluate the significance of abnormally distributed data. For categorical data, we employed the χ^2 test, Fisher's exact test, or binomial test of proportions. Multivariate logistic regression models were used to adjust for covariate effects on the odds ratio (OR). Statistical significance was set at $P < 0.05$.

RESULTS

Prevalence of NAFLD and MS in Chinese obese children

Of 861 obese children, 587 (68.18%) were diagnosed as having NAFLD, and 221 (25.67%) as having MS. The prevalences of hypertension, dyslipidemia, hyperuricacidemia, impaired fasting glucose, IGT and diabetes were 37.28% (321), 42.04% (362), 28.69% (247), 6.38% (55), 8.01% (69) and 1.39% (12), respectively. Moreover, the incidence of NAFLD in MS patients reached 84.61% (187/221), which was significantly higher than that of hypertension (57.46%, 127/221) and glucose metabolic anomalies (22.62%, 50/221), but almost equal to the prevalence of dyslipidemia (89.14%, 197/221).

NAFLD is associated with MS and its components among obese children

To investigate whether liver disorders are associated with MS, participants were divided into three subgroups: group 0 (normal liver in ultrasound and normal transaminases); group 1 (fatty liver in ultrasound and normal transaminases); and group 2 (fatty liver ultrasound and elevated transaminases). Table 2 indicates that sex, age and Tanner stage were comparable among the three subgroups. Nevertheless, the occurrence rates of MS increased with deterioration of liver from 12.04% in group 0 to 29.36% in group 1, and 39.74% in group 2 ($P < 0.05$). The prevalence of hypertension, dyslipidemia, IGT and diabetes in group 2 was significantly higher than that in group 0 ($P < 0.05$). Further investigation indicated that the prevalence of dyslipidemia and IGT increased steadily from group 0 to group 1 and group 2

Figure 1 Liver B-ultrasound scans show the panel of four different classes of liver steatosis. A: Class 0: not observed; B: Class 1: mild, liver-kidney contrast without vascular blurring and deep attenuation; C: Class 2: moderate, liver-kidney contrast with vascular blurring, but no deep attenuation; D: Class 3: severe, combination of liver-kidney contrast with vascular blurring and deep attenuation.

Table 2 Comparison of prevalence of metabolic syndrome and its components among three groups			
	Group 0 (n = 274)	NAFLD	
		Group 1 (n = 436)	Group 2 (n = 151)
Age (yr)	10.36 ± 2.15	10.59 ± 1.85	10.40 ± 2.28
Sex (M/F)	187/87	305/131	106/45
Tanner stage (T1/T2-4)	130/144	209/227	74/77
BMI	26.88 ± 3.19	28.78 ± 3.96 ^a	28.85 ± 3.69 ^a
Hypertension	68 (24.82)	180 (41.28) ^a	73 (48.34) ^a
Dyslipidemia	42 (15.32)	204 (46.78) ^a	116 (76.82) ^{a,c}
Impaired fasting glucose	5 (1.82)	30 (6.88)	20 (13.24) ^{a,c}

Diabetes	0 (0.00)	5 (1.14)	7 (4.63) ^{a,c}
MS	33 (12.04)	128 (29.36) ^a	60 (39.74) ^{a,c}

^a*P* < 0.05 *vs* group 0; ^c*P* < 0.05, group 1 *vs* group 2. Data are expressed as percentage, mean ± SD. NAFLD: Non-alcoholic fatty liver disease; BMI: Body mass index; IGT: Impaired glucose tolerance; MS: Metabolic syndrome.

(15.32% to 46.78% to 76.82%; 1.82% to 6.88% to 13.24%, *P* < 0.05). In addition, the levels of triglycerides, cholesterol, ALT and uric acid in group 2 were significantly higher than those in group 1 and group 0 (*P* < 0.05) (Table 3). It was indicated that the NAFLD was closely associated with progression of MS and its components in these obese children.

NALFD is accompanied by insulin resistance in obese children

Insulin resistance is a key event that causes MS in both

adults and children^[21]. To investigate whether NAFLD is associated with insulin resistance, we performed OGTT and insulin releasing test in all the participants. As for the results of blood glucose, fasting blood glucose and 120-min OGTT glucose levels in group 2 were significantly higher than those in group 0 (*P* < 0.05). The blood level of insulin, including fasting insulin, 30-min OGTT insulin and 120-min OGTT insulin, were significantly increased in groups 1 and 2 as compared with those in group 0 (*P* < 0.05). The HOMA-IR and WBISI reflected insulin resistance and sensitivity respectively. Our analysis indicated that HOMA-IR was elevated significantly in groups 1 and 2, whereas WBISI decreased significantly as compared with that of group 0 (*P* < 0.05) (Table 3). This finding revealed that NAFLD was significantly associated with insulin resistance among these obese children.

MS is associated with liver steatosis found by ultrasound examination

Fatty infiltration is another indicator that reflects liver damage, which can be easily detected by ultrasound examination. Based on B-ultrasound examination, 861 obese children were classified into class 0 (274 cases without steatosis), class 1 (105 cases with mild steatosis), and classes 2-3 (482 cases with moderate and severe steatosis). It was indicated that the relative risk of MS increased to 3.10 [95% confidence interval (95% CI): 1.20-8.00] in class 1 and 3.77 (95% CI: 1.90-7.47) in classes 2-3 (*P* < 0.01) (Table 4). Based on the B-ultrasound scales, the presence of moderate and severe liver fatty infiltration carried a high risk of

developing hypertension (OR: 2.18, 95% CI: 1.27-3.75), dyslipidemia (OR: 7.99, 95% CI: 4.34-14.73), impaired fasting glucose (OR: 3.65, 95% CI: 1.04-12.85), and hyperuricacidemia (OR: 3.76, 95% CI: 2.03-6.96) (Table 4, Figures 2-4). We also determined whether HOMA-IR and WBISI were associated with the degree of fatty liver. It was revealed that the HOMA-IR increased significantly from 2.64 in class 0 to 3.57 in classes 2-3, but the WBISI decreased from 3.97 in class 0 to 2.67 in classes 2-3 among the obese subjects. All these findings indicated that the scale of fatty infiltration in liver was closely related to MS and insulin resistance among Chinese obese children.

DISCUSSION

The prevalence of both NAFLD and MS was higher in this study at 68.18% and 25.67%, respectively, than that of 9.6% and 4.2% in the general pediatric population^[22]. NAFLD is regarded as an increasing clinical problem in children and adolescents, and accounts for the vast majority of cases with elevated serum liver enzymes^[23]. Moreover, NAFLD is known to be related to the factors that predict the development of coronary heart disease, such as dyslipidemia, central obesity and MS.

Apart from that, NAFLD has been shown increasingly and more convincingly to be an important component of MS. In this study, we demonstrated that the prevalence of MS was three times higher in NAFLD obese children than in those without liver disorders (39.74% *vs* 12.04%, *P* < 0.05). The incidence of each component of MS was also

significantly higher in NAFLD subjects (*P* < 0.05). Moreover, the presence of moderate and severe liver infil-

Figure 2 Oral glucose tolerance test in obese patients based on liver B-ultrasound gradings. When patients were stratified according to the presence of liver fatty infiltration based on the B-ultrasound scans, their glucose levels at 60 min and 90 min after tolerance were significantly higher in classes 1-3 ($P < 0.05$) than in class 0, but there was no difference between class 1 and classes 2-3 ($P > 0.05$).

Figure 3 Insulin releasing test in obese patients based on liver B-ultrasound gradings. There was no difference in fasting insulin among the three groups, but 60, 90 and 120 min insulin levels were markedly increased in the class 2-3 groups compared with class 0 ($P < 0.05$).

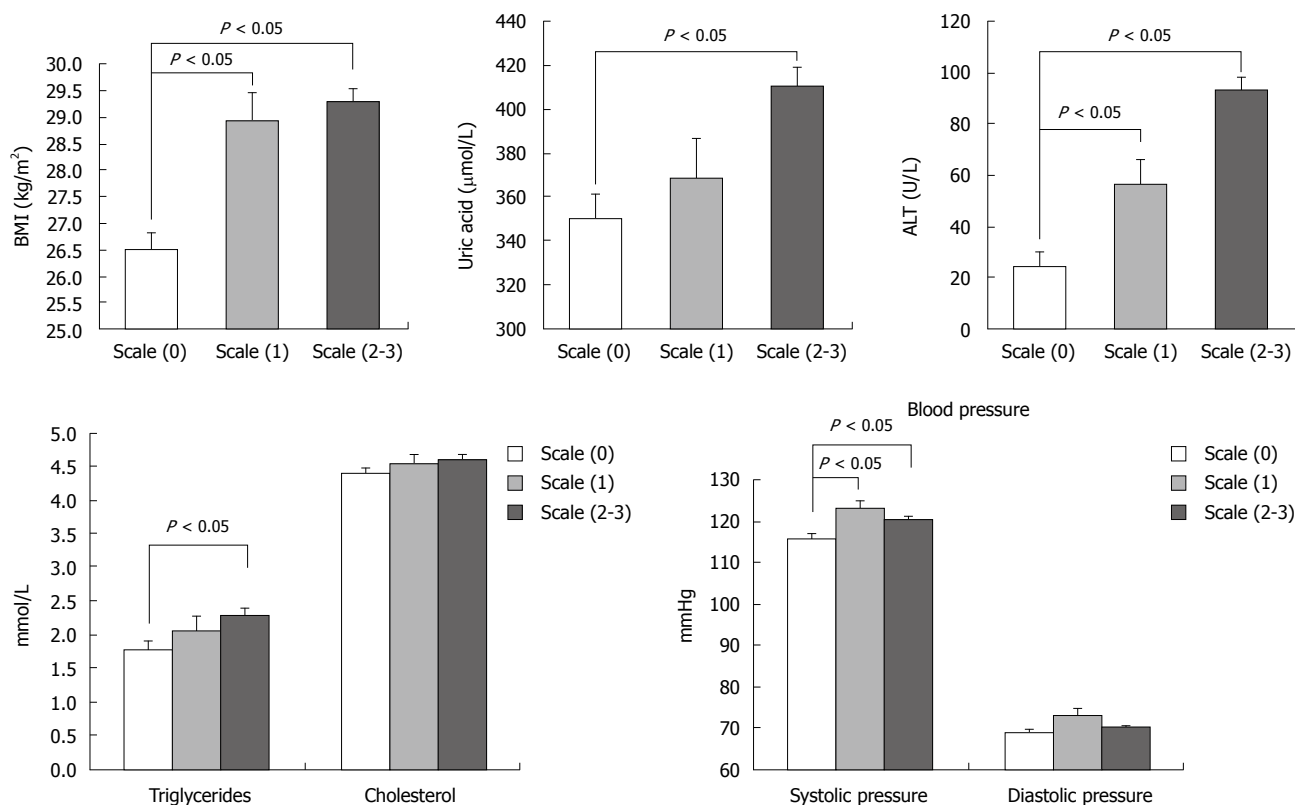

Figure 4 Clinical features of the metabolic syndrome in obese patients based on liver B-ultrasound gradings. Concerning the individual metabolic component, body mass index (BMI), alanine aminotransferase (ALT) and systolic pressure were significantly higher in class 1 and classes 2-3 compared with class 0 ($P < 0.05$), but there was no difference between class 1 and classes 2-3 ($P > 0.05$). The levels of uric acid and triglyceride were only markedly increased in classes 2-3 compared with class 0 ($P < 0.05$). There was no difference in cholesterol levels among the three groups ($P > 0.05$).

tration confirmed by B-ultrasonography carried a high risk of development of MS, which highlights that NAFLD is closely associated with features of MS. In contrast, the incidence of NAFLD in MS patients reached 84.61%, which was significantly higher than that of hypertension (57.46%) and glucose metabolic anomalies (22.62%), and almost equal to the prevalence of dyslipidemia (89.14%). This indicates that NAFLD might be an early stage mediator for prediction of MS.

To date, the biological mechanisms that are involved in the higher risk of developing metabolic disorders in patients with NAFLD are not fully understood. Insulin resistance seems to be the key event. Nevertheless, most obese patients with NAFLD had hyperinsulinemia and higher insulin resistance compared with those without liver disorders, as calculated by fasting insulin, 30 min and 120 min insulin after glucose loading, HOMA-IR and WBISI. In contrast, patients with NAFLD were more

obese and exhibited higher insulin resistance and more marked metabolic complications than those with simple obesity. Fatty liver itself is an insulin resistance status^[24], and because hepatic fat accumulation can lead to hepatic insulin resistance, the latter may occur before any alteration in peripheral insulin action or peripheral insulin resistance. Moreover, insulin resistance may cause abnormalities of lipid storage and lipolysis in insulin-sensitive tissues, which may induce increased fatty acid flux from adipose tissue to the liver and result in steatosis^[25]. Insulin resistance may also cause lipid peroxidation, which in turn, activates inflammatory cytokines and promotes the progression of innocent steatosis to non-alcoholic steatohepatitis and liver fibrosis^[26]. The impairment in fat and glucose metabolism when insulin resistance occurs, can lead to similar biochemical and clinical abnormalities in patients with NAFLD, and sooner or later it will inevitably develop to systemic MS.

An accurate fatty liver diagnosis and staging of non-alcoholic steatohepatitis requires liver biopsy. However, liver biopsy is not performed often in patients, especially in children, with no significant or trivial liver diseases. Most of the patients with liver steatosis can be well-managed without a need for liver biopsy. In our study, steatosis was assessed by liver ultrasonography with a sensitivity of 83% and a specificity of 100% in comparison with the gold standard of histological diagnosis. Therefore, liver ultrasonography is being strongly suggested as a non-invasive study of NAFLD^[18,27,28]. It was particularly interesting to find that both the prevalence of MS and every component of MS increased as the liver ultrasonographic grade deteriorated. Moreover, liver fat is highly significantly associated with all components of MS. Compared with abdominal and overall obesity, fatty liver has the highest frequency of clustering, greater specificity, higher positive predictive value and the most attributable risk for detecting risk factors of cardiovascular disease, type 2 diabetes and MS^[29,30]. Thus, fatty liver seems to be an early mediator for prediction of other metabolic disorders. Since B ultrasound scan can be easily and widely applied in hospitals, this simple and effective scanning technique may provide a new method of MS screening in the future.

All findings in our study have stimulated interest in the possible role of NAFLD in the development of metabolic complications. Their coexistence in the same individual increases the likelihood of having more severe dysmetabolic status. Several studies in adults also have demonstrated that NAFLD is the primary hepatic complication of obesity and insulin resistance, and may be considered the early hepatic manifestation of MS. Early treatment, such as lifestyle or diet modification, aerobic exercise, or medication (metformin or vitamin E), for NAFLD may not only improve the prognosis of liver disease, but also reduce the occurrence of underlying metabolic and vascular complications. Furthermore, it is also implied that earlier adjustment to mobilizing fat out of the liver might reduce the risks of MS.

ACKNOWLEDGMENTS

We are grateful to Dr. Li-Qin Chen and Zhong-Sheng Yu for their assay expertise. We sincerely thank the parents and children for participating in these studies. We thank the nursing staff of our department for their dedicated care of these young patients during the collection and evaluation of blood samples.

COMMENTS

Background

There is a growing concern for non-alcoholic fatty liver disease (NAFLD) and metabolic syndrome (MS) in obese children. NAFLD and MS often are seen in the same individual, and insulin resistance is a probable key event that links them together. NAFLD may not only be a liver disease, but also an early mediator of type 2 diabetes mellitus and MS in adults. However, the impact of NAFLD on MS among the young population is still not clear.

Research frontiers

NAFLD is now considered a metabolic pathway to advanced liver disease, cirrhosis and hepatocellular carcinoma. Type 2 diabetes mellitus, obesity and dyslipidemia are the principal factors associated with NAFLD, which is now considered the hepatic expression of MS. The risk of liver disease associated with the classical features of MS in children is still unclear. We still need to clarify the mechanisms that are responsible for liver disease progression from pure fatty liver to steatohepatitis and to cirrhosis, and the reasons why only a few NAFLD cases progress to terminal liver failure while others (the majority) will have a cardiovascular outcome.

Innovations and breakthroughs

An accurate fatty liver diagnosis and staging of non-alcoholic steatohepatitis require liver biopsy. However, liver biopsy is not performed often in patients, especially children, with no significant, or trivial liver diseases. Most of the patients with liver steatosis can be well-managed without a need for liver biopsy. In this study, steatosis was assessed by liver ultrasonography, which showed that both the prevalence of MS and every component of MS increased as the liver ultrasonographic grade deteriorated. Liver fat was highly significantly associated with all components of MS.

Applications

Since B ultrasound scan can be easily and widely applied in hospitals, this simple and effective scanning technique may provide a new method of MS screening in the future in the general population.

Peer review

The authors addressed an important subject and described a population of patients referred for obesity with respect to the presence of sonographic evidence for NAFLD, and their metabolic profiles with respect to the insulin axis.

Abstract

AIM: To investigate associations between perinatal risk factors and subsequent inflammatory bowel disease (IBD) in children and young adults.

METHODS: Record linked abstracts of birth registrations, maternity, day case and inpatient admissions in a defined population of southern England. Investigation of 20 perinatal factors relating to the maternity or the birth: maternal age, Crohn's disease (CD) or ulcerative colitis (UC) in the mother, maternal social class, marital status, smoking in pregnancy, ABO blood group and rhesus status, pre-eclampsia, parity, the infant's presentation at birth, caesarean delivery, forceps delivery, sex, number of babies delivered, gestational age, birthweight, head circumference, breastfeeding and Apgar scores at one and five minutes.

RESULTS: Maternity records were present for 180 children who subsequently developed IBD. Univariate

analysis showed increased risks of CD among children of mothers with CD ($P = 0.011$, based on two cases of CD in both mother and child) and children of mothers who smoked during pregnancy. Multivariate analysis confirmed increased risks of CD among children of mothers who smoked (odds ratio = 2.04, 95% CI = 1.06-3.92) and for older mothers aged 35+ years (4.81, 2.32-9.98). Multivariate analysis showed that there were no significant associations between CD and 17 other perinatal risk factors investigated. It also showed that, for UC, there were no significant associations with the perinatal factors studied.

CONCLUSION: This study shows an association between CD in mother and child; and elevated risks of CD in children of older mothers and of mothers who smoked.

INTRODUCTION

Both Crohn's disease (CD) and ulcerative colitis (UC) are considered to be immune-mediated disorders, although the exact pathogenetic mechanisms are not yet clear. It is thought that a combination of environmental factors in genetically susceptible people lead to disordered im-

munity and chronic inflammation. Over the last 50 years, there have been large increases in the incidence of CD and UC in the UK, in other western countries^[1-3], and more recent increases in Asia^[4], which indicate changes over time in the environmental factors that can lead to inflammatory bowel disease (IBD).

In recent decades, there have been changes in the management of births, including large increases in caesarean deliveries, advances in neonatal medicine and substantial reductions in neonatal mortality. As perinatal risk factors have been associated with some immune-mediated diseases including asthma^[5-7] and type 1 diabetes^[8-10], perinatal risk factors and early life events may be relevant to other immune-mediated diseases, including IBD. One case-control study identified that infectious and non-infectious perinatal health events were linked with 40% of all cases of IBD in the study group^[11]. A systematic review and meta-analysis of 17 (mainly case-control) studies found a small but significant protective effect of breastfeeding against both CD and UC^[12]. However, its authors commented that this finding was far from conclusive, and advocated the need for larger studies. There have been relatively few studies of other perinatal risk factors and IBD.

The aim of this study was to investigate associations between 20 perinatal risk factors and the subsequent development of IBD in children and young adults in a large geographically defined population of South East England. These perinatal risk factors include nine maternal characteristics, such as maternal age, parity, smoking during pregnancy, ABO blood group and social class, and 11 neonatal characteristics, including birthweight, gestational age, head circumference, breastfeeding and Apgar scores.

MATERIALS AND METHODS

Ethical approval for analysis of the record linkage study data was obtained from the Central and South Bristol Multi-Centre Research Ethics Committee (04/Q2006/176).

We used the Oxford record linkage study (ORLS). The ORLS comprises abstracts of records of birth registrations, maternities, day cases and inpatient admissions in a defined geographical region of South East England around Oxford. The maternity data covered all National Health Service (NHS) hospitals in two health districts of the ORLS over the 20-year period from 1970 to 1989. The maternity data are linked to data on all inpatient and day case care for all clinical specialties in the ORLS up to 1999, in two health districts of the ORLS from 1970 to 1999 (population 0.9 million) and a further four adjacent districts (total population 1.9 million) from 1975 to 1999. We used the record linked data to identify cases of subsequent IBD in the children covered by the maternity data. We also used the linked data to identify records of IBD in the mothers, before and after childbirth. The original data comprising the ORLS were abstracted from hospital records by staff who were specifically trained for this purpose by senior clinicians.

We excluded maternity records in the ORLS for 985 abortions, 1560 stillbirths and 1567 early deaths that oc-

curred within 30 d of birth. We also excluded 289 births in which the birthweight was recorded as < 1000 g, because most of these records had implausibly low values and/or substantial missing data for many of the perinatal risk factors that we were investigating. None of these excluded babies were subsequently identified as having IBD. After applying these exclusion criteria, a total of 248 659 births remained in the study.

Cases of CD and UC among offspring and mothers were identified using the following ICD codes on inpatient or day case records: 563.0 and 563.1 for CD and UC, respectively (in the ICD-8th revision), 555 and 556 (ICD-9) and K50 and K51 (ICD-10), when recorded in any diagnostic position on the hospital record. There were 114 and 66 children with both a maternity record and a subsequent admission for CD or UC, respectively. We compared 20 perinatal factors studied in these cases with those in the other 248 479 children without a record of inpatient admission or day case care for CD or UC. Parity was defined as the pregnant woman's number of previous live and still births, as recorded on the ORLS maternity record. The length of "follow-up" for offspring ranged from 30 years for those born in 1970 to 10 years for those born in 1989, with an average follow-up of 18 years.

Statistical methods used included the chi-square test with Yates' correction, odds ratios (ORs) and their 95% CI, and multivariate logistic regression. Statistical significance was accepted at the conventional 5% level. When using logistic regression, all perinatal risk factors that were significant ($P < 0.05$) in the univariate analysis were included in an initial model. Each of the factors that were not significant in the univariate analysis were then re-entered, one at a time, into the regression model. This approach was taken to test whether any perinatal factor that was not significant in the initial univariate analysis, became significant when assessed simultaneously with other significant factors in the multivariate analysis. Cases with missing data for the perinatal risk factors were excluded only for those risk terms that were included in the logistic regression model. Year of birth was routinely included in all of the models, as a potential confounder, because of the different periods of follow-up after different years of birth.

RESULTS

For the 114 and 66 children identified with CD and UC respectively, the age at first admission (mean \pm SD) was 17.5 ± 5.1 years and 17.7 ± 6.0 years. Approximately half of the cases of both CD and UC had a first recorded admission in early adulthood (when aged 18 to 30 years) rather than in childhood (Table 1). A majority of cases were female; 59 (52%) for CD and 37 (56%) for UC.

CD

Considering risk factors relating to the maternity, in univariate analysis there was a significant association ($P =$

0.011) between CD in the mother and CD in the child (OR = 8.36, 95% CI = 2.06-33.9), based on two cases of CD in both (Table 2). There was a borderline significant association (*P* = 0.05) for maternal smoking and CD in the child (OR = 1.92, 95% CI = 1.03-3.56). There was no significant association between CD and mother's age in the age groupings that we originally selected (< 25, 25-34 and 35+ years; Table 2), but there was a non-significantly increased risk among children of older mothers aged 35+ years, when compared with mothers aged under 35 years (OR = 1.70; 0.97-2.08). Accordingly, we recategorised mothers'

age as < 35 years *vs* 35+ years in the multivariate analysis (see below).

We found no significant associations between CD and birth order or with any of the other six maternal risk factors considered, including marital status, ABO blood group, rhesus status and presentation at delivery (Table 2). We found no significant associations between CD and any of the perinatal risk factors relating to the birth, including birthweight, gestational age, caesarean delivery, forceps, Apgar scores and breastfeeding (Table 3).

Using multivariate analysis to assess the independent

^{1,2}*P*-values obtained through χ^2 tests, with Yates continuity corrections; ¹Comparing those with Crohn's disease with those without known inflammatory bowel disease (IBD); ²Comparing those with ulcerative colitis with those without known IBD.

significance of perinatal risk factors, there was a significantly increased risk of CD among the offspring of mothers who were aged 35+ years, compared with those aged under 35 years (OR = 4.81, 95% CI = 2.32-9.98), and an increased risk of CD among children of mothers who smoked during pregnancy compared with those who did not (2.04, 1.06-3.92). Numbers were too small to warrant inclusion of maternal CD in the multivariate analysis (Table 4).

UC

For UC, in univariate analysis there was only a (marginal) significantly reduced risk for mothers who were not married (*P* = 0.042), although this was based on only one case of an unmarried mother with a child with UC (Tables 2 and 3). Numbers were too small to warrant inclusion of marital status, i.e. a stratum with just one case, in the multivariate analysis. Using multivariate analysis, there were no

other significant associations between UC and any of the other 19 perinatal risk factors relating to either the mother or the birth (Table 4).

DISCUSSION

A strength of our study is that we have investigated 20 perinatal risk factors for IBD, unlike other studies that have mostly investigated one, two or only a few factors. The study is based on a geographically defined population, covering prospective data collected over 30 years. Another important strength is that information about the perinatal risk factors and the main outcome measure - IBD in offspring - were collected independently of each other. They were subsequently brought together independently through systematic record linkage, such that information collected for each risk factor was not influenced by knowledge of

Table 4 Perinatal factors with significant, independent effect on Crohn's disease in the child

Perinatal risk factor	Odds ratio	95% CI
Maternal age (yr)		
14-34	1.00	Ref.
35-49	4.81	2.32-9.98
Maternal smoking during pregnancy		
No	1.00	Ref.
Yes	2.04	1.06-3.92

the outcome measure. Our study is therefore not subject to potential interviewer and recall bias, e.g. about whether the mother smoked during pregnancy, which can affect studies based on interviews or self-reporting, and which provide much of the evidence about IBD and perinatal risk factors. The Oxford record linkage study has also been used as the basis of previous studies of perinatal risk factors^[7,10,13,14].

The study has several limitations. There was variable follow-up after birth, with shorter durations of follow-up for those born in the more recent years of the study period. However, there was at least 10 years follow-up for all IBD cases among offspring. Maternities during the early years of the study period, and among younger mothers, had fewer years of pre-pregnancy inclusion to ascertain maternal IBD, while data for three of the 20 risk factors (social class, smoking and breastfeeding), were not available for the first four years of the study period. The study would not have identified offspring who were diagnosed with IBD after migrating out of the ORLS region, which would reduce the number of observed cases of IBD.

The identification of cases of IBD in the offspring was restricted to those who were admitted as inpatients or day cases. We will have missed some cases of IBD where the only inpatient or day case admission was for a diagnostic endoscopy and biopsy in patients with suspected IBD, and where the pathology results were not available to create a record of the diagnosis at the time of discharge. We will also have missed people without any day case or inpatient care. Migration over time in the Oxford region population would also have lowered our observed incidence of IBD, particularly among adults. Our age-specific cumulative incidence rates of 1.6 and 0.9 per 100 000 for CD and UC among 0-29 year olds, and 1.0 and 0.5 respectively among 0-19 year olds, are lower than those in some UK studies, but comparable with those in other UK studies^[2,3,15-18].

There were two cases of CD in both the mother and child. Previous studies have identified associations between both maternal CD and maternal UC and IBD in offspring^[19,20], which are part of a well-established genetic association of IBD in families^[21-23]. There was some evidence of increased risks of CD, but not UC, among children whose mothers smoked during pregnancy. Previous studies have reported no association with smoking during pregnancy^[19,24], although one case-control study found modest protection against both CD and UC^[25]. Our data refers to smoking by the mother: in the general literature, there is strong evidence that active smoking increases the

risk and perhaps the severity of CD^[26,27]. Although we did not have information on smoking status of the IBD subjects themselves, it is of some interest that we found an association between maternal smoking and CD.

Some studies have identified slightly increased risks of IBD among children from lower socio-economic groups^[11,20], others have reported reduced risks of CD among children from lower socio-economic backgrounds^[18,28], and some have found no association between social background and IBD^[29,30]. More generally, studies that have investigated the relationship between IBD and socio-economic group have often reported conflicting findings^[31-37]. Overall, this indicates that any possible association between socio-economic background and subsequent IBD in children is probably quite weak. We did not find a significant association between social class and either CD or UC.

A systematic review and meta analysis of (mainly case-control) studies reported a small but significant protective effect of breastfeeding against subsequent IBD in offspring^[12], although it concluded that new larger studies were required. More recent studies have shown little association between breastfeeding and IBD^[19], or even increased risks of CD^[30,38]. We found no association between breastfeeding at the time of discharge from hospital and IBD, although this includes those who subsequently discontinued breastfeeding after discharge, and is therefore an incomplete marker of breastfeeding.

Through the use of multivariate analysis, we found higher risks of CD, but not UC, among children of older mothers (aged 35+ years). This is consistent with a Swedish study that reported an increased risk of paediatric CD among female offspring born to older mothers^[35], although other studies have identified no link between mother's age and IBD in children^[25,39]. Births among older mothers are sometimes associated with increased risks of prenatal medical and obstetric complications, intrapartum complications, perinatal and neonatal morbidity and mortality, as well as increased subsequent risks of various disorders. It is possible that children born to older mothers may be more exposed, or more susceptible, to factors associated with the aetiology of subsequent CD, but not with UC, in their children. It is also possible that our finding on maternal age, though significant, was a chance one, especially as our study investigated 20 perinatal factors. It is worth noting, however, that the finding was highly significant ($P < 0.01$ in multivariate analysis).

We found an indication of reduced risks of IBD, particularly UC, among children of mothers who were unmarried at the time of birth, which is consistent with findings from Sweden^[11] and Australia^[28].

It has been suggested that caesarean section might increase the risk of subsequent IBD in children, because there is less exposure to maternal bacteria than in vaginal delivery^[40]. The reasoning behind this is that, according to the hygiene hypothesis, inadequate exposure to microorganisms in early life might result in higher levels of immune-mediated pathology in later life. Although one study found an increased risk of CD for elective caesarean

sections^[28], another found no association for either CD or UC^[19]. We also found no association for either CD or UC.

We found no association between maternal parity and IBD. Although increased risks of IBD have been reported occasionally for first born^[41,42], or subsequent siblings^[43], most studies have found no association between birth order and IBD^[11,20,25,30,39]. We also found no association between IBD and any of the other perinatal factors studied, including pre-eclampsia, birthweight, gestational age and Apgar score. These perinatal factors have not usually been associated with IBD in previous studies^[11,19,25,28,30].

To summarise, of the 20 perinatal risk factors investigated in this study, we found that maternal CD, smoking during pregnancy and advanced maternal age were associated with increased risks of CD in offspring. For UC, there were no factors associated with increased risks after multivariate adjustment. This, and the fact that the few factors that were associated with CD had quite small effect sizes, suggests that perinatal risk factors have only a minor role in the aetiology of IBD.

ACKNOWLEDGMENTS

The Oxford Record Linkage Study database was funded by the former Oxford Regional Health Authority in the years covered by the maternity data collection and, over many years, it was built by Leicester Gill, Glenys Bettley and Myfanwy Griffith. The views expressed in this paper are those of the authors and not necessarily those of the funding body.

COMMENTS

Background

Both Crohn's disease (CD) and ulcerative colitis (UC) are considered to be immune-mediated disorders, although the exact pathogenetic mechanisms are not yet clear. Perinatal risk factors have been linked with other immune-mediated diseases, including asthma and type 1 diabetes. Other than a suggested, small protective effect of breastfeeding, little has been reported on the role of perinatal factors for either CD or UC.

Research frontiers

This study investigated associations between 20 perinatal risk factors relating to the maternity or the birth and subsequent inflammatory bowel disease (IBD) in offspring in the Oxford region, UK. Risk factors investigated included maternal characteristics such as maternal age, IBD, social class, marital status, smoking in pregnancy, ABO blood group, rhesus status and parity; and characteristics of the birth such as caesarean delivery, number of babies delivered, gestational age, birthweight, breastfeeding and Apgar scores.

Innovations and breakthroughs

The study found increased risks of CD among children of mothers with CD, among children of mothers who smoked during pregnancy, and of older mothers aged 35+ years. There were no significant associations between CD and the 17 other perinatal risk factors investigated, and no associations for UC.

Applications

The findings indicate that these three perinatal risk factors might have some influence on subsequent IBD in children. Overall, however, perinatal factors appear to have a limited role in the aetiology of IBD. This study will help stimulate further research into the influence of perinatal risk factors on IBD. The findings should also provide an important source of information for future systematic reviews and meta analyses of perinatal factors and IBD.

Terminology

Odds ratios were used to assess any increased risks of developing IBD. These denote the chance or odds of developing IBD for a child exposed to a given

perinatal risk factor (e.g. caesarean delivery) as a ratio of the chance or odds for a child not exposed to caesarean delivery. The study used record linkage of maternity exposure data and IBD outcome data, which were collected independently of each other.

Peer review

This is a very well written original article. I would like to congratulate the authors on such a nicely done original paper that contributes a lot of new information about perinatal and early risk factors for IBD.

cells were stimulated with *Lactobacillus rhamnosus* (*L. rhamnosus*) GG (LGG®), *L. rhamnosus* Lc705 (Lc705), *Propionibacterium freudenreichii* ssp. *shermanii* JS (PJS) and *Bifidobacterium animalis* ssp. *lactis* Bb12 (Bb12) and their combination for 3 or 24 h, and were subjected to global microarray analysis using an Affymetrix GeneChip® Human Genome U133 Plus 2.0 Array. The gene expression differences between unstimulated and bacteria-stimulated samples were further analyzed with GOrilla Gene Enrichment Analysis and Visualization Tool and MeV Multiexperiment Viewer-tool.

RESULTS: LGG and Lc705 were observed to suppress genes that encoded allergy-related high-affinity IgE receptor subunits α and γ (FCER1A and FCER1G, respectively) and histamine H4 receptor. LGG, Lc705 and the combination of four probiotics had the strongest effect on the expression of genes involved in mast cell immune system regulation, and on several genes that encoded proteins with a pro-inflammatory impact, such as interleukin (IL)-8 and tumour necrosis factor alpha. Also genes that encoded proteins with anti-inflammatory functions, such as IL-10, were upregulated.

CONCLUSION: Certain probiotic bacteria might diminish mast cell allergy-related activation by downregulation of the expression of high-affinity IgE and histamine receptor genes, and by inducing a pro-inflammatory response.

Abstract

AIM: To investigate the effects of four probiotic bacteria and their combination on human mast cell gene expression using microarray analysis.

METHODS: Human peripheral-blood-derived mast

mast cells. *World J Gastroenterol* 2011; 17(6): 750-759 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i6/750.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i6.750>

INTRODUCTION

Mast cells are multifunctional regulator cells that are located at strategic host-environment interfaces including skin, vascular barriers and gastrointestinal tract, where they encounter antigens and pathogens, as well as commensal microbes. In the healthy intestinal mucosa, mast cells constitute 2%-3% of the cells of the lamina propria^[1]. Mast cells are very heterogeneous cells that are traditionally classified by the content of their specific proteases tryptase and chymase. A mast cell subtype that contains only tryptase (MC_T) is predominant in the lung and intestine, whereas mast cells that contain tryptase and chymase (MC_{TC}) are prevalent in the skin and conjunctiva^[2]. Mast cell subtypes can even vary between different parts of the same organ. Thus, MC_T cells are enriched in the mucosal layer of the intestine but MC_{TC} cells outnumber them in the intestinal submucosa. However, this classification is thought to be interchangeable and can be shaped according to the microenvironment of the cells^[3].

Mast cells participate in a variety of physiological functions, such as epithelial secretion and permeability, blood flow, peristalsis, neuroimmune interactions, and wound healing. One significant task for mast cells is host defence against pathogenic microbes. By secreting several mediators including histamine, proteases, lipid mediators and pro- and anti-inflammatory cytokines, mast cells regulate the immune system and interact with other immune cells^[4]. The multifunctionality of mast cells can explain why they are also involved in the pathogenesis of many inflammatory diseases, such as allergy. The number of mast cells and the amount of mast-cell-derived mediators, such as histamine, which is the key mediator in allergy, are increased at sites of allergic inflammation. The released mediators induce mucus and electrolyte secretion, smooth muscle contraction, nerve-cell activation and other symptoms common in allergic reactions^[5]. The regulation of mast-cell mediators is complex. The best characterized mechanism of mast cell activation is high-affinity IgE receptor (FcεR1)-mediated activation^[6]. IgE-receptor aggregation induces multiple signaling pathways that control the secretion of allergy-related mediators, such as histamine and leukotrienes, and the induction of T helper cell 2 (Th2) type cytokine and tumor necrosis factor (TNF) gene transcription^[7]. The inflammatory effects of the released histamine are mediated by histamine receptors H1-H4^[8]. However, some of the mast cell mediators, including interleukin (IL)-10 and histamine^[9] can have anti-inflammatory effects and decrease inflammation^[10].

Probiotics are defined as live microbes that have beneficial effects on the host's health when administered in adequate amounts^[11]. In clinical intervention studies, certain probiotics have been documented to be effective in the prevention and treatment of various clinical condi-

tions. The most promising results of the health effects of probiotics have been discovered in studies of diarrhea^[12], allergy^[13], irritable bowel syndrome (IBS)^[14,15], and respiratory infections^[16,17]. The effects of probiotics are suggested to be strain-specific, although one strain can have multiple influences^[18]. In the treatment of a complex and heterogeneous condition such as IBS, the use of combinations of different strains of probiotics can have advantages over using a single strain^[14]. The most investigated and used probiotic genera are *Lactobacillus* and *Bifidobacterium*. *Lactobacillus* strains have been effective in beneficially modulating commensal microbes and inhibiting pathogen adhesion to gut mucosa. *Lactobacillus* and *Bifidobacterium* have been shown to produce antimicrobial agents and to alleviate symptoms of allergy^[19]. Dairy *Propionibacterium*, which has been observed to exclude pathogenic microbes from gut mucosa^[20], has also been used as a probiotic.

Evidence from two clinical trials performed with the combination of four probiotic bacteria, i.e. *Lactobacillus rhamnosus* (*L. rhamnosus*) GG (LGG), *L. rhamnosus* Lc705 (Lc705), *Propionibacterium freudenreichii* ssp. *shermanii* JS (PJS) and *Bifidobacterium animalis* ssp. *lactis* Bb12 (Bb12), suggests that the consumption of such combination alleviates the symptoms in IBS patients^[14,21]. As mast cells are believed to be important in regulating intestinal immunity and perhaps also intestinal sensory functions, we chose to study the effects of the above probiotic combination and each bacterium alone on the global gene expression of primary peripheral-blood-derived human mast cells.

MATERIALS AND METHODS

Cell culture

Freshly collected buffy coats from healthy adult blood donors were provided by the Finnish Red Cross Blood Transfusion Service (Helsinki, Finland). The health of the subjects for blood donation is strictly controlled. The donors must be 18-65 years of age, free of infections including HIV, hepatitis B and C, and free of allergic symptoms and most chronic illnesses including autoimmune diseases. Mononuclear cells were purified from heparinized blood by Ficoll-Paque™ Plus (GE Healthcare, Uppsala, Sweden) density gradient centrifugation. Mast cell precursor cells were isolated by positive immunomagnetic selection using indirect CD34 MicroBead Kit and MACS® separation columns (Miltenyi Biotec, Bergish Gladbach, Germany) according to the manufacturer's instructions. After selection, the CD34⁺ cells were cultured for 9-11 wk in serum-free Stem Span™ cell culture medium (Stem Cell Technologies, Vancouver, Canada) supplemented with penicillin and streptomycin (GIBCO BRL, Grand Island, NY, USA), human recombinant stem cell factor (SCF; Peprotech, Rocky Hill, NJ, USA), IL-3 (Peprotech), IL-9 (Peprotech), IL-6 (Peprotech) and human low-density lipoprotein, as previously described^[22]. Cultured mast cells were phenotypically and functionally similar to mature MC_{TC} cells as measured by c-kit and IgE receptor (FcεR1) expression, and the presence of chymase, tryptase, heparin and histamine in their granules, as described previously in detail^[23].

Bacterial strains

L. rhamnosus GG (ATCC 53103), *L. rhamnosus* Lc705 (DSM 7061), *P. freudenreichii* ssp. *shermanii* JS (DSM 7067) and *B. animalis* ssp. *lactis* Bb12 (DSM 15954) were provided by Valio Research Centre (Helsinki, Finland). LGG and Lc705 were grown as previously described^[24]. PJS was grown under optimized aerobic conditions at 30°C in whey broth (Valio) twice for 2 d at a concentration of 2%. Bb12 was grown under anaerobic conditions at 37°C in de Man, Rogosa and Sharpe (MRS) broth enriched with 5 g/L L-cysteine hydrochloride monohydrate (Merck, Darmstadt, Germany) three times for 17–18 h at a concentration of 2%^[25]. LGG, Lc705, PJS and Bb12 were grown to logarithmic growth phase and the number of bacteria was determined by counting in a Petroff-Hauser counting chamber. *Chlamydia pneumoniae* isolate Kajaani 6 (Cpn) was used as a reference strain, and was obtained from the National Institute for Health and Welfare (Helsinki, Finland) and was propagated as described previously^[22].

Mast-cell stimulation with bacteria

After differentiation, mast cells were collected and re-suspended in fresh Stem SpanTM medium that contained antibiotics and SCF as described above. Single live bacterial strains were added to the cell culture in a bacterium-to-cell ratio of 5:1 based on preliminary experiments (data not shown). When the stimulation was performed with the combination of bacteria, each of the four strains was dosed in a bacterium-to-cell ratio of 1.25:1, thus the total bacterium-to-cell ratio of the combination was 5:1. The cells were incubated with bacteria for 3 or 24 h at 37°C in 5% CO₂. After incubation, mast cells were separated from the medium by centrifugation, and the medium was aliquoted and stored at -20°C. The cells were washed free of bacteria, lysed and homogenized in RLT buffer (Qiagen, Valencia, CA, USA) and stored at -70°C before RNA isolation. All experiments were performed with mast cells obtained from three different blood donors. For analysis, the cells from different donors of each experiment were pooled.

RNA isolation and microarray

Total RNA was isolated from the cell lysates using RNeasy Mini Kit (Qiagen) according to the protocol provided by the manufacturer. Microarray experiments were performed at Biomedicum Genomics (Helsinki, Finland) using an Affymetrix GeneChip[®] Human Genome U133 Plus 2.0 Array (Affymetrix, Santa Clara, CA, USA). Integrity and purity of the RNA were verified with Agilent 2100 Bioanalyzer (Agilent Technologies, Palo Alto, CA, USA). Total RNA was prepared and hybridized using the two-cycle protocol of the GeneChip[®] Expression Analysis kit (Affymetrix) according to the manufacturer's recommendations. Double-stranded cDNA was synthesized from total RNA. Next, biotin-labeled cRNA was transcribed from the cDNA, and the cRNA was fragmented and hybridized. The hybridization reactions were scanned using a GeneChip Scanner 3000 (Affymetrix).

Microarray analysis

The robust multiarray averaging algorithm^[26] in the Bioconductor simpleaffy package^[27,28] was used to calculate expression estimates from GeneChip signal intensity data. To provide better precision and accuracy and to overcome interpretation problems related to conflicting id gene references^[27], an updated probe set definition was used^[29], based on Ensemble gene information. In contrast to the default Affymetrix chip description file with 54675 probe sets, the used custom chip description file (version 11.0.1) contained 17492 unique Ensemble gene probe sets. The significance of differential expression was assessed using the empirical Bayes moderated paired *t* statistics (eBayes function) in the limma package, followed by intensity-based hierarchical Bayes analysis^[30,31]. In the analysis, a moderated paired *t* test was computed by constructing cell line effects in the linear model. All *P* values were adjusted for multiple hypotheses testing using the bootstrapped *q* value approach in the *q*value package^[32]. Genes with *P* values ≤ 0.05 were identified as significantly differentially expressed.

The GOrilla Gene Enrichment Analysis and Visualization Tool^[33] was used to discover functional categories that were enriched at either end of a gene list sorted by the moderated *t* test score, which was calculated using limma. The input gene set was used as a background. Clustering and visualization of the gene expression differences were done using MeV Multiexperiment Viewer tool and hierarchical clustering with Euclidean as a distance, and average linkage clustering as the linkage method^[34,35].

Quantitative reverse transcriptase-polymerase chain reaction

To validate the microarray data, TaqMan[®] real-time reverse transcriptase-polymerase chain reaction (RT-PCR) was performed as previously described^[22] for selected genes. Total RNA from the same samples used for the microarray experiments was reverse transcribed to cDNA using random hexamers (Invitrogen, Paisley, UK) and Moloney murine leukemia virus reverse transcriptase (Invitrogen). TaqMan[®] Gene Expression assays (Applied Biosystems, Foster City, CA, USA) were chosen for detection of *IL8* (Hs00174103_m1), *CCL2* (Hs00234140_m1), *IL10* (Hs00174086_m1), *HRH4* (Hs00222094_m1), *FCER1A* (Hs00758600_m1) and *FCER1G* (Hs00610227_m1). Transcripts for *TNF-α* were detected by using sense primer 5'-GCTGCACITTTGGAGTGATCG-3', antisense primer 5'-GTTTGCTACAACATGGGCTACAG-3' and probe 5'-FAM-CCCAGGCAGTCAGATCATCTTCTC-GA-BHQ1-3'. Samples were analyzed in triplicate. β-Actin was used as an endogenous normalization control. Relative quantification was determined by standard 2^{-ΔΔCT} calculations^[36].

RESULTS

Gene expression profiling

In order to explore the effects of different probiotic bacteria or their combination on mast cells, transcrip-

Figure 1 Schematic representation of statistically significant changes ($P < 0.05$) in mast-cell gene expression after 24 h stimulation with *Lactobacillus rhamnosus* Lc705, *Lactobacillus rhamnosus* GG and the combination of four probiotic bacteria. LGG: *Lactobacillus rhamnosus* GG; Lc705: *Lactobacillus rhamnosus* Lc705.

tional changes of the bacteria-stimulated mast cells were studied using a whole genome microarray. A total of 42 Affymetrix GeneChip® Human Genome U133 Plus 2.0 Arrays were used to analyze gene expression profiles of unstimulated mast cells or those stimulated with live LGG, Lc705, PJS, Bb12, or the combination of these four bacteria. Cpn was included in the analysis as a reference bacterium, which represented a non-probiotic, pathogenic microbe with certain known transcriptional effects on mast cells^[22]. Results are representative of three independent experiments, each performed with cells from three donors at two different time points (3 and 24 h). After 3 h bacterial stimulation, the differences in the levels of mast-cell gene expression were so low that no statistical significance was observed as compared to unstimulated samples (data not shown). At 24 h, however, a statistically significant change was observed in 698 genes. Numbers of differentially expressed genes are illustrated in Figure 1. Lc705, LGG and the combination of the four probiotic strains were the most effective stimulators. Bb12 affected the expression of only one gene, and PJS and Cpn failed to change mast-cell gene expression significantly. Lc705 affected mast-cell gene expression the most by changing the expression of 629 genes significantly. Of these genes, 288 were upregulated and 341 were downregulated. LGG altered the expression of 345 genes (160 upregulated and 185 downregulated), and the combination of the four probiotic strains changed the expression of 91 genes (57 upregulated and 34 downregulated). Raw data of the microarray analysis are available at http://ekhidna.biocenter.helsinki.fi/poxo/download_data.

Gene functional category analysis and hierarchical clustering

To characterize the biological significance of the differentially expressed mast-cell genes, a gene ontology category analysis was performed. GOzilla Gene Enrichment Analysis and Visualization Tool^[33] was used to discover whether some functional categories showed statistically significant,

concordant differences between the stimulated sample and the unstimulated sample. The enrichment analyses were carried out for the whole array gene set, including the genes that did not reach statistical significance in the array analysis, that were ranked based on their moderated t values. For the analysis, the ranked genes were sorted in the order of the highest and lowest t value of each sample. The analysis software used the sorted gene lists to classify the genes of each sample into gene ontology categories^[37] by their biological function. Selected functional groups and examples of genes that represented each category are depicted in Table 1.

Stimulation of mast cells with LGG, Lc705, Bb12, combination of probiotics, or Cpn resulted in upregulation of genes that belong to categories that involve immune system processes, regulation of programmed cell death, and leukocyte activation. Stimulation with LGG, Lc705, Bb12 or the combination of probiotics suppressed mast-cell genes that are involved in general cell activities and metabolism such as cell cycle and lipid biosynthetic processes. Lc705 was found to suppress genes that are related to mast-cell activation.

Representative genes from the functional categorization (Table 1) were selected to compare the expression patterns of different samples. Mast cells have a central role in many inflammatory responses as well as in allergy, therefore, immunologically relevant genes and genes involved in mast cell activation and mediator release were selected. In order to compare the expression of the selected genes, a hierarchical comparison analysis with the MeV two-way hierarchical clustering method was performed. As expected, LGG and Lc705 but also the combination of four probiotics showed similar expression patterns in the clustering analysis, and were therefore considered to alter mast-cell gene expression in a similar manner (Figure 2). Genes that are involved in similar processes were also grouped: genes that encode Toll-like receptor (TLR) 1, nucleotide-binding oligomerization domain containing 2 (NOD2), FCER1A and FCER1G (high-affinity IgE receptor 1 gene subunits α and γ , respectively) grouped together; and genes that encode proteins with inflammatory functions, such as IL-1 β and IL-8 constituted another distinct cluster.

Although there were differences in the intensity of the expression levels, all bacteria except PJS induced upregulation of mast-cell genes included in the functional group of immune system regulation. Examples of upregulated genes in this category were *TLR1*, *TLR6*, *NOD2*, *IL1B*, *IL8*, chemokine (C-C motif) 2 (*CCL2*), *TNF* and *IL10*. Genes that are involved in regulation of programmed cell death, such as caspases 3 and 8 (*CASP3* and *CASP8*) and cyclin-dependent kinase inhibitor 1B (*CDKN1B*), were observed to be upregulated in LGG, Lc705, and the combination-stimulated cells. LGG, Lc705 and the combination also significantly enhanced the expression of the cluster of differentiation 8 A (*CD8A*) and lymphocyte cytosolic protein 2 (*LPC2*) genes, which are involved in leukocyte activation.

Cyclin A2 (*CCNA2*) and mitogen-activated protein kinase 12 (*MAPK12*) genes involved in the regulation of cell

The three selected highly upregulated or downregulated functional categories from the enrichment analysis performed with GOrilla Gene Enrichment Analysis and Visualization Tool. *P* value is the enrichment *P* value reported by GOrilla. The resultant categories reflect the gene expression differences of the bacteria-stimulated sample compared to unstimulated sample in 24 h time point. LGG: *Lactobacillus rhamnosus* GG; Lc705: *Lactobacillus rhamnosus* Lc705; PJS: *Propionibacterium freudenreichii* ssp. *shermanii* JS; Bb12: *Bifidobacterium animalis* ssp. *lactis* Bb12; Cpn: *Chlamydia pneumoniae* isolate Kajaani 6; TNF: Tumor necrosis factor; IL-1B: Interleukin-1β; IL-8: Interleukin-8; IL-10: Interleukin-10; CCL2: Chemokine (C-C motif) 2; TLR1: Toll-Like receptor 1; TLR6: Toll-Like receptor 6; NOD2: Nucleotide-binding oligomerization domain-containing protein 2; CASP3: Caspase 3; CASP8: Caspase 8; CDKN1: Cyclin-dependent kinase inhibitor 1; CD8A: Cluster of differentiation 8 A (T cell surface glycoprotein); LCP2: Lymphocyte cytosolic protein 2; CCNA2: Cyclin A2; MAPK12: Mitogen-activated protein kinase 12; FCER1A: Fc fragment of IgE high affinity I receptor for α polypeptide; FCER1G: Fc fragment of IgE high affinity I receptor for γ polypeptide; LPGAT1: Lysophosphatidylglycerol acyltransferase 1.

Figure 2 Two-way hierarchical clustering of representative genes selected from the functional category analysis (Table 1). Data are average expression differences between unstimulated and bacteria-stimulated mast cells from three independent experiments at the 24-h time point. Analysis was performed using MeV software. PJS: *Propionibacterium freudenreichii* ssp. *shermanii* JS; Bb12: *Bifidobacterium animalis* ssp. *lactis* Bb12; Cpn: *Chlamydia pneumoniae* isolate Kajaani 6; Lc705: *Lactobacillus rhamnosus* Lc705; LGG: *Lactobacillus rhamnosus* GG; TLR1: Toll-Like receptor 1; NOD2: Nucleotide-binding oligomerization domain-containing protein 2; IL-1B: Interleukin-1β; IL-8: Interleukin-8; TNF: Tumor necrosis factor; IL-10: Interleukin-10; CDKN1B: Cyclin-dependent kinase inhibitor 1B; TLR6: Toll-Like receptor 6; CASP3: Caspase 3; CASP8: Caspase 8; CCL2: Chemokine (C-C motif) 2; CD8A: Cluster of differentiation 8 A (T cell surface glycoprotein); LCP2: Lymphocyte cytosolic protein 2; CCNA2: Cyclin A2; MAPK12: Mitogen-activated protein kinase 12; FCER1A: Fc fragment of IgE high affinity I receptor for α polypeptide; FCER1G: Fc fragment of IgE high affinity I receptor for γ polypeptide; LPGAT1: Lysophosphatidylglycerol acyltransferase 1.

cycle, and the latter also in IgE receptor signaling, were observed to be downregulated in cells stimulated with LGG, Lc705, and the combination of four probiotics. Stimulation

of mast cells with Lc705 significantly suppressed the expression of *FCER1A* and *FCER1G* genes. The same trend was also observed after stimulation with LGG and the combination, although these changes in the analysis failed to reach statistical significance. Bb12 was found to suppress the expression of *LPGAT1* (lysophosphatidylglycerol acyltransferase 1), a mast cell gene that is related to lipid biosynthesis, and also the other bacteria studied had a similar impact on the expression of this gene.

Manual screening of the array data

To gain further insight into the probiotic-induced changes in mast-cell activation, the array data set was screened for additional genes that were related to the IgE receptor signaling pathway and mast-cell activation and immunomodulation. The screening was performed manually using the list of genes that reached statistical difference in the array analysis at the 24-h time point (http://ekhidna.biocenter.helsinki.fi/poxo/download_data). The gene that encodes phospholipase C (PLC) that is involved in the mast-cell IgE receptor signaling pathway was observed to be significantly downregulated by LGG and Lc705. The gene that encodes prostaglandin E2 receptor (*PTGER*), which mediates the effects of this inflammatory prostaglandin, was also downregulated by LGG and Lc705. Although only Lc705 was categorized in the functional group as downregulating mast-cell activation, LGG-stimulated cells also reached statistical significance in suppressing *FCER1A* expression in the microarray analysis. Both Lc705 and LGG also suppressed the expression of the gene that encodes mast-cell histamine H4 receptor (*HRH4*). Expression alterations of the genes that encode the end-products of the IgE receptor signaling pathway were also screened, but no changes were observed in the mast-cell expression of leukotrienes, heparin or Th2 type cytokines, such as IL-3, IL-4, IL-5 and IL-15 after bacterial stimulation.

Figure 3 Verification of mast-cell microarray results by quantitative reverse transcriptase-polymerase chain reaction with seven selected genes that are involved in mast-cell immune system regulation (A) and mast-cell activation (B). Gene expression was quantified after 24 h stimulation with four probiotic bacteria; *Lactobacillus rhamnosus* GG (LGG), *Lactobacillus rhamnosus* Lc705 (Lc705), *Propionibacterium freudenreichii* ssp. *shermanii* JS (PJS), *Bifidobacterium animalis* ssp. *lactis* Bb12 (Bb12) and their combination or with *Chlamydia pneumoniae* isolate Kajaani 6 (Cpn). Data are mean values \pm SE of three independent experiments. IL: Interleukin; TNF- α : Tumor necrosis factor- α ; CCL2: Chemokine (C-C motif) 2; FCER1A: Fc fragment of IgE high affinity I receptor for α polypeptide; FCER1G: Fc fragment of IgE high affinity I receptor for γ polypeptide; HRH4: Histamine H4 receptor.

Quantitative RT-PCR

Findings from the microarray analysis were verified by quantitative RT-PCR. Seven genes with statistical significance after 24 h stimulation with at least one of the bacteria in the array analysis or in the functional categorization analysis were selected. Four of the genes encoded proteins that are involved in mast-cell regulation of immunological events: *IL8*, *TNF- α* , *CCL2* and *IL10* (Figure 3A). Three of the genes encoded proteins that are involved in mast-cell activation and in allergy: *FCER1A*, *FCER1G* and *HRH4* (Figure 3B). With minor differences in the levels

of intensities, all of the selected genes followed a similar expression pattern detected in the microarray analysis, and thus confirmed the results of the microarray data.

DISCUSSION

In the present study, microarray analysis was used to gain a broad understanding of interactions between probiotic bacteria and human primary mast cells. We report here, that live probiotic bacteria have species-specific effects on human mast cells. The most significant changes in mast-

cell gene expression were observed in the regulation of genes related to mast-cell activation and mediator release, including *FCER1A*, *FCER1G* and *HRH4*, and immunological responses such as *IL8*, *TNF*, *CCL2* and *IL10*.

In the microarray analysis, lactobacilli affected mast-cell gene expression more than the other bacteria. Stimulation of mast cells with both LGG and Lc705 significantly downregulated the expression of the high-affinity IgE receptor subtype α (*FCER1A*) and *HRH4* (*HRH4*) genes after 24 h stimulation. In addition, Lc705 stimulation downregulated the gene expression of FC ϵ R1 receptor subtype γ (*FCER1G*). PJS, Bb12, the combination, or Cpn did not have an effect on *FCER1* and *HRH4* genes. FC ϵ R1 plays a key role in mediating the allergy-related IgE-dependent activation and degranulation of mast cells^[38] as demonstrated in FC ϵ R1-deficient mice that fail to show allergic reactions after sensitization^[39]. After FC ϵ R1 aggregation, mast cells release inflammatory mediators, such as histamine. Histamine is the key mediator in causing the symptoms of allergy, and it also has a potent role as a modulator of immune responses^[40]. The effects of histamine are mediated through histamine receptors H1-H4 that are expressed on the surface on many cell types, including mast cells and other inflammatory cells as well as epithelial cells^[41]. The most recently discovered *HRH4* has been shown to have mainly immunomodulatory effects^[41]. The expression of histamine receptors is suggested to be influenced by inflammatory stimuli^[40]. In addition, modification of histamine receptor gene expression is suggested to play a role in the pathogenesis of allergy, atherosclerosis and rheumatoid arthritis^[7]. By suppressing the expression of *FCER1* and *HRH4* genes, probiotic lactobacilli could attenuate mast-cell activation and release of allergy-related mediators.

To obtain more evidence of the possible ability of probiotics to suppress mast-cell activation, the array gene set was manually screened for other genes involved in IgE receptor signaling. Expression of the gene that encodes PLC, which is involved in the release of intracellular calcium and in mast-cell degranulation^[39], was suppressed significantly after Lc705 and LGG stimulation. Additionally, the gene that encodes expression of the member of the mitogen-activated protein kinase (MAPK) family, *MAPK12*, that participates in the signaling events that lead to the production of Th2 type cytokines IL-3, IL-4, IL-5 and IL-13, and in the generation of eicosanoids^[38], was also downregulated in Lc705 and LGG-stimulated mast cells. These findings suggest that Lc705 and LGG have an inhibitory effect on mast-cell genes that are involved in the IgE signaling cascade, beyond inhibition of IgE receptor gene expression.

Our results with human primary mast cells are in line with those of two previous studies of the effects of non-pathogenic bacteria on human or mouse mast cells. *Escherichia coli* (*E. coli*) K12 strain has been found to downregulate *FCER1A* in the malignant human mast cell line (LAD3)^[42]. The other study has reported that *E. coli* strain DSM 17252 inhibits mast-cell degranulation in mouse peritoneal mast cells^[43]. Commensal non-pathogenic *E. coli*

and probiotic LGG and Lc705 seem to downregulate mast-cell IgE responses similarly. These results suggest that commensal and probiotic bacteria do not stimulate mast cells but rather diminish their activation. However, it is worth noticing that this effect is not universal response to bacteria, because not all probiotic bacteria or pathogenic Cpn affected the gene expression of high-affinity IgE receptor similarly.

Probiotic bacteria were also observed to alter the expression of genes that have inflammatory functions. In the functional categorization analysis, the expression of a category of immune system process that contains, for example, a gene that encodes an inflammatory mediator that is also regulated by the MAPK pathway, TNF α ^[44], was upregulated in mast cells stimulated with LGG, Lc705, Bb12 and the combination. The categorization analysis also highlighted upregulated functions in known inflammatory genes such as *IL8*, *CCL2*, and *IL1B* in cells stimulated with LGG, Lc705, Bb12 and the combination. The same genes were also upregulated in mast cells stimulated with Cpn, which is in line with our previous study in which Cpn elicited pro-inflammatory effects in mast cells^[22]. However, no upregulation in any of the Th2 type cytokine genes in mast cells after probiotic stimulation in the gene microarray was observed. In the prevention of the symptoms in allergic diseases, probiotics have been suggested to elicit low-grade inflammation and thus shift the immune response away from the allergy-related Th2 type inflammation^[45,46]. In *in vitro* studies, probiotic bacteria have been observed to induce the secretion and expression of Th1 type cytokines in monocytes, macrophages and dendritic cells^[47,49]. Additionally, in a clinical study, low-grade inflammation induced by LGG in allergy-prone children has been proposed to be one mechanism to prevent atopic diseases^[45]. The ability of LGG, Lc705, Bb12 and the combination to induce in mast cells pro-inflammatory rather than Th2 type cytokine expression could have contributed to the observed beneficial low-grade inflammatory response in the above-cited study. Our findings in mast cells support the idea that some probiotic strains shift the mast-cell-mediated immunological response from the Th2 to Th1 type, by inducing expression of pro-inflammatory mediators.

Mast cells stimulated with LGG, Lc705, Bb12, the combination, or with Cpn also induced the expression of a gene that encodes anti-inflammatory IL-10. Mast-cell-derived IL-10 has been observed to be crucial in restriction of chronic skin inflammation in hypersensitivity reactions^[50]. Probiotic *Bifidobacterium* strains have been observed to stimulate IL-10 production in immune cells^[51]. IL-10 induction in mast cells could participate in balancing the inflammatory impact. *In vivo*, the combination of affected genes after bacterial stimulation is likely to be more important than a change in the expression of any single gene. Thus, the downregulation of *FCER1* and *HRH4* genes combined with the upregulation of *IL10* after stimulation with probiotic *Lactobacillus* might be involved in downregulation of inflammatory responses in allergy and other inflammatory diseases in which mast cells are known to play a role, such as atherosclerosis, rheumatoid

arthritis, inflammatory bowel disease and IBS^[5,52-54]. As Cpn upregulated only *IL10* without affecting *FCER1* and *HRH4*, mast cells stimulated with pathogenic Cpn might not have the same clinical effects as those stimulated with probiotic bacteria.

In addition to *FCER1* and *HRH4*, the function of mast cells is regulated through a variety of other receptors, such as TLRs. In our previous study, we have shown that TLR2 is a receptor for LGG, which triggers the nuclear factor- κ B signaling cascade, which leads to expression of different cytokines in human primary macrophages^[55]. In addition, probiotic bacteria have been shown to suppress mast-cell degranulation by interrupting *FCER1*-mediated signaling through TLR2^[56]. The paradox of the ability of probiotic LGG and Lc705 to diminish mast-cell activation, but enhance the mast-cell immune response, could be regulated through the same receptor, TLR2.

PJS failed to change mast-cell gene expression significantly at either time point. Previously, PJS has been observed to induce TNF α expression after 3 h stimulation, and IL-10 expression after 3 and 24 h stimulation in human peripheral blood mononuclear cells (PBMCs)^[24]. It could be that mast cells are unresponsive to PJS unlike the PBMC population. It could also be that the quantitative spectrum of microarray is a limiting factor, especially if the expression differences between unstimulated and stimulated samples are low or if the gene is expressed in low quantities^[57]. In our experiments, the differences in the gene expression levels of the microarrays were relatively low, which is in accordance with other microarray studies performed with probiotic bacteria^[58].

Crosstalk between probiotic bacteria and intestinal mast cells is likely to occur mainly through gut epithelial cells^[59]. Probiotic bacteria or their products could incidentally translocate to the lamina propria through intestinal M cells and make direct contact with immunological cells such as mast cells. Additionally, mast cells are suggested to have the possibility to be in direct contact with bacteria or bacterial fragments in atherosclerotic plaques^[53,60]. Fragments of Firmicutes and Proteobacteria, which are probably of intestinal origin, as well as Cpn have been detected from atherosclerotic plaques^[60]. The intestinal barrier is believed to leak also in healthy humans, which would allow probiotic bacteria to access spaces that contain macrophages, dendritic cells and mast cells. Even though *in vivo* evidence of direct contact between mast cells and probiotic bacteria in the human intestine is missing, *in vitro* interaction studies performed with direct contact between bacteria and host cells, such as mast cells, are required for better understanding of the molecular basis of the immunomodulative properties of probiotic bacteria.

The mast cells differentiated by the peripheral-blood-derived isolation method comprise mainly the MC_{Tc} phenotype^[23], whereas the gut contains both MC_{Tc} and MC_T phenotypes; the latter being the predominant mucosal mast-cell phenotype^[2]. However, the MC_T and MC_{Tc} phenotypes both express high-affinity IgE receptors and produce a variety of inflammatory mediators. The responses observed in this study could be further evaluated in a

more physiological context, e.g. in *ex vivo* culture models using mast cells derived from human intestinal tissues, or in *in vivo* animal or clinical studies.

The present study is believed to be the first to describe the effects of probiotic bacteria on human mast cells. Our data suggest that especially probiotic *L. rhamnosus* Lc705 and *L. rhamnosus* GG could diminish mast-cell activation and the effects of allergy-related mediators by down-regulating expression of the high-affinity IgE and *HRH4* receptors, and by stimulating mast-cell immune responses. Mast cells are important mediators of allergic responses on host surfaces including the intestine, therefore, we propose that mast cells participate in regulating the beneficial immunological responses to probiotic bacteria.

ACKNOWLEDGMENTS

Professor Heikki Vapaatalo is acknowledged for his advice and critical comments on the study and the manuscript. The authors thank Mirja Puolakkainen in the National Institute for Health and Welfare for kindly providing Cpn for this study. The authors acknowledge the excellent technical assistance of Anna-Maija Ahonen in growing bacteria, and Mari Jokinen and Maija Atuegwu for their help with culturing mast cells.

COMMENTS

Background

Probiotic bacteria are widely used to prevent or relieve symptoms of various clinical conditions, such as intestinal disorders and allergy. However, it is not fully understood what make probiotics effective.

Research frontiers

Mast cells are important immunological cells that have many functions. Mast cells also participate in the pathogenesis of many inflammatory diseases, with allergy being the best-known example. In the prevention of the symptoms in allergic diseases, probiotics have been suggested to elicit low-grade inflammation. In the present study, the authors explored for the first time the role of human mast cells in contributing to the beneficial effects of probiotic bacteria.

Innovations and breakthroughs

In the present study, the authors found that probiotic lactobacilli strains *Lactobacillus rhamnosus* (*L. rhamnosus*) GG and *L. rhamnosus* Lc705, but not propionibacteria or bifidobacteria, downregulated expression of high-affinity IgE and histamine H4 receptors, and enhanced mast-cell immune activity, and thus, might diminish the impact of the allergenic response.

Applications

Understanding the mechanisms by which probiotic bacteria elicit their health effects is crucial when designing and using different probiotic strains for specific preventive or therapeutic purposes.

Terminology

Probiotic bacteria are defined as live microorganisms that have beneficial effects on human health. High-affinity IgE receptor mediates mast-cell activation and histamine production in allergy. Histamine H4 receptor is a protein on mast cells that mediates the effects of histamine.

Peer review

In this well-designed study, the authors explored the action of four probiotic strains and their combination on human mast-cell global gene expression. The analysis revealed changes in genes involved in immune responses and mast-cell activation, which are especially involved in the pathogenesis of inflammatory diseases, such as allergy. The authors suggest that lactobacilli are able to diminish the impact of allergenic responses by downregulating expression of high-affinity IgE and histamine H4 receptors, and by enhancing mast-cell immune activity. The study addresses an interesting and important question.

62 years. More than half the subjects (59.8% in the case group and 51.9% in the control group) were NAT2 slow acetylators. The odds ratio for colorectal cancer was 1.38 (95% CI: 0.90-2.12) in slow acetylators. Although the number of women was small ($n = 76$ in the case group), the cancer risk was found to be lower in intermediate (W/Mx) acetylators [odds ratio (OR): 0.55, 95% confidence interval (95% CI): 0.29-1.02]. This difference was not observed in men (OR: 0.56, 95% CI: 0.16-2.00). Among NAT2 fast acetylators (W/W or W/Mx), meat consumption more than 3 times a week increased the risk of colorectal cancer (OR: 2.05, 95% CI: 1.01-4.16). In contrast, cigarette smoking increased the risk of CRC among slow acetylators (OR: 1.97, 95% CI: 1.02-3.79).

CONCLUSION: The risk of CRC was higher among fast acetylators who reported a higher meat intake. Slow NAT2 acetylation was associated with an increased risk of CRC.

Abstract

AIM: To investigate the possible association between meat intake, cigarette smoking and N-acetyltransferase 2 (NAT2) genetic polymorphisms on colorectal cancer (CRC) risk.

METHODS: Patients with CRC were matched for gender and age to healthy controls. Meat intake and cigarette smoking were assessed using a specific frequency questionnaire. DNA was extracted from peripheral blood and the genotypes of the polymorphism were assessed by polymerase chain reaction-restriction fragment length polymorphism. Five NAT2 alleles were studied (WT, M1, M2, M3 and M4) using specific digestion enzymes.

RESULTS: A total of 147 patients with colorectal cancer (76 women and 90 men with colon cancer) and 212 controls were studied. The mean age of the two groups was

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers in the world. In Brazil, 13 310 new cases in men and

14800 in women are estimated to occur in 2010^[1].

N-acetyltransferase 2 (NAT2) is an enzyme found in a large number of organs such as the lungs, colon, breast, prostate, and liver. The expression of this enzyme suggests that it plays a key role in the protection against reactive molecules resulting from environmental insults not only in the liver but in all target tissues^[2]. The *NAT2* gene is located in the chromosome 8p22 region and has no introns. The gene contains an 870-bp open reading frame and encodes a protein of 290 amino acids^[3]. It is an important phase II enzyme that catalyzes the acetylation of aromatic and heterocyclic amines and hydrazines present in carcinogenic compounds and medicines. Individuals can be divided into three different phenotypes based on the acetylation activity of NAT2: fast, intermediate, and slow. These phenotypes are determined by single nucleotide polymorphisms in *NAT2*^[4].

Some NAT2 polymorphisms have been consistently associated with a reduction in acetylation activity (e.g. T³⁴¹C). The functional state of the phenotype is due to the impairment of protein translation or stability. No changes in mRNA levels are detected. For several polymorphisms, the classification as “fast” or “slow” is not final^[5].

The probability of developing cancer depends on the natural response of each organism to different aggressive agents. Humans present different susceptibilities to carcinogens^[6,7]. This difference in susceptibility to various environmental aggressors is related to genetic polymorphisms^[8].

Studies have associated meat consumption with an increased risk of CRC^[9]. Red meat, especially meat that is well done, is a source of chemical carcinogens such as heterocyclic aromatic amines, polycyclic aromatic hydrocarbons, and other products. The fast acetylation genotype is probably related to larger amounts of metabolic activators of heterocyclic aromatic amines when compared to the slow NAT2 acetylation genotype. Metabolic activators are transported to colorectal tissues through the bloodstream, causing DNA damage and mutations in tumor suppressor genes involved in the carcinogenesis of CRC^[10].

The association between genetic polymorphisms in the *NAT2* gene and CRC has been studied extensively; however, the results are not conclusive, possibly because of ethnic differences and differences in the lifestyle and number of patients studied. The proportion of fast and slow acetylation phenotypes varies markedly depending on ethnicity and geographic origin^[11]. Thus, there is an urgent need for studies investigating the distribution of NAT2 genotypes in different countries.

The aim of the present study was to investigate NAT2 polymorphisms in Brazilian patients from São Paulo.

MATERIALS AND METHODS

A case-control study involving 147 patients with CRC and 212 healthy subjects was carried out between March 2008 and December 2009. All patients were born in Brazil and were treated at the Oncology Division, Department of Gastroenterology, University Hospital, Universidade Fed-

eral de São Paulo (UNIFESP). The study was approved by the Ethics Committee of UNIFESP and all patients signed an informed consent form.

The patients answered a questionnaire regarding food habits and food frequency, whether they were current or former cigarette smokers, and their pattern of alcohol consumption.

Peripheral blood was collected for genomic DNA extraction. The *NAT2* gene polymorphisms were investigated by the polymerase chain reaction (PCR)-restriction fragment length polymorphism genotyping technique.

DNA extraction

Leukocyte DNA was extracted from peripheral venous blood collected with ethylenediaminetetraacetic acid using the Invisorb® Spin Blood Mini Kit.

Analysis of NAT2 genetic polymorphisms

The genotypes of the NAT2 polymorphism were analyzed as described previously^[9]. Genomic DNA was amplified using the following primers: 5'-GGAACAAATTG-GACTTGG-3' and 5'-TCTAGCATGAATCACTCTGC-3'. After amplification, the PCR product was digested with KpnI (M1 allele), BamHI (M3 allele) and MspI/AluI (M4 allele), and with TaqI (M2 allele). The digestion products were separated on agarose gels stained with ethidium bromide, and were then visualized under UV light^[15]. The W/W and W/MX genotypes were classified as conferring the fast acetylation phenotype and the Mx/MX genotype as conferring the slow acetylation phenotype.

Statistical analysis

The Student *t*-test was used for the comparison of age between groups. Differences in the polymorphisms between the two groups were determined by the χ^2 test. This test was also used to compare clinical variables between NAT2 genotypes and alleles in the group of cancer patients. The association between the risk of developing cancer and these variables was assessed by calculating the odds ratio (OR) and 95% confidence interval (95% CI). A *P* value < 0.05 was considered to be statistically significant and a *P* value of 0.05 to 0.10 was considered to be marginally significant.

RESULTS

A case-control study including 147 patients with CRC and 212 healthy controls was conducted to determine whether NAT2 genetic polymorphisms are associated with the development of this disease. The characteristics of the cancer patients and controls are shown in Table 1. No difference in age or gender was observed between groups. Among the 147 patients with cancer, 90 (61.2%) had colon cancer and 57 (38.8%) had rectal cancer. According to the TNM classification, most patients were stage II (44.2%) or stage III (26.5%).

Four different NAT2 alleles were found, including the wild type (WT) and the M1, M2 and M3 polymorphisms. The M4 allele was not detected. Among healthy control

subjects, the observed genotype frequency of the NAT2 polymorphisms were consistent with the expected frequency of the Hardy-Weinberg equilibrium ($P = 0.56$), suggesting that the distribution of NAT2 genotypes is adequate in the cancer-free population.

The slow acetylation phenotype predominated in the two groups (59.8% in the case group and 51.9% in the control group). No significant differences in the frequency of the NAT2 polymorphisms were observed between groups (Table 2).

The odds ratio for CRC was 1.38 (95% CI: 0.90-2.12) in slow acetylators. The M1 allele was the most frequent allele in the two groups, with a frequency of 45% in the control group and of 44.5% in the case group, followed by the WT allele (28% in the control group and 25.1% in the case group).

No significant association was observed between NAT2 polymorphism and acetylation phenotype or tumor site. Comparison of patients in TNM stage I or II *vs* stage III or IV showed a higher frequency of the slow acetylation phenotype in stage I and II patients (60.1%).

Analysis of red meat intake showed that half of the subjects consumed red meat more than 3 times a week. Subjects with the fast acetylation phenotype who consumed meat more than 3 times a week presented an increased risk of CRC (OR: 2.05, 95% CI: 1.01-4.16) (Table 3). With respect to cigarette smoking, the number of ex-smokers was marginally higher in the cancer group. Cigarette smoking increased the risk of CRC among slow acetylators (Mx/Mx) (OR: 1.97, 95% CI: 1.02-3.79) (Table 4).

DISCUSSION

CRC is one of the most common cancers. Almost 70% of CRC patients are diagnosed at age 65 years or older^[12]. Most of the subjects studied here were women ($n = 76$, 51.7%), and the mean age was 61.9 years. These findings agree with data published by the Brazilian National Cancer Institute^[11].

According to the Annual Report to the Nation on the Status of Cancer, prostate cancer is the most frequent cancer among men, followed by lung, colon and rectal

cancer, except for Latin America where the incidence of CRC is slightly higher than that of lung cancer. Among women, the most frequent cancer is breast cancer, followed by lung cancer and CRC^[13].

Variations in the frequency of NAT2 genotypes/phenotypes among different populations and ethnic groups have been reported in several studies carried out in different regions around the world. In this respect, a high frequency of the slow acetylator phenotype is observed in populations of European and African descent. Other populations are characterized by a high frequency of fast acetylation phenotypes, such as Japanese, Chinese and Amerindians^[14-16].

In the present study, the slow acetylation phenotype was slightly more frequent in the two groups, although the difference was not statistically significant. However, when divided by gender, the fast acetylation phenotype tended to be more common among women. The M1 allele was the most frequent allele in the two groups (45% in the control group and 44.5% in the case group), followed by the WT allele (28% in the control group and 25.1% in the case group). The M4 allele was not detected. These data are consistent with the literature, which indicates a difference in the frequency of the WT, M1 and M4 alleles between Caucasians and Africans, whereas the frequency of the M2 and M3 alleles is similar. The M4 allele is detected at a rate of less than 1% in Caucasians, whereas its frequency is 18% in the African population^[9,17,18].

No significant difference in NAT2 polymorphism or acetylation phenotype was observed between tumor sites. Analysis according to TNM stage showed that the slow acetylation phenotype was more frequent among stage I or II patients (60.1%) compared to stage III or IV. This finding might be explained by the fact that the NAT2 fast acetylation phenotype activates carcinogens and produces mutations more quickly, resulting in aggressive tumors. However, these findings should be analyzed carefully because of the small number of patients participating in the present study.

For a long time, genetic susceptibility to cancer has been attributed to xenobiotic exposure. This view was mainly due to the fact that the molecular mechanisms involved in carcinogenesis were not known. However, this view has changed over recent years with the advances in molecular biology. It is now known that exposure to xenobiotics and the development of cancer vary among individuals because of variations that occur at the molecular level which, in turn, are under genetic control^[19]. In recent studies, lifestyle habits including alcohol and tobacco use and dietary habits (i.e. adequate protein and fiber intake) have been associated with gene mutations in an attempt to obtain more consistent results regarding cancer risk factors and prognosis. Although currently available data are controversial due to ethnic differences and differences in lifestyle, this has been the best approach to better understand carcinogenesis at the molecular level.

Smoking has been associated with several types of cancer other than lung cancer, including cancer of the oral cavity, pancreas, and kidney^[20]. A recently published meta-

Table 2 Distribution of N-acetyltransferase 2 polymorphism and the risk of cancer

Genetic polymorphism NAT2 ^a	Cancer, <i>n</i> (%)	Control, <i>n</i> (%)	<i>P</i>	OR (95% CI)

Slow	40 (61.5)	39 (44.8)	0.06	1.97 (1.02-3.79)
Fast	25 (38.5)	48 (61.0)		

^aHomozygous individuals with genotype W/W, and heterozygote W/Mx, are grouped into fast acetylation phenotype, while homozygous Mx/Mx are grouped in slow acetylators. NAT2: N-acetyltransferase 2; OR: Odds ratio; 95% CI: Confidence interval.

analysis reported a strong association between smoking and the development of CRC^[12]. However, smoking is currently not recognized as a risk factor for CRC by the International Agency for Research on Cancer (IARC) or the US Surgeon General^[12]. Sørensen *et al*^[21] studied the association between NAT1 and NAT2 polymorphisms, smoking, meat consumption and CRC risk in 379 cancer patients and 769 healthy subjects. In that study, only the NAT1 polymorphism affected cancer risk. However, the NAT1 and NAT2 fast acetylation phenotype increased the risk of CRC among patients who smoked more cigarettes, suggesting that N-acetylation status affects the relationship between smoking and CRC risk.

In the present study, most subjects in the two groups had never smoked, but the rate of ex-smokers was higher in the case group than in the control group. Once diagnosed with cancer, individuals tend to break old habits that may affect the prognosis and treatment of the disease even if it is not possible to reverse the previous damage. The slow acetylation phenotype was more frequent among smokers of the case group, suggesting an increased risk of cancer (OR: 1.97, 95% CI: 1.02-3.79) in subjects with this phenotype. A higher frequency of the slow acetylation phenotype among patients with lung and bladder cancer has been demonstrated in other studies. Carcinogens

present in tobacco are metabolized by NAT enzymes and activation of these enzymes is reduced in slow acetylators, thus increasing the risk of cancer^[22].

An association between red meat consumption and a higher risk of CRC has been reported in case-control studies, prospective epidemiological studies and in a recent meta-analysis^[23]. The last study suggested that this increased risk is due to the production of polycyclic aromatic hydrocarbons and heterocyclic amines when meat is cooked at high temperatures^[24].

Tamer *et al*^[25], studying 125 patients with CRC and 82 healthy subjects, observed an association between NAT2 polymorphisms and cancer development. In that study, high protein intake was found to be correlated with an increased risk of colon cancer (OR: 1.73, 95% CI: 1.10-3.07). Patients with the NAT2 * 14A (M4 allele) fast acetylation phenotype and high meat intake presented an increased risk of CRC (OR: 3.03, 95% CI: 1.56-5.86). In the present study, the risk of cancer was higher among patients consuming meat more than 3 times per week (OR: 1.65, 95%

CI: 1.05-2.61). The risk of CRC was increased among patients presenting the fast acetylator genotypes (W/W or W/Mx) and a high frequency of meat intake (OR: 2.05, 95% CI: 1.01-4.16).

Heterocyclic amines are formed when meat is cooked by the condensation of creatinine with amino acids. The NAT2 fast acetylation phenotypes are more readily able to convert N-hydroxy heterocyclic amines into carcinogens, a fact predisposing to cancer. Thus, heterocyclic amines require metabolic activation to induce DNA mutations and to initiate carcinogenesis. After N-oxidation, N-hydroxy aromatic and heterocyclic amines are activated (*via* O-acetylation) by NAT to acetoxy intermediates, which react spontaneously with DNA to form adducts^[26,27]. The increased cancer risk observed in patients with the NAT2 fast acetylation phenotype and high meat consumption suggests that heterocyclic amines mediated by metabolic activation of NAT2 fast acetylation might be important carcinogens and increase the risk of cancer.

In conclusion, the proportion of subjects with the slow acetylation phenotype was high in this study. No association was observed between the risk of CRC and NAT2 polymorphisms. However, the slow acetylation phenotype increased the risk of CRC in smokers and the fast acetylation phenotype increased this risk among subjects with high red meat intake.

COMMENTS

Background

Colorectal cancer (CRC) is considered the fourth leading cause of cancer worldwide and is one of the most common malignancies in the West. The probability of developing cancer depends on the natural response of each organism to different exposures from various aggressors. Humans have different susceptibilities to different carcinogens and lifestyle may be a risk factor for cancer. The interaction between diet, alcoholism, cigarette smoking, obesity and physical inactivity can lead to its development.

Research frontiers

The HAAs (present in red meat, tobacco, *etc.*) are bioactivated through N-oxidation by the enzymes CYP1A2 in the liver or by CYP1A1/CYP1B1 in extra hepatic tissues. The products of this oxidation are the N-hydroxy-N, which in turn suffer the bioactivation in the liver by O-acetylation of N-acetyltransferase (NAT) enzymes (mainly NAT2) and sulfotransferase. NAT2 fast acetylation individuals may have larger amounts of metabolic activators of HAA than slow acetylation NAT2 subjects that can be transmitted to the colorectal tissues through the bloodstream, causing DNA damage and mutations.

Innovations and breakthroughs

Previous studies linking meat consumption and colorectal cancer have concluded that diets rich in meat consumption increase the risk of this disease. In the case of red meat, the degree of cooking can be a source of exposure to chemical carcinogens such as heterocyclic amines, nitrosamines and other products. This study aimed to identify the distribution of NAT2 gene polymorphism in a Brazilian population from São Paulo correlating these polymorphisms and the phenotypes of NAT2 acetylation with the consumption of red meat, alcohol and cigarette smoking and the colorectal cancer risk.

Applications

The proportion of people with the phenotype of fast and slow acetylation varies considerably depending on the ethnicity and geographic origin. This variability lead to the investigation into the frequency of NAT2 genotypes and the association of this polymorphism with colorectal cancer in a Brazilian population of São Paulo. The relationship between the mechanism of acetylation by NAT2 and susceptibility to colorectal cancer may possibly screen patients who have a higher risk of developing this disease.

Terminology

The NAT2 is an important phase II enzyme that catalyzes the acetylation of heterocyclic aromatic amines and hydrazines, which include carcinogenic compounds and drugs. Based on the activity of NAT2 acetylation, subjects are divided into three different phenotypes: fast, intermediate and slow. Single nucleotide polymorphisms in NAT2 determine this phenotype.

Peer review

The authors examined the phenotypes and polymorphisms of NAT2 acetylation on a case-control study, involving the eating habits and lifestyle as risk modifiers of colorectal cancer development. The results indicated that cigarette smokers with slow acetylation phenotype had an increased risk of developing colorectal cancer and individuals with fast acetylation phenotype intake of red meat increased the risk of developing the disease. These results are interesting because the study of NAT2 acetylation may identify individuals with a higher risk of developing CRC in relation to environmental factors and diet.

Abstract

AIM: To determine the prevalence of a family history suggestive of Lynch syndrome (LS) among patients with colorectal cancer (CRC) followed in a coloproctology outpatient clinic in Southern Brazil.

METHODS: A consecutive sample of patients with CRC were interviewed regarding personal and family histories of cancer. Clinical data and pathology features of the tumor were obtained from chart review.

RESULTS: Of the 212 CRC patients recruited, 61 (29%) reported a family history of CRC, 45 (21.2%) were diagnosed under age 50 years and 11 (5.2%) had more than one primary CRC. Family histories consistent with Amsterdam and revised Bethesda criteria for LS were identified in 22 (10.4%) and 100 (47.2%) patients, respectively. Twenty percent of the colorectal tumors had features of the high microsatellite instability phenotype, which was associated with younger age at CRC diagnosis and with Bethesda criteria ($P < 0.001$). Only

5.3% of the patients above age 50 years had been previously submitted for CRC screening and only 4% of patients with suspected LS were referred for genetic risk assessment.

CONCLUSION: A significant proportion of patients with CRC were at high risk for LS. Education and training of health care professionals are essential to ensure proper management.

INTRODUCTION

Family history of colorectal cancer (CRC) is a clinically significant risk factor and may be reported by up to 15% of all patients with the disease. Lynch syndrome (LS, OMIM: # 120435), also called hereditary non-polyposis colorectal cancer syndrome (HNPCC), is the most common inherited colon cancer predisposition syndrome. It is an autosomal dominant syndrome caused by germline mutations in the mismatch repair (MMR) genes *hMLH1*, *hMSH2*, *hMSH6* and *PMS2*. The syndrome accounts for 2%-3% of all CRC diagnoses and for 5%-9% of the diagnoses of endometrial cancer in patients under age 50 years^[1-4]. Other extra-colonic tumors including ovarian, upper urologic tract, gastric, small bowel, biliary/pancreatic and brain cancers have been described at an increased frequency in families with LS^[5]. The cumulative lifetime risk of cancer varies depending on geographic/environmental factors and the age-related incidence of each tumor type^[6-8]. Furthermore, the cancer spectrum in families affected with the syndrome varies significantly based upon the DNA MMR gene mutated and the specific mutation^[9,10].

Determining the prevalence of LS among patients with CRC is an important public health issue. Affected patients have an increased risk for second primary cancers and their identification can lead to specific screening and intervention recommendations for patients and their at-risk relatives^[11-13].

Cancer family history is an important tool to identify at-risk patients and families. The Amsterdam criteria, ini-

tially including only CRC and later all tumors of the LS cancer spectrum, define clinical diagnosis of LS and are in themselves an indication for MMR mutation testing. However, even the revised Amsterdam II criteria have a relatively low sensitivity (< 80%) which has turned out to be a major limitation for LS diagnosis. More recently, the Bethesda guidelines were developed to identify a larger proportion of MMR mutation carriers (Table 1)^[14].

Multiple other strategies for identifying individuals with LS have been proposed, including predictive mathematical models to define prior probabilities of carrying a germline MMR mutation, family history instruments and routine testing of CRCs from patients with specific risk factors (e.g. age < 50 years), but the effectiveness of these approaches continues to be debated and has limited applicability in clinical practice^[9,10].

In this study, we aimed to determine the prevalence of a family history suggestive of LS among patients with CRC followed in a coloproctology outpatient clinic of a University Hospital in Southern Brazil, and to identify all potential LS patients who should be referred for genetic counseling. Also, we investigated the frequency of tumors with histopathologic features suggestive of microsatellite instability (MSI) and whether screening recommendations were correctly modified according to the risk identified.

MATERIALS AND METHODS

Ethics

This study was approved at the Institutional Ethics Committee (GPPG-HCPA) under the number 05-257.

Patients

All consecutive patients with a diagnosis of CRC who had an appointment in the outpatient Coloproctology clinic of Hospital de Clínicas de Porto Alegre (HCPA), in Porto Alegre, Southern Brazil, from December 2005 to December 2006, were considered for participation in this study. From a total of 250 patients seen in this period, 212 unrelated patients with adenocarcinoma of the colon and rectum and without a previous diagnosis of inflammatory bowel disease were invited and agreed to participate in the study. After signature of informed consent forms, data regarding personal and family cancer history, pathology reports and additional relevant clinical and/or surgical information were collected. Information collected included types of cancer and age at diagnosis, presence of multiple (synchronous or metachronous) tumors, type and periodicity of colorectal screening, tumor histology, clinical and histological stage of tumors (Dukes and TNM Staging System), family history of cancer (first, second and third degree). Tumor diagnoses in family members were confirmed by medical records and/or death certificates whenever possible.

“Early-onset” colorectal or endometrial cancer was defined as cancer diagnosed before the age of 50 years. All other extra-colonic tumors described in the LS (ovarian, upper urologic tract, gastric, small bowel, biliary/pancre-

	Bethesda 3: Colorectal cancer with the MSI-H histology ³ under the age of 60		
	Bethesda 4: Colorectal cancer in one or more first-degree relatives with an LS-related tumor, with one of the cancers under the age of 50		
	Bethesda 5: Colorectal cancer in two or more first- or second-degree relatives with LS-related tumors, regardless of age		

¹Data on sensitivity and specificity of Amsterdam criteria from Syngal *et al.*^[14] and Revised Bethesda from Piñol *et al.*^[46]; ²Lynch syndrome (LS)-associated tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, brain tumors, sebaceous gland adenomas and keratoacanthomas in Muir-Torre syndrome, and carcinoma of the small bowel; ³Presence of tumor infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern. FAP: Familial adenomatous polyposis; MSI-H: Microsatellite instability-high.

atic and brain) were considered in the pedigree analyses^[5]. Colorectal surveillance was considered appropriate when colonoscopy was performed by or after age 50 years in patients with no history of CRC in first- or second-degree relatives, and in those with a positive family history, when performed 10 years before the earliest diagnosis of CRC in the family, and every 1-2 years thereafter.

The criteria used to identify patients with LS or at-risk for the syndrome included the Amsterdam I and/or II criteria for clinical diagnosis^[5,15] and the Bethesda Revised Criteria^[16] for a potential diagnosis.

Statistical analysis

SPSS version 16.0 was used for data handling and statistical analyses. For descriptive analysis, categorical variables were described by their absolute and/or relative frequencies and quantitative variables were expressed as mean \pm SD. For analytical statistics, the existence of an association between categorical variables was examined using χ^2 . The Student's *t* test was used to determine the significance between different ages at diagnoses among two independent groups. A difference with a *P* value of less than 0.05 was considered significant.

RESULTS

Clinical information on the 212 patients studied is summarized in Table 2. Mean age of the patients at recruitment was 62.33 years (range: 24-99 years, SD = 12.8 years), and 113 (53.3%) were female. Of the 212 patients, 45 (21.2%) were diagnosed with CRC under the age of 50 years and the mean age at first CRC diagnosis was 59.8 years (range: 20-99 years, SD = 13.1 years). Approximately

Table 2 Sample description by criteria for Lynch syndrome (*n* = 212)

5.2% of the patients had a synchronous or metachronous colorectal tumor (*n* = 11) and the mean age at diagnosis in this group was 51.6 years (range: 36-80 years, SD = 13.1 years), lower than the mean age in patients without metachronous colorectal tumor (59.3 years, range: 20-99 years, SD = 12.8 years), as expected (*P* = 0.051). Two patients (0.9% of the sample) were diagnosed with familial adenomatous polyposis.

The age at diagnosis of the first cancer varied from 20 to 86 years (mean = 58.9 years; median = 59 years; SD = 12.9 years). A second primary cancer was present in 33 patients: CRC in 11 (33.3%), endometrial in 2 (6.1%), breast in 2 (6.1%), prostate in 6 (18.2%). The age at diagnosis of the second primary varied from 39 to 99 years (mean = 66.5 years, SD = 13.2 years). One patient was diagnosed with four different primary tumors: two colon cancers at ages 36 and 55 years, endometrial can-

¹Cases with missing data were excluded from the analysis; ²Cases included all patients with microsatellite instability-high phenotype, independent of age.

cer at 45 years, bladder cancer at 61 years and renal carcinoma at 62 years; all of them confirmed with pathology records. This patient was later found to carry a germline mutation in *hMLH1* (data not shown).

Among the 212 unrelated probands, family history of cancer up to second-degree relatives was observed in 60.4% of patients with early-onset and 52.4% of those with late-onset CRC diagnoses. Twenty-nine percent of the patients reported a family history of CRC and almost 50% fulfilled criteria for LS: 22 (10.4%) fulfilled Amsterdam I and/or II criteria and 100 (47.2%), Revised Bethesda Criteria. In the families of probands with LS criteria, 180 relatives had cancer and the most frequent primary sites were: colon and rectum (43.4%), lung (8.9%), breast (7.8%), stomach (6.7%), endometrium (6.7%), ovaries (3.9%) and prostate (3.4%). As expected, this distribution was different in patients without LS criteria: colon and rectum (30.8%), lung (12.3%), breast (12.3%), stomach (4.6%), uterus (1.5%), ovarian (0%) and prostate (12.3%). About 2.5% of the patients had relatives with multiple primary tumors: one case was diagnosed with uterine and ovarian cancer, and another with colorectal, esophageal and gastric cancer.

Family history of breast cancer was present in 6.4% of the sample with available information (11/171). Among the patients with at least one of the Bethesda criteria, 12% had a family history of breast cancer, compared to 7.1% among patients with none of the criteria ($P = 0.248$).

Table 4 Comparison of different features among patients with and without the microsatellite instability-high phenotype (n = 197¹) n (%)

¹15 patients were excluded due to missing data on tumor histology. MSI: Microsatellite instability.

In the overall sample, 22 (9.9%) patients had a tumor in the ascending colon and 21.3% had colorectal tumors with histology suggestive of MSI-high (MSI-H) phenotype (Table 3). The clinical features of patients with and without this phenotype are shown in Table 4. As expected, MSI-H histological features were more commonly seen in patients with CRC diagnosed at a younger age (18 patients from a total of 42, $P = 0.001$) and in patients who fulfilled the Bethesda criteria (in all 42 patients, $P < 0.001$). Opposite to what was expected, in a significant number of tumors from individuals fulfilling Amsterdam criteria, histological features suggestive of MSI-H phenotype were not encountered.

Of the 212 charts reviewed, 17% had the family history previously documented. Furthermore, when the previously documented family histories were compared to the pedigrees obtained during patient interview for this study, there was concordance of data in only 56.6% of cases. On the other hand, of the 100 patients with a family history of cancer and fulfilling Bethesda criteria for LS, 57.0% had their family history previously collected and/or reported in the chart by clinicians or surgeons, but a clinical suspicion of LS was not documented in the chart in any of these cases. Only 4% of the patients with clinical criteria for LS were referred for genetic cancer risk evaluation.

Finally, 5.3% of patients with indications for population-based screening by colonoscopy starting at age 50 years had been submitted at least once for colonoscopy before the diagnosis of CRC. Among the 100 patients at risk for LS, only 4.1% had been offered surveillance colonoscopy previously.

DISCUSSION

As in most familial cancer syndromes, early age of onset and multiplicity of cancers have been considered hallmarks of LS. In registry-based series, the mean age at first CRC is about 45 years, compared to 65 years for sporadic CRC, and some LS patients present with CRC in their twenties. Similarly, the mean age of endometrial cancer is about 50 years, which is about 10 years younger than the average age of sporadic endometrial cancer.

As our knowledge of the influences of genetics on cancer risk has increased, so has the need to improve physicians' awareness of the importance of familial cancer history and its proper recording in the medical chart^[17]. Although there is no consensus about the correct method for obtaining information on cancer family history, and using it as a screening tool^[18], general practitioners usually collect the family history data at the time of registration^[19] and different groups have reported screening the adult population for increased genetic risk of cancer using postal questionnaires^[20,21]. Unfortunately, however, health professionals in the first line of patient contact are usually unaware of how and when to contact genetic services. Many specialists, especially coloproctologists and gastroenterologists, have a key role in identifying high-risk patients; the ability to suspect a patient to be at risk for a cancer predisposition syndrome is crucial for a rapid diagnosis and to ensure appropriate care.

Nearly 30% of patients in our study reported a positive family history of CRC, which is much higher than observed positive CRC family history in the general population: approximately 9.0%^[22]. Our findings also indicate that the hereditary CRC phenotype can be easily identified in outpatient coloproctology units, using a systematic approach after proper training of the staff, as reported previously^[20,21].

Surprisingly, a high number of patients fulfilling Amsterdam criteria were found in our sample (22/212, 10.4%), significantly higher than previously reported in the Brazilian population. Viana *et al.*^[23], reviewing 311 medical records of CRC patients from São Paulo, Brazil, found a frequency of 1.3% in families with Amsterdam criteria. The reason for such a high incidence remains to be explained. One potential limitation of this study is the fact that the outpatient coloproctology clinic from which the patients derive is located in a tertiary care university hospital, and reference center for many diseases in the region. Thus, a higher percentage of high-risk patients, including those at risk for hereditary cancer may exist in this setting than in other general hospitals.

An additional point to consider is the fact that this institution has, since 2001, one of the few cancer risk evaluation clinics in Southern Brazil. This fact, however, would ideally be associated with high indices of correct identification and referrals of the hereditary cases, which was not observed in most cases. Most patients evaluated in our study did not have an accurate family history assessment in their charts, (description of family history was present in the charts of only 57.0% of potential LS patients). Moreover, only 4% of patients with LS criteria were referred for genetic counseling, suggesting that even when detailed family cancer history is obtained, it may not be granted the necessary importance. Previous investigations have already reported significant gaps in the documentation of family cancer history in medical charts. Analyzing data from the Direct Observation of Primary Care study, Medalie *et al.*^[24] found that only 40% of 2333 audited charts documented the presence or absence of a family history of breast or colon cancer. Even when family cancer history is obtained, its interpretation seems to

be problematic as referrals often focus on rarer, hereditary cancer syndromes, neglecting cases of average and moderate risk individuals. Tyler and Snyder found a similar deficiency in the referral process among family physicians: from 10 patients considered at moderate or high risk, only 3 had been identified and none had been referred for cancer genetic consultation^[25].

Also, although previous studies have shown a clear benefit for surveillance colonoscopy in patients with suspected or proven LS^[26,27], in our series it was not common practice. Several factors could be contributing to this observation: patient's refusal, physician omission of adequate familial risk assessment and or referral and/or limited access to screening examinations. Our results are in agreement with those previous studies, considering that only 5% of the patients evaluated were undergoing proper screening. The identification of high-risk precursor lesions is considered critically important and colonoscopy screening for individuals with LS is recommended to begin at age 25 years, or 10 years younger than the earliest diagnosis of CRC in the family, whichever comes first, every 1-2 years^[28].

Multiplicity of cancers is a hallmark of LS and according to the literature about 10% of identified Lynch patients have more than one cancer by the time of diagnosis. Although CRC is the most common, other frequent findings include cancers of endometrium, ovary, stomach, small bowel, pancreas, hepatobiliary system, renal pelvis, ureter and glioblastoma. Approximately 20%-40% of patients have been reported to develop metachronous CRC after initial resection if a subtotal colectomy is not performed^[29]. Similarly, clustering of more than one Lynch-associated cancer (colorectal and uterine) in an individual patient should raise suspicion of LS. In our population, among all CRC cases, approximately 15% of patients had a second primary cancer. The most common second primary was CRC (metachronous or synchronous), endometrium, breast and prostate.

The most common extra-colonic tumor in LS is endometrial carcinoma, which develops in up to 70% of women who are mutation gene carriers^[30]. Thus, the presence of endometrial cancer in the family history of an individual with CRC, a feature encountered in 12 (6.7%) of the patients studied here, should always raise a suspicion of LS. When the endometrial cancer is diagnosed under the age of 50 years, the probability of LS is particularly high. This has been confirmed by a high rate of MMR deficiency (up to 40%) in women with early-onset endometrial cancer^[31,32]. Consistent with this, the National Comprehensive Cancer Network (NCCN) has recently revised its guidelines and currently recommends annual surveillance of the endometrium for LS families, as well as MMR deficiency investigation for all women diagnosed with endometrial cancer under age 50 years^[28].

There is some debate with regard to whether prostate or breast cancers might be part of the LS, since some studies have found a high frequency of such tumors among HNPCC families^[33,34]. Oliveira Ferreira *et al.*^[22] found a 26.5% frequency of breast cancer in families fulfilling Amsterdam criteria from São Paulo, Southeastern

Brazil, a higher rate than found in general population-based studies, which could suggest existence of a subset of mutations in this region that are also associated with a higher breast cancer risk. In our study, we found breast cancer at a frequency of approximately 9% in families fulfilling Amsterdam criteria. Although it is common to see LS pedigrees with breast cancer, most genetic and immunohistochemical studies on familial breast cancers have not found any strong relationship with the MMR system deficiency^[35,36]. Recently, a case report of a Lebanese family with LS found a *MSH2* gene defect in a breast cancer tumor of early-onset, suggesting that it could be involved in accelerated breast carcinogenesis^[37]. However, more studies are needed to define such association.

Different studies have shown that CRC in LS differs from typical sporadic CRCs in location, histology, and natural history. Also, it usually displays findings that are suggestive of MSI, such as intense lymphocytic infiltrates, extensive areas with poorly differentiated tissue and mucinous histology^[38]. Overall, 20.3% of the tumors evaluated in this series demonstrated one or more histological features suggestive of MSI-H, similar to previous studies^[39]. In the last few years, it has been suggested that histology could be useful in selecting CRC patients for molecular testing for LS^[40-43], since limiting testing to patients with MSI-H histology could reduce the burden of molecular testing by 60% compared with testing all patients who meet the Revised Bethesda Criteria. More importantly, it could help identify LS among patients with late onset and no cancer family history^[39].

Interestingly, among patients who fulfilled the Amsterdam criteria, only 28.6% presented tumors with features of MSI-H phenotype. This is somewhat surprising and could indicate that in this group of patients, the strong family history of CRC may not be related to abnormalities in the MMR system, and that there could be an increased prevalence of what has been called in the literature the Familial Colorectal Cancer Type X^[44]. Recently, Abdel-Rahman *et al*^[45] analyzed the molecular features of the tumors in CRC patients with MMR germline mutations and in sporadic CRC. They concluded that tumors from the MMR gene-negative group exhibited a novel molecular pattern characterized by a paucity of changes in the common pathways to CRC, which could be associated with non MSI-H histology. Molecular studies with this population are now being carried out in order to test such hypothesis.

Large population-based studies have shown that a family history of CRC in first-degree relatives is associated with an increased risk of CRC. In this study we have shown that a significant proportion of patients diagnosed with CRC and followed in an outpatient clinic of a university hospital in Southern Brazil have either a significant family history of cancer or pathology features suggestive of LS. Our findings underscore the importance of adequate familial risk assessment and, also, of considering MSI-H pathology features in the identification of at-risk patients. Education and training of physicians is essential to ensure that hereditary cancer patients and families are identified and properly referred for genetic counseling and

long-term cancer screening programs. The reason for the high prevalence of patients at risk for LS in our population requires further investigation.

ACKNOWLEDGMENTS

We are indebted to the patients and their family members who agreed to participate in this study and to Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Fundação de Amparo à Pesquisa do Estado do Rio Grande do Sul (FAPERGS), Programa de Pós-Graduação em Ciências Gastroenterológicas (UFRGS) and Fundação de Incentivo à Pesquisa do Hospital de Clínicas de Porto Alegre (FIPE-HCPA) who provided funding for this study. PKS was supported by a postdoctoral fellowship from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq).

COMMENTS

Background

The incidence of colorectal cancer (CRC) is currently rising in Southern Brazil. Patients at-risk for the hereditary forms of the disease are diagnosed at younger ages, and have an increased risk for second colorectal tumors and extra-colonic malignancies. Identification of these patients can lead to specific screening and intervention recommendations.

Research frontiers

In this study, the authors describe high prevalence of patients at-risk for Lynch syndrome (LS) in a coloproctology clinic and results support the principle that education and training of health care professionals are essential to ensure proper management of these individuals.

Innovations and breakthroughs

The study draws attention to the high frequency of potential LS patients in a coloproctology clinic in Southern Brazil. It reinforces the importance of correct identification of these cases and suggests further investigations of the origins for these observations.

Applications

Description of the high frequency of hereditary CRC cases in this setting is the first step to demonstrate that adequate familial risk assessment is fundamental to identify at-risk patients.

Peer review

Study was undertaken very well. It's a well written paper. It highlights the importance of identifying high risk groups in order to carry on with surveillance in CRC.

Abstract

AIM: To identify optimum timing to maximize diagnostic yield by capsule endoscopy (CE) in patients with obscure gastrointestinal bleeding (OGIB).

METHODS: We identified patients who underwent CE at our institution from August 2003 to December 2009. Patient medical records were reviewed to determine type of OGIB (occult, overt), CE results and complications, and timing of CE with respect to onset of bleeding.

RESULTS: Out of 385 patients investigated for OGIB, 284 (74%) had some lesion detected by CE. In 222 patients (58%), definite lesions were detected that could unequivocally explain OGIB. Small bowel ulcer/erosions secondary to Crohn's disease, tuberculosis or non-steroidal anti-inflammatory agent use were the commonest lesions detected. Patients with overt GI bleeding for < 48 h before CE had the highest diagnostic yield (87%). This was significantly greater ($P < 0.05$) compared to

that in patients with overt bleeding prior to 48 h (68%), as well as those with occult OGIB (59%).

CONCLUSION: We established the importance of early CE in management of OGIB. CE within 48 h of overt bleeding has the greatest potential for lesion detection.

INTRODUCTION

Obscure gastrointestinal bleeding (OGIB) is responsible for about 5% of all gastrointestinal (GI) bleeding^[1]. Although it represents a small proportion of patients with GI bleeding, OGIB continues to be a challenge because of delay in diagnosis and consequent morbidity and mortality. In recent times, capsule endoscopy (CE) and device-assisted enteroscopy have established their position in the management algorithm for OGIB, and have had a significant impact on the outcome. CE is superior to push enteroscopy^[2,3], small bowel follow-through^[4] and computed tomography (CT)^[5] for detection of the bleeding source in the small bowel. There is however concern about sensitivity of CE in the setting of ongoing GI bleeding, due to possible visualization of blood limiting the interpretation.

Most published reports on CE in OGIB are limited to small groups of patients^[6-8]. Although most differentiate between occult and overt GI bleeding when analyzing diagnostic yield, they do not identify the optimum time for performing CE in the overt GI bleeding group. We evaluated the diagnostic yield of CE in identifying the source of bleeding in OGIB. We further analyzed our patients to answer the question regarding proper timing of performing CE in overt OGIB, to maximize diagnostic yield. To the best of our knowledge, the present study of 385 patients with OGIB is the largest single-center experience of CE in OGIB.

MATERIALS AND METHODS

Patient selection

Patients who presented with evidence of GI bleeding at the clinic or emergency department were enrolled in the present study after negative upper GI endoscopy and full-length colonoscopy. Between August 2003 and December 2009, 505 patients underwent CE at our center. 345 patients underwent the procedure as inpatients, whereas 160 were outpatients. Of these, 385 (76.2%) had CE for OGIB (Figure 1). Patients with OGIB were further classified into three categories: (1) persistent overt bleeding, i.e. bleeding documented within 48 h at the time of first evaluation; (2) recent overt bleeding, i.e. last episode of bleeding > 48 h prior to the first evaluation; and (3) obscure occult bleeding, i.e. anemia associated with positive fecal occult blood without overt bleeding.

CE procedure

The GIVEN Video Capsule system (Given Imaging, Yoqneam, Israel) was used with M2A/SB capsules. The reader system was updated during the study period from Rapid 3 to Rapid 5. The real time viewer (Given Imaging) was used during the final 6 mo of the study. Patients were allowed a light diet on the previous evening and were prepared by using an oral purge at night (2 L polyethylene-glycol-based solution or 90 mL sodium phosphate mixed with 350 mL lime-based drink followed by 1 L water). Patients swallowed the capsule between 09:00 and 11:00 h, and were maintained on nil by mouth for the next 4 h. Six patients had swallowing difficulty and had their capsule delivered into the stomach using an endoscope with the help of an AdvanCE device. Patients with known diabetes mellitus and history of vomiting that was suggestive of gastroparesis were given two doses of intravenous metoclopramide (10 mg) during the study. Intravenous metoclopramide was also given to three of 40 patients who were found to have their capsule in the stomach on real time study, even at 2.5 h after capsule ingestion. The recorder of CE was disconnected only after the battery stopped blinking at 8-11 h after capsule ingestion. Only one procedure had technical difficulty with the capsule not becoming active after removal from the container, and had to be replaced with another capsule. All other patients had a smooth examination.

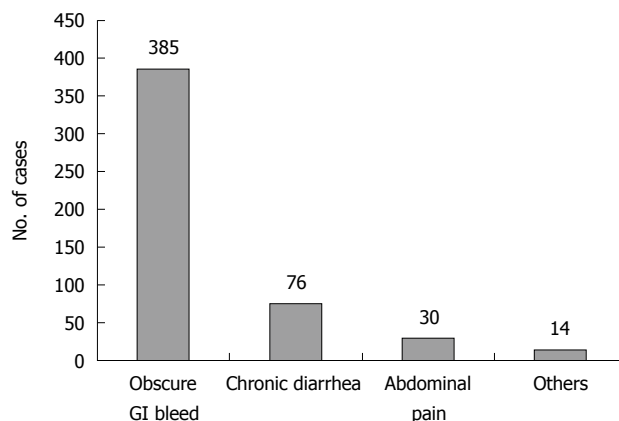

Figure 1 Indication for capsule endoscopy (n = 505).

Image interpretation

The interpretation of images was done by a single gastroenterologist (MKG) after initial detailed evaluation by a trained technician who had been involved in > 50 000 GI endoscopic procedures. Findings were categorized as definite, suspicious or negative as follows: (1) definite: lesions with definite bleeding potential that clearly explained the clinical situation; (2) suspicious: mucosal lesions identified, but bleeding could not be conclusively attributed to them, or blood was seen in the small intestine without any definite lesion being identified; and (3) negative: no lesion or bleeding identified, or incomplete study.

Follow-up

Patients were asked to note evacuation of the capsule, and those who were uncertain or concerned, as well as those who were suspected to have retained the capsule, as suggested by capsule image interpretation, were followed by serial X-ray/fluoroscopic screening at weekly intervals. Patients were also followed up with medical therapy (such as treatment of Crohn's disease, institution of antitubercular therapy, or antihelminthic therapy), surgical therapy (for tumors or bleeding ulcers) or enteroscopic evaluation (ulcers, polyps, or bleeding angiodysplasia), depending on the CE results. Those with negative CE were followed up with expectant treatment or surgery with preoperative enteroscopy. The study was approved by our institutional review board.

Statistical analysis

Statistical methods included χ^2 analysis for comparison of the positive diagnostic yield of CE between the three different categories of OGIB. $P < 0.05$ was considered to be statistically significant.

RESULTS

OGIB was the commonest (76.2%) indication for CE during the study period (Figure 1). Out of the 385 patients with OGIB, 275 (71%) were male with age ranging from 12 to 80 years. One hundred and one patients (26.2%) had a negative examination, either because no obvious lesion was found until the small intestine ($n = 93$) or because

Table 1 Positive/suspicious lesions detected by capsule endoscopy in patients with obscure gastrointestinal bleeding ($n = 284$)

	Definite ($n = 222$)	Suspicious ($n = 62$)	Total ($n = 284$)

Tumor	48	0	48
AVM	18	7	25
Worms	0	8	8
Only blood	0	15	15

101 patients had negative capsule endoscopy. AVM: Arteriovenous malformation.

the progress was slow ($n = 8$). Of the eight patients with slow progress of the capsule, six had diabetes mellitus. Of the 101 patients with negative CE, nine underwent laparotomy because of recurrent/persistent bleeding, and in eight, some lesion was found at preoperative enteroscopy (Meckel's diverticulum, 1; small-intestinal ulcers, 3; and angiodysplasia, 4). One patient had negative laparotomy. Of the remaining 92 patients in this group, only 52 were available for a follow-up of 1 year and none had any significant bleeding.

Two hundred and eighty-four patients (73.8%) had some lesion detected at CE. Although 272 of these lesions were located in the small intestine, 12 (ulcers/erosions, 8; angiodysplasia, 3; and gastric fundal tumor, 1) had findings in the stomach/duodenum that were missed at pre-CE gastroscopy. Two hundred and twenty-two patients (57.7%) were considered to have definite lesions that could explain OGIB, whereas another 62 (16.1%) had lesions that were suspicious but bleeding could not be completely attributed to these findings. The latter included 32 patients with small ulcers and erosions, seven with doubtful angiodysplasia, eight with worms (3 roundworm, 3 whipworm, and 2 hookworm) and 15 patients with blood in the jejunum or ileum, without any underlying lesion being identified. Four of these patients with evidence of bleeding but no underlying lesions underwent mesenteric angiography that also detected bleeding, but no obvious pathology was found and bleeding stopped with supportive treatment alone.

As demonstrated in Table 1, the 222 patients with definite lesions at CE included ulcers/erosions in 156, tumors in 48, and angiodysplasia in 18. Among those with tumors, two had multiple polyps that were suggestive of Peutz-Jeghers syndrome. It was difficult to characterize ulcers/erosions, but at least 12 were considered to be tubercular (based on abdominal CT scan \pm fine needle aspiration cytology and follow-up), 42 patients were considered to have Crohn's disease (based on fissuring serpiginous ulcers with cobble-stone appearance, or histology from tissue obtained at enteroscopy or surgery), and 12 were nonsteroidal anti-inflammatory drug (NSAID)-induced. Of the 18 patients with arteriovenous malformation (AVM), four underwent double-balloon enteroscopy (DBE), three had successful treatment with argon plasma coagulation, and the others were put on hormonal therapy/tranexamic acid.

Figure 2 shows the distribution of patients according

**Figure 2** Diagnostic yield of capsule endoscopy according to category of bleeding ($n = 385$)**Figure 3** Capsule endoscopy images. A: Cobble-stone appearance characteristic of Crohn's disease; B: An ileal tumor; C: Circumferential ulcer with narrowing and minor ongoing bleeding in a patient with Crohn's disease; D: Small intestinal ulcers in a patient with tuberculosis.

to category of bleeding. In patients with ongoing bleeding (Category I), positive findings were seen in 87.2% (definite in 78.3%), whereas in patients with previous overt bleeding (Category II), it was 68.2% (definite in 48.5%), and in the occult OGIB group (Category III), only 59.3% (definite in 36.4%). The ability of CE to identify a definite bleeding source was significantly higher for Category I than Category II and III patients ($P < 0.05$), but there was no significant difference in the diagnostic yield when comparing Category II and III patients (Figure 3).

Capsule retention was noted in six of 385 patients (1.6%). All these patients had strictures in the small bowel either due to tuberculosis or Crohn's disease, which were not suspected or identified prior to CE. Three of these patients underwent surgery, two were lost to follow-up, and one refused surgery and continues to have capsule retention, but has been asymptomatic during follow-up of 9 mo.

DISCUSSION

CE has gained widespread clinical acceptance in the diagnostic algorithm of OGIB^[9,10]. As in our study, OGIB is now the leading indication for CE in most centers around the world. Prior to the introduction of CE, barium examination, push enteroscopy and angiography were the principle diagnostic tools for OGIB. The diagnostic yield of these tests has been shown to be unequivocally inferior to CE in several studies. Recently, DBE has been used in several centers for diagnosis of OGIB. However, diagnostic yield of CE has been found to be significantly higher compared to a single DBE examination done via the oral or anal route (137/219 *vs* 110/219, OR: 1.67, 95% CI: 1.14-2.44, $P < 0.01$)^[11].

The reported yield of CE in OGIB varies widely. Previous studies have shown that detection rates for the source of bleeding varies from 38% to 93%, and is in the higher range for those with overt OGIB^[9,10]. This is further influenced by subjective interpretation of positive findings. To address this issue in our study, we divided positive findings into definite and suspicious groups. Although the overall diagnostic yield in our study cohort was 73.8%, a definite lesion that could explain OGIB was obtained in only 57.7%. A recently published study by Hindryckx *et al.*^[8] which considered CE to be positive only when lesions with sufficient bleeding potential were detected, reported a similar diagnostic yield of 59.8%.

Recent studies have indicated that the optimum timing of CE in OGIB is within the first few days, with acceptable maximum duration of 2 wk^[13-17]. In a recently reported series of 260 patients with OGIB, the yield was 87% in patients with ongoing overt OGIB and 46% in those with occult OGIB^[10]. In our patients, a definite lesion could be detected in 64.7% of patients with overt OGIB compared to 36.4% in patients with occult OGIB ($P < 0.01$). Moreover, the diagnostic yield of CE was significantly higher in patients who had evidence of bleeding within 48 h of CE (Category I) compared to those who had remote overt bleeding (Category II) [123/157 (78.3%) *vs* 64/132 (48.5%) OR: 3.84, 95% CI: 2.31-6.41, $P < 0.01$, respectively]. The diagnostic yield of CE was not significantly different when comparing patients with remote overt OGIB (> 48 h before CE) (Category II) and those with occult OGIB (Category III). This highlights the importance of using CE early in the diagnosis of OGIB. Pennazio *et al.* also have found the highest yield in patients with ongoing GI bleeding, and therefore have recommended ordering CE earlier in the setting of overt OGIB. There have been concerns in the past regarding the possibility of blood obscuring proper visualization of the mucosa in patients who are actively bleeding. A recent study that has compared massively bleeding patients with chronic overt OGIB has found a similar positive yield in both groups [59.18% (29/49) and 52.69% (137/260), respectively]^[18]. These results demonstrate that, for optimum diagnostic efficacy, CE should be done within 48 h of bleeding in patients with OGIB.

The definition of a positive finding on CE continues

to be ambiguous. For the purpose of this study, nonspecific mucosal changes such as red spots, focal erythema and fold thickening, were not considered to be clinically significant. Ulcers and erosions were included as positive findings in this series if they could completely or partially account for the GI bleeding. Moreover, active bleeding without definite lesions was described as a suspicious finding in this study. The commonest lesion detected in our patients was small-bowel ulcers and erosions, followed by tumors and AVM. A previous study from India also has documented small-bowel ulcers to be the commonest lesion detected by CE in OGIB^[19]. A definite underlying etiology could be established in 66 (42.3%) out of the 156 patients with ulcers/erosions, and nearly two-thirds (42/66) of them were considered to be due to Crohn's disease.

The current study has several limitations. In the first place it is a retrospective single-center study. However data was obtained from forms filled at the time of CE, thereby minimizing data collection bias. Secondly this study does not offer long-term follow-up of the patients and hence makes it impossible to draw a strong conclusion as to the fate of CE-negative OGIB. Moreover a large proportion of ulcers/erosions could not be characterized due to inherent difficulty of obtaining small bowel mucosal biopsies. However, this study enabled us to analyze positivity rates, nature of lesions and optimum timing of CE in a relatively large cohort of subjects comprising of a heterogeneous population of patients with OGIB. Although the data demonstrates the diagnostic utility of early CE in OGIB it does not reflect whether an early diagnostic intervention and unequivocal identification of a bleeding source affects clinical outcome in this group of patients.

In summary, high diagnostic yield, relative safety and tolerability have established CE as an important diagnostic tool for OGIB. In this large cohort of OGIB patients, we demonstrate that small bowel ulcer/erosions secondary to Crohn's disease, tuberculosis or NSAID-use are the commonest lesions responsible for OGIB in this part of the world. Moreover, the diagnostic yield is significantly affected by the timing of CE and studies done within 48 h of an episode of overt bleed have the greatest potential for detecting a definite lesion.

ACKNOWLEDGMENTS

We would like to acknowledge the services of our capsule endoscopy nurse Ms. Sonali Chattopadhyay who assisted us throughout the duration of the study.

COMMENTS

Background

The advent of video capsule endoscopy (CE) has resulted in a paradigm shift in the approach to the diagnosis and management of patients with obscure gastrointestinal bleed (OGIB). With increasing global availability of this diagnostic tool, it has now become an integral part of the diagnostic algorithm for OGIB in most parts of the world. However there is scant data on optimum timing of CE for maximizing diagnostic yield. OGIB continues to be a challenge because of delay in diagnosis and consequent morbidity and mortality.

Research frontiers

Previous studies have shown that capsule endoscopy detection rates for the source of bleeding varies from 38% to 93%, being in the higher range for those with overt OGIB. Results in most studies are further influenced by subjective interpretation of "positive findings". The authors classified our patients depending on time since last episode of bleed and looked at diagnostic yield in the different groups with the aim to identify a time-frame to guide clinical decision-making on when to do a capsule endoscopy in this cohort of patients.

Innovations and breakthroughs

Diagnostic yield is significantly affected by the timing of CE and studies done within 48 h of an episode of overt bleed have the greatest potential for detecting a definite lesion. The diagnostic yield of CE was not significantly different when comparing patients with overt OGIB prior to 48 h of CE and those with occult OGIB. This highlights the importance of obtaining a CE early in the diagnosis of OGIB.

Applications

This article suggests a potential benefit of doing a capsule endoscopy within 48 h of an episode of bleed in patients with OGIB in terms of increasing chances of detecting a bleeding source. However, further studies are needed to determine if early detection of lesion translates into better patient outcome.

Peer review

The paper provides well-collected information about early detection of small intestinal lesions by CE in obscure GI bleed. Research should be aimed at finding if early detection results in improved patient outcome.

of the control group [2.2 (2.0-2.2) mg/dL] ($P < 0.001$). The highest value was 3.2 mg/dL. Renal magnesium clearance was significantly increased in the constipation group. Serum magnesium concentration in the constipation group decreased significantly with age ($P < 0.01$). There was no significant correlation between the serum level of magnesium and the duration of treatment with magnesium oxide or the daily dose. None of the patients had side effects associated with hypermagnesemia.

CONCLUSION: Serum magnesium concentration increased significantly, but not critically, after daily treatment with magnesium oxide in constipated children with normal renal function.

Abstract

AIM: To determine whether hypermagnesemia recently reported in adult patients possibly develops in children with functional constipation taking daily magnesium oxide.

METHODS: We enrolled 120 patients (57 male and 63 female) aged 1-14 years old (median: 4.7 years) with functional constipation from 13 hospitals and two private clinics. All patients fulfilled the Rome III criteria for functional constipation and were treated with daily oral magnesium oxide for at least 1 mo. The median treatment dose was 600 (500-800) mg/d. Patients were assessed by an interview and laboratory examination to determine possible hypermagnesemia. Serum magnesium concentration was also measured in sex- and age-matched control subjects ($n = 38$).

RESULTS: In the constipation group, serum magnesium concentration [2.4 (2.3-2.5) mg/dL, median and interquartile range] was significantly greater than that

INTRODUCTION

Magnesium-containing cathartics are used worldwide to treat chronic constipation^[1-3]. Approximately 45 million Japanese patients are estimated to undergo treatment with magnesium oxide as an antacid or cathartic annually^[4]. Many children with functional constipation are taking these drugs for long periods of time; sometimes over several years.

Hypermagnesemia is a rare clinical condition^[5,6]. Most cases are iatrogenic and due to increased intake of magnesium, which occurs after intravenous administration of magnesium^[7,8] or oral ingestion of high doses of magnesium-containing antacids or cathartics^[9-12]. Magnesium homeostasis is dependent mainly on gastrointestinal absorption and renal excretion. The kidney is the principal organ involved in magnesium regulation. Renal magnesium excretion is very efficient, because the thick ascending limb of Henle has the capacity to reject completely magnesium reabsorption under conditions of hypermagnesemia^[5,6], and therefore, hypermagnesemia commonly arises in patients with renal dysfunction.

In 2008, the Ministry of Health, Labour and Welfare (MHLW) of Japan reported 15 adult patients with hypermagnesemia, including two cases of death due to oral ingestion of magnesium oxide from April 2005 to August 2008^[4]. Although most of these elderly patients with constipation had dementia, schizophrenia, or renal dysfunction, the MHLW has recommended measuring the serum level of magnesium in patients who regularly use magnesium oxide.

It is now important for pediatricians to know whether hypermagnesemia can develop in children without abnormal renal function after administration of a common or high dose of magnesium oxide. The purpose of this study was to determine serum magnesium concentration in children with functional constipation treated with daily magnesium oxide.

MATERIALS AND METHODS

Patients

We enrolled 120 patients (57 male and 63 female) aged 1-14 years with functional constipation from 13 hospitals and two private clinics in Japan. At entry, all patients fulfilled the Rome III criteria for functional constipation, which meant that they had at least two of the following characteristics: fewer than three bowel movements weekly; more than one episode of fecal incontinence weekly; large stools in the rectum shown by digital rectal examination or palpable on abdominal examination; occasional passage of large stools; retentive posturing and withholding behavior; and painful defecation. All patients had been treated for at least 1 mo with daily magnesium oxide as an oral laxative. The medication was given once daily or in split doses. The dose was dependent on the patient's condition.

Children with known organic causes of constipation, including Hirschsprung disease, spinal and anal congenital abnormalities, previous colon surgery, inflammatory bowel disease, allergy, metabolic or endocrine diseases, renal dysfunction, and severe neurological disability were excluded from the study. Patients with poor drug compliance were also excluded.

In each patient, we recorded the date of initiation of constipation, daily dose of magnesium oxide, and duration of treatment. We also determined whether the patient had symptoms that could be side effects of hypermagnesemia, such as vomiting, nausea, thirst, blushing, feeling of

Table 1 Subject characteristics and serum magnesium concentrations

	Control group (<i>n</i> = 38)	Constipation group (<i>n</i> = 120)	<i>P</i> value
Age (yr)	5.5 (2.0-10.8)	4.7 (3.0-6.8)	NS ^a
Gender, male (%)	63.2	47.5	NS ^b
Serum magnesium concentration (mg/dL)	2.2 (2.0-2.3)	2.4 (2.3-2.5)	< 0.001 ^a

^aMann-Whitney *U* test; ^b χ^2 test. NS: Not significant.

exhaustion, or somnolence. The laboratory examinations carried out were as follows: serum level of magnesium, calcium, phosphorus, blood urea nitrogen (BUN), and creatinine concentration. Urinary concentrations of magnesium and creatinine were also measured. Magnesium clearance and fractional excretion of magnesium (FEMg) were calculated as follows: Magnesium clearance = urine magnesium (mg/dL)/urine creatinine (mg/dL); FEMg = urine magnesium (mg/dL)/serum magnesium (mg/dL) \times serum creatinine (mg/dL)/urine creatinine (mg/dL).

Control group

Serum magnesium concentrations were also measured in the control group which comprised 38 children (24 male and 14 female) aged 1-15 years who visited the Department of Pediatrics at Gunma University Hospital, and were without any history of hematological disease, tumor, heart failure, metabolic or endocrine diseases, renal dysfunction, or severe neurological disability. None of these children were treated with magnesium oxide.

Statistical analysis

Laboratory values, duration of treatment, and daily dose of magnesium oxide are shown as the median and interquartile ranges. Statistical significance of differences was tested by χ^2 test or Mann-Whitney *U* test, as appropriate. Spearman's rank correlation coefficients were calculated for the correlation between the serum level of magnesium and age, duration of treatment, and drug dose. *P* < 0.05 was regarded as significant. All analyses were carried out using SPSS for Windows (SPSS statistics 17.0).

RESULTS

Subject characteristics and serum magnesium concentrations are shown in Table 1. In the constipation group, the median treatment duration with magnesium oxide was 1.3 (0.4-2.6) years and median daily dose was 600 (500-800) mg/d; 33 (25-45) mg/kg per day. After administration of magnesium oxide, the outcome of constipation was investigated in 83 patients. Bowel habits in all patients were improved, and 75% of patients were stable. However, 11% of children had fewer than three bowel movements weekly, 28% of them had withholding behavior, and 34% had painful defecation during the follow-up period. None of the patients still had overflow-incontinence.

The median serum magnesium concentration in the

Figure 1 Correlation between serum level of magnesium and age (A), and duration of treatment with magnesium oxide (B), and dose of magnesium oxide (C).

constipation group was significantly greater than that in the control group (Table 1). The highest magnesium concentration was 3.2 mg/dL in a 3.5-year-old patient treated with 1320 mg/d; 88 mg/kg per day magnesium oxide for 2.8 years.

The median urinary magnesium to creatinine ratio in the constipation group was significantly elevated compared with that reported previously [0.23 (0.15-0.37) ($n = 76$) vs 0.15 (0.12-0.20) ($n = 16$), $P < 0.05$]^[13]. The median FEMg in the constipation group was 0.03 (0.02-0.05).

Serum magnesium concentration in the constipation group decreased significantly with age ($P < 0.01$) (Figure 1A). There was no significant correlation between the serum level of magnesium and duration of treatment (Figure 1B). The treatment dose had no effect on serum magnesium level (Figure 1C).

Serum level of calcium [9.9 (9.5-10.2) mg/dL], phosphorus [5.2 (4.8-5.6) mg/dL], creatinine [0.3 (0.3-0.4) mg/dL], and BUN [13.0 (10.8-15.5) mg/dL] were not abnormal in any of the patients. None of the patients had side effects associated with hypermagnesemia.

DISCUSSION

In 2008, the MHLW of Japan reported that 15 patients aged 32-98 years (median, 71 years) who had been treated with magnesium oxide developed severe side effects of

magnesium toxicity, such as hypotension, bradycardia, electrocardiographic changes (atrial fibrillation), loss of consciousness, coma, respiratory depression, and cardiac arrest. The serum magnesium concentration in two fatal cases was 20.0 mg/dL and 17.0 mg/dL. As a result of these reported cases, the MHLW has recommended that the serum concentration of magnesium in subjects on continuous magnesium therapy should be determined^[4].

Most cases of hypermagnesemia in adults result from large intravenous doses of magnesium^[7,8] or from excessive enteral intake of magnesium-containing cathartics^[9-12]. Symptomatic hypermagnesemia is likely to occur in patients with renal dysfunction. In fact, 10 of the 15 Japanese patients reported as cases of hypermagnesemia by the MHLW had renal dysfunction.

Several cases of hypermagnesemia from enteral magnesium intake in patients with normal renal function have been reported previously^[14-17]. It is known that non-renal risk factors for hypermagnesemia are age, gastrointestinal tract disease, and administration of concomitant medications, particularly those with anticholinergic and narcotic effects^[18]. Five elderly Japanese patients without renal dysfunction had intestinal necrosis, severe constipation, and abnormal abdominal distention with intestinal expansion, and these abdominal risk factors could have increased the serum concentration of magnesium.

Hypermagnesemia has also been reported in pediatric

practice^[14,19]. These case reports include a 14-year-old girl without renal dysfunction who was taking magnesium hydroxide because of severe constipation^[14], and a 2-year-old boy with neurological impairments who was taking 2400 mg/d of magnesium oxide administered as part of a regimen of megavitamin and megamineral therapy^[19]. These cases developed increased serum magnesium levels as high as 14.9 mg/dL and 20.3 mg/dL, respectively.

Magnesium oxide is commonly used in patients with chronic constipation; however, not only has the optimum dose for children not been established, but there has been no study to evaluate the concentration of serum magnesium after oral administration of magnesium oxide. The aim of the present study was to determine the serum magnesium concentration in pediatric cases receiving magnesium cathartics for chronic constipation.

In our study, the median serum magnesium concentration was 2.4 mg/dL in the constipation group, which was significantly greater than that in the control group (2.2 mg/dL). Thirty patients (25%) in the constipation group and none in the control group had a serum magnesium concentration greater than the maximum value of the normal range in healthy Japanese children (2.6 mg/dL). The high critical limit of serum magnesium concentration has been reported as 4.9 ± 2.0 mg/dL in adults and 4.3 ± 1.1 mg/dL in children^[20]. The highest value in our study was 3.2 mg/dL, and none of our patients reached the critical limit of serum magnesium concentration or developed symptoms due to hypermagnesemia. The median urinary magnesium to creatinine ratio in the constipation group was significantly elevated compared with that in healthy subjects, which suggests that serum magnesium level is regulated by an increase in renal excretion in those children with normal renal function, and is maintained within its appropriate range.

In our study, serum magnesium level in constipated children treated with magnesium oxide, but not in the control children, decreased significantly with age. No correlation was found between duration of treatment or daily dose of magnesium oxide and serum magnesium concentration. These data are consistent with those reported by Woodard *et al.*^[21] They reported that the increase in serum magnesium concentration in 102 adults who received multiple doses of magnesium citrate did not correlate with the quantity of magnesium administered^[21]. Elderly patients are at risk of magnesium toxicity as kidney function declines with age, but it is not clear whether young children have a higher risk of hypermagnesemia. Alison *et al.*^[22] reported on a 6-week-old infant who had increased serum magnesium level (14.2 mg/dL) and life-threatening apnea due to 733 mg/d magnesium hydroxide that was used to treat constipation. Brand *et al.*^[23] and Humphrey *et al.*^[24] reported on premature infants with hypermagnesemia following antacid administration in order to decrease the risk of gastrointestinal hemorrhage. One infant had an increased serum magnesium level of 13.3 mg/dL and developed intestinal perforation. These reports indicate that infancy, prematurity or young age might be a possible risk factor for hypermagnesemia.

According to our results, we conclude that serum magnesium concentrations increase significantly after daily magnesium oxide intake, but the magnitude of the increase appears modest. Younger age, but not prolonged use of daily magnesium oxide might be a relative risk factor, and it should be determined by further studies whether serum magnesium concentration should be assessed in these subjects.

ACKNOWLEDGMENTS

The following doctors are members of the Japanese Pediatric Constipation Study Group and have provided data and samples for this study: Dr. Mitsuru Kubota (Department of Pediatrics, Teine Keijinkai Hospital, Department of Pediatrics, Hokkaido University Graduate School of Medicine), Dr. Mika Sasaki, Dr. Hisayuki Tsukahara, and Dr. Mutsumi Chiba (Iwate Medical University), Dr. Kazuko Okada (Okada Pediatric Clinic), Dr. Yasuko Wakabayashi (Department of Pediatrics, Tokyo Women's Medical University Medical Center East), Professor Toshiaki Shimizu (Department of Pediatrics, Juntendo University School of Medicine), Dr. Yoshiko Nakayama (Department of Pediatrics, Showa Inan General Hospital, Department of Pediatrics Shinshu University School of Medicine) and Dr. Hitoshi Tajiri (Department of Pediatrics, Osaka General Medical Center).

COMMENTS

Background

Magnesium-containing cathartics are commonly used to treat chronic constipation. Although hypermagnesemia is a rare clinical condition, it can occur as a side effect of increased intake of magnesium salts.

Research frontiers

The Japanese government has recently reported fatal cases of hypermagnesemia in adults treated with magnesium oxide. In our study, serum magnesium concentrations increased significantly after daily magnesium oxide intake, but the magnitude of the increase appeared modest. Serum magnesium levels in constipated children treated with magnesium oxide, but not in the control children, decreased significantly with age. No correlation was found between duration of treatment or daily dose of magnesium oxide and serum magnesium concentration.

Innovations and breakthroughs

Recent reports have highlighted that serum magnesium concentration increases significantly, but not critically, after daily treatment with magnesium oxide in children with normal renal function.

Applications

The present study indicated the safety of daily magnesium oxide treatment for children with chronic constipation.

Peer review

The authors are to be congratulated for providing evidence of the apparent safety of a commonly used and effective therapy to treat an important health issue seen commonly in children.

Abstract

AIM: To examine the association between parity and gastric cancer (the cases are almost all premenopausal women) risk in a cohort of young parous women.

METHODS: The study cohort consisted of all women with a record of a first and singleton childbirth in the Birth Register between 1978 and 1987. We tracked each woman from the time of her first childbirth to December 31, 2008. Their vital status was ascertained by linking records to the computerized mortality database.

Cox proportional hazard regression models were used to estimate hazard ratios of death from gastric cancer associated with parity.

RESULTS: There were 1090 gastric cancer deaths (85.87% of them were premenopausal) during 33686828 person-years of follow-up. The mortality rate of gastric cancer was 3.24 cases per 100000 person-years. A trend of increasing risk of gastric cancer was seen with increasing parity. The adjusted hazard ratio was 1.24 [confidence interval (95% CI): 1.02-1.50] for women who had borne two to three children, and 1.32 (95% CI: 1.01-1.72) for women with four or more births, when compared with women who had given birth to only one child.

CONCLUSION: These results suggest that higher parity may increase the risk of death from gastric cancer among premenopausal women.

Chang CC, Chen CC, Chiu HF, Yang CY. Higher parity associated with higher risk of death from gastric cancer. *World J Gastroenterol* 2011; 17(6): 784-788 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i6/784.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i6.784>

INTRODUCTION

In Taiwan, gastric cancer (GC) is the fifth leading cause of cancer mortality for males and females^[1]. The age-adjusted mortality rate for gastric cancer was 14.1 per 100000 among males and 7.4 among females in 2007. There is

substantial geographic variation in gastric cancer mortality within the country. In most areas, however, its mortality rate is about two-fold higher among men than women^[1]. Known risk factors, such as *Helicobacter pylori* (*H. pylori*) infection, tobacco smoking, and low fruit and vegetable intake cannot entirely explain the gender difference^[2].

The difference between male-to-female incidence rates is greatest during the reproductive ages, and the rates become more similar after menopause; it has been hypothesized that sex hormones play a role in the development or progression of gastric cancer^[3]. The influence of sex hormones on gastric cancer risk is supported by the presence of steroid-hormones receptors in the gastric mucosa and gastric cancer tissues^[4,5]. In rat experimental studies, there is also a greater preponderance of GC in males compared with females^[6,7].

Few epidemiological studies have investigated the association between parity and gastric cancer, and results have been inconsistent. Parity was associated with increased risk of gastric cancer in four studies^[8-11]. Three studies found a suggestive inverse relationship, but no significant dose-risk trend^[12-14], whereas five others reported no association^[15-19].

A previous study on gastric cancer in young individuals indicated that gastric cancer diagnosed in women within two years after delivery was more progressive, and proposed that pregnancy or delivery might accelerate the growth of gastric cancer^[20]. Maeta *et al.*^[21] found that the pathological features of gastric cancer that occurred more frequently in young women were more common among pregnancy-related cases. These results suggested the need for separate analysis of pre- and postmenopausal women when examining the relationship between parity and gastric cancer risk.

Four of the above-mentioned studies, which studied the relationship between parity and gastric cancer risk, were restricted to postmenopausal women^[11,12,17,18]. Only one recent Swedish study has examined the relationship between parity and gastric cancer separately for pre- and postmenopausal women^[14]. Other studies did not categorize the gastric cancer cases into pre- or postmenopausal because of the lack of sufficient premenopausal gastric cancer cases to support a complete analysis.

The objective of this study was to examine the effect of parity on the risk of gastric cancer in a cohort of 1 292 462 young parous women in Taiwan, followed over a period of 31 years.

MATERIALS AND METHODS

Data source

Registration of births is required by law in Taiwan. It is the responsibility of the parents or the family to register infant births at a local household registration office within 15 d. The Birth Registration System, which is managed by the Department of the Interior, released computerized data on live births since 1978. The registration form, which requests information on maternal age, education, parity, gestational age, date of delivery, infant gender, and

birth weight, is completed by the physician attending the delivery. Most deliveries in Taiwan take place in either a hospital or a clinic^[22], the birth certificates are completed by physicians attending the delivery, and it is mandatory to register all live births at local household registration offices; therefore the birth registration data are considered complete, reliable, and accurate^[22].

Study population

The study cohort consisted of 1 292 462 women with a record of a first and singleton childbirth in the Birth Register between January 1, 1978 and December 31, 1987. Information on any subsequent births was also retrieved from the Birth Register.

Follow-up

Each woman has her own unique personal identification number, which was used to track the women from the time of their first childbirth to December 31, 2008. Their vital status was ascertained by linking records with the computerized mortality database, identifying the date of any deaths.

Statistical analysis

We categorized parity (the number of children recorded in the last childbirth record of each woman registered during follow-up) into three categories: one, two to three, and four or more. We compared selected baseline characteristics of the cohort by parity using χ^2 tests or analysis of variance, as appropriate. Death rates were calculated by dividing the number of deaths from gastric cancer (ICD-9 code 151) by the number of person-years of follow-up. Cox proportional hazard regression models were used to estimate the hazard ratio of death from gastric cancer associated with parity. The 95% confidence intervals (CIs) for the hazard ratios were also calculated. We used two Cox proportional hazard models: an age-adjusted model and a multivariate-adjusted model, which was additionally adjusted for marital status (married, unmarried), years of schooling (≤ 9 , > 9 years), and birthplace (hospital/clinic, home/other). The proportion hazards assumption was assessed for all above-mentioned variables and no violations were observed. Analyses were performed using the SAS statistical package (version 8.02, SAS Institute Inc). All statistical tests were two-sided. Values of $P < 0.05$ were considered statistically significant.

RESULTS

The study cohort was comprised of 1 292 462 primiparous women with complete information. A total of 33 686 828 person-years were observed in this study. The mean follow-up period was 26.09 (standard deviation = 3.28) years. During the follow-up period, 1090 gastric cancer deaths were recorded, yielding a mortality rate of 3.24 cases per 100 000 person-years.

Table 1 presents the baseline characteristics of the study population by parity. Compared with women who had given birth to only one child, women with four or

more children were more likely to have lower educational level, younger age at first birth, and a lower chance of being born in a hospital or clinic.

Table 2 presents the hazard ratios of gastric cancer mortality by parity. After adjustment for age at first birth, the hazard ratio for gastric cancer death was 1.23 (95% CI: 1.01-1.49) for women who had two to three children, and 1.33 (95% CI: 1.02-1.73) for women with four or more births, when compared with women who had given birth to only one child. In the multivariate-adjusted model, the hazard ratios were only slightly altered. The adjusted hazard ratio was 1.24 (95% CI: 1.02-1.50) for women who had borne two to three children, and 1.32 (95% CI: 1.01-1.72) for women with four or more births, when compared with women who had given birth to only one child. There was a significant increasing trend in the adjusted hazard ratios of gastric cancer with increasing parity (*P* for trend = 0.035).

DISCUSSION

To our knowledge, this is the largest cohort (*n* = 1 292 462 women) published to date to examine the relationship between parity and gastric cancer risk. In this prospective cohort study, we found a positive association between parity and gastric cancer risk. Our finding of an increased risk of gastric cancer associated with higher parity agrees with some previous studies^[8-11], but not with other studies that reported the reverse effect^[12-14] or no association^[15-19] with parity. Pregnancy elevates serum estrogen levels by about 100 fold^[23]. Increasing parity is associated with an overall increase in lifetime exposure to sex hormones. There is experimental evidence that gastric cancer carcinogenesis might be inhibited by estrogens^[6,7]. Thus, if estrogens are associated with a

reduced risk of gastric cancer, we would expect pregnancy to offer some protection from gastric cancer. Our data did not provide support for this hypothesis.

On the other hand, it has been reported that estrogen stimulates the growth of gastric cancer cell lines^[24], and there is evidence that pregnancy or delivery might accelerate the growth of gastric cancer^[20]. The mean age at death for gastric cancer was 42.90 \pm 7.08 years in this study. The majority of gastric cancer deaths (85.87%) were premenopausal (using age 50 as the cut-off value^[14]). Women included in this study tended to be younger (with the large majority of the gastric cancer deaths occurring before menopausal age) than in previous studies. The mean time of gastric cancer was about 14 years after last delivery (age at the birth of the last child = 28.97 \pm 4.01; age at the death for gastric cancer = 42.90 \pm 7.08). It is possible that these premenopausal gastric cancers were influenced by hormonal conditions caused by the actual events of pregnancy or delivery^[17]. Our finding of an increased risk of gastric cancer associated with higher parity may therefore plausibly be related to a short-term increase in risk after a delivery^[16]. The incidence of gastric cancer in premenopausal women is low; therefore, such effects are easily lost in overall analyses^[17]. Some studies have been restricted to postmenopausal women^[11,12,17,18]. To our knowledge, this is the first cohort study to indicate that a positive association between parity and gastric cancer may be only restricted to premenopausal women. However, because there is no consistent evidence to date for an association between parity and risk of death from gastric cancer, the possibility that this is a chance finding must also be considered. Clearly, more work will be needed before the influence of parity on the risk of gastric cancer is understood.

In the event of a death in Taiwan, the decedent's family is required to obtain a death certificate from the hospital or local community clinic, which then must be submitted to the household registration office to cancel the decedent's household registration. The death certificate is required to have the decedent's body buried or cremated. Death certificates must be completed by physicians in Taiwan. It is also mandatory to register all deaths at local household registration offices; thus, the death registration is reliable and complete^[22]. The complete population coverage and follow-up made possible by the national identification number has left the study without selection bias. Information bias is also unlikely to be important for parity.

Taiwan is a small island with a convenient communication network. It is believed that all gastric cancer cases had access to medical care. Mortality data rather than data on inpatient cases was used to assess the association between parity and gastric cancer in this study. The mortality of a disease is a function of its incidence and fatality. Gastric cancer has been reported to have the fifth poorest five-year relative survival rate among all cancer sites^[25]. Deaths from gastric cancer may therefore be regarded as a reasonable indicator of the incidence of gastric cancer.

Hormone replacement therapy (HRT) has been reported to reduce the risk of gastric cancer in population with higher HRT use^[26]. We were unable to adjust for this factor in the current study because of the lack of available data. HRT use is low in Taiwan compared with Western countries^[27]; therefore, the confounding effect resulting from this factor should be small, if it exists at all. Furthermore, if the association between this potential confounding variable and the risk of gastric cancer is not as strong as the one that has been observed for parity, adjustment of this variable will not qualitatively change the conclusion.

Cigarette smoking^[2] and a family history of gastric cancer^[28] have been documented as risk factors for gastric cancer in Taiwan. Unfortunately, there is no information available on these variables for the individual study subjects and, thus, they could not be adjusted in the analysis. However, there is no reason to believe that there would be any correlation between these two variables and parity.

An increased susceptibility to infection by *H. pylori* during pregnancy might affect the increased risk of gastric cancer^[29]. We could not adjust for this variable because of the lack of information on *H. pylori* infection. However, it has been reported that most women acquired the infection in childhood rather than during pregnancy^[30]. Furthermore, there is no reason to believe that *H. pylori* status would be associated with parity, and, therefore, the estimated effect of parity is likely to be free of a confounding effect of *H. pylori* status.

The birth registration system in Taiwan covers only live births and did not include stillbirths and abortions. Therefore we were unable to examine the possible role of gravidity on the risk of gastric cancer. Our study design only allowed for the study of mortality among parous women. Again, we were unable to examine the possible role of nulliparity on the risk of gastric cancer because the birth registry ascertained births rather than pregnan-

cies. The generalizability of this findings is thus limited. Misclassification of menopausal status may have occurred by using age 50 as the cut-off point. Any effect of this is, however, is probably nondifferential (the misclassification is unlikely to be related to parity) and would probably lead to underestimation of the results.

In summary, we found that there was a trend for increasing parity to be associated with increasing risk for gastric cancer among a cohort of young parous women. This study suggests that the relation between parity and risk of gastric cancer should be considered separately for pre- and postmenopausal women.

COMMENTS

Background

Previous studies that examined this association rarely categorized the gastric cancer cases into pre- or postmenopausal because of the lack of sufficient premenopausal gastric cancer cases to support a complete analysis.

Research frontiers

This study was undertaken to examine the association of parity and gastric cancer (the cases are almost all premenopausal women) risk in a cohort of young parous women.

Innovations and breakthroughs

The results of this study suggest that higher parity may increase the risk of death from gastric cancer among premenopausal women.

Applications

This study suggests that the relation between parity and risk of gastric cancer should be considered separately for pre- and postmenopausal women.

Peer review

The study is worthy of being accepted. The study population is large enough to detect minor differences.

An end-to-end anastomosis model of guinea pig bile duct: A 6-mo observation. *World J Gastroenterol* 2011; 17(6): 789-795 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i6/789.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i6.789>

Abstract

AIM: To establish the end-to-end anastomosis (EEA) model of guinea pig bile duct and evaluate the healing process of bile duct.

METHODS: Thirty-two male guinea pigs were randomly divided into control group, 2-, 3-, and 6-mo groups after establishment of EEA model. Histological, immunohistochemical and serologic tests as well as measurement of bile contents were performed. The bile duct diameter and the diameter ratio (DR) were measured to assess the formation of relative stricture.

RESULTS: Acute and chronic inflammatory reactions occurred throughout the healing process of bile duct. Serology test and bile content measurement showed no formation of persistent stricture in 6-mo group. The DR revealed a transient formation of relative stricture in 2-mo group in comparison to control group (2.94 ± 0.17 vs 1.89 ± 0.27 , $P = 0.004$). However, this relative stricture was released in 6-mo group (2.14 ± 0.18 , $P = 0.440$).

INTRODUCTION

Bile duct injury (BDI) is a severe consequence of gastrointestinal surgery. Unrecognized or improperly treated biliary injuries can lead to severe complications such as biliary cirrhosis, hepatic failure, and death^[1,2]. Treatment of BDI remains a challenge for gastrointestinal surgeons. Reconstruction of bile ducts following iatrogenic injuries is associated with a high risk of stricture and stricture recurrence in the anastomosis^[3,4]. Therefore, effective and safe bile duct reconstruction is very important.

Although the method of biliary tract reconstruction has been extensively studied, no consensus is reached concerning the ideal model of biliary tract reconstruction. The most frequently recommended procedure is Roux-Y hepaticojejunostomy (HJ) for its reconstruction^[3-5].

However, Roux-Y HJ has its obvious drawbacks, including a large number of postoperative complications, such as a high occurrence of biliary tract stenosis leading to secondary biliary cirrhosis. The diagnostic and thera-

peptic endoscopic access to the biliary tract becomes impaired or hindered since the reconstruction of biliary tract with Roux-en-Y HJ is not anatomical^[6]. The changed bile flow pathway is also a cause of disturbance in fat metabolism^[7]. In case of poor drainage of the excluded loop, especially when applied in thin biliary tract with an intense inflammatory process, ascending cholangitis may also ensue. As the reconstruction of biliary tract with Roux-en-Y HJ is not physiological, the bile bypass induces gastric hypersecretion leading to a pH change secondary to altered bile synthesis and release of gastrin, therefore peptic ulcer occurs frequently in the long term^[8,9].

End-to-end anastomosis (EEA) of bile duct is seldom used in surgical treatment of BDI. However, this procedure is routinely performed during hepatic transplantation with good results^[10,11] and can achieve a better long-term outcome than Roux-en-Y HJ. Establishing a physiological bile pathway allows proper digestion and absorption. Also, control endoscopic examination in these patients is possible. Therefore, some authors recommend EEA as the first choice of bile duct reconstruction^[6,12].

However, no large-scale clinical trial and a suitable animal model of EEA are available to evaluate the bile duct healing process. Therefore, to gain a better understanding of the healing process after EEA, and provide some valuable information for the etiology, development and prophylaxis of BDI, an animal model of bile duct reconstruction with EEA was established after total resection of common bile duct (CBD) in guinea pigs in this study. Guinea pigs were raised for 2, 3, and 6 mo after operation to observe the short- and long-term healing and possible complications. General conditions, survival rate and histological characteristics of the animals were detected and serology test was performed, as well as content and size of bile duct were measured before and after operation.

MATERIALS AND METHODS

Animal model and experimental design

Thirty-two male guinea pigs weighing 350-400g, purchased from Laboratory of Experimental Animals, Peking University Health Science Center, Beijing, were housed under controlled conditions at a temperature of $21 \pm 2^\circ\text{C}$ and a relative humidity of 30%-70% in a 12-h dark and light cycle. The animals were fasted with free access to water 8 h before and after operation. This study was performed in accordance with the rules for the protections of animals and approved by the Animal Ethical and Welfare Committee of Peking University Health Science Center (LA2008-021).

The animals were randomly divided into control group (group 1), and 2-, 3-, 6-mo groups (groups 2-4) after EEA model was established, 8 in each group.

Microsurgical reconstruction of bile duct

Surgical microscope (XTS-4A Jiangsu Surgical Instruments Company, China), microsurgical instruments (SSW-4, Shanghai Surgical Instruments Company, China), and 10-0 monofilament sutures (Double Arrow, China) were used.

Figure 1 Microsurgical reconstruction of common bile duct with end-to-end anastomosis.

The animals were anesthetized with pentobarbital (30 mg/kg) by intraperitoneal injection under sterile conditions. Peritoneal cavity was accessed *via* a midline incision (approximately 3 cm). After the liver lobes were pressed to the upper region and the duodenum was tracked toward left, the CBD was identified. Gallbladder was drained through a cystic duct joined with hepatic duct into the CBD. The CBD in control group was exposed and freed with forceps. A complete transection between the portal hilus and duodenum was performed with sharp dissection in the other 3 groups. The bile duct was reconstructed with the microsurgical instruments.

EEA was performed with interrupted sutures passing through the layers of the duct wall. The first stitch was placed at the side wall to join the two cut ends. Then, posterior walls of the proximal and distal cut ends were clockwise sutured. After the posterior wall was sutured, anterior wall was sutured in the same way (Figure 1). The proximal and distal cut ends were connected precisely and all stitches were distributed evenly with no tension on the approximate distal and proximal ends. Leaked bile was constantly wiped out to keep the operation area clean. The peritoneal cavity was flushed with normal saline to wash away the remaining bile after suturing was completed. The whole process took about 40 min with 8-10 sutures. No clasper was used to disturb the blood supply and bile flow during operation. No T-tube or drainage was placed.

General conditions and survival rate of animals

The general conditions and body weights of guinea pigs were carefully observed. The causes of death of guinea pigs were examined by autopsy. Overall survival rates of the animals were calculated and recorded.

Measurement of bile duct diameter

By the end of two, three and six months after the EEA model was established, guinea pigs in the 4 groups were sacrificed by exsanguination. The maximum diameter of the proximal end (MDP) of CBD and the maximum diameter of anastomosis (MDA) were measured using a sliding caliper. The diameter ratio (DR, $\text{DR} = \text{MDP}/\text{MDA}$) in every group was calculated to assess the formation of relative stricture. Tissue samples were harvested from the anastomosed bile duct for histological examination.

Histological and immunohistochemical examination

Tissue samples, taken from the anastomosed bile duct, were fixed in 10% formalin, embedded in paraffin, and cut into 5- μ m thick cross-sections which were stained with hematoxylin and eosin (HE). Immunohistochemical staining was performed using proliferating cell nuclear antigen (PCNA monoclonal antibody, Medical and Biological Laboratories, Japan). Histological characteristics were reported by the professional pathologist.

Cells were considered positive when their nuclei were stained distinctly brown. Negative control sections were fixed with a safe buffer and positive control sections were used.

The sections of PCNA stained with immunohistochemistry were examined under a light microscope and graded using a modified 0-4 numerical scale provided by Hunt *et al.*^[13] (Table 1).

Serology examination

Serum alkaline phosphatase (ALP) and γ -glutamyltransferase (GGT) levels were measured and analyzed with an automatic biochemical analyzer (Type 5421-04, MISHIMA OLYMPUS CO., Shizuoka-ken, Japan).

Measurement of bile content

The changes of bile contents in 3- and 6-mo groups were analyzed, and the presence of biliary sludge and gallstones was detected. The bile was drained in sterile conditions to examine its pH value. The levels of total bilirubin (TBIL), total bile acid (TBA), and calcium ions were measured with an automatic biochemical analyzer (Type 5421-04, Mishima Olympus Co., Shizuoka-ken, Japan).

Statistical analysis

Levene's test for equality of variances was performed to assess the equality between groups. Independent sample *t* test and Mann-Whiney *U* test were used to compare the differences in the 4 groups. Data were expressed as mean \pm SE. Statistical analysis was conducted using the SPSS for Windows (Chicago, Illinois, USA). $P < 0.01$ was considered statistically significant.

RESULTS

General conditions and survival rate of animals

The animals in 4 groups survived throughout the experiment with a survival rate of 97%. One guinea pig in the control group died of anaesthetic intolerance before surgery. The total survival rate was 91% and two guinea pigs (one in 3-mo group and 1 in 6-mo group) died of bile leak age within seven days after operation. No fever, bile leakage, jaundice, infection, cholangitis, peritonitis, or other postoperative complications were noted in the surviving animals during the follow-up. All animals fed with usual diet gained their weight gradually (Table 2) and remained in a good condition till euthanized.

Measurement of bile duct

The mean value of MDA in groups 2-4 was 3.51 ± 0.12 mm,

Table 1 Immunohistochemical grading scale

Table 2 Body weight of guinea pigs

Groups	<i>n</i>	mean \pm SE (g)	<i>P</i>
Group 1	7	380.86 \pm 3.04	
Group 2	8	871.38 \pm 15.23	0.002 ^{1,b}
Group 3	7	963.00 \pm 39.90	0.002 ^{1,b}
Group 4	7	1101.71 \pm 31.96	0.002 ^{1,b}

¹Mann-Whitney *U* test; ^b $P < 0.01$ vs group 1.

3.15 ± 0.23 mm, and 3.47 ± 0.16 mm, respectively, which was significantly higher than that (1.71 ± 0.17 mm) in control group ($P < 0.01$). The mean value of MDP in groups 2-4 was 10.24 ± 0.48 mm, 8.66 ± 0.47 mm, and 8.05 ± 0.52 mm, respectively, which was also significantly higher than that (2.95 ± 0.15 mm) of control group ($P < 0.01$). The MDP value in group 2 was the highest. The MDP values were comparable between groups 3 and 4.

The DR indicates the formation of relative stricture and the postoperative DR suggests the remodeling status and restoration of physiological function. A significant difference was observed in DR between the control and 2-mo groups (1.89 ± 0.27 vs 2.94 ± 0.17 , $P = 0.004$). The DR in groups 3 and 4 was 3.24 ± 0.65 and 2.14 ± 0.18 , respectively (Table 3).

Histological examination

Gross inspection of the bile duct after operation revealed that the anastomosed bile duct was narrowed due to local inflammation and edema. The thickened bile duct wall looked like a "stricture ring" (Figure 2).

In this study, normal bile duct contained abundant elastic fibers with a good contract property. Its intima was lined with a single glandular epithelium. Lamina propria contained a small amount of gland elements. Scattered smooth muscle cells were distributed unevenly in the media wall. Adventitia contained fibroblasts and other connective tissues (Figure 3A).

Two months after operation, significant epithelial proliferation, intra- and extramural glandular hyperplasia, fibrous thickening of the duct and dense infiltration of inflammatory cells were noted in the anastomosis (Figure 3B). Inflammatory reactions were gradually subsidized in 3- and 6-mo groups. Hyperplasia of gland elements was observable in 6-mo group (Figure 3C and D).

Immunohistochemical examination

PCNA, a 36-kDa nuclear protein, is an auxiliary protein for DNA polymerase -delta. PCNA expression and distribution

are correlated with cell proliferation, DNA synthesis, and cell proliferative activity^[14,15]. In this study, positive PCNA cells were concentrated on the glandular-epithelia and peribiliary glands of control group. After bile duct reconstruction in 2- and 3-mo groups, an increased number of positive cells were distributed in all layers of the duct wall. By the end of six months, positive PCNA cells were located mainly in glandular elements and epithelial cells (Figure 4). The number of proliferated PCNA cells was significantly greater in groups 2-3 than in control group (*P* < 0.01) (Table 4).

Serum ALP and GGT levels

One serum sample taken from control group was abandoned due to contamination. The mean serum ALP and GGT level was 55.33 \pm 8.44 U/L and 14.67 \pm 2.76 U/L, respectively, in control group and groups 2-4 (*P* < 0.01, Table 5).

Measurement of bile contents

The bile contents were measured to show whether there is a tendency to form gallstones. No biliary sludge or gallstones were found in the biliary system of all groups, and no significant difference was observed in levels of TBIL, TBA, calcium ions and pH value among the 4 groups (Table 6).

DISCUSSION

In this study, EEA was performed instantly after total transection of CBD in guinea pigs. A few weeks after EEA, the anastomosed bile duct was narrowed due to local inflammation, edema and proliferation of glandular elements. The thickened bile duct wall looked and functioned as a "stricture ring", leading to a significantly higher hydrodynamic pressure on the proximal bile duct end and noticeable dilation of the proximal bile duct end above the stenosis zone. The increased pressure of the proximal bile duct end would pass on the pressure to the anastomosed area of bile duct and influence its remodeling. The "stricture ring" took on adaptive changes with inflammation gradually subsidized after a

few months. The MDA and MDP values were significantly higher in groups 2-4 than in control group. Therefore, a single MDA parameter could not reliably reflect the remodeling process of the anastomosed bile duct. Moreover, the body weight of guinea pigs increased throughout the experiment in 6-mo group. The DR parameter of ($\text{DR} = \text{MDP}/\text{MDA}$) was used to assess the remodeling status and evaluate whether there is a relative stricture formation. If the DR was significantly higher in groups 2-4 than in control group, a relative stricture would form.

The DR was significantly higher in 2-mo group than in control group, which might be the indication for relative stricture formation. The animals remained in a good condition with their weight gradually increased. The MDP, MDA and DR values were lower in 6-mo group than in 2-mo group, while comparable to those in 3-mo group. No significant difference was noted in levels of ALP, GGT, and bile contents among 4 groups, indicating that normal bile duct anatomy and physiological function can

be gradually restored after a transient formation of “relative stricture”.

Although the body weight of guinea pigs was notably increased in six months, the bile duct parameters did not increase in proportion, suggesting that the growth of animals is not the only cause of bile duct enlargement. We hypothesize that besides hydrodynamic pressure of bile flow to the side walls and normal growth of the animals, neurological factors may also account for the changes during bile duct remodeling.

Consequently, the postoperative remodeling process in 6-mo group was a synergetic and balanced result of tissue injury and repair, as well as hydrodynamic and neurological changes in injured CBD. Further study is needed to explain the neurological mechanism underlying the postoperative remodeling process of bile duct.

It has been shown that biliary stasis can induce pigment stone formation in animals^[16,17] and in patients with biliary stricture^[18]. It was reported that the increased bile

Figure 4 Proliferating cell nuclear antigen immunohistochemical staining. pH and changes in bile contents when ligation results in bile duct stricture are the early events, leading to the formation of gallstone^[17,19]. In our experiment, the levels of TBIL, TBA, calcium ions and the pH value were measured. No biliary sludge or gallstones were found in the biliary system of guinea pigs.

Guinea pig is an ideal animal for the reconstruction of bile duct with EEA. The EEA model is frequently used in studies of biliary system, especially in investigation of gallstone formation^[17,19]. Rats have no gallbladder and the diameter of their CBD is only 1 mm^[20]. The anatomy of bile duct in guinea pigs is very similar to that of human beings. Since the diameter of bile duct in guinea pigs is approximately 1.7 mm, it is easy to reconstruct the bile duct with a good reproducibility. The bile contents differ in species. The bile in guinea pigs contains the same bilirubinic acid as in human beings, while the bile in rabbits contains biliverdinic acid which renders it unusable in this respect^[21]. Moreover, although dogs might be the better candidates for the reconstruction of bile duct, guinea pigs were chosen in this preliminary experiment from the animal welfare and ethical point of view.

In the present study, the histological characteristic of normal CBD tissue taken from guinea pigs were similar to those taken from human beings, which are consistent with the reported findings^[22-24], indicating that guinea pigs are ideal for the establishment of EEA models.

The tissue repair of injured biliary tract is a scar healing process. Two important changes in tissue repair can restore the morphological consistency and physiological

function, namely the formation of granulation tissue with contractile properties and the epithelial cell proliferation, migration and the closure of the wound^[25]. MFB is the major constituent of inflammatory and reparative granulation tissues. By forming a net work of contracting system, MFB may last scar contraction and result in stricture formation. MFB disappear due to apoptosis when the epithelialization is completed and the remodeling process becomes stable^[26,27]. The presence of MFB can lead to excessive scarring and fibrotic conditions. Geng and his colleagues established the bile duct anastomosis model of dogs by making an incision on the anterior wall of CBD with one third of its circumference, and found that the number of myofibroblasts can reach its peak 3 mo after operation, and decrease due to apoptosis 6 mo after operation^[28], suggesting that six months is enough for the examination of the healing process of bile duct anastomosis. However, the long-term outcome is critical in surgical treatment of BDI in clinical practice. No biliary anastomosis stricture formation is a proof of successful surgical management. Therefore, further study is needed to observe the longer postoperative outcome.

In this preliminary study, we presented a simple and reliable animal EEA model for bile duct reconstruction with a good reproducibility and satisfactory survival rate. No permanent biliary anastomosis stricture was noticed in 6-mo group and no serology or bile content revealed stricture formation. The overall animal survival rate was 91%. The animals gained their weight with no postoperative biliary obstruction found in all groups.

In conclusion, the EEA animal model of bile duct established in this study can be used in studies of BDI etiology, development, and possible prophylaxis, and provide some valuable information for the postoperative healing process of bile duct.

COMMENTS

Background

Treatment of bile duct injury (BDI) remains a great challenge for gastrointestinal surgeons. No consensus has been reached concerning the ideal method for bile duct reconstruction. No large scale clinical study is available on bile duct reconstruction.

Research frontiers

Some surgeons prefer end-to-end anastomosis (EEA) as a more physiological method in bile duct reconstruction. However, no large-scale clinical study or suitable animal model is available or analyzed. In this study, by establishing a reliable animal EEA model of common bile duct (CBD) and observing the post-operative results of histological, immunohistochemical examination, serologic and bile content analysis, as well as bile duct parameters, the authors demonstrated that EEA can be utilized in treatment of BDI.

Innovations and breakthroughs

The authors provided a simple and reliable animal EEA model of CBD with a good outcome in this study, which may shed light on studies of BDI etiology, development, and possible prophylaxis.

Applications

The animal EEA model of CBD we established in the present study can be utilized in studies on BDI etiology, development, and possible prophylaxis as well as provide some valuable information for the post-operative healing process of EEA.

Terminology

EEA, an end-to-end anastomosis procedure, is a more preferable choice of treatment than Roux-en-Y maneuver. MFB are the myofibroblasts with α -SMA expression in stress fibers. In wound healing, inflammation mediators and mechanical tension lead to generation of actin-containing microfilaments or stress fibers which confer contractile property to fibroblasts, and convert them into terminally differentiated MFB. MFB are the major constituent of inflammatory and reparative granulation tissue and can last scar contraction and stricture formation.

Peer review

In this study, the animals gained their weight and no postoperative biliary obstruction was observed in any group after bile duct reconstruction with EEA in this study, showing that EEA is a simple and reliable procedure for bile duct reconstruction with a satisfactory survival rate, which provides some valuable information for the postoperative healing process of bile duct.

Abstract

AIM: To characterize the differentially expressed gene profiles in livers from biliary atresia (BA) patients including, ascertain genes, functional categories and pathways that play a central role in the pathogenesis of BA, and identify the novel prognostic markers for BA.

METHODS: Liver tissue samples from control patients, neonatal cholestasis patients, and BA patients at the age of < 60 d, 60-90 d, and > 90 d were pooled for DNA microarray analysis. Bioinformatics analysis was performed using, series test cluster of gene ontology, and Pathway-Finder software. Reverse-transcription polymerase chain reaction was performed to confirm changes in selected genes. Relation between RRAS gene expression and prognosis of 40 BA patients was analyzed in a 2-year follow-up study.

RESULTS: The 4 identified significant gene expression profiles could confidently separate BA liver tissue from normal and other diseased liver tissues. The included

genes were mainly involved in inflammation response and reconstruction of cellular matrix. The significant pathways associated with BA were primarily involved in autoimmune response, activation of T lymphocytes and its related cytokines. The *RRAS*, *POMC*, *SLC26A6* and *STX3* genes were important regulatory modules in pathogenesis of BA. The expression of RRAS was negatively correlated with the elimination rate of jaundice and positively correlated with the occurrence rate of cholangitis.

CONCLUSION: Autoimmune response mediated by T lymphocytes may play a vital role in the pathogenesis of BA. The *RRAS* gene is an important regulatory module in the pathogenesis of BA, which may serve as a novel prognostic marker for BA.

INTRODUCTION

Biliary atresia (BA) is a devastating disease of infants, invariably leading to cirrhosis, end-stage liver disease, and death if untreated^[1]. A recent review reported that BA may involve a primary perinatal hepatobiliary viral infection and a secondary autoimmune-mediated bile duct inju-

ry^[2]. However, the cause and pathogenesis of BA remain largely unknown.

Microarray technology, emerged as an indispensable research tool for gene expression profiling, has been used to study the mechanism underlying BA, and allows the simultaneous analysis of thousands of transcripts within a single experiment^[3]. Some studies have been performed to investigate the gene expression profiling of livers from BA patients^[4-6]. However, to our knowledge, none of them was designed to identify genes that play a key role in the pathogenesis and prognosis of BA. In the current study, DNA microarrays for whole genome gene expression and bioinformatics analysis were used to characterize the differentially expressed gene patterns of normal livers and livers from BA patients at different ages, as well as to ascertain the genes and pathways that play a central role in the pathogenesis of BA. Furthermore, reverse-transcription polymerase chain reaction (RT-PCR) was performed to confirm the changes in selected genes. The relation between selected gene expression and prognosis of BA patients was also analyzed.

MATERIALS AND METHODS

Patients and specimens

Biopsy specimens were obtained from livers of 9 patients with BA, 3 patients with neonatal cholestasis and 3 control patients suffering from liver trauma (as normal control) at Children's Hospital of Fudan University from November 2007 to December 2008. Nine patients with BA were further divided into < 60 d group ($n = 3$), 60-90 d group ($n = 3$) and > 90 d group ($n = 3$). Liver samples from 3 groups of BA patients, neonatal cholestasis and control groups were immediately dissolved in a RNeasy lysis reagent (Qiagen, Germany) and then stored at -80°C. Liver samples from each group were pooled and total RNA was isolated from them for DNA microarray experiments. Clinical data about these patients are summarized in Table 1. Liver samples were collected from the other 14 patients with neonatal cholestasis and 40 patients with BA for RT-PCR experiments. All subjects gave their informed consent to participate in the study which was approved by the Research Ethics Committee of Fudan University.

RNA extraction, processing and microarray analysis

Total RNA was extracted from liver tissue samples using the Trizol reagent (Invitrogen) according to its manufacturer's protocol, and then further purified using a NucleoSpin RNA clean-up kit (Macherey-Nagel, Germany). Quantification analysis of RNA was performed on a spectrophotometer and quality of RNA was analyzed by denaturing formaldehyde gel electrophoresis. Five micrograms of total RNA from each group was amplified and labeled with biotin using an Illumina total Prep RNA amp kit (Ambion, Austin, TX, USA) and hybridized to Illumina's Sentrix Human-6 (Version 3) Expression Bead-Chips containing 48000 transcripts (Illumina, San Diego, CA, USA). Three duplicated chips were also used in each

group to test the variations in duplications from the same pooling. The hybridized Illumina chips were scanned on a BeadArray reader (Illumina, San Diego, CA, USA) and microarray analysis was performed using the BeadStudio software (Illumina, San Diego, CA, USA). Raw data were normalized using the cubic spline method and the resulting genes were filtered. Finally, only genes with a differential expression score (Diffscore) greater than 20 or less than -20 were included.

Bioinformatics analysis of differentially expressed genes

Differentially expressed genes were analyzed by a series test of cluster (STC) to search a set of model expression profiles that were distinct in 5 groups as previously described^[7,8]. These profiles were assigned to significant gene ontology categories using series test cluster of gene ontology (STC-GO)^[9], and analyzed with the Pathway-Finder software to obtain the significance of pathway categories^[10,11]. Moreover, dynamic gene networks were constructed to find the key genes that may play a central role in the pathogenesis of BA^[12,13]. The principle and algorithmic details are available in supplementary data.

Validation of microarray data by RT-PCR

RT-PCR was performed on liver tissue samples from 14 patients with neonatal cholestasis and 40 patients with BA to confirm changes in selected genes, including RRAS, POMC, SLC26A6 and STX3. Total RNA was extracted from liver tissue samples and purified as previously described^[14]. Five micrograms of total RNA was reverse transcribed using MMLV reverse transcriptase (Merck, Germany) and random primers in a 20 µL reaction volume at 42°C for 1 h. Oligonucleotide primers for the RRAS, POMC, SLC26A6, STX3 and β-actin are shown in Table 2. The PCR conditions were as follows: an initial denaturation at 94°C for 5 min, followed by 35 cycles of denaturation at 94°C for 30 s, annealing at 58°C for 30 s, extension at 72°C for 30 s, and a final extension at 72°C for 7 min. The PCR products were separated by electrophoresis and UV illuminated on a 2% agarose gel containing ethidium bromide (0.5 µg/mL). The gel image was stored using the UVP gel documentation system 5000 (Ultra-Violet Products Ltd., Cambridge, United Kingdom). Expression levels of the selected genes relative to β-actin were measured with densitometric scanning using the multi-analysis/PC system (Bio-Rad, Hercules, California, USA).

Prognostic biomarker and follow-up research

Fibrosis of liver biopsy specimens from 40 patients with BA was histologically classified into different groups. Elimination rate of jaundice (TB < 20 µmol/L) within 6 mo after operation, 2-year survival rates of cholangitis patients and of 40 BA patients were calculated. The diagnostic criteria for cholangitis included fever, increasing jaundice, acholic stools, with other causes of infection excluded. Follow-up data were obtained from our outpatient and inpatient referrals, as well as from interview by

telephone or questionnaires. These patients were further classified based on the follow-up data, including presence of jaundice 6 mo after operation, occurrence of cholangitis within 2 years after operation, and 2-year survival rate.

Statistical analysis

Data were expressed as mean \pm SD. Variations in duplications were detected by Fisher's exact test, χ^2 test, *t*-test and Cochran-Mantel-Haenszel test using the STATA 8.0 software (Stata Co., College Station, TX, USA). Pair-wise test was used to confirm the limited variations in duplications from the same pooling. $P < 0.05$ was considered statistically significant.

RESULTS

Differentially expressed gene profiles in liver tissue samples from BA patients

Total RNA was extracted from liver tissues of the normal group, neonatal cholestasis group, and 3 groups of BA patients at different ages (< 60 d, 60-90 d and > 90 d). Denaturing formaldehyde gel electrophoresis showed no degradation (data not shown). Illumina's Sentrix Hu-

Figure 1 Four most significant expression profiles in liver samples from biliary atresia patients. 0: Normal control group; 1: Neonatal cholestasis group; 2: Group of biliary atresia (BA) patients > 90 d; 3: Group of BA patients at the age of 60-90 d; 4: Group of BA patients < 60 d. Y axis represents the expression change expressed as $\log_2 [v(i)/v(0)]$.

man-6 (Version 3) Expression BeadChip was used for each of pooled liver tissue samples from the 5 groups. Pair-wise test confirmed a limited variation in duplications from the same pooling (data not shown). A total of 795 differentially expressed genes were identified from different groups with a Diffscore greater than 20 or less than -20. Further STC analysis yielded 80 expression profiles. Of these expression profiles, 20 were statistically significant ($P < 0.05$) and 4 had the lowest P value (Figure 1). These 4 expression profiles could confidently separate livers in groups of BA patients from those in normal and neonatal cholestasis groups. Specifically, all the differentially expressed genes in 5 groups were included in profile 76, which showed no significant difference in the 3 groups of BA patients at different ages (< 60 d, 60-90 d and > 90 d). The 611 genes represented in profile 75 were mainly involved in inflammation mediated by activation of T lymphocytes, and reconstruction of extracellular matrix. As shown in Figure 1, the global expression level of

the genes in profile 75 was much lower in livers from the group of BA patients at the age of < 60 d than from the groups of BA patients at the age of 60-90 d and > 90 d. The 372 genes represented in profile 74 were associated with an apoptotic pathway and inflammatory response mediated by nuclear factor- κ B (NF- κ B). The global expression level of profile 74 genes was much lower in the group of BA patients at the age of 60-90 d than in the groups of BA patients at the age of < 60 d and > 90 d. Moreover, the 285 genes represented in profile 49 were mainly involved in inflammatory response mediated by the major histocompatibility complex (MHC) class II antigen. The global expression level of profile 49 genes was much higher in the 3 groups of BA patients at different ages (< 60 d, 60-90 d and > 90 d) than in the normal and neonatal cholestasis groups. Little variance in gene expression was observed neither in the 3 groups of BA patients at different ages (< 60 d, 60-90 d and > 90 d) nor in the normal and neonatal cholestasis groups (See supplementary data for a complete list of these 4 expression profiles).

Involvement of significant pathways in BA focused on autoimmune response associated with inflammatory response of T lymphocytes

Based on the Kyoto Encyclopedia of Genes and Genomes Database and the most significant 4 gene expression profiles, Fisher's exact test and χ^2 test were performed to identify the significant pathways involved in BA as previously described^[15]. The significant pathways ($P < 0.01$) highly associated with BA were mainly focused on (1) autoimmune response associated with asthma, systemic

lupus erythematosus, allograft rejection graft-versus-host disease, type I diabetes mellitus, antigen processing and presentation; (2) activation of T lymphocytes and inflammatory response including transendothelial migration of T leukocytes, cell adhesion molecules, NF- κ B and MAP kinase (MAPK) signaling pathways, chemokine signaling pathway, cytokine-cytokine receptor interaction, transendothelial migration of leukocytes, Toll-like receptor signaling pathway; and (3) reconstruction of extracellular matrix, including matrix-metalloproteinases. The significant pathways are shown in Table 3.

Construction of dynamic gene networks

Dynamic gene networks^[16] were constructed to find the key regulators that may play a central role in the pathogenesis of BA (Figure 2). Circles indicate genes in the 4 expression profiles, solid lines indicate direct interactions, size of circles indicates their interactions with other molecules, coloring is classified according to the k core and red indicates high k core. The genes with the highest degree and k-core from Figure 2, are listed in Table 4, including the related RAS viral (r-ras) oncogene homolog (RRAS), POMC, SLC26A6 and STX3 genes, indicating that they play a crucial role in the pathogenesis of BA.

Expression of RRAS, POMC, SLC26A6 and STX3 genes in liver tissue samples from patients with BA confirmed by RT-PCR

The mRNA expression levels of RRAS, POMC, SLC26A6 and STX3 in liver tissue samples from 40 patients with BA and 14 patients with neonatal cholestasis, measured in order to validate the results derived from microarray data, were significantly higher in liver tissue samples from patients with BA than from those of neonatal patients

Figure 2 Dynamic gene networks constructed showing the key regulators that may play a central role in the pathogenesis of biliary atresia. Circles indicate genes in the 4 expression profiles, solid lines indicate direct interactions, and size of circles indicates their interactions with other molecules. Coloring is classified according to the k core, and red indicates high k core.

Correlation between expression of RRAS in liver tissue samples and prognosis of BA patients

To address whether the RRAS expression is associated with the prognosis of BA patients, we performed a 2-year

Table 6 Fibrosis scores for different groups of biliary atresia patients at different ages

Group	Fibrosis score (n)					Total
	0	1	2	3	4	
< 60 d	1	3	8	2	0	14
60-90 d	0	2	3	6	4	15
> 90 d	0	0	1	4	6	11
Total	1	5	12	12	10	40

**Figure 5** Correlation between expression of RRAS in liver tissue samples and prognosis of biliary atresia patients within 2 years.

follow-up study in 40 patients with BA. Six months after operation, The RRAS expression level was significantly higher in patients with their jaundice not eliminated than in those with their jaundice eliminated ($P = 0.007$). Furthermore, the expression level of RRAS was significantly higher in patients with cholangitis reoccurred 3 or more times than in those with no cholangitis recurred ($P = 0.028$). However, no significant difference in RRAS expression was found between the surviving and dead patients ($P = 0.094$, Figure 5). In addition, the fibrosis was more serious in group of BA patients at the age of > 60 d than in group of BA patients at the age of < 60 d (Table 6), which was consistent with that observed in profile 75.

DISCUSSION

The pathogenesis of BA has not yet been delineated. It has been shown that factors such as genetic susceptibility, congenital heteroplasia, and infectious and abnormal immune response lead to BA^[17-23], and its clinical course and surgical outcome are correlated with the age of such patients^[24-26]. Although there are some studies involving DNA microarrays in BA^[4-6], very few studies are available on gene expression profiling of BA at its different stages of clinical course. That is why the clinicopathologic characteristics of BA vary with the age of such patients.

The differential gene expression patterns of RRAS in

liver tissue samples from BA patients at different ages, as well as normal liver tissue samples and liver tissue samples from neonatal cholestasis patients were characterized in this study using the expression DNA microarray technology and bioinformatics. The 4 significant expression profiles identified using STC could confidently separate BA liver tissues from normal and diseased liver tissues. STC-GO analysis revealed that the genes represented in the 4 profiles were mainly involved in inflammatory response and reconstruction of extracellular matrix. Notably, as validated by fibrosis classification, profile 75 showed that the expression level of genes involved in fibrosis and inflammation was much lower in BA patients at the age of < 60 d than in those at the age of > 60 d, which may explain why BA patients at the age of < 60 d often have a good prognosis after a Kasai's operation^[27]. Additionally, this phenomenon may also result from fibrosis due to the continuous hepatic inflammatory response-induced activation of stellate cells^[28]. Moreover, a set of genes were involved in apoptosis represented in profile 74, which is in agreement with the reported findings^[29]. In this profile, the BA patients at the age of > 90 d and < 60 d showed obvious inflammatory response and apoptosis mediated by NF-κB, which might be associated with the inflammatory response of local bile ducts in BA patients at the age of < 60 d and severe inflammatory response induced by fibrosis in BA patients at the age of > 90 d.

Mack *et al.*^[30,31] showed that CD4⁺ Th1-mediated bile duct inflammation is responsible for the development of BA. Profile 74 in the present study contains a set of genes associated with MHC class II antigen-mediated Th1 inflammatory response, which is in agreement with the findings of Mack *et al.*^[31] and Osada *et al.*^[32]. It is well known that antigens associated with MHC class II can bind to T cell receptors of CD4⁺ Th1 cells, and thereby produce functional T lymphocytes. Furthermore, the significant pathways highly associated with BA were mainly focused on the autoimmune response, activation of T lymphocytes and its related cytokines, suggesting that autoimmune response mediated by T lymphocytes may play a vital role in the pathogenesis of BA, which is consistent with the widely accepted hypothesis of BA^[2,22,23,32].

In this study, the RRAS, POMC, SLC26A6 and STX3 genes were found to be important regulatory modules in BA. The RRAS gene is a component of the MAPK signaling pathway with GTP kinase activity^[33,34]. The MAPK pathway is associated with BA^[35]. Based on the results of this study, it is reasonable to speculate that the RRAS gene plays an important role in the pathogenesis of BA. The human POMC gene is located on chromosome 2p23.3 encoding a preprohormone. The adrenocorticotropin hormone and α melanocyte-stimulating hormone are cleavage products of POMC, which are associated with immune regulation and participate in the pathogenesis of experimental autoimmune encephalomyelitis^[36,37]. The SLC26A6 is an anion exchanger involved in the secretion of bile acid. The STX3 has been implicated in the development and differentiation of dendritic cells^[38,39]. Nonetheless,

the precise role of these genes in the pathogenesis of BA needs to be further elucidated.

Given the key role of RRAS gene in the pathogenesis of BA, we evaluated the relation between the expression of RRAS and prognosis of BA patients through a 2-year follow-up study. The RRAS expression was negatively correlated with the elimination rate of jaundice and positively correlated with the occurrence rate of cholangitis, indicating that up-regulation of RRAS expression may inhibit the recovery of BA from jaundice and cholangitis *via* activation of the MAPK pathway, continuous inflammatory response, inflammatory cell infiltration, as well as activation of stellate cells^[40]. However, no significant difference was found in the 2-year survival rate of patients with different expression levels of RRAS. Validation may require a long-term follow-up and a larger number of subjects.

In summary, autoimmune response mediated by T lymphocytes may play a vital role in the pathogenesis of BA. The RRAS gene and its related MAPK pathway are important regulatory modules in the pathogenesis of BA, which may serve as a novel prognostic marker for BA.

ACKNOWLEDGMENTS

The authors thank Dr. Duan Ma for his technical assistance and Song Zai for his collection of clinical samples.

COMMENTS

Background

Biliary atresia (BA) is an inflammatory obliterative cholangiopathy with unknown etiology, leading to progressive fibrosis and cirrhosis. Although there are some studies involving DNA microarrays on BA, very few studies are available on gene expression profiling of BA at different stages of its clinical course, which is why the clinicopathologic characteristics of BA vary with the age.

Research frontiers

Microarray technology and bioinformatics, emerged indispensable research tools for gene expression profiling, have been used to study the pathogenesis of BA and allow the simultaneous analysis of thousands of transcripts within a single experiment. In this study, genes that play a key role in the pathogenesis and prognosis of BA were identified.

Innovations and breakthroughs

In the current study, DNA microarrays for whole genome gene expression and bioinformatics analysis were used to characterize the differentially expressed gene patterns in normal livers and livers from BA patients at different ages, as well as to ascertain genes and pathways playing a central role in the pathogenesis of BA. The results demonstrate that RRAS gene and its related MAP kinase (MAPK) pathway are important regulatory modules in the pathogenesis of BA, which may serve as a novel prognostic marker for BA.

Applications

By identifying genes and pathways playing a central role in the pathogenesis of BA, this study may represent a future strategy for therapeutic intervention in treatment of BA.

Terminology

RRAS gene is a component of the MAPK signaling pathway with GTP kinase activity. The MAPK pathway is associated with BA. Consequently, it is reasonable to speculate that the RRAS gene plays an important role in the pathogenesis of BA.

Peer review

This paper is interesting and valuable for other researchers. BA is a pediatric liver disease, which can lead to liver-related death and is the most common indication for liver transplantation in children. Therefore, the early proper treat-

ment of BA with Kasai procedure is important in this group of patients. Early diagnosis of BA and knowledge of its prognostic factors can improve the treatment outcome of BA. Different prognostic factors have been described in the literature, but no report is available on RRAS as a key regulator and an important prognostic biomarker for BA identified by DNA microarray and bioinformatics.

Abstract

AIM: To evaluate the effect of hepatitis B virus (HBV) infection on liver metastasis of colorectal cancer.

METHODS: A total of 1298 colorectal cancer patients were recruited from January 2001 to March 2005 in this study. Enzyme-linked immunosorbent assay was used to

test serum HBV markers for colorectal cancer. Patients were divided into study (infection) group and control (non-infection) group. Clinical features of patients in two groups were compared.

RESULTS: Liver metastasis was found in 319 out of the 1298 colorectal cancer patients. The incidence of liver metastasis was significantly lower in study group than in control group (14.2% vs 28.2%, $P < 0.01$). HBV infection significantly decreased the risk of liver metastasis [hazard ratio (HR): 0.50, 95% confidence interval (95% CI): 0.38-0.66], but the incidence of extrahepatic metastasis was significantly higher in study group than in control group (31.9% vs 17.0%, $P < 0.01$). The HR was the lowest in chronic hepatitis B group (HR: 0.29, 95% CI: 0.12-0.72). The number of liver metastatic lesions was significantly less in study group than in control group with a higher surgical resection rate. However, no significant difference was found in survival rate between the two groups ($P = 0.95$).

CONCLUSION: HBV infection decreases the risk of liver metastasis in patients with colorectal cancer and elevates the surgical resection rate of liver metastatic lesions.

INTRODUCTION

Colorectal cancer (CRC) accounts for 10%-15% of all cancers and is the second leading cause of cancer-related deaths in Western countries^[1]. Approximately half of CRC patients develop metastatic disease^[2]. Of the CRC patients, 15%-25% present with synchronous liver metastasis and 80%-90% are initially found to have unresectable liver metastatic disease^[3]. Metastatic liver disease more frequently develops metachronous metastasis following treatment of CRC. It is estimated that over half of dead CRC patients have liver metastasis at autopsy^[4].

Hepatitis B virus (HBV) infection is the most common cause of chronic liver diseases worldwide, an estimated 350 million persons are chronically infected with HBV worldwide, and China is a highly endemic area of HBV infection with approximately 170 million HBV carriers^[5]. It has been demonstrated that HBV infection plays an important role in the development of hepatocellular carcinoma (HCC)^[6]. It was reported that HBV infection finally reduces the risk of intrahepatic metastasis in HCC patients with a higher survival rate and therefore can be considered an important prognostic factor for HCC patients^[7].

Rare reports are available on the relation between HBV infection and hepatic metastasis of CRC. Utsunomiya *et al.*^[8] reported that CRC seldom metastasizes to liver of patients infected with HBV or hepatitis C virus (HCV), but most patients in their study were infected with HCV. Song *et al.*^[9] showed that chronic HBV infection with viral replication reduces hepatic metastasis of CRC and prolongs the survival time of CRC patients. However, their study was hard to demonstrate the relation between HBV infection and hepatic metastasis of CRC due to its small sample size. Alternatively, investigation of experimentally induced hepatic metastasis of colon cancer demonstrated that activated immune cells residing in livers can effectively kill metastatic tumor cells, indicating that alterations in liver-associated immunity play an important role in hindering hepatic metastasis^[10]. Thus, we designed this cohort study to observe the relation between HBV infection and liver metastasis of CRC.

MATERIALS AND METHODS

Patients

A total of 1298 CRC patients at the age of > 16 years, admitted to Sun Yat-Sen University Cancer Center (Guangzhou, China) from January 2001 to March 2005, were recruited in this study and divided into study (infection) group and control (non-infection) group. All patients gave their written informed consent to receive a test for HBV infection at their first visit. The study was approved by The Ethics Committee of Sun Yat-Sen University Cancer Center.

Serologic assay for viral infection

HBsAg, anti-HBs, HBeAg, anti-HBe, and anti-HBc were detected by enzyme-linked immunosorbent assay and HBV deoxyribonucleic acid (HBV-DNA) was detected by polymerase chain reaction.

Treatment

Primary colorectal adenocarcinoma was completely removed from all eligible patients with no prior chemotherapy or radiotherapy, and staged according to AJCC Cancer Staging Manual, 6th edition^[11]. All patients received 5-fluorouracil-based FOLFOX6 or XELOX regimen. Patients with liver metastasis underwent palliative treatment (including chemotherapy, radiotherapy, surgical resection and radio-frequency ablation) according to the update NCCN Guidelines for CRC^[12].

Assessment of study and follow-up of patients

Patients were assessed by abdominal and pelvic computed tomography (CT) scan or magnetic resonance imaging (MRI), thoracic radiography or thoracic CT or MRI before surgery. Patients who underwent surgery were assessed again during operation. All patients, after discharged from hospital, were followed up according to a standard protocol^[13]. The patients were followed up every 3 mo in the first 2 years after surgery, during which clinical examination, routine blood test, assessment of tumor markers, and abdominal ultrasonography or CT scan and endoscopy were performed. In the next 3 years, the patients were followed up every 6 mo and underwent endoscopy every 12 mo. The relapse of CRC (defined as local recurrence or metastasis at distant sites) at other sites was detected and staged. The follow-up was terminated in April 2010.

Statistical analysis

Differences in baseline clinical parameters and treatment outcomes between the two groups were evaluated by chi-square test or Student *t* test. Hazard ratio (HR) and 95% confidence interval (95% CI) were calculated with the Cox proportional-hazards model. Overall survival (OS) and disease-free survival (DFS) curves were plotted with the Kaplan-Meier method, and compared by log-rank test. OS rate was calculated from the date of discharge to death. DFS time was defined as the time between discharge and first relapse of CRC. A two-tailed *P* value less than 0.05 was considered statistically significant. Statistical analysis was performed with SPSS for Windows V.13.0.

RESULTS

The 1298 patients were divided into study group and control group. Three hundred and thirty-two patients (25.6%) with chronic HBV infection included in study group were further divided into 3 subgroups according to their natural history of HBV infection^[14]. Chronic hepatitis B (CHB) was identified in 37 patients (2.9%) according to the presence of HBsAg and HBeAg or HBV-DNA which are markers of active viral replication. Inactive HBsAg carriers (IC), identified in 108 patients (8.3%), were characterized

¹Comparison was made only in 1156 cases after primary tumor resection, including 299 cases in study group and 857 cases in control group; ²Chronic hepatitis or liver cirrhosis was clinically diagnosed according to the findings in serum chemistry, ultrasonography and computed tomography. LDH: Lactate dehydrogenase; GGT: γ -glutamyl transferase; ALP: Alkaline phosphatase; NS: Not significant.

by the presence of HBsAg and anti-HBe and the absence of HBeAg or HBV-DNA. Resolved hepatitis B (RHB) observed in 187 patients (14.4%) was characterized by negative HBsAg and the presence of anti-HBc \pm anti-HBs. Nine hundred and sixty-four patients (74.6%) were included in control group. No significant difference was found in sex, age, depth of tumor invasion, lymph-node metastasis, lactate dehydrogenase, γ -glutamyl transpeptidase, alkaline phosphatase, albumin, and total bilirubin between the two groups (Table 1). However, the liver function was significantly worse in study group than in control group.

Follow-up

The mean follow-up time of patients was 6 mo after operation. The median interval time of patients was 6 mo after operation. The median follow-up time of patients was 57.2 mo (range 0-110.4 mo) after operation.

Liver and extrahepatic metastasis

Liver metastasis occurred in 319 patients including synchronous liver metastasis in 193 cases and metachronous liver metastasis in 127 cases. Of the 193 patients, 39 had synchronous liver metastases. Of the 127 patients, 18 had metachronous liver metastasis. Synchronous or metachronous extrahepatic metastasis occurred in 270 patients was defined as distant metastasis but not as liver metastasis. The incidence of recurrence or metastasis to the distant sites is summarized in Table 2. The incidence of liver and extrahepatic metastasis was comparable between the two

groups. The incidence of liver metastasis was significantly lower in study group than in control group (14.2% *vs* 28.2%, *P* < 0.01). The Mantel-Haenszel χ^2 analysis showed that HBV infection significantly decreased the risk of liver metastasis (HR: 0.50, 95% CI: 0.38-0.66). The incidence of extrahepatic metastasis was significantly higher in study group than in control group (31.9% *vs* 17.0%, *P* < 0.01). No difference was found in liver metastasis between the two groups.

The liver metastasis rate in patients with CHB, IC and RHB is listed Tables 3-5. CHB, IC and RHB decreased the risk of liver metastasis and increased the risk of extrahepatic metastasis. The HR was the lowest in patients with CHB (HR: 0.29, 95% CI: 0.12-0.72).

The number, size and surgical resection rate of metastatic lesions are listed in Table 6. The number of liver metastatic lesions was significantly less in study group than in control group with a higher surgical resection rate

Size of liver metastatic lesions is expressed as mean ± SD. NS: Not significant.

(*P* < 0.05). No significant difference was found in size of liver metastatic lesions between the two groups.

Survival rate

The 5-year survival rate was 57.0% and 58.2%, respectively, for the patients in two groups. No significant difference was found in OS and DFS rate between the two groups (Figure 1A and B).

DISCUSSION

In the current study, the risk of liver metastasis was significantly lower in study group than in control group (HR: 0.50, 95% CI: 0.38-0.66, *P* < 0.05). A significant difference was found in extrahepatic metastasis rate and no significant difference was found in survival rate between the two groups, suggesting that HBV infection may have a significant effect on liver metastasis of CRC. It was reported that the liver metastasis rate is low in patients with other malignancies due to HBV infection^[7,15].

In this study, the liver metastasis rate of CRC was lower in CHB, IC and RHB subgroups than in control group (*P* < 0.05). CHB was characterized by positive HBeAg while the serum HBV DNA level and normal aminotransferase level were very low or undetectable in IC. RHB results from previous HBV infection without further virological, biochemical or histological evidence of active virus infection or disease^[14,16]. Thus, it is reasonable to postulate that HBV infection with or without virus replication, may affect liver metastasis of CRC. In this study, CHB most significantly decreased the risk of liver metastasis of CRC followed by RHB.

Hepatic resection remains the only curative therapy for liver metastasis of CRC. In this study, the 5-year survival

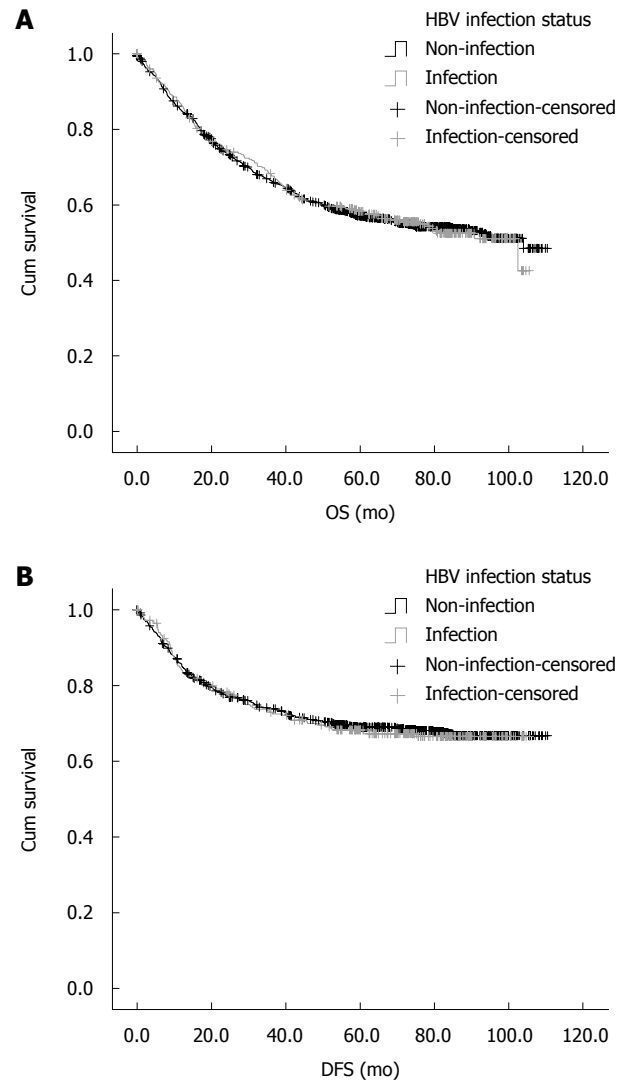

Figure 1 Overall survival rate (A) and disease-free survival rate (B) for patients in two groups after operation. HBV: Hepatitis B virus; OS: Overall survival; DFS: Disease-free survival.

rate of CRC patients was 25%-40% after operation, which is consistent with the reported findings^[17,18]. The number of liver metastatic lesions was much less in study group than in control group, leading to a higher surgical resection rate of liver metastatic lesions, indicating that HBV infection plays an important role in the pathogenesis of liver metastasis of CRC. However, no difference was found in overall survival and disease-free survival rate between the two groups, suggesting that liver metastasis of CRC results from the difference in extrahepatic metastasis.

Whether changes in liver-associated immunity contribute to the impediment of CRC colonization in patients infected with HBV remains unclear. The liver has a rich diversity of innate immune cells, particularly lymphocytes including natural killer cells, which respond to altered expression of self-antigens and lyse neoplastic target cells in the absence of additional activating stimuli^[19]. A large number of phagocytic and antigen-presenting cells including liver sinusoidal endothelial cells, Kupffer cells and dendritic cells play an important role in local innate immunity of the liver^[20]. Furthermore, it was reported

that HBV replication enhances the cytotoxicity of immunocytes during chronic HBV infection. Cytotoxic T lymphocytes (CTL) and Kupffer cells are essential for the immune response during HBV infection. HBV replication activates the specific lytic pathways of cell injury by CTL and Kupffer cells^[21]. A previous study showed that the hepatic microenvironment in patients with HBV-positive metastatic liver cancer can greatly change their gene expression profiles, and the two significant clusters in the profile revealed notable changes-associated with gene products involved in immune function. In fact, over 30% of the genes in these clusters are related to this process^[22]. Another study on tumor and stroma interaction suggested that the propensity of metastatic liver cancer is inherent to the tumor cells and affected by the local environment of metastatic sites^[23].

In conclusion, activation of liver-associated immunity due to HBV infection reduces the incidence of liver metastasis in CRC patients.

The authors thank all medical staff at Department of Colorectal, Gastric and Pancreatic Surgery, Sun Yat-Sen University Cancer Center, for their help.

COMMENTS

Background

Colorectal cancer (CRC) is the second leading cause of cancer-related deaths in Western countries. Metastatic liver disease more frequently develops metachronous metastasis following treatment of CRC. It was reported that hepatitis B virus (HBV) infection finally reduces the risk of intrahepatic metastasis in hepatocellular carcinoma (HCC) patients with a higher survival rate and therefore can be considered an important prognostic factor for HCC patients. Rare reports are available on the relation between HBV infection and hepatic metastasis of CRC.

Research frontiers

The authors designed a cohort study to observe the relation between HBV infection and liver metastasis of CRC.

Applications

The major points summarized in the article can be applied in further studies on the correlation between liver metastasis and colorectal cancer.

Peer review

In this manuscript, the authors evaluated the effect of HBV infection on liver metastases in patients with colorectal cancer. Some discussions should be added and survival curves should be reconsidered.

METHODS: Genomic DNA was isolated from frozen tissues. Pyrosequencing analysis was conducted to detect mutations in the *K-ras* (codons 12, 13, and 61) and *BRAF* genes (codon 600). Statistical analysis was carried out using SPSS-15.0 software.

RESULTS: Among the 118 colorectal cancer patients, we detected 41 (34.7%) mutations in the *K-ras* gene. Mutation frequencies at codon 12 and codon 13 were 23.7% (28/118) and 10.2% (12/118), respectively. Only one patient harbored a point mutation at codon 61 (0.8%, 1/118). Gender was the only factor that showed an obvious relationship with *K-ras* gene mutation (female 44.7% vs male 28.2%, $P = 0.037$). Other clinicopathological features, such as age, location of the tumor, tumor differentiation, Tumor, Node and Metastases classification, and the Union for International Cancer Control staging, showed no positive relationship with *K-ras* gene mutations. No significant correlation was observed between the presence of K-ras mutations (codons 12, 13, and 61) and the survival of the patients. BRAF mutations were rare, and only two patients (1.7%) harbored a detectable mutation at codon 600.

CONCLUSION: *K-ras* gene mutation is a common event in our 118 Chinese CRC patients, with an obvious relationship with gender. However, it seems not to be an independent prognostic factor in CRC patients. The *BRAF* gene is rarely mutated in Chinese CRC patients.

Abstract

AIM: To identify and assess mutations in the *K-ras* and *BRAF* genes in a cohort of Chinese patients with colorectal cancer (CRC) for their association with various clinicopathological parameters and prognosis.

2011; 17(6): 809-816 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v17/i6/809.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i6.809>

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies in the world. In recent years, the morbidity and mortality of colorectal cancer has risen in the Chinese population. The development of CRC is a multistep process, which can arise due to the cumulative effect of mutations in various proto-oncogenes, tumor suppressor genes, and also from epigenetic changes in DNA. Recent evidence suggests that the extracellular signal-regulated kinase (ERK)/mitogen-activated protein kinase signaling pathway, which mediates cellular responses to growth factors and regulates the elements of the cell cycle, apoptosis and differentiation^[1], plays a critical role in the pathogenesis of colorectal cancer. Both the *K-ras* and *BRAF* genes encode proteins that act in the ERK signaling pathway. The *K-ras* proto-oncogene encodes a 21 kDa RAS protein, a member of a highly conserved family of GTPases involved in signal transduction processes. Mutations in the *K-ras* gene render the protein constitutively active in signaling by eliminating the GTPase activity. More recently, mutations in the *K-ras* gene have proved to be predictors of response to epidermal growth factor receptor-targeted therapies, such as cetuximab and panitumumab, for patients with metastatic colorectal cancer.

In human CRC, mutations in the *K-ras* gene are very frequent (20%-50%), whereas mutations of the *BRAF* gene, a downstream molecule of *K-ras*, occur in only 9%-11% of patients with sporadic diseases. Mutations in the *K-ras* and *BRAF* genes are frequently found to be mutually exclusive in colorectal cancer^[2,3]. Both genes harbor the majority of mutations in distinct hotspots in the *BRAF* gene at codons 463-468^[4] and 600^[3,4], and in the *K-ras* gene at codons 12, 13^[5], and, more infrequently, at codon 61^[6]. Approximately 90% of the activating mutations in the *K-ras* gene are scored at codon 12 (wild-type: GGT) and codon 13 (wild-type: GGC) in exon 1, while only 5% are located at codon 61 (wild-type: CAA) in exon 2^[5,7,8]. Some studies have been conducted about the relationship between *K-ras* gene mutation and various clinicopathological characteristics, but no consistent results were obtained. The prognostic significance of *K-ras* gene mutations is still controversial. As for the *BRAF* gene, very few papers regarding its prognostic significance are available in Western countries or China.

For the detection of mutations in the *K-ras* and *BRAF* genes, various techniques have been described, including temporal temperature gradient electrophoresis^[9], denaturing gradient gel electrophoresis^[10], restriction endonuclease-mediated selective polymerase chain reaction (PCR)^[11], and direct sequencing of a PCR product^[12]. For all non-sequencing methods, it is difficult to independently confirm the existence of any mutations that are identified. In addition, our previous work showed that direct sequenc-

ing of a PCR product was not a sensitive method for the detection of *K-ras* gene mutations^[12]. Pyrosequencing has emerged as a sensitive and rapid sequencing method for single-nucleotide polymorphism (SNP)/mutation analysis, which overcomes the above limitations^[13]. It is a non-electrophoretic, real-time sequencing technic, and a sequence-by-synthesis method that relies on the lumino-metric detection of pyrophosphate released upon nucleotide incorporation *via* a four-enzyme mixture reaction cascade^[14,15]. It can analyze multiple samples in a short time, which makes it attractive for clinical use. So far, few papers have reported the use of pyrosequencing for the detection of *K-ras* gene mutations in colorectal cancer patients. Pyrosequencing studies on the *BRAF* gene are even fewer.

In this paper, we detected mutations in the *K-ras* and *BRAF* genes from 118 Chinese CRC patients using pyrosequencing. Correlations with various clinicopathological characteristics and the prognosis of patients were further analyzed.

MATERIALS AND METHODS

Patients and specimens

Tumor specimens used in this study were obtained from 118 CRC patients who received a radical resection operation in the 2nd Affiliated Hospital of Zhejiang University College of Medicine from February 2001 to January 2005. All patients were followed up by the Cancer Research Institute until September 2010, and the data concerning cancer recurrence and patient survival were collected. Tumor stage was classified according to the 7th edition of the Tumor, Node and Metastases (TNM) classification of the Union for International Cancer Control (UICC) staging. The clinicopathological data of all patients are shown in Table 1. Data and tissue collection was approved by the Ethics Committee of Zhejiang University College of Medicine, following the ethical guidelines of the 1975 Declaration of Helsinki.

DNA preparation and pyrosequencing

Tumor tissues were collected from the Zhejiang University Cancer Institute tissue bank. All the tissue samples were confirmed independently by two gastrointestinal pathologists. Genomic DNA was extracted with the QIAamp DNA Mini-Kit (QIAGEN, Mississauga, ON), according to the manufacturer's recommendations. The primers for the amplification and pyrosequencing assay of *K-ras* and *BRAF* gene are listed in Table 2.

PCR was performed using 100 ng genomic DNA as template. Each mixture contained 10 pmol of each primer. The reactions were performed in 1 × reaction buffer, 0.2 μmol/L dNTPs, 2 mmol/L MgCl₂, and 1.25 U Blend Taq polymerase (ToYoBo) in a total volume of 50 μL. The amplification reactions were as follows: an initial denaturing cycle of 94°C for 2 min; 35 cycles of 94°C for 30 s, 55°C for 25 s, and 72°C for 30 s; and a final extension cycle at 72°C for 2 min.

The PCR products were directly subjected to the se-

the K-ras wild-type/mutation type and the clinicopathological variables of patients [Mann-Whitney *t* test for dichotomous variables (gender, metastasis *vs* no metastasis); Kruskal-Wallis test for no dichotomous variables (age, tumor region, differentiation and TNM stage). Kaplan-Meier survival analysis was performed to evaluate the relationship between K-ras wild-type/mutation type and survival of CRC patients. Calculations were carried out using the SPSS-15.0 software (SPSS Inc., Chicago, IL). *P* value less than 0.05 was regarded as statistically significant. All statistical tests were two-sided.

RESULTS

Mutation characteristics of K-ras gene

A total of 41 mutations of *K-ras* gene were detected in the 118 patients, with a mutation rate of 34.7% (41/118). And 23.7% (28/118) of mutations were at codon 12 and 10.2% (12/118) at codon 13. Only one patient harbored a point mutation at codon 61 (0.8%, 1/118). The mutations in the *K-ras* gene are summarized in Table 3. Figure 1 shows an example of pyrosequencing analysis of mutations located at codon 12, 13, and 61. Compared with the wild-type sequence of codons 12, 13, and 61 (GGT/GGC/CAA), one mutation was detected at codon 12 (Figure 1A) (GGT > GAT), one at codon 13 (Figure 1B) (GGC > GAC), and one at codon 61 (Figure 1A) (CAA > CAT).

The distribution of all the detected mutations is shown in Figure 2. The most frequently observed mutations were G-A transitions (30/41, 73.2%), followed by G-T transversions (8/41, 19.5%), two G-C transversions (2/41, 4.9%), and one A-T transversion (1/41, 2.4%). A total of 28 mutations were detected at codon 12 (wild-type GGT), representing four different mutational types. Two G-A transitions (2/28, 7.1%) were located at the first nucleotide of codon 12, resulting in an amino acid change from glycine (Gly) to serine, while the other base substitutions were all located at the second nucleotide of codon 12. The mutated GAT leading to an amino acid change from Gly to aspartic acid (Asp) (16/28, 57.1%) was the most frequently observed mutation. Eight patients were found to harbor a GTT mutation leading to an amino acid change from Gly to valine (Val) (8/28, 28.6%), while the other two patients harbored a GCT mutation (2/28, 7.1%), changing Gly to alanine. Twelve patients (12/118, 10.2%)

Figure 1 Pyrosequencing analysis of K-ras codons 12, 13, and 61 DNA sequences in colorectal cancer patients. The highlighted arrow shows the nucleotide change at the mutation site.

had detectable mutations at codon 13. The G-A transition was the only mutational type found, resulting in an amino acid change from Gly to Asp. Among all the 118 CRC patients, only one (1/118, 0.8%) had a detectable point mutation (A-T transversion) at codon 61, which resulted in an amino acid change from glutamine to histidine.

Correlation between K-ras gene mutations and clinicopathological features

As shown in Table 4, differences in the categorical vari-

ables, including age, gender, anatomical location of the tumor, tumor differentiation, TNM classification and UICC staging, between patients with and without K-ras mutations were evaluated for significance with χ^2 tests. Gender was the only variable that showed a significant relationship with K-ras gene mutation status. The prevalence of

Table 5 Relationship in K-ras mutation between gender and tumor location

	No. of K-ras mutated patients (%)		Total No. of patients
	Colon	Rectum

Female	5 (10.6)	16 (34)	47

**Figure 3** Kaplan-Meier survival curve in colorectal cancer patients with regard to K-ras gene codon mutations.

gene mutations was higher in female patients than in male patients (44.7% *vs* 28.2%, $P = 0.037$). The K-ras mutation frequency in the rectum was higher in female than in male patients (34.0% *vs* 11.2%, $P < 0.05$). Male patients had a higher mutation rate in the colon than female patients (16.9% *vs* 10.6%, $P < 0.05$) (Table 5).

Correlation of K-ras gene mutations with patient survival

As shown in Figure 3, patients with the wild-type K-ras gene had a median survival of 84.0 mo, which was a little longer than the patients with a mutated K-ras gene, whose median survival was 63.0 mo. However, this difference was not statistically significant (Figure 3A) ($P = 0.25$). The patients with a mutation at codon 12 and codon 13 had a median survival of 45.0 mo and 63.0 mo, respectively. The patient harboring a mutation at codon 61 had a rather long survival

**Figure 4** Pyrosequencing analysis of BRAF gene codon 600 DNA sequences in colorectal cancer patients. The highlighted arrow shows the nucleotide change at the mutation site.

of 73.0 mo. There were no significant correlations between the presence of K-ras mutations at codons 12, 13 and 61) and patient survival (Figure 3B).

Mutation characteristics of BRAF gene

Of the 118 CRC patients analyzed, only two patients (1.7%, 2/118) harbored a detectable mutation at codon 600 in exon 15 of the BRAF gene (Figure 4). Both mutations were T > A transitions (GTG > GAG) at codon 600, which resulted in an amino acid change from Val to glutamic acid (Glu). Both patients had a wild-type K-ras gene. One patient was a 70-year-old man with a moderately differentiated adenocarcinoma in the ascending colon at pathological stage of T3N1M0. The patient survived for 13 mo after the operation, but died of other diseases without evidence of tumor recurrence and metastasis. The other patient was a 56-year-old man. He was operated on for a well-differentiated adenocarcinoma in the transverse colon also at pathological stage of T3N1M0. Sixty-three months after operation, the patient died of tumor recurrence.

DISCUSSION

In this study, we detected various mutations of the K-ras and BRAF gene in 118 Chinese CRC patients using pyrosequencing. Mutations in the K-ras gene occurred very frequently (20%-50%) in CRC. It was reported in Western countries that approximately 90% of the activating K-ras mutations were found at codon 12 and codon 13 of exon 1, and about 5% at codon 61 located in exon 2. In domestic reports, with a limited number of samples, there was a similar mutation rate at codon 12 and 13, and a rather lower rate at codon 61 (0%-4.8%).

In our previous studies published in the 1990s, K-ras gene mutations were detected in 12 out of 35 (12/35, 34.3%) CRC patients by the PCR-RFLP method^[14]. Eleven out of the 12 detected mutations (11/35, 31.4%) were located at codon 12, while the other one was at codon 61 (1/35, 2.9%). None of the patients had a mutation at codon 13. Mutations were also found in the pericancer-

ous mucosa in some cases^[17], indicating that the *K-ras* gene might play an important role in the early stage of colorectal carcinogenesis. In the present study, a similar mutation rate was observed. Among the 118 patients in this study, the rates of mutated (41/118, 34.7%) and non-mutated (77/118, 65.3%) *K-ras* genes were similar to those reported by other countries. The *K-ras* mutation rates at codon 12, codon 13 and codon 61 were 23.7% (28/118), 10.2% (12/118) and 0.8% (1/118), respectively. Among all 41 mutations detected in *K-ras* gene in this study, 68.3% (28/41) were located at codon 12, 29.3% (12/41) at codon 13, and 2.4% (1/41) at codon 61. Similar to the previously reported data, G-A transitions were the most frequently found type of *K-ras* gene mutations in our study, followed by G-T transversions. Among the four different mutations detected at codon 12, Gly12Asp was the most frequent point mutation, accounting for about 40% of all mutations detected in the *K-ras* gene and 60% of all mutations at codon 12. All 12 point mutations detected at codon 13 were Gly13Asp. This base substitution accounted for 30% of all mutations detected in the *K-ras* gene. The distribution of the six different mutations (Figure 1) among the mutated patients was in concordance with the published data^[18]. These point mutations resulting in amino acid substitution would activate RAS proteins, produce an alteration in the transduction of signals in the RAS pathway and ultimately lead to increased mitogenic signaling.

It is widely accepted that mutations in the *K-ras* gene are early events in colorectal carcinogenesis. As described by Vogelstein *et al.*^[5], a *K-ras* gene mutation might happen in the progression from adenoma to carcinoma. Some studies have investigated the relationship between *K-ras* mutation and various clinicopathological parameters, but the results remain controversial. For example, it was reported by Zlobec *et al.*^[19] that *K-ras* mutations were associated with neither clinicopathological parameters, such as gender, age, tumor location, histological type, tumor T and N stage, tumor grade and vascular invasion nor survival time of patients. Naguib *et al.*^[20] reported a mutation rate of 22% in the *K-ras* gene (codon 12 and 13), and a positive relationship with more advanced Dukes' stage and microsatellite stable status. In the present study, we did not find any significant correlations between the presence of *K-ras* mutations at codons 12, 13, and 61 or mutation type and various clinicopathological features, such as age, anatomical location of the tumor, tumor differentiation, TNM classification, and UICC staging. Gender was the only variable that showed an obvious relationship with *K-ras* gene mutation, and suggested that female patients had a higher prevalence of gene mutation than male patients (44.7% *vs* 28.2%, $P = 0.037$). Breivik *et al.*^[7] demonstrated that *K-ras* mutations were much less frequent in colon samples from male patients compared with female patients at codon 12 and 13 in Western populations. However, we found that male patients had a higher mutation rate in colon samples than female patients in the Chinese population (16.9% *vs* 10.6%, $P < 0.05$). Ethnicity, environment, and lifestyle differences may explain the difference in *K-ras* mutation frequency in the colon between Chinese

and Western population. However, a larger population of Chinese patients is needed to confirm our findings.

Some studies have indicated the importance of *K-ras* alterations in predicting long-term outcome, while others have failed to show such a relationship. The collaborative RASCAL study reported a correlation between the specific *K-ras* mutation Gly12Val and poor prognosis, especially in Dukes' C CRC patients^[21]. The Gly12Val mutation at codon 12 reported by Al-Mulla *et al.*^[22] and the G > A mutation at codon 13 reported by Samowitz *et al.*^[18] both might be related to the poor survival of the patients. On the other hand, Tortola *et al.*^[23] and Dix *et al.*^[24] failed to prove a positive relationship between *K-ras* mutation and shorter survival. In our study, prognostic analysis for *K-ras* mutations showed that none of the *K-ras* mutations were predictive of patient survival. Patients with a wild-type *K-ras* gene had a median survival of 84.0 mo, which was slightly longer than patients with a mutated *K-ras* gene (63.0 mo); however, this difference was not statistically significant ($P = 0.25$). There was also no significant difference in survival between patients harboring a mutation at codon 12 and those at codon 13 (45.0 mo *vs* 63.0 mo, $P = 0.97$). The shorter survival in the patients reported by Al-Mulla *et al.*^[22] (Gly12Val mutations at codon 12) and by Samowitz *et al.*^[18] (G > A mutation at codon 13), was not observed in our study. A further study with a larger number of samples will hopefully confirm the results in this study.

The *K-ras*/BRAF/ERK signaling pathway plays an important role in colorectal carcinogenesis. Encoding a downstream molecule of *K-ras*, the *BRAF* gene (codon 600) is mutated in 12%-15.6% (45/374) of colorectal carcinomas^[19,20]. It was reported by Zlobec *et al.*^[19] that *BRAF* gene mutations are strongly associated with right-sided tumor location, higher tumor grade, absence of peritumoral lymphocytic inflammation, and microsatellite instability (MSI-H)^[19]. It was also reported that a mutated *BRAF* gene is an adverse prognostic factor in right-sided colon cancer patients independent of MSI status, and in patients with lymph node-negative disease^[19]. More recently, Richman^[25] showed that mutations in either KRAS or BRAF are factors for poor prognosis and the overall survival (OS), and have minimal impact on progression-free survival (PFS). The mutation status of either gene does not affect the impact of irinotecan or oxaliplatin on PFS or OS. To our knowledge, this is the first paper reporting mutations in the *BRAF* gene in a large population of Chinese CRC patients. In our study, only two mutations (1.7%, 2/118) at codon 600 in exon 15 of the *BRAF* gene were detected in 118 Chinese CRC patients. Both patients had a wild-type *K-ras* gene. The mutation rate was very low compared with that reported in Western studies. Both mutations were T to A transversions (GTG > GAG), resulting in an amino acid change from Val to Glu. Both patients were male, with a Dukes' C (T3N1M0) carcinoma at the right-side of the colon. Due to the limited mutations detected, it was impossible to analyze the correlation of *BRAF* gene mutations with various clinicopathological features or prognosis. There might be a few explanations for the low incidence of *BRAF* gene mutations in our study. First, we only ana-

lyzed mutations at codon 600 in exon 15 of the *BRAF* gene. Therefore, mutations at other sites (e.g. codons 463-468) might affect the result. Second, ethnic differences might exist in CRC between Chinese and Western populations. Liao *et al.*^[26] found that the *BRAF* mutation frequency was only 4.9% in 61 Chinese colorectal tissues, which is also lower than that in Western populations. Wójcik *et al.*^[27] screened for mutations in exons 11 and 15 of the *BRAF* gene in 163 resected adenocarcinomas in a Polish population and only six (3.7%) tumors had a missense point mutation (G469A, D594G, G596R, K601N, and two V600E). Future studies containing a larger number of Chinese samples are expected to further clarify the result.

In conclusion, the mutation of the *K-ras* gene was a common event in our 118 Chinese CRC patients, with an obvious relationship with gender. Female patients had a higher prevalence of gene mutation than male patients. *K-ras* gene mutation seemed not to be an independent prognostic factor in CRC patients. The *BRAF* gene was rarely mutated in Chinese CRC patients.

ACKNOWLEDGMENTS

The authors are grateful to Hang Zhang for her kind help in collecting the tumor samples and for the clinical information concerning the colorectal cancer patients. The authors would like to thank Wei-Ting Ge for his help with the DNA sequencing data analysis.

COMMENTS

Background

In recent years, the morbidity and mortality of colorectal cancer (CRC) has risen in the Chinese population. The *K-ras* and *BRAF* genes encode proteins that act in the extracellular signal-regulated kinase signaling pathway, which mediates cellular responses to growth factors and regulates the elements of the cell cycle, apoptosis and differentiation. Both *K-ras* and *BRAF* are prone to mutations in sporadic CRC. Mutations in *K-ras* could lead to constitutive activation of this pathway, resulting in cancer progression. Several recent studies have shown a strong correlation between *K-ras* and *BRAF* mutations and response to panitumumab and cetuximab.

Research frontiers

Results were in consistent among studies of the relationship between *K-ras* gene mutations and various clinicopathological characteristics. The prognostic significance of *K-ras* gene mutations is also controversial. With regard to the prognostic significance of the *BRAF* gene, less information is available in both Western and Chinese populations.

Innovations and breakthroughs

Recent reports have highlighted the importance of *K-ras* and *BRAF* gene mutations, the clinicopathological characteristics of CRC and its response to epidermal growth factor receptor-targeted therapies. Pyrosequencing is a powerful, sensitive and rapid sequencing method for single-nucleotide polymorphism (SNP)/mutation analysis. This is the first study to report mutations of *K-ras* and *BRAF* genes in a large population of Chinese CRC patients using pyrosequencing.

Applications

Using pyrosequencing technology, the authors found that *K-ras* gene mutations were common in Chinese CRC patients, with an obvious relationship with gender. The *BRAF* gene was rarely mutated in Chinese CRC patients.

Terminology

Pyrosequencing: Pyrosequencing is a method of determining the order of nucleotides in DNA based on the "sequencing by synthesis" principle. It relies on the detection of pyrophosphate release on nucleotide incorporation, rather than chain termination with dideoxynucleotides. It is a powerful, sensitive and rapid sequencing method and can be used for DNA SNP/mutation analysis.

Peer review

This paper presents new results on the frequency of *K-ras* and *BRAF* mutations in colorectal carcinomas of Chinese patients.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organizations]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:..., B:..., C:..., D:..., E:..., F:..., G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindIII*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

lated miRNA expression is involved in carcinogenesis at many sites, including the pancreas. Aberrant expression of miRNAs may upregulate the expression of oncogenes or downregulate the expression of tumor suppressor genes, as well as play a role in other mechanisms of carcinogenesis. The purpose of this review is to summarize our knowledge of deregulated miRNA expression in pancreatic cancer and discuss the implication for potential translation of this knowledge into clinical practice.

Abstract

Ductal adenocarcinoma of the pancreas is a lethal cancer for which the only chance of long-term survival belongs to the patient with localized disease in whom a potentially curative resection can be done. Therefore, biomarkers for early detection and new therapeutic strategies are urgently needed. miRNAs are a recently discovered class of small endogenous non-coding RNAs of about 22 nucleotides that have gained attention for their role in downregulation of mRNA expression at the post-transcriptional level. miRNAs regulate proteins involved in critical cellular processes such as differentiation, proliferation, and apoptosis. Evidence suggests that deregulated

INTRODUCTION

Pancreatic cancer is the fourth leading cause of cancer-related mortality in the United States, with 36 800 estimated deaths in 2010, with the great majority being due to ductal adenocarcinomas^[1]. Due to the asymptomatic onset of pancreatic cancer, most patients are in advanced or metastatic condition at the time of diagnosis, resulting in poor prognosis. Most patients found to have pancreatic cancer die within 12 mo, and few survive 5 years after diagnosis. The poor prognosis of these patients is due to its late clinical presentation with symptoms, early and aggressive local invasion, and high metastatic potential^[2]. Advances in chemo-radiation therapy have been slow over the last few decades, and the overall prognosis in pancreatic cancer has remained essentially unchanged. The only chance of long-term survival with pancreatic adenocarcinoma belongs to

patients with localized disease in whom a potentially curative resection can be performed. Earlier diagnosis and better treatments are urgently needed to improve the survival rate of pancreatic cancer.

Histologically, the pancreas is divided largely into the exocrine and endocrine pancreas, the former consists of ducts and acini, and the latter constitutes the islets that have a hormone secretory function. The most common type of pancreatic cancer, representing about 85% of all pancreatic cancer types^[3], arises from the epithelial lining of the exocrine pancreatic duct. Therefore, in this review, we mainly focus on miRNA expression in pancreatic ductal adenocarcinoma (PDAC).

Pancreatic cancer originates from the sequential accumulation of multiple genetic alterations^[4]. In the past several decades, significant progress in the identification and characterization of cancer-related gene abnormalities has been made. However, this progress has not yet been effectively translated into new reliable biomarkers that lead to the earlier diagnosis or more effective treatment of this deadly disease. Specific miRNAs affecting tumor suppressor genes or oncogenes may be critical biomarkers that lead to early detection, or potential drug targets for pancreatic cancer.

Although regulation of oncogenes and tumor suppressor genes, by genetic and epigenetic changes has been regarded as being important in the development of pancreatic cancer^[5-8], the exact molecular mechanisms of carcinogenesis and of pancreatic cancer progression remain unknown. Gene silencing is frequently caused by epigenetic changes, such as DNA methylation or altered miRNA expression rather than by genetic events such as mutation or deletion. miRNA binding at the 3' untranslated region (UTR) in tumor suppressor genes is an epigenetic change that may contribute to carcinogenesis and cancer progression. Although relatively few genetic mutations have been identified in PDAC, aberrant miRNA expression has been found in both pancreatic tumor tissues and cell lines.

BIOGENESIS, FUNCTION AND TARGETS OF miRNAs

miRNAs are about 22-nucleotide non-protein-coding RNA molecules that regulate gene function in various gene silencing pathways. These molecules are phylogenetically conserved and play important roles in cell survival, proliferation, differentiation, apoptosis and angiogenesis^[9,10]. miRNA expression patterns differ, depending upon cell, tissue, and disease types, and changes in these expression patterns have been implicated as an important player in carcinogenesis.

The miRNA, lin-4, was first discovered in 1993 as a small non-coding RNA that regulates *Caenorhabditis elegans* development by negative regulation of lin-14 protein expression^[11]. In 2000, the second miRNA, let-7, was identified from *C. elegans* and confirmed as a 21-nucleotide small RNA^[12]. Since the discovery of lin-4 and let-7, many more miRNAs have been identified using various experimental

and computational methods^[13]. In the most recent database (miRBase 15 release), over 15000 mature miRNAs are identified in 133 species^[14]. Although they do not encode proteins, miRNAs are transcribed by RNA polymerase II as independent units in the nucleus (Figure 1). The primary transcript (pri-miRNA) is processed by the nuclear RNase III Drosha and its cofactor DGCR8/Pasha to generate precursor miRNA (pre-miRNA), a 60-70-nucleotide RNA that has a stem loop structure^[15-17]. Pre-miRNA is rapidly exported to the cytoplasm by exportin 5 in a Ran-GTP-dependent manner, where it is further processed by a second RNase III, dicer, which cuts off the terminal loop and generates a mature about 22-nucleotide miRNA. Mature miRNA is initially part of an imperfect double-stranded RNA duplex called miRNA/miRNA*. This double-stranded RNA duplex binds to a protein (Argonaute 2) as a part of the RNA induced silencing complex (RISC), while the strand of the duplex that is complementary miRNA* is released. The RISC, containing its miRNA, binds to the target mRNA and triggers either mRNA degradation or inhibition of translation, depending on the degree of complementarity between miRNA and its target^[18-21].

Each miRNA regulates multiple target genes. In fact, bioinformatics predict that miRNAs may regulate about 50% of all human genes^[22]. Therefore, precise identification of miRNA targets is critical to advance our understanding of the role of miRNA regulation in carcinogenesis. Accurate identification of physiologically active miRNA targets is now a considerable impediment to the functional characterization of individual miRNAs.

miRNAs negatively regulate their target mRNAs primarily through base-pairing interactions, which leads to either mRNA degradation or translational inhibition depending upon the degree of match between the "seed sequence" (positions 2-7 at the 5' side) of miRNA and 3'UTR of mRNA (Figure 1). When the seed sequence perfectly or partially matches with target 3' UTR of mRNA, then it may lead to degradation of the mRNA or inhibit translation^[18-21]. Based upon publicly available algorithms, each miRNA has several hundred potential target mRNAs. Recent reports have further indicated that secondary structures of mRNA contribute to target recognition sites, due to the fact that there is energetic cost to free base-pairing interactions for accessible targets^[23-25]. Kertesz *et al.*^[26] have shown that target site accessibility is as important as sequence match in the seed sequence region, and that effective miRNA binding requires unpairing of local regions that flank the target, as well as that the target region is unpaired in thermodynamic equilibrium. Thus, simultaneous profiling of miRNA and mRNA, as well as protein expression, has recently been shown to be a timely strategy to achieve the required precision in the identification of functional miRNA targets^[27-30].

In summary, miRNAs regulate their targets by direct mRNA cleavage or translational inhibition. miRNAs are coded by genes and are transcribed by RNA polymerase II. They have their own regulatory elements and appear as transcriptional units containing either unique or multiple

Figure 1 Schematic representation of miRNA biogenesis. miRNA genes are transcribed by RNA polymerase II (RNA pol II) into long transcripts called primary miRNAs (pri-miRNA) that contain multiple stem-loop/hairpin structures as independent units in the nucleus. pri-miRNA is processed by the nuclear RNase III Drosha and its cofactor DGCR8/Pasha to generate precursor miRNA (pre-miRNA). The pre-miRNA is rapidly exported to the cytoplasm by exportin 5, where it is further processed by a second RNase III, Dicer, that cuts off the terminal loop and generates a mature about 22-nucleotide miRNA. The mature miRNA is an imperfect double-stranded RNA duplex called miRNA/miRNA*. The double-stranded RNA duplex binds to a protein (Argonaute 2) as a part of the RNA induced silencing complex (RISC), while one of the strands of the duplex, which is complementary miRNA*, is released. The RISC, which contains its miRNA, binds to the target mRNA and triggers either mRNA degradation or inhibition of translation, depending on the degree of complementarity between miRNA and its target.

miRNAs (polycistronic). Circumstantial evidence linking miRNAs and carcinogenesis has been observed in over 50% of miRNA genes, which are located within regions of loss of heterozygosity, amplification, fragile sites, viral integration sites, and other cancer-associated genomic regions. Recent high-throughput methodologies have shown deregulated miRNA expression in an increasing number of human cancers, including pancreatic cancer. Differences in miRNA expression patterns have been found to distinguish tumors of different developmental origin, even better than traditional mRNA expression profiling^[31].

miRNA AND HUMAN CANCER

The first evidence of miRNA involvement in human cancer came from a study that characterized chromosome 13q14 in chronic lymphocytic leukemia (CLL)^[32]. Calin *et al.*^[32] have shown that miR-15 and miR-16 are deleted or downregulated in about 70% of CLL cases. The tumor suppressive role of miR-15a and miR-16-1 has been supported further by the discovery that expression of both miRNAs inversely correlates with expression of the anti-apoptotic BCL2 protein^[33]. BCL2 expression is inhibited by miR-15a and miR-16-1 and these repressions induce apoptosis in leukemic cells. These data suggest a model whereby somatic deletions of miR-15a and miR-16-1 aid leukemogenesis by allowing tumors to escape apoptosis.

Since this first report of aberrant miRNA expression in CLL, deregulation of a number of miRNAs has been found in other human cancers. While some miRNAs, including miR-125b and miR-145 in breast cancer, and let-7 in lung cancer, are reduced, others such as miR-21 and miR-155 in breast cancer, miR-155 in lung cancer, the precursor of miR-155 in Burkitt lymphoma, miR-17-92 cluster and miR-155 in B-cell lymphoma, are overexpressed^[31,34-39]. These studies also have shown that miRNA expression signatures correlate well with specific clinical cancer characteristics, and could be used to differentiate normal and cancerous tissues, as well as subtypes of malignancy^[40-43].

Deregulation of miRNA in cancer could be caused by: (1) chromosomal regional gain, loss or translocation; (2) aberrant expression and activation of transcriptional factors; (3) epigenetic alterations; and (4) changes in miRNA processing^[44]. As described above, the association between chromosomal abnormality and miRNA expression in CLL is due to downregulation of the miR16-1/15a cluster in chromosome 13q14.3^[32]. In contrast, upregulation of miR-155 in tumor appears to be due to transcriptional regulation and aberrant miRNA processing^[36,45]. miR-155 is encoded in non-coding DNA known as BIC (B-cell integration cluster), located at chromosome 21q21.3, where neither amplification nor loss of heterozygosity is observed. Several studies have shown that miR-155 is in-

duced at the transcriptional level by transforming growth factor β /Smad, nuclear factor- κ B and activator protein-1 family transcription factors through direct interaction with the miR-155/BIC promoter^[46-48]. Further studies have shown that miR-155 processing also regulates mature miR-155 expression levels^[36,45], suggesting that overexpression of miR-155 in cancer is due to transcriptional activation and miRNA processing.

miRNA EXPRESSION PROFILE IN NORMAL PANCREATIC TISSUE AND PANCREATIC TUMOR

miRNA expression profiles in pancreatic tumor tissues are different from those identified in normal pancreas or in chronic pancreatitis. Most miRNA expression profile analyses show that miRNAs are deregulated in tumor tissues as compared to normal pancreas, and that the expression pattern is tissue specific. Several studies focusing on miRNA expression profiles in pancreatic tissues have identified a number of differentially expressed miRNAs. Table 1 summarizes the aberrantly expressed miRNAs in human pancreatic cancer and their association with patient survival.

Szafranska *et al*^[50] have performed the first comprehensive miRNA expression profile study in tissues from normal pancreas ($n = 7$), chronic pancreatitis ($n = 7$), PDAC ($n = 10$) and 33 human tissues of different non-pancreatic origin, to identify miRNA candidates with a potential for future clinical application from a pool of 377 known and novel miRNAs. The authors have found that two miRNAs, miR-216 and miR-217, are pancreas-specific. These results were in agreement with those of two previous studies^[58,59]. Furthermore, both miR-216 and miR-217 are absent or only minimally expressed in pancreatic carcinoma tissues and cell lines. Therefore, miR-216 and miR-217 are potential biomarkers. Based upon clustering analysis, the three pancreatic tissues types can be classified according to their respective miRNA expression profiles. Among 26 miRNAs that have been identified as most prominently deregulated in PDAC, only miR-217 and miR-196a have been found to discriminate between normal pancreas, chronic pancreatitis and tumor tissues. These miRNAs are also potential biomarkers.

Recently, expression of 201 miRNA precursors (representing 222 miRNAs) was profiled in pancreatic adenocarcinoma, paired with benign tissue, normal pancreas, chronic pancreatitis and pancreatic cancer cell lines with the real-time PCR miRNA array^[49]. These three cell types could be classified by the clustering algorithm. One hundred miRNA precursors have been identified as aberrantly

expressed miRNAs including known ones in other cancers and novel ones in pancreatic tumor. A list of the top 20 aberrantly expressed miRNA precursors has been proposed as a signature for pancreatic adenocarcinoma.

Bloomston *et al.*^[51] have identified a large global expression pattern of miRNAs that can differentiate PDAC from chronic pancreatitis with 93% accuracy. Among several deregulated miRNAs in the pancreatic cancers, most notably, miR-21 and miR-155 are uniquely overexpressed in pancreatic tumor, as compared to tissues from normal pancreas and chronic pancreatitis. Both miR-21 and miR-155 have been suggested to play an important role in functioning as a proto-oncogene and have been shown to be overexpressed in several cancers. These authors have performed an miRNA microarray profiling with about 1100 miRNA probes, which included 326 human miRNAs, using microdissected pancreatic tumor tissues.

Zhang *et al.*^[52] have evaluated 95 miRNAs, selected from pancreatic cancer profiling, and correlated them to their potential biological functions related to cancer biology, cell development, and apoptosis. Among them, eight miRNAs (miR-196a, miR-190, miR-186, miR-221, miR-222, miR-200b, miR-15b, and miR-95) are differentially expressed in most pancreatic cancer tissues and cell lines. All of these eight genes are significantly unregulated, from 3- to 2018-fold, in pancreatic tumors as compared with normal control samples.

In summary, these profiling data may provide novel insights into the miRNA-driven mechanisms involved in pancreatic carcinogenesis, and offer new potential targets for early detection and therapeutic strategies in pancreatic cancer.

miRNAs AS BIOMARKERS FOR PANCREATIC CANCER DIAGNOSIS

Development of biomarkers for pancreatic cancer is especially critical because most patients with this disease remain asymptomatic until the disease progresses to become locally advanced or develops distant metastases. Therefore, most of these patients are surgically inoperable at the time of diagnosis. Sensitive and specific biomarkers for pancreatic cancer are urgently needed to offer better therapeutic options and survival outcome.

Over the years, a number of protein- and DNA-based biomarkers have been proposed as markers of early detection for pancreatic cancer. However, most of these markers fail to have clinical potential, and they have not influenced patients' survival. Since the first discovery of miRNAs by Lee *et al.*^[11] in 1993, many researchers have investigated expression profiles, biological functions and targets of miRNAs in carcinogenesis and tumor progression, with the purpose of translating the results to clinical settings.

Endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) of the pancreas is not likely to be used routinely for screening for PDAC because of its invasive na-

ture. However, this procedure has recently emerged as a specific and minimally invasive modality for preoperative diagnosis and staging of pancreatic cancer. Furthermore, EUS-FNA may also be useful for screening high-risk individuals, as well as for the prognosis and predicting the response to treatment in cases in which the tumor is inoperable^[60-62]. Szafranska *et al.*^[63] have identified potential miRNA markers in EUS-FNA biopsies of pancreatic tissue. The combination of expression pattern of miR-196a and miR-217 can differentiate PDAC cases from healthy controls and chronic pancreatitis in the FNA samples. Furthermore, miR-196a expression is likely specific to PDAC cells and is positively associated with the progression of PDAC.

Carcinogenesis in PDAC develops with a multistep progression from morphologically distinct non-invasive precursor lesions within exocrine pancreatic ducts^[64]. These precursors include the intraductal papillary mucinous neoplasms (IPMNs), the mucinous cystic neoplasms, and pancreatic intraepithelial neoplasia (PanIN). Two studies have been carried out to detect expression patterns of miRNA in IPMNs and PanIN. IPMNs are grossly visible, non-invasive, mucin-producing precursors of pancreatic cancer within the main pancreatic duct or one of its branches^[65,66]. In contrast, PanINs are non-invasive, microscopic epithelial neoplasms, arising within smaller pancreatic ducts, < 5 mm in diameter, and characterized by cytological and architectural atypia^[65,67]. Habbe *et al.*^[68] have reported significant overexpression of 10 miRNAs in IPMNs ($n = 15$). miR-155 and miR-21 show the highest relative fold-changes in the precursor lesions. These results have been validated by *in situ* hybridization analysis. miR-155 and miR-21 are upregulated in most IPMNs [83% (53/64) and 81% (52/64)] as compared to normal ducts [7% (4/54) and 2% (1/54)]. With these promising data, the potential use of these miRNAs as biomarkers has been evaluated in pancreatic juices. A total of 15 pancreatic juice samples from 10 patients with IPMNs, and five with other pancreatobiliary disorders obtained at the time of surgical resection were measured for relative levels of miR-155 and miR-21 by quantitative real-time RT-PCR. Upregulation of both miR-155 and miR-21 in the subset of IPMN-associated pancreatic juices was observed, as compared with control samples. These results indicate that aberrant miRNA expression occurs early in the precursor lesion during the multiple stages of pancreatic cancer development, and miRNA profiles may be assessed with more accessible clinical samples, such as pancreatic juice, and could be used as a diagnostic tool.

du Rieu *et al.*^[69] have investigated miRNAs in PanIN tissues from a conditional Kras (G12D) mouse model ($n = 29$) and from human origin ($n = 38$). Expression of miR-21, miR-205 and miR-200 has been found to be positively associated with PanIN progression in the Kras (G12D) mouse model. In the human tissues, expression of miR-21, miR-221, miR-222 and let-7a increases with PanIN grade. The authors, using *in situ* hybridization analysis, have observed that miR-21 expression is concen-

Table 2 miRNAs and their targets involved in human pancreatic cancer

miRNA	Function	Targets	Related cellular events	Ref.
let-7	Suppress	RAS ^[71]	Inhibit cell proliferation, KRAS expression, and mitogen-activated protein kinase activation	[53]
let-7, miR-200	Suppress		Reverse EMT	[72]
Let-7a	Suppress	RAS	Attenuate KRAS expression and radiosensitize tumor cell	[73]
miR-10a	Oncogenic	HOXB1, 3	Promote metastatic behavior	[54]
miR-21	Oncogenic		Induce cell proliferation, invasion, chemoresistance	[56]
miR-21	Oncogenic		Potentially associated with cell proliferation	[74]
miR-200c	Suppress		Potentially associated with G0/G1 arrest and increased apoptotic rate	
miR-21, miR-221	Oncogenic	PTEN, RECK, CDKN1B	Arrest cell cycle, induce apoptosis, and sensitize the effects of gemcitabine with inhibition of miR-21 or -221	[75]
miR-22	Suppress	SP1, ESR1	Potentially inhibit tumorigenesis	[76]
miR-34	Suppress	BCL2, NOTCH1/2	Inhibit clonogenic cell growth and invasion, induce apoptosis and G1 and G2/M arrest in cell cycle, sensitize to chemotherapy and radiation, and potentially inhibit pancreatic cancer stem cells	[77]
miR-107	Suppress	CDK6	Induce in vitro cell growth downregulation	[78]
miR-155	Oncogenic	TP53INP1	Inhibit apoptosis	[79]
miR-194, miR-200b, miR-200c, miR-429	Oncogenic	EP300	Potentially promote metastatic behavior	[80]
miR-224, miR-486	Oncogenic	CD40	Potentially associated with invasion and metastasis	[81]

BCL2: B-cell CLL/lymphoma 2; CD40: CD40 molecule; CDK6: Cyclin-dependent kinase 6; CDKN1B: Cyclin-dependent kinase inhibitor 1B; EP300: E1A binding protein p300; ESR1: Estrogen receptor 1; HOXB1, 3: Homeobox B1, 3; KRAS: v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog; NOTCH1/2: Notch 1/2; PTEN: Phosphatase and tensin homolog; RECK: Reversion-inducing-cysteine-rich protein with kazal motifs; SP1: Sp1 transcription factor; TP53INP1: Tumor protein p53 inducible nuclear protein 1; EMT: Epithelial-to-mesenchymal transition.

trated in the dysplastic ductal epithelial cells. Using PDAC-derived cell lines, they also have noted that miR-21 expression is regulated by Kras (G12D) and epidermal growth factor receptor (EGFR).

Wang *et al.*^[70] have studied plasma samples from patients with PDAC and have found that four miRNAs (miR-21, miR-210, miR-155 and miR-196a) are able to differentiate pancreatic cancer patients from healthy controls, with moderate accuracy (sensitivity: 64%, and specificity: 89%). In summary, these studies suggest a potential value of miRNAs in the clinical setting as a potential diagnostic tool for PDAC.

miRNAS AS ONCOGENES AND TUMOR SUPPRESSORS

miRNAs are functionally classified into oncogenes or tumor suppressors based upon their targets, thus binding to oncogenes or tumor suppressor genes. Therefore, oncogenic miRNAs are upregulated in tumors, whereas tumor suppressor miRNAs are downregulated. The functions and targets of a handful of miRNAs have been investigated in pancreatic cancer (Table 2).

Torrisani *et al.*^[53] have reported that tumor suppressor let-7 miRNA is expressed in normal acinar pancreatic cells, but is extensively downregulated in PDAC samples, as compared with adjacent non-involved tissues. Transfection of pancreatic cancer cell lines with let-7 miRNA inhibits cell proliferation, Kras expression, and mitogen-activated protein kinase activation. This study has demonstrated that intracellular restoration of let-7 miRNA reverts neoplastic characteristics of PDAC, suggesting that let-7 miRNA functions as a tumor suppressor in pan-

creatic cancer. In addition, the results of this study suggest let-7 miRNA as a replacement therapy for pancreatic cancer.

miRNAS AS THERAPEUTIC TARGETS IN PANCREATIC CANCER

Most epithelial tumors, including pancreatic cancer, are believed to progress toward loss of epithelial differentiation and acquisition of a mesenchymal phenotype that leads to enhanced cancer cell invasion and migration^[82,83]. The aggressiveness of pancreatic cancer is, in part, due to its drug resistance characteristics, which are also associated with the epithelial-to-mesenchymal transition (EMT). Several studies have shown that the events leading to EMT are regulated by miRNAs^[84-89]. Li *et al.*^[72] have investigated the effects of let-7 and miR-200 on the morphological changes of EMT in gemcitabine-resistant pancreatic cancer cells (GRPCCs). They have found that: (1) the expression of miR-200 and let-7 is significantly downregulated in GRPCCs, which have EMT characteristics; and (2) transfection of GRPCCs with miR-200 rescues the epithelial phenotype by upregulating the epithelial marker E-cadherin and downregulating the mesenchymal markers ZEB1 and vimentin. These authors also have demonstrated that tumor cell sensitivity to gemcitabine is increased after re-expression of miR-200b. These results suggest that EMT could be regulated by miRNAs, and provide a potential strategy for treatment.

RAS mutations are frequent in human tumors and are known to be one of the responsible factors for radiation-induced cell death^[90,91]. Using transfection of Lin28 siRNA into pancreatic cancer cells harboring Kras mutation,

Oh *et al*^[73] have shown that upregulation with let-7a results in attenuated expression of Kras and increased radiosensitization of pancreatic cancer cells. This suggests that miRNA could be used as a valuable therapeutic option in radioresistant tumors that have Kras mutations.

The main reason for poor survival in pancreatic cancer is the presence of metastasis at the time of diagnosis. Weiss *et al*^[54] have shown that miR-10a expression promoted metastasis, and repression of miR-10a inhibited invasion and metastasis in xenotransplantation experiments using zebrafish embryos. They have further identified tumor suppressors HOXB1 and HOXB3 as targets of miR-10a, and have reported that retinoic acid receptor antagonists inhibit miR-10a expression and suppress metastasis. These data suggest new therapeutic applications for miRNA in patients with metastatic pancreatic cancer.

Several studies have reported significant overexpression of miR-21 in pancreatic tumors^[49,51], suggesting the potential role of miR-21 in pancreatic cancer. Moriyama *et al*^[50] have confirmed that miR-21 is overexpressed in pancreatic cancer cells. They also have observed that miR-21 contributes to cell proliferation, invasion, and chemoresistance. They also have found that mRNA expression of invasion-related genes, matrix metalloproteinase (MMP)-2 and MMP-9, and vascular endothelial growth factor is positively correlated with miR-21 expression. The above studies show that miR-21 functions as an oncogene, and that it is involved in pancreatic cancer chemoresistance. Therefore, miR-21 could be a target for a therapeutic strategy for patients with chemoresistant pancreatic cancer.

Zhang *et al*^[74] have found that pancreatic cancer cells treated with trichostatin A (TSA), one of the common histone deacetylase inhibitors^[92,93], are arrested in G0/G1 phase, and exhibit an increased in apoptotic rate. The treatment also induces downregulation of miR-21 and upregulation of miR-200c. The data support the oncogenic function of miR-21, and the tumor suppressor function of miR-200, suggesting that epigenetic regulation of miRNAs with histone deacetylase inhibitor could be used as a therapeutic option in pancreatic cancer.

It has been shown that antisense oligonucleotides (ASOs) can inhibit upregulated miRNAs in tumors^[94]. Park *et al*^[75] have investigated miR-21 and miR-221 biological function using ASOs in pancreatic cancer. ASOs for miR-21 and miR-221 both reduce proliferation of pancreatic cancer cell lines, increase apoptosis by 3-6-fold, and induced G1 arrest. ASOs also increase the levels of the miR-21 targets PTEN and RECK, and the miR-221 target, CDKN1B, at the protein level. The authors have found that ASO targeting of miR-21 and miR-221 sensitizes tumor cells to the effects of gemcitabine, and that ASO-gemcitabine combination treatments generate synergistic antiproliferative effects in pancreatic cancer cells. These results imply that targeting miRNAs with ASOs could be a potential new therapeutic strategy for pancreatic cancer.

In vitro and *in vivo* studies have reported the anticancer activity, with low toxicity, of curcumin (diferuloylmethane)^[95,96], a naturally occurring flavonoid from the rhizome of *Curcuma longa*^[97,98]. Sun *et al*^[76] have investigated whether

curcumin affects the expression profiles of miRNAs in pancreatic cancer, and have reported overexpression of miR-22 and downregulation of miR-199a* in pancreatic cancer cells treated with curcumin. The predicted target genes of miRNA-22 are Sp1 transcription factor (SP1) and estrogen receptor 1 (ESR1). The expression of these genes (SP1 and ESR1), which are involved in cell growth, metastasis and apoptosis, is suppressed by upregulation of miR-22. Thus, Sun *et al* have suggested that one of the important anticancer mechanisms of curcumin is modulation of miRNA expression, such as miR-22.

Some cancer stem cells are involved in tumor initiation, self-renewal and survival^[99], and miRNAs have been shown to have critical roles in cancer stem cell differentiation. Ji *et al*^[77], using cell sorting of CD44⁺/CD133⁺, have examined the roles of miR-34 in p53-mutant human pancreatic cancer cell lines, to find a potential link between stem cells and pancreatic cancer. These authors have observed that miR-34 upregulation results in significant inhibition of clonogenic growth and cell invasion, induction of apoptosis, G1 and G2/M cell cycle arrest, and sensitization of the cells to chemotherapy and radiation. They also have detected an 87% reduction in tumor initiating cells (or cancer stem cells), which was mediated by downregulation of its downstream targets BCL2 and NOTCH. This study has shown that restoration of miR-34 could have significant promise as a novel molecular therapy for human pancreatic cancer *via* inhibiting pancreatic cancer stem cell differentiation.

Aberrations in epigenetic regulation are common in human cancers, and tumor suppressor genes are frequently silenced by this mechanism in nearly all malignancies^[100,101]. Recent studies have shown that subsets of miRNAs are also silenced by the same mechanism^[102,103]. For example, Lee *et al*^[78] have shown that miR-107 is silenced by promoter DNA methylation in pancreatic tumors. These authors treated human pancreatic cancer cell lines with the demethylating agent, 5-aza-2'-deoxycytidine or the histone deacetylase inhibitor, TSA, or with a combination of the two, and identified the upregulation of 14 miRNAs, including miR-107. Retroviral expression of miR-107 in pancreatic cancer cells downregulates *in vitro* cell growth by repressing cyclin-dependent kinase 6, a putative miR-107 target. This study shows that epigenetic mechanisms of miRNA may be involved in pancreatic carcinogenesis.

Tumor protein p53 inducible nuclear protein 1 (TP53-INP1) is a pro-apoptotic stress-induced gene. TP53 is able to activate TP53INP1 transcription as a target^[104,105]. However, overexpression of TP53INP1 induces cell cycle arrest and apoptosis *in vitro*, independently from TP53. Gironella *et al*^[79] have reported that TP53INP1 is expressed in normal tissues but is markedly downregulated or lost in early stages of pancreatic cancer development. TP53INP1 repression by transfection of miR-155 causes loss or significant decrease in expression of TP53INP1. These data suggest that TP53INP1 is an additional potential target of miR-155.

Several studies have suggested that EP300 may func-

tion as a tumor suppressor. This gene is located on chromosome 22q; a region known for its frequent loss of heterozygosity in different cancers, including pancreatic cancer^[106-109]. Mees *et al.*^[80] have classified 16 human PDAC cell lines into three hierarchical groups according to their metastatic potential, and have profiled their mRNA and miRNA expression. The highly metastatic PDAC cell lines, when compared to the non-metastatic cell lines, have shown decreased mRNA and protein expression of EP300, which is related to significant upregulation of EP300-targeting miRNAs (miR-194, miR-200b, miR-200c and miR-429). Using the same 16 human PDAC cell lines, these authors have found markedly reduced expression of CD40 protein, which is involved in the host antitumor immune response^[110,111]. CD40-targeting miR-224 and miR-486 are upregulated in the highly invasive and metastatic PDAC^[81]. These results show that miRNAs are involved in regulating the metastatic behavior of PDAC, and in modulating metastasis-specific tumor suppressor genes. Targeting of these miRNAs may have potential therapeutic value in PDAC.

miRNAS AS CLINICAL ASPECTS IN PANCREATIC CANCER

Most tumors show deregulation of miRNAs for the initiation and progression of human cancer, therefore, many researchers have been trying to exploit these miRNAs for therapeutic applications, and to develop novel therapies for human cancer^[112-115]. Thus, oncogenic miRNAs can be suppressed with ASOs to their precursor or mature forms^[94,116], and tumor suppressor miRNAs can be up-regulated^[53,72].

Numerous miRNA studies have demonstrated that miRNA-directed targeting therapy has therapeutic potential in human cancer. Recent studies have further demonstrated synergistic effects when miRNA-directed therapy is used in combination with conventional chemotherapy or radiotherapy for pancreatic cancer^[73,75]. However, currently, there is no miRNA that is used in the clinical setting for treatment of cancer patients. Significant work needs to be done before miRNA-directed therapeutic strategies can be applied. However, current data have shown encouraging preliminary results to support their clinical applications in human cancer.

Several investigators have attempted to utilize miRNA expression profiles as a diagnostic tool to differentiate tumors from normal tissues^[43,117,118], and as predictors of clinical outcome. However, there have not been sufficient studies that have investigated the correlation between alterations in miRNA expression and patient outcome in PDAC.

A few miRNA expression patterns have been investigated to predict prognostic outcome from specimens of patients with pancreatic cancer^[51,55,57]. Bloomston *et al.*^[51] have analyzed the association between survival of patients and miRNA expression patterns. In the subgroup analysis of patients with lymph-node positive disease, a

panel of six miRNAs (miR-452, miR-105, miR-127, miR-518a-2, miR-187 and miR-30a-3p) was able to differentiate between long-term survivors and short-term survivors who died within 2 years. Furthermore, high expression of miR-196a-2 is associated with poor outcome; patients with high miR-196a-2 expression have a shorter median survival of 14.3 mo when compared with patients with low miR-196a-2 expression, who have a median survival of 26.5 mo.

Dillhoff *et al.*^[55] have performed *in situ* hybridization after microdissection and tissue microarray analysis of 80 resected pancreatic cancer specimens, and found 79% of the pancreatic cancer samples, 27% of the chronic pancreatitis samples, and 8% of the normal pancreatic samples had positive miR-21 expression. Among the subset of patients with node-negative disease, high miR-21 expression resulted in poorer survival than in patients with low miR-21 expression (median: 27.7 mo *vs* 15.2 mo, *P* = 0.037), although miR-21 expression did not correlate with tumor size, differentiation, nodal status, or T stage.

Greither *et al.*^[57] have measured the levels of miR-155, miR-203, miR-210, miR-216, miR-217 and miR-222, which are known to be differentially expressed in pancreatic tumors. From 56 microdissected PDACs, they found that elevated levels of miR-155, miR-203, miR-210 and miR-222 were associated with poorer overall survival rates. They further noted that higher expression of all four miRNAs had a 6.2-fold increased risk of tumor-related death as compared to cases in which the expression of these miRNAs was low.

CONCLUSION

Since the discovery of miRNAs, growing evidence has confirmed a link between miRNAs and malignant diseases, and has identified their functions and targets that affect the complex process of carcinogenesis. Like other malignant tumors, PDAC has its unique miRNA expression patterns, which are different from those of other human tumors, and are able to differentiate normal pancreas from benign inflammatory pancreatic tissues and pancreatic cancer. At present, several important oncogenic and tumor suppressor miRNAs, and their molecular targets, have been identified in PDAC. More importantly, this information will lead to new development of prognostic, diagnostic, and treatment strategies. However, additional studies are required to find ways to utilize miRNAs as a therapeutic target in the clinical setting.

Abstract

Management of rectal cancer has evolved over the years. In this condition preoperative investigations assist in deciding the optimal treatment. The relation of the tumor edge to the circumferential margin (CRM) is an important factor in deciding the need for neoadjuvant treatment and determines the prognosis. Those with threatened or involved margins are offered long course chemoradiation to enable R₀ surgical resection. Endoanal ultrasound (EUS) is useful for tumor (T) staging; hence EUS is a useful imaging modality for early rectal cancer. Magnetic resonance imaging (MRI) is useful for assessing the mesorectum and the mesorectal fascia which has useful prognostic significance and for early identification of local recurrence. Computerized tomography (CT) of the chest, abdomen and pelvis is used to rule out distant metastasis. Identification of the malignant nodes using EUS, CT and MRI is based on the size, morphology and internal characteristics but has drawbacks. Most of the common imaging techniques are suboptimal for imaging following chemoradiation as they struggle to differentiate fibrotic changes and tumor. In this situation, EUS and MRI may provide complementary information to decide further treatment. Functional imaging using positron emission

tomography (PET) is useful, particularly PET/CT fusion scans to identify areas of the functionally hot spots. In the current state, imaging has enabled the multidisciplinary team of surgeons, oncologists, radiologists and pathologists to decide on the patient centered management of rectal cancer. In future, functional imaging may play an active role in identifying patients with lymph node metastasis and those with residual and recurrent disease following neoadjuvant chemoradiotherapy.

INTRODUCTION

Nearly one million patients are diagnosed with colorectal cancers (CRC) annually in the world^[1]. The incidence of CRC is highest in the western world where it is the second commonest cause of cancer death and fourth commonest cause of death from cancer worldwide^[2]. In the western world there is a life time risk of CRC of 5%. Overall the 5 year survival has improved in the UK (55% in males and 51% in females) but to a lesser extent than in the USA and Europe^[3].

Around 30%-40% of colorectal cancer is defined to arise from the rectum which is defined as the distal margin of tumor within 15 cm of the anal verge^[4,5].

Colonoscopy and biopsy is considered as the gold

standard investigation to confirm the diagnosis of rectal cancer and to exclude synchronous lesions. Patients are then staged to assess the extent of local disease and to identify the distant spread.

Traditional rectal cancer surgery is associated with high rates of local recurrence of 5%-20%^[9]. However, with the combination of high quality surgery using total mesorectal excision^[7] along with use of neoadjuvant and adjuvant treatment there has been a significant reduction in local recurrence and improved survival^[8]. The surgeon aims to achieve a microscopic tumor free (R₀) resection. Despite this, there is a risk of local failure. Careful preoperative assessment of the pelvis identifies high risk patients in whom the resection margins are either involved or within 1 mm of the mesorectal fascia. Involvement or threatened CRM (tumors within 1 mm of the mesorectal fascia) have a reduced chance of obtaining complete clearance. Thus, the status of the CRM has become more important than the TNM staging. In Europe and the UK, patients with involved CRM/threatened CRM are considered for long course chemoradiation prior to surgery.

IMPORTANCE OF PREOPERATIVE STAGING IN RECTAL CANCER

Accurate pre-operative staging of rectal cancer is crucial in planning the surgical treatment and is the strongest predictor for recurrence^[9]. The staging helps us to formulate a structured multidisciplinary management care plan and assess the prognosis. It is also used to compare the results of hospitals offering rectal cancer treatment and to define the role of different treatment modalities.

Preoperative staging of rectal cancer can be divided into either local or distant staging. Local staging incorporates the assessment of mural wall invasion, circumferential resection margin involvement, and the nodal status for metastasis. Distant staging assesses for evidence of metastatic disease.

Rectal cancer is palpable in 40%-80% of cases^[10]. Digital rectal examination helps in documentation of the size, location, distance from the anal verge, and fixity. Lesions felt by digital rectal examination can be visualized using a rigid proctoscope. The procedure allows an accurate localization and assessment of the tumor including fixity. Biopsies can be carried out where necessary. Rectal examination using proctoscopy may be considered as an important tool for newly diagnosed rectal cancers. Painful local perineal and anal conditions such as fissures or abscesses can restrict the use of this excellent tool. A trial comparing the use of CT virtual proctoscopy with rectal ultrasound examination in determining the stage of rectal cancer is being conducted in the USA and its results are awaited (<http://clinicaltrials.gov/ct2/show/NCT00585728>).

Currently, several modalities exist for the preoperative staging of rectal cancer. A combination of modalities involving use of computed tomography (CT), magnetic resonance imaging (MRI), and/or endorectal ultrasonography (EUS) is used to precisely assess the extent of spread of rectal cancer. The choice of investigations performed,

however, is influenced by local expertise, guidelines and availability. Imaging in rectal cancer plays a crucial role in optimizing radiotherapy target definition to avoid adjacent vital structures^[11]. EUS and MRI of the pelvis are used to assess the local spread while CT is the main modality to assess systemic spread. PET is indicated when there is clinical, biochemical or radiological suspicion of local recurrence or systemic disease.

Computerized tomography and computerized tomography colonography or virtual colonoscopy

CT scan of the entire chest, abdomen and pelvis is used for the detection of metastatic disease. CT is widely available and has faster acquisition times. However, it is not considered as the investigation of choice when it comes to assessing the layers of the rectal wall; hence it is not useful for local staging in rectal cancer and certainly is poor at evaluating superficial rectal cancers. The accuracy of CT to assess the tumor has been reported to be between 80%-95% in patients with advanced local disease^[12]. The accuracy, however, decreased to around 63% when a broader spectrum of tumor sizes was analyzed. Sensitivity to pick up nodal disease has been found to be between 55%-70%^[13]. In a meta-analysis involving 5000 patients, CT showed an accuracy for T staging of 73% and for nodal staging of 22%-73%^[14].

The use of contrast enhanced multidetector CT colonography has improved the staging accuracy^[15], by achieving superior spatial resolution and visualizing pictures in a variety of planes. However, its role in staging remains to be determined and currently it is used mainly to assess the distant metastatic disease (Figure 1A and B).

Virtual colonoscopy or CT colonogram (CTC) has been reported to be safer than colonoscopy^[16] while being more sensitive than barium enema, and appears to be more acceptable to patients than either of the other tests^[17]. The procedure can be performed by technicians thus saving clinicians time. In principle the data could be analysed by computer-assistance thus accelerating diagnosis time^[18]. The results of the SIGGAR trial evaluating CTC versus colonoscopy or barium enema in symptomatic elderly patients are awaited^[19]. CTC is the best radiological imaging for assessing the colon and rectum and at the same time identifies nodal disease and distant metastasis. The diagnosis of rectal cancer still needs to be confirmed by colonoscopy and biopsy.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is routinely used for preoperative staging of rectal cancer as it provides an accurate assessment of the tumor and the surrounding mesorectal fascia. It identifies patients at risk of local recurrence and those likely to benefit from neoadjuvant therapy. When compared with CT and ultrasound, MRI is more reliable for the evaluation of the extent of locoregional disease, planning radiation therapy, assessing postoperative changes and pelvic recurrence. The evaluation of nodal metastases remains a challenge with MRI (Figure 2).

Earlier MRI studies used body coils which lacked the

Figure 1 Computerized tomography. A: Computerized tomography (CT) abdomen showing a patient with rectal cancer having liver metastasis and ascites; B: CT Chest showing a patient with rectal cancer having lung metastasis.

Figure 2 Coronal magnetic resonance imaging (arrow) showing possible lymph node or early vascular involvement.

resolution to differentiate the different layers of the rectal wall and added no advantage to conventional CT^[20]. Subsequent use of phased-array coils permitted reliable identification of the mesorectal fascia which is crucial in the management of rectal cancer^[21]. Initial studies suggested a histological clearance of at least 10 mm could be accurately predicted when the radiological clearance from the mesorectal fascia and critical structure was at least 5 mm^[22]. Subsequent single centre study showed 92% accuracy in prediction of CRM involvement when the CRM cutoff of 1 mm was used and this is now confirmed from the multicentre European MERCURY study^[21,23]. In Europe, MRI is now routinely used in the preoperative investigation for rectal cancer. Techniques for obtaining optimal

Figure 3 Magnetic resonance imaging (arrow) showing possible extension beyond the muscularis propria, radiologically staged as early T₃.

Figure 4 Coronal T2 W magnetic resonance imaging (arrow) showing the intact muscularis propria in a patient with rectal cancer. Radiologically staged as T₁ or T₂.

MRI images are described in the literature^[24]. An axial picture enables identification of the distance of the CRM to the tumor. Coronal sections are useful in low rectal tumors to identify the relation to anal sphincter complex, pelvic floor, and pelvic side wall^[25]. High signal intensity of the tumor on T2 w images suggest the presence of mucinous carcinoma which has poor prognosis compared to non-mucinous carcinoma^[26]. The standard phased array MRI produces good quality images with good contrast resolution and a relatively large field of view. Routine use of intravenous contrast does not appear to improve the accuracy^[27]. MRI cannot differentiate between T₂ and early T₃ lesions; a nodular or rounded advancing margin at the interface between muscularis propria and perirectal fat is suggestive of T₃ (Figure 3). Sometimes spiculations in the perirectal fat are considered as T₃ when in fact they are T₂ with desmoplastic reaction^[22,28]. MRI certainly cannot differentiate between a T₁ and T₂ cancer (Figure 4). Another area of drawback is restaging following long course chemoradiotherapy. Studies by Chen and Hoffmann found T staging accuracy was 52% and 54% when compared to histology^[29]. This is due to the inability to distinguish fibrosis from tumor with MRI similar to EUS. In low anterior tumors where the mesorectal fascia is close to the muscularis propria early T₃ can still infiltrate the mesorectal fascia^[24]. Extramural vascular invasion is known to be an independent predictor of local recurrence^[30,31]. The presence of a tubular structure in

proximity to a T₃ tumor or nodules with an irregular margin probably represents vascular invasion^[21,32]. Recently there has been interest in the use of functional imaging such as diffusion weighted MRI imaging (DWI) and CT/PET to distinguish fibrosis from tumor^[33].

MRI has been found to be useful in more advanced disease by providing clearer definition of the mesorectum and mesorectal fascia and seems to be a promising tool in assessing the locally advanced disease. With the advent of endorectal coils, the T staging accuracy has been reported to be between 70%-90%^[34]. However, this technique has its limitations specially when evaluating the surrounding tissue, owing to signal attenuation at a short distance from the coil. Patient's compliance, limited availability and cost also contribute to its less wide application. Obstructing or nearly obstructing lesions can be difficult to negotiate as are high rectal cancers leading to failed/improper coil insertion in approximately 40% of patients^[34].

Nodal accuracy has also been found to be variable although use of superparamagnetic iron oxide particles appears to be promising^[35] as evidenced by studies in head, neck and urological cancers.

Ultrasound

Abdominal ultrasound (USS) is used to evaluate liver for metastasis, ascites, adenopathy, and for omental cake. The false negative rate is reported to be around 8%^[36]. The technique, although inexpensive and widely available, is operator dependent. Intraoperative USS is rarely used apart from when synchronous rectal and liver resections are planned. Rapid advancement in imaging modalities has made USS a less favoured imaging modality in rectal cancer staging^[37].

Endorectal ultrasound

Endorectal ultrasound (EUS) is sensitive for early rectal cancers (T₁ and T₂ lesions) with an accuracy of 69%-97%^[38-43] and is useful in the surveillance following post transanal surgery. The standard technique involves a transanal probe enclosed in a water filled balloon introduced into the rectum to allow radial visualization of the rectum. High resolution allows the assessment of the rectal wall but the assessment of the mesorectal fascia is not possible and the assessment of the lymph nodes can be an issue and overstating has been a concern. Peritumor inflammation and artifacts due to faeces may lead to an ultrasound appearance which can be misinterpreted as tumor. These drawbacks can be exaggerated between the muscle layer and the surrounding fat which makes T₂ and T₃ lesions difficult to distinguish^[44]. The accuracy of the T stage evaluation varies from 62%-92%^[45]. In a meta-analysis of 11 studies it has been shown that sensitivities for superficial tumors are better than advanced lesions^[46]. A 20 year (1984-2004) systematic review looking at studies with a minimum of 50 patients, evaluating the use of endorectal ultrasound and magnetic resonance imaging (MRI) in the local staging of rectal cancer, have found a complementary role for these imaging modalities in the assessment of tumor depth. Ultrasound was found to be highly accurate in early lesions (T_{1,2}, 40%-100%; T_{3,4}, 25%-100%, overall 82%).

The review also found a similar accuracy in the assessment of nodal metastases^[47]. Two meta-analyses in literature have shown that the sensitivity is affected by T stage^[48]. A meta-analysis including 84 studies found EUS to be slightly superior in assessing the local involvement such as lymph nodes, however, no significant differences were noted when compared to other imaging modalities such as MRI. The results suggest that none of the current imaging modalities enable reliable detection of metastatic nodal disease^[49].

EUS however, has its limitations as it cannot reliably distinguish an irregular outer rectal wall due to peritumoral inflammation or transmural tumor extension. Obstructing lesions may be difficult to scan especially with rigid probes leading to suboptimal staging. The scanning, although less expensive and portable, is operator dependent and has a steep learning curve. Bulky, high, stenotic, advanced (T₃) lesions or post-neoadjuvant therapy downstaged tumors can be a challenge^[50-52].

EUS nodal staging accuracy is around 75%^[53]. Morphologic characteristics suggestive of malignant involvement include hypoechoic appearance, round shape, peritumoral location, and size > 5 mm^[45,46,51-53]. The loco-regional tumor assessment using three-dimensional EUS consists of transverse, coronal and sagittal scan and has been found to be superior to CT and two-dimensional EUS. The 3D-reconstructed image shows tumor protrusion infiltrating into adjacent structures, thus, allowing for improved T and N staging^[54]. Further, EUS-guided fine-needle aspiration can be carried out at the same time from the lesion or suspiciously looking lymph nodes.

Positron emission tomography

The principle of positron emission tomography (PET) is based on the differential metabolic profile of tumors compared to normal tissue. Fluoro-deoxy-glucose (FDG) is the most common PET tracer used. Due to increased metabolic activity, and change in the tumor biology, tumors preferentially show an increased uptake which results in radiolabelling^[55]. Although selective, FDG accumulates in areas of infection, inflammation, in organs of increased metabolic activity such as brain, myocardium, liver or kidneys leading to false positive results^[55]. FDG uptake is also influenced by the presence of mucin. PET is useful in identifying non-mucinous tumors compared to mucinous tumors. FDG/PET is mainly useful in the assessment of local recurrence and metastatic disease when conventional imaging is not helpful^[56,57]. Currently it is not used as a primary staging modality in rectal cancers. Interpretation of PET without anatomic correlation poses difficulties hence PET-CT fusion scans where the pictures of both investigations are fused using software is used. This offers a detailed anatomical and functional imaging and is gaining rapid popularity and acceptance. The combination provides additional value to localize the hot spots. There are some technical limitations with this combination imaging and with the false positive rates due to other disease and physiological processes. The role of PET CT fusion scan has not changed compared to PET scans.

However, a recent study has found preoperative PET

changed the management in 17% of patients^[58] with improved staging accuracy in combination with CT^[56]. Another study carried by Gearhart in 37 patients reported an altered management plan for 27% of patients using FDG-PET/CT imaging modality for low rectal cancer^[59].

Staging accuracy post-neoadjuvant therapy

With the increasing use of pre-operative neoadjuvant therapy, rectal tumor re-staging is increasingly performed prior to curative resection.

A reduction in staging accuracy has been noted which may be as a result of effects of neoadjuvant treatment due to post-radiation edema, inflammation, fibrosis, and necrosis^[60].

A recent study of 29 patients undergoing neoadjuvant therapy and pretreatment and post-treatment staging with CT, MRI, and PET showed that PET was 100% sensitive in predicting response to therapy (compared with 54% for CT and 71% for MRI). Corresponding specificity for predicting tumor response to treatment was 60%, 80%, and 67% for PET, CT, and MRI, respectively^[61], thus suggesting a further possible role of PET in predicting response to neoadjuvant therapy.

Tumor re-staging following post-neoadjuvant therapy remains problematic and it is hoped that a combination of imaging technique (CT, MRI, and EUS) and functional (PET) imaging may improve staging accuracy.

Suggested investigations for tumor staging of rectal cancer

On review of the literature, phased array MRI and EUS should be considered as the initial modalities to stage the local tumor. A fixed, locally advanced rectal cancer may be imaged better by MRI (Figure 5), whereas EUS is more appropriate for an early mobile rectal tumor (T₁-T₂ lesions). MRI has been shown to be highly accurate in predicting a clear circumferential resection margin in patients undergoing TME. Although both MRI and EUS provide a comparable overall T- and N-staging, use of these modalities is limited by issues such as availability, costs and technical expertise. CT scanning, although still the current standard for distant staging, may not be an effective tool to stage the local disease. A combination of CT and PET offering a detailed anatomical and functional imaging, however, seem to be promising and gaining popularity and acceptance for recurrent rectal cancers.

Suggested investigation for nodal staging of rectal cancer

The accuracy of MRI, CT and EUS for identifying malignant nodes is poor. Current criteria are based on size, shape and morphology. Any node of 1 cm and over is taken as significant^[62]. The enlarged lymph node can be as a result of the inflammatory process but normal size nodes can have micrometastases. Brown *et al*^[54] found 58% of positive malignant nodes were less than 5 mm. Morphological characteristics such as round shape, irregular borders and heterogenous signal intensity suggest nodal involvement^[63].

Nodal accuracy has also been found to be variable, although use of superparamagnetic iron oxide particles

Figure 5 Magnetic resonance imaging. A: Magnetic resonance imaging (MRI) (arrow) showing the rectal cancer involving the circumferential resection margin; B: MRI (arrow) showing the rectal cancer invading the ischioanal fat on the right (T₄).

(SPIO) seem to be promising as evidenced by studies in head, neck and urological cancers. The technique involves use of a contrast media containing SPIO which accumulates in normal lymph nodes, whereas due to defective phagocytosis, the uptake is poor or absent in malignant nodes. Hence by using T2 weighted imaging, these nodes can be identified. Initial studies are promising but further research is needed^[35].

CHOOSING THE CORRECT MANAGEMENT BASED ON STAGING IN THE ELDERLY

Over the age of 80, there is 10% mortality with rectal cancer surgery^[64]. Studies from Brazil have shown a complete pathological response with chemoradiation^[65] and it is well known that the elderly respond better to radiotherapy. Hence in a selected group of patients, imaging with EUS and MRI can identify patients who can be treated with neoadjuvant treatment and those with a complete radiological response can be followed by active surveillance with an intensive imaging protocol to identify those who recur to be considered for standard salvage surgical treatment or for local excision, thereby avoiding the risks associated with major rectal cancer surgery and possibly avoiding the need for permanent stoma and enabling organ preservation. This is possible only with high quality imaging techniques to assess the loco-regional disease.

CONCLUSION

Imaging in rectal cancer helps in deciding the treatment and determining the prognosis. The newer techniques help in superior image resolution, three-dimensional viewing, with decreased image acquisition times, minimal bowel preparation, and sometimes with functional qualities. This may be important following neo-adjuvant treatment. The most accurate method of rectal wall staging of rectal cancer is endorectal ultrasound and MRI but accurate staging of mesorectal fascia and lymph nodes is by phased array MRI. The management of rectal cancer is based on the proximity of the tumor to the mesorectal fascia. Hence the phased array MRI is the best overall technique for local staging of rectal cancer. Neoadjuvant treatment is not without risks; hence careful staging is important in obtaining good oncological and functional results and improving patient experience in the management of rectal cancer. In symptomatic patients local excision is beneficial in only 5% and this is the group which benefits most from EUS. With the introduction of colorectal screening it is felt nearly 50% of cancers may be of early stage disease which can be identified by EUS and managed by organ preserving intervention. Hence the role of EUS is likely to increase as part of the staging investigations in future and all these investigations are complementary in the management of rectal cancer.

INTRODUCTION

In 2009, there were approximately 41 000 new cases of rectal cancer in the United States^[1]. In general, 70%-80% of those presenting patients have resectable disease and are treated curatively. Of these patients, nearly 40% develop recurrence, with the majority not being candidates for re-treatment with curative intent^[2]. The goal of curative-intent operations is to remove all disease present. In contrast, the goal of palliative intent operations is to relieve symptoms, and by definition, leave local or metastatic residual disease. Approximately half of patients with rectal cancer may be candidates for palliative therapy at some point during their disease process, either because of locally advanced or metastatic disease at the time of presentation, or the late development of metastases^[3].

Palliative treatment strategies for advanced stage rectal cancer should be individualized to patients according to their symptoms. Chemotherapy for metastatic disease is the current recommendation for asymptomatic patients^[4]. Symptomatic patients can present particularly difficult challenges and can be treated with chemotherapy or combined chemoradiation therapy in conjunction with a procedure, if necessary, to relieve their symptoms. Local interventions can often effectively treat symptoms and increase quality of life. Options include extirpative resection, diversion procedures, endoscopic stenting, and laser or argon photocoagulation. The choice of treatment is partially dependent upon the patient's symptoms, age, comorbid conditions, and extent of disease.

Although the most appropriate treatment option is not always evident, a careful multidisciplinary approach with the surgeon playing the central role of determining when

Abstract

Approximately 30% of patients with rectal cancer present with metastatic disease. Many of these patients have symptoms of bleeding or obstruction. Several treatment options are available to deal with the various complications that may afflict these patients. Endorectal stenting, laser ablation, and operative resection are a few of the options available to the patient with a malignant large bowel obstruction. A thorough understanding of treatment options will ensure the patient is offered the most effective therapy with the least amount of associated morbidity. In this review, we describe various options for palliation of symptoms in patients with metastatic rectal cancer. Additionally, we briefly discuss treatment for asymptomatic patients with metastatic disease.

aggressive operative intervention is warranted can ensure the most appropriate treatment strategy is devised. The goals in palliation should include the alleviation of symptoms, enhancing quality of life and improving comfort^[5]. Herein, we review the current relevant literature on various treatment strategies as they are related to the palliative treatment of rectal cancer.

EVALUATION

Rectal cancer is defined as a malignant lesion within 15 cm of the anal verge as seen by rigid proctoscopy^[6-8]. Subsequent to histological confirmation of diagnosis *via* tumor biopsy, initial work-up of the extent of disease guides subsequent treatment^[4,9]. Proper staging is essential as decisions regarding neoadjuvant versus adjuvant therapy and operative versus palliative surgical intent will be based on clinical stage. The patient should undergo proctoscopy to determine distance from anal verge, as well as colonoscopy to interrogate the entire colon for synchronous lesions. Cross-sectional imaging of the chest, abdomen and pelvis in conjunction with endoscopic ultrasound (EUS) can assess depth of tumor penetration or invasion of local structures, lymph node status, and presence of metastatic disease^[9,10]. Although EUS has appropriate sensitivity and specificity for differentiating muscularis propria invasion (94% and 86%), as well as perirectal tissue invasion (90% and 75%), magnetic resonance imaging (MRI) has proven to be an important adjunct for accurate staging of rectal cancer as well^[9,11,12]. MRI has been found to have an 85% diagnostic accuracy for T-stage with 57%-85% accuracy for correctly identifying spread to lymph nodes; furthermore, the relationship to mesorectal fascia in conjunction with detection of adjacent organ invasion is superior utilizing MRI versus EUS^[13-18]. In addition to imaging, a preoperative carcinoembryonic antigen level combined with basic laboratory values, comprehensive history and complete physical examination to assess performance status and comorbidity play important roles in the preoperative workup, because these factor significantly for choice of intervention^[19].

When the pretreatment evaluation has determined a patient to no longer be appropriate for curative intent due to the presence of distant metastases or local invasion precluding a margin-negative resection, quality of life and symptom relief must become the main focus. In general, findings indicative of unresectability are utilized to predict the ability to achieve resection with negative margins. In those situations presented in Table 1, negative margins are obtained in 6%-36% of cases and surgical extirpation can result in significant postoperative disability^[20]. However, resectability of the disease should be assessed by an experienced surgeon. In a study by Mathis *et al.*^[21], patients who were initially deemed locally unresectable, secondary to advanced primary colon and rectal cancer, were treated with aggressive multimodal therapy and found to have median survival of 3.7 years. Conversely, decision stratification must be influenced by expected survival in those patients evaluated properly and determined not to be candidates for aggressive resection. Consideration of

Table 1 Contraindications to resective operative intervention

Sciatic nerve pain
Bilateral ureteral obstruction
Extensive fixation to lateral pelvic side wall (CT/MRI or trial dissection)
Sacral involvement above S2 (resection produces spinal instability or post-operative complications)
Bilateral lymphedema or bilateral venous thrombosis (indicating encasement of major vascular structures)
Multiple peritoneal metastasis or metastasis fixed to or invading vital structures

CT: Computed tomography; MRI: Magnetic resonance imaging.

operative interventions is more appropriately included in the conversation of palliative treatment for patients with expected outcomes exceeding 6 mo^[19,22-25].

Approximately 50% of patients either present with distant metastases or develop distant metastases after primary treatment. Those that cannot be treated curatively should have care guided by patient wishes, functional status, expected life duration, and extent of disease and debilitating symptoms. In a study by Law *et al.*^[26], the most common presenting symptoms of patients undergoing palliative intervention for colorectal cancer were intestinal obstruction and rectal bleeding. In another study, 42% of patients presenting for palliative treatment were obstructed, 37% of patients experienced rectal bleeding, and 5% were asymptomatic, with the remainder (16%) experiencing pain or rectal discharge^[27]. Taking into consideration the presenting symptoms and the underlying condition of the patient, palliative management can be divided into operative versus non-operative treatment.

CLINICAL SCENARIOS AND MANAGEMENT OPTIONS

Obstruction

Patients with rectal cancer can present with any number of symptoms that prompt evaluation (e.g. bleeding, perforation, abdominal pain, anemia, hematochezia, tenesmus, and malaise) and 10%-25% of patients present with obstructive symptoms^[19,22,26,28]. Such a clinical scenario requires expedient yet thorough evaluation of the patient for resectability and potential for cure, because these patients often necessitate urgent, if not emergency, surgical intervention^[28]. Rosen retrospectively analyzed 116 patients initially presenting with stage IV colorectal cancer and found that 26% presented with obstructive symptoms^[22]. In another study, although the most common symptom precipitating medical evaluation in advanced colorectal cancer was bleeding (24%), Law *et al.*^[26] found that obstruction (23%) in conjunction with change in bowel habits (15%) comprised a significant proportion of patient presentations. Phang *et al.*^[29] found that nearly 10% of patients with rectal cancer presented with a bowel obstruction and required some emergency intervention. In that series, patients who underwent primary resection of the tumor at the time of emergency surgery had

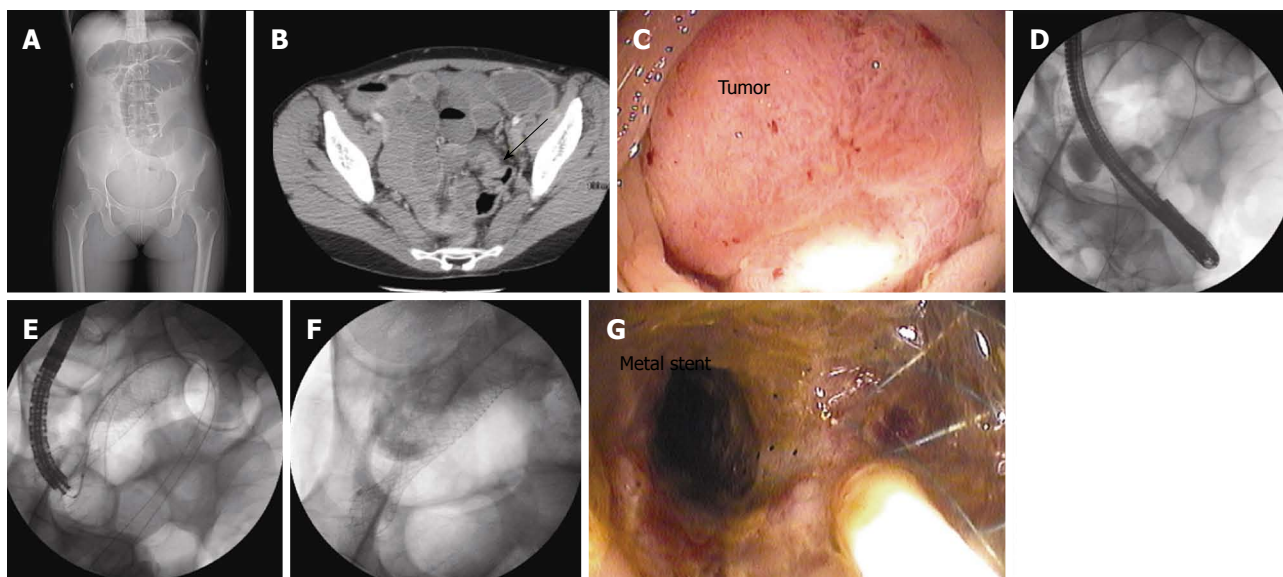

Figure 1 A young patient was diagnosed with an obstructing cancer in the upper rectum. Computed tomography demonstrated findings consistent with peritoneal metastases. She was referred for an endorectal stent to relieve the obstruction. A: Single-view plain radiography demonstrated colonic distension; B: A single-axial section with the arrow demonstrated the tumor; C: Luminal view of the tumor at time of sigmoidoscopy; D: Fluorography during stent placement demonstrated the wire across the tumor; E: Fluoroscopic view demonstrated the endoluminal stent being deployed; F, G: Fluoroscopic and endoscopic views of the stent in place.

worse overall survival and higher local recurrence rates than those patients who had elective surgery. Data such as these support the notion that interventions other than surgical resection should be entertained in those patients with rectal cancer who present in an emergency situation.

Non-operative approach: Self-expanding metallic stents have been widely utilized for maintaining patency in the biliary tree and esophagus. Transition to endorectal stenting was described in case reports in 1995, and since then, its use has increased with development of stents specifically designed for use in the large intestine^[30]. Endorectal stents present one potential option to treat the obstructing rectal cancer. When utilized in this setting, they can be definitive treatment in the patient with widespread disease, or serve as a bridge to elective primary resection and anastomosis in the patient with acute obstruction.

Self-expanding metallic stents (SEMSs) are expandable metallic tubes placed in a collapsed state across the obstructing tumor under fluoroscopic guidance, endoscopic guidance or a combination procedure^[31]. Various stents are utilized and when deployed expand to relieve the obstruction caused by tumor growth. Dedicated colonic stents are generally flared at the ends with a smaller mid-body diameter and differ with respect to length and diameter. Therefore, appropriate stents can be selected based on location and length of lesion as well as severity of obstruction. Examples of available stents include the colonic Z-stent (Wilson-Cook Medical, Winston-Salem, NC, USA) with 25-mm mid-body and 28-mm end diameters and the Ultraflex Precision Colonic Stent (Microvasive, Boston Scientific Corp., Natick, MA, USA) with 25-mm mid-body and 30-mm end diameters. The patient scenario presented in Figure 1 demonstrates a successful stent placement using a combination of fluoroscopic and endoscopic guidance.

Once deployed, the stent eventually becomes incorporated into the tumor and surrounding tissue *via* pressure necrosis, which allows anchoring and prevents migration^[32]. Stent procedures are generally well tolerated with minimal sedation required for placement, which make them an enticing option for palliation of obstruction. In fact, a recent systematic review of 88 studies with 1785 patients who underwent SEMS placement for the relief of malignant colorectal obstruction reported a median success rate of 96.2%, with relief of obstructive symptoms 92% of the time^[31]. When failure did occur, the most common cause was inability to pass a guidewire through the tortuous anatomy. On follow-up, 90.7% of patients in 11 of the studies reporting outcome had a patient stent upon death or at end-point for a mean duration of 106 d^[31]. Studies such as these indicate that stents can be placed successfully in most situations, whether as a bridge to surgery or for definitive palliation.

Unfortunately, few randomized controlled trials have compared effectiveness of SEMSs and surgery for incurable, obstructing rectal cancer. In a non-randomized, prospective study, patients underwent SEMS placement or palliative surgery for obstructing, non-resectable rectal cancer. SEMS was successfully placed in 38/40 patients with mean duration of 269 d^[33]. Although the stent group was statistically older with higher ASA classification, median survival was 296 d in the stent group *vs* 234 d for the surgery group. The length of hospital stay in the stent group was 2 d *vs* 9.5 d in the surgery group. Furthermore, complications requiring intervention occurred in 19% of the stent patients with no postoperative mortality *vs* 32% complication rate in the surgery group with 5% mortality. These results are consistent with the conclusion that surgical intervention confers no significant survival advantages and that SEMSs should be considered a reasonable alternative^[33].

Another series from Germany has found that many patients are relieved of their obstruction and never require further surgery. Hünnerbein *et al.*^[34] has found that 26 of 33 (79%) patients had long-term relief of bowel obstruction. Furthermore, 20 patients died with the stent in place at a mean of 5.3 mo and required no surgical interventions. The findings of this group corroborates those of others indicating the SEMSs are a safe option for the treatment of a malignant large bowel obstruction.

Overall, SEMSs are associated with less risk, shorter hospital stay and less morbidity and mortality than surgical resection or diversion. Although a certain percentage of patients with stent placement may require subsequent surgical intervention, SEMSs appears to have an appropriate role in the therapeutic options for palliation of obstruction. In fact, mortality after surgery for malignant large bowel obstruction in most series is 5%-10%, with one study reporting 18% mortality after surgery for obstructing colon cancer^[22,35-40]. Postoperative complications have been found to range between 20% and 30% in most series, with one study reporting 54% postoperative complications^[22,35-40].

Complications after stent placement such as bleeding, malposition and perforation can occur early after deployment. Late complications after stent placement include stent migration and occlusion. Given the limited life expectancy of the patient population in whom stents are typically placed, long-term complications or failures have been difficult to assess. Long-term complications such as obstruction have been documented to occur in approximately 15% of patients. These complications were successfully treated in all cases with another endoscopic procedure^[34]. Bleeding was a rare complication (< 5% of patients) that was treated with endoscopic electrocoagulation. In this same series, short-term failure occurred in approximately 20% of patients and included stent migration, severe pelvic pain, incomplete stent expansion, and incontinence^[34].

Perforation is an especially morbid complication in that violation of the colon or rectum carries significant consequences for these patients who are often quite debilitated from their primary disease process. This complication can occur as a result of over-expansion in the tumor bed or pressure necrosis in the normal colon. Rates of perforation are approximately 5% and surgical treatment requires a relatively high-risk operative intervention^[31]. Song *et al.*^[41] have found the rate of perforation to be approximately 10%. Although one patient in their series ultimately died as a direct result of the perforation, there were no significant differences in median survival between patients with and without perforation.

Operative approach: Patients with obstruction who require an operative approach can be treated with either resection of the primary tumor or a diverting stoma. Because of the constraints associated with the pelvis and proximity of structures with tumor extension and fixation, complete resection often requires pelvic exenteration or

removal of other organs along with the primary tumor^[19]. These operations tend to be morbid and a less than ideal option in the patient with a limited life expectancy. Therefore, a colostomy is the preferred operation in the patient with an acute malignant obstruction of the large bowel. The sigmoid and transverse colon are the most commonly used conduits for creating a loop colostomy^[42].

Other situations that necessitate operative intervention are those in which a SEMS is contraindicated. For example, the patient with cancer in close proximity to the anal canal (within 3 cm) can have intractable anal pain, tenesmus, and incontinence after placement of a SEMS^[34]. Diverting colostomy can relieve the obstructing symptoms effectively and avoid these intractable symptoms. Additionally, an extended narrowing involving a long segment of the lumen with significant angulation can make SEMS placement impossible and the attempt can be high risk. Difficulty with passing the wire or pre-stent balloon dilation of the stricture may result in perforation, with these difficult obstructions necessitating emergency surgery^[41]. Colostomy formation may be the better alternative in these cases^[42].

A diverting colostomy can be placed using a laparoscopic or open approach. Laparoscopic fecal diversion is an attractive alternative in patients presenting with obstruction. Patients have smaller incisions with less associated pain, shorter hospital stay, quicker onset to return of bowel function, fewer postoperative complications, and the potential to initiate chemotherapy at a shorter interval when compared to open operations^[19,43,44]. However, the laparoscopic approach can be difficult in this setting as the colon is often massively dilated and manipulation of the large organ can be impossible.

A particularly treacherous situation is presented in the setting of emergency decompressive surgery in which mortality approaches 20%, a complication occurs in nearly 50%, with half of patients incurring a permanent stoma^[45]. Furthermore, complications resulting from the stoma are higher in patients undergoing emergency surgery^[46]. In this setting, an expandable rectal stent can be placed as a bridge to surgery or as definitive palliation. In the recent comprehensive review of endorectal stents, patients were able to undergo elective surgery 2-16 d after stent placement. Rates of primary anastomosis for elective surgery after stent placement were twice that of emergency surgery for obstruction with shorter hospital stay, decreased morbidity, and decreased mortality in the elective surgery group^[31].

Negative effects on quality of life and associated complications with a permanent colostomy are other reasons only to approach the obstruction operatively in those patients not amenable to other non-operative approaches^[47]. Complications directly related to the colostomy can occur in up to one-third of patients, and include skin irritation, leakage, prolapse, pain, partial necrosis and retraction^[19,48,49]. In conjunction with these complications, patients are more likely to feel socially restricted as a result of their colostomy when events such as leakage, prolapse

or retraction occur^[50]. Furthermore, many patients are unhappy after the operation, contending that their education was not sufficient to prepare them to deal with the colostomy^[51]. In a study evaluating patient satisfaction after colostomy placement in colorectal cancer, 31% of patients were dissatisfied with the information received regarding the colostomy procedure^[52]. An additional study by Nugent *et al.*^[53] has revealed only 65% of patients felt sufficiently informed regarding what an ostomy entails. Moreover, 20%-35% of patients felt significant impact on quality of life including change in work, travel or social habits; consequently, patients expressed desire to supplement deficiencies with further counseling and follow-up. In fact, it has been shown that intensive preoperative education directed by a nurse with expertise in stoma care improves postoperative outcomes^[54]. Despite these problems, fecal diversion remains an option for relief of symptoms in this patient population, and conversation with the patient to address any concerns may alleviate reservations and improve outcomes.

Primary tumor resection is occasionally indicated and can provide a reasonable quality of life postoperatively in selected patients. The most commonly performed procedures for palliative resection include abdominoperineal resection (APR), Hartmann procedure, low anterior resection (LAR), and exenteration. These operations are less commonly utilized for obstruction due to the expected short duration of survival of the patient. The decision between APR, LAR or Hartmann depends on tumor location and size, comorbidity, and ability to achieve clear margins. When addressing a rectal tumor in which resection does not preclude preservation of sphincter function, intervention would likely include low resection versus Hartmann procedure. An advantage of utilizing LAR is the maintenance bowel continuity and fecal continence. However, if there is poor predicted anal function, or concern for the anastomosis in an irradiated field, the formation of a proximal diverting ostomy negates the advantages of LAR over the Hartmann procedure^[42,55]. With regard to low-lying rectal cancer, an advantage of the Hartmann operation over APR is the avoidance of a perineal wound and associated wound healing complications^[56-58]. The Hartmann operation requires surgical dissection below the tumor for appropriate resection, therefore, studies have reported higher incidence of pelvic abscess than occurs with APR^[57,59]. However, investigating patient outcomes following the Hartmann procedure versus APR for palliation in low-lying rectal cancer (approximately 5-5.5 cm from the anal verge), patients had similar rates of abdominal wound infection, pelvic/abdominal pain and stoma complications, whereas the APR group had a 46% occurrence of perineal wound sepsis and 38% incidence of perineal wound pain^[57]. In contrast, if the rectal cancer involves the anal sphincter, APR is the preferred surgical option^[42].

Pelvic exenteration is considered an extended radical resection in which surrounding organs are removed. This operation should be avoided when the goal of the operation is that of symptom palliation because the operation

is generally fraught with complications and provides little if any improvement in quality of life^[60]. Anterior exenteration includes resection of anterior pelvic organs; posterior exenteration involves a partial sacrectomy when excising the tumor; and complete exenteration is performed when significant invasion of most surrounding structures occurs^[20]. Mortality rate from these procedures when performed for recurrent rectal cancer ranges from 0.6% to 5% at 30 d, with morbidity of 30%-60% and sphincter salvage of 5%-15%^[20]. Therefore, patients who undergo an extended resection may experience prolonged hospital stay as well as higher rates of postoperative complications and re-admissions, while still requiring the formation of a stoma. There have been reports of symptom improvement and enhanced quality of life when performed in symptomatic individuals with unresectable disease^[19]. However, pelvic exenteration is rarely performed for symptom palliation in symptomatic patients with unresectable rectal cancer.

Bleeding

Non-operative approach: Laser ablation is a well established treatment modality for palliation of rectal cancer, in which endoscopy is utilized to deliver focused energy to the rectal lesion^[61]. The most frequently used laser is the neodymium yttrium argon garnet (Nd:YAG) laser, which has the ability to treat bleeding lesions and vaporize tumor tissue. Energy can be delivered to promote coagulative necrosis or vaporization depending on the goal of the treatment, with repeated treatments usually necessary^[61]. Laser ablation has been utilized to palliate obstruction in inoperable rectal carcinoma, especially in cases in which tumor ingrowth causes obstruction, urgency or tenesmus after stent placement. However, laser ablation has been best utilized in cases in which bleeding is the prominent symptom. Coagulation is usually achieved after 2-5 sessions in 80%-90% of patients with complications ranging from 2% to 15%^[61]. In a study by Rao *et al.*^[62], 8/11 patients were treated *via* endoscopic laser ablation for bleeding, with a median symptom-free interval of 10 mo. The average number of treatment episodes was six, with an immediate overall success rate of 91%. Another group that utilized endoscopic diode laser therapy for unresectable rectal cancer found lifelong symptom relief to be achieved in 51/57 patients. Obstruction was relieved in 22/24 patients and bleeding controlled in 29/30^[27].

Complications associated with laser ablation occur in 2%-15% of patients^[61,62]. The majority of complications reported tend to be minor, however, perforation requiring laparotomy occurred in 2/57 patients in a study of laser therapy^[27]. Furthermore, successful palliation becomes less likely to be achieved with improvement in overall survival. Additionally, ablation is relatively ineffective with long-segment or circumferential tumors, or with angulated segments of the rectum. Despite these negative aspects, laser ablation is a relatively low cost, minimally invasive modality for palliation of bleeding that provides acceptable results in high-risk individuals.

Argon plasma coagulation (APC) utilizes electrocautery to ionize argon gas that acts to fulgurate the neoplasm and bleeding vessels. It has been utilized in open surgery to achieve hemostasis in superficial diffuse hemorrhage. This surface coagulation is fairly effective and thus APC has become more widely utilized than laser therapy in many centers for palliation of bleeding^[61]. Because of the minimal depth of penetration (2-3 mm), with concomitant, efficient tissue coagulation, the risk of perforation is decreased compared to that with laser therapy. However, due to its limited penetration, it is not as effective for relieving obstruction. Compared to laser therapy, APC is easier to use, cheaper and more portable, which provides for an attractive option for palliating bleeding in an advanced-stage rectal cancer patient.

Chemotherapy has also been found to provide symptomatic improvement within 1-2 wk of initiating therapy, especially in cases of imminent obstruction or bleeding. In a study by Poultides of 233 patients with synchronous metastatic disease and unresected primary tumor, 217 (93%) never required surgical palliation of their primary tumor, with only 16 patients (7%) requiring emergency surgery for primary tumor obstruction or perforation^[63]. These data indicate that many patients can be treated with systemic therapy alone as preventive palliation, with the caveat that it requires a certain time period to produce desired effect.

In addition to bleeding, patients who present with locally advanced or recurrent disease often experience pelvic pain secondary to involvement of nerve structures within the pelvis, or from involvement of the sacrum. Radiotherapy can provide relief of pain and bleeding in 75% of patients for a median duration of 6-9 mo^[64]. The range of doses studied varied from 20 to 60 Gy. However, radiotherapy has not been shown to confer a survival benefit and is best utilized for palliation of symptoms in patients with short life expectancy (6 mo)^[65]. Outside of palliation for pain and bleeding, external beam radiation plays an integral role in the multimodal treatment of rectal cancer. In patients with locally advanced or recurrent disease, radiation should be utilized as multimodal therapy for potentially resectable disease^[64].

Operative approach: Surgical options for the treatment of bleeding are similar to those for the treatment of obstruction. However, unlike the patient with a large obstructing lesion, the bleeding tumor may be smaller and more amenable to local or transanal excision (TAE) options. Although not a curative operation for locally advanced rectal cancer, TAE for rectal cancer may provide symptomatic relief of bleeding. Transanal endoscopic microsurgery has been successfully used for this indication^[66,67].

Asymptomatic patients

One of the principal concerns when evaluating an asymptomatic patient with metastatic rectal cancer is whether the primary lesion itself will become symptomatic, and necessitate intervention in order to avoid debilitating complications. This concern is what traditionally prompted

surgical resection of primary disease, even in asymptomatic individuals. Proponents state that extirpation of the primary tumor can preclude development of obstruction, perforation or bleeding, thus avoiding a surgical emergency in already compromised patient receiving chemotherapy^[68]. However, patients who are unfit candidates for complete resection do not achieve survival benefit with excision of the primary tumor^[38,69,70]. Additionally, multiple studies have confirmed that asymptomatic or minimally symptomatic patients with incurable colon and rectal cancer have a low risk of developing debilitating symptoms prior to death from progressive disease^[19,38,63,65,71-73]. Tebutt *et al*^[71] have evaluated patients undergoing chemotherapy for metastatic disease, of whom, a subset had undergone resection of the primary, while another cohort initiated chemotherapy immediately after diagnosis. There was no difference in obstruction, peritonitis, gastrointestinal bleed or fistula formation between the two groups. Similarly, in a report by Scoggins *et al*^[38], operative intervention was required in only 9% of patients managed initially without resection (chemotherapy subset), while morbidity and mortality were 30% and 5%, respectively, for asymptomatic patients undergoing initial operation. In a study by Poultides *et al*^[63] which has investigated outcomes in patients with synchronous colorectal metastases treated with chemotherapy, 217 out of 233 (93%) patients never required intervention for perforation, bleeding, obstruction or any other cancer-related complication. From these studies, it is apparent that, for asymptomatic individuals with unresectable metastatic disease, chemotherapy is the appropriate first-line therapy, and surgical resection without removal of all tumor burden will result in delay in starting therapy.

In contrast to systemic treatment alone, certain patients with advanced stage metastatic rectal cancer benefit from combined surgical resection and systemic therapy. The discussion regarding resection of metastatic foci for curative intent is extensive, therefore, it will be briefly reported here. When resection of a primary tumor combined with metastectomy was performed with curative intent, overall 5-year survival rates range from 35% to 58%, which significantly surpassed the 5-year survival attained by non-curative resection or systemic treatment alone^[74-79]. With the development of newer biological agents, combined with more efficacious combination chemotherapy and improvement in surgical techniques that increase the efficacy and safety of resection, the number of potentially curable patients with disease amenable to resection has increased. Patients who present with widespread disease should be evaluated for surgical resectability at 2-mo intervals during cytotoxic chemotherapy^[4]. The purpose of re-evaluation is to ascertain whether response to therapy has reduced the malignant neoplasm to a state in which R0 resection may be achieved^[80]. Coincident with this, expanding criteria for patients amenable to safe resection of rectal cancer metastases has allowed allocation of patients into the "cure" category versus palliative measures. Therefore, understanding which patients should be considered for curative treatment provides an appropriate cohort that should be considered for palliation.

Traditionally, specific characteristics of metastases in colorectal cancer have governed suitability for liver resection. These include ≤ 3 metastases, no evidence of additional extra-hepatic disease, ability to achieve 1-cm resection margin, and small size of metastases (< 5 cm)^[76,78,81-83]. Fortunately, with improvement in medical therapy and surgical proficiency (including imaging modalities, techniques such as portal vein embolization, and adjunct procedures such as radiofrequency ablation), these previous contraindications have become less absolute^[74,76,84]. In a recent study, patients with > 3 hepatic metastases undergoing hepatic resection achieved similar survival as those with < 3 metastases given a microscopically negative resection margin (R0) and sufficient liver remnant^[85]. As a result, the focus has shifted towards potential hepatic function after surgical extirpation instead of quantifying numerically disease pre-resection^[68,76]. Additionally, while hepatic metastasis size > 5 cm has historically predicted poor outcome, tumor size is now only considered a contraindication if attaining a negative margin is impossible (i.e. insufficient remnant liver or proximity to critical structures, which precludes complete resection)^[76,78]. Moreover, despite earlier reports of worse outcome when margins were < 1 cm, the extent of the negative margin has not been shown to confer increased survival (< 1 cm *vs* > 1 cm); rather, only microscopically negative margins are a requisite for survival benefit^[75,82,83]. Furthermore, addressing extra-hepatic disease (specifically pulmonary metastases), plausibility of R0 resection should be the preferential concern dictating tumor resectability. Investigations have demonstrated survival benefit in those patients with both liver and pulmonary metastases that were amenable to margin-negative resection^[86-90]. Similar to evaluation of liver metastases, isolated pulmonary metastases have been extensively investigated with the consensus that resection of pulmonary metastases with microscopically negative margins portends a favorable prognosis compared to chemotherapy alone^[81,86,88,89,91,92]. From these types of data, it is obvious that evaluation of a patient with metastatic disease is complicated and the treatment plan should be jointly developed by a team of well-trained medical, surgical, and radiation oncologists.

Chemotherapy

The presence of synchronous metastases clearly decreases survival. However, those patients who are surgical candidates and can have all sites of disease removed have a better overall prognosis^[93-95]. On the other hand, individuals who do not fall into the category of resectable advanced stage disease, and are also asymptomatic, should have systemic treatment initiated expeditiously after diagnosis.

Since the approval by the FDA in 1962 of 5-fluorouracil (5-FU) for systemic treatment of colorectal cancer, advances in our understanding of the molecular alterations that accrue in malignant colorectal disease have enabled significantly more efficacious chemotherapeutic regimens^[96]. Moreover, specific characterization of the mechanism of action of various cytotoxic agents also has contributed to increasingly potent combination therapies.

Utilized as monotherapy, 5-FU has generated response rates of 10%-15% in patients with advanced colorectal cancer^[97]. Early modifications included addition of folinic acid (leucovorin) which increases the efficacy of 5-FU, as well as varying the method of administration (i.e. bolus *vs* continuous infusion), which demonstrates a higher response rate and increased overall survival (OS) in the continuous infusion group^[96-98]. An oral formulation, capecitabine, also has become available and was approved by the FDA in 2001. A subsequent landmark in the development of a pharmaceutical regimen arose upon inclusion of agents such as irinotecan and oxaliplatin in the armamentarium against colorectal cancer.

Irinotecan, a topoisomerase I inhibitor, had initially demonstrated improved outcomes (overall survival, quality of life) *vs* supportive care alone in patients whose metastatic disease had progressed while on the standard chemotherapeutic regimen of 5-FU and leucovorin^[99]. Additionally, in a similar study comparing irinotecan and 5-FU infusion in patients not responding to or progressing while on first-line 5-FU/leucovorin, patients within the irinotecan arm benefitted from increased progression-free survival (PFS) in conjunction with OS^[100]. Consequently, irinotecan has been evaluated as first-line therapy in combination with bolus 5-FU and leucovorin (IFL), as well as infusional 5-FU and leucovorin (FOLFIRI). Because the addition of this new agent generated favorable results (increased PFS and OS), irinotecan has been incorporated into the armamentarium of primary chemotherapeutic treatments for metastatic disease^[96,101,102].

Concordantly, oxaliplatin, a third-generation platinum complex, has demonstrated efficacy as an antitumor agent in advanced stage colorectal cancer patients with documented progression on standard fluorouracil-based chemotherapy^[103,104]. This again prompted further evaluation of the efficacy of the platinum agent when administered in conjunction with 5-FU/leucovorin. In an equivalent manner to irinotecan, oxaliplatin demonstrated comparably favorable results (longer duration of PFS, higher response rate) when incorporated with leucovorin and 5-FU compared with the latter two agents alone^[105]. Oxaliplatin potentiation of 5-FU cytotoxic activity has resulted in modification of first-line chemotherapy in which folinic acid, fluorouracil, and oxaliplatin (FOLFOX) has emerged as a therapeutic standard for metastatic disease.

In order to determine the best first-line agent for treatment of colorectal cancer, a randomized controlled trial was conducted evaluating FOLFOX and IFL^[106]. This trial demonstrated an improved response to FOLFOX, thereby establishing this regimen as the new gold standard for the treatment of metastatic disease. This postulation was succeeded by the hypothesis that utilization of all three active drugs (5-FU, oxaliplatin, irinotecan), as well as infusional (and not bolus) 5-FU, were the underlying etiologies of increased survival^[96]. A trial comparing first-line FOLFOX6 *vs* FOLFIRI (folinic acid, fluorouracil, irinotecan) followed by FOLFIRI and FOLFOX6 respectively was conducted to determine the appropriate sequence of

combination chemotherapy. OS was comparable in both groups (20.6 mo *vs* 21.5 mo), which was longer than OS in previous studies that have evaluated protocols with only two active drugs (oxaliplatin and 5-FU or irinotecan and 5-FU)^[95]. These results were corroborated by a meta-analysis that has investigated the synergistic impact on survival when implementing therapy with 5-FU, leucovorin, irinotecan and oxaliplatin during the course of treatment^[107].

The improved understanding of the biology of colorectal cancer has led to the development of several new agents that are active against members of the growth factor family. Although several novel agents have been evaluated in a number of diseases, three select therapies have been approved by the FDA for use in metastatic colorectal cancer: bevacizumab (2004), cetuximab (2004), and panitumumab (2006)^[96,108]. FDA approval of cetuximab and panitumumab was contingent upon tumor expression of epidermal growth factor receptor (EGFR) (which occurs in 70%-80% of human colorectal carcinomas), as demonstrated by immunohistochemistry^[96,109,110]. However, differential expression of EGFR *via* immunohistochemistry does not seem to correlate with response to or benefit from anti-EGFR therapy^[110-112]. This finding engendered the question of whether different methods to ascertain EGFR levels in tumors (i.e. fluorescence *in situ* hybridization, RT-PCR) are needed, or whether more specific markers exist that predict response to anti-EGFR treatment. As a result of numerous studies demonstrating association between KRAS mutation status and response to cetuximab/panitumumab therapy (discussed below), current recommendations are for use in colorectal cancer without specified KRAS mutations^[4,113,114].

Cetuximab and panitumumab are high-affinity monoclonal antibodies (chimeric mouse/human IgG1 and human IgG2, respectively) directed against the extracellular ligand binding domain of EGFR. Their efficacy has been demonstrated in both irinotecan-based (FOLFIRI) and oxaliplatin-based (FOLFOX4) treatments^[111,115-117]. When bound by ligand, EGFR activation triggers a cascade of events that propagate growth signals that ultimately promote cell proliferation and survival^[118-120]. Within this signaling cascade lies KRAS, an intracellular G-protein that is mutated in 30%-50% of colorectal cancers; when this genetic aberration occurs in specific codons (12 and 13), the resultant constitutively active protein is no longer dependent upon upstream input from EGFR^[96,109,112,121,122]. The relevance of KRAS mutations becomes apparent for patients treated with anti-EGFR therapy: abolishing the upstream signal does not likely provide any benefit. This principle has been validated by several studies that have evaluated cetuximab treatment in metastatic colorectal cancer, and KRAS mutational status, in which only patients with wild-type KRAS show improved response, PFS and OS^[109,116,120-124]. Furthermore, this disparity in efficacy has also been observed in a study of KRAS mutational status and panitumumab therapy in refractory metastatic colorectal cancer^[112,125]. Moreover, when evaluated as first-line treatment in conjunction with FOLFOX4, panitu-

mumab increased PFS in patients with wild-type KRAS, while those with mutant KRAS suffered a decrease in PFS^[115]. Heinemann has provided an excellent review of the clinical relevance of EGFR and KRAS status with respect to anti-EGFR therapy in patients with metastatic colorectal cancer^[109].

Bevacizumab is a humanized monoclonal antibody directed against soluble vascular endothelial growth factor A (VEGF-A). The biological agent inhibits VEGF-A binding to vascular endothelial growth factor receptor, thus restricting angiogenesis, a process critical to tumor formation, invasion and metastasis^[126-128]. In 2004, a cardinal study investigating the benefit of bevacizumab addition to IFL therapy compared to IFL alone in patients with previously untreated metastatic colorectal cancer demonstrated increased response rate, PFS and OS in the group receiving the anti-angiogenic biological agent^[129]. Additionally, in patients with disease progression after first-line irinotecan-based therapy, bevacizumab supplementation of FOLF-FOX4 generated increased PFS and OS versus FOLFOX4 or bevacizumab alone^[130]. A subsequent study evaluating first-line bevacizumab or placebo combined with FOLF-FOX4 as well as capecitabine/oxaliplatin (XELOX) revealed two important findings. Addition of bevacizumab to oxaliplatin-based therapy increased PFS when used as first-line therapy^[131]. Combination of capecitabine and oxaliplatin was not inferior to FOLFOX4 therapy^[132]. To explore further the clinical effects of targeted therapeutics, in a phase IIIb trial in 2009, patients received oxaliplatin or irinotecan with bevacizumab, leucovorin and 5-FU as initial treatment for advanced systemic disease^[133]. These patients were then randomly assigned to receive panitumumab or placebo. Remarkably, in the oxaliplatin-based group, those that received panitumumab showed decreased PFS and OS compared to the control group, while there was no difference seen with panitumumab addition in the irinotecan-based group^[133]. In confirmation of this detrimental effect of combined anti-VEGF and anti-EGFR therapy, capecitabine, oxaliplatin and bevacizumab were administered as first-line therapy with or without cetuximab in patients with metastatic colorectal cancer, and addition of cetuximab resulted in decreased PFS^[122].

Currently, according to the National Comprehensive Cancer Network guidelines, patients with unresectable, asymptomatic metastatic disease should undergo initial therapy consisting of one of the following: choice of FOLFOX, CapeOX or FOLFIRI, with or without bevacizumab; or FOLFOX or FOLFIRI with or without cetuximab/panitumumab (specifically for disease characterized by wild-type KRAS gene)^[4]. Alternatively, FOLFOX or FOLFIRI alone can be utilized in an attempt to render patients possible candidates for resection^[4]. Additionally, concomitant use of anti-EGFR and anti-VEGF therapy should be avoided^[4]. Patients should be re-evaluated after 2 mo to determine if conversion to resectability has been achieved. Symptomatic improvement is often seen within weeks of initiating chemotherapy, thus negating the need for local intervention^[63]. With these regimens, response

rates of approximately 50% have been achieved, with 50% reduction in bi-dimensional measurements occurring, and another 25% of patients demonstrating a minor response or stabilization^[64]. In addition, chemotherapy is the only modality that has been demonstrated to increase survival in stage IV colorectal cancer, with median OS of 18-20 mo, which indicated that chemotherapy itself is effective for survival benefit and palliation of disease^[4].

CONCLUSION

Approximately 20% of patients presenting with rectal cancer have stage IV disease^[1,134]. Therefore, a thorough knowledge of palliative options is required to optimize quality of life and provide the best chance of long-term survival. Patients undergoing palliative treatment have a relatively short duration of survival (median: 6-9 mo), with dismal 5-year survival rates (0%-5%)^[64]. This is especially true for patients who present symptomatically with obstruction, pain, bleeding and perforation. Patients undergoing chemotherapy for disseminated metastatic colorectal cancer have demonstrated median survival of 15-20 mo with various treatment options^[4]. Therefore, when evaluating patients with metastatic rectal cancer, the patient's age, comorbidity, extent of disease, functional status, tumor characteristics, and symptoms must be taken into account to determine the best possible treatment approach. Given the fact that the majority of patients ultimately succumb to their disease, the constellation of factors must be utilized to provide the most effective relief with the minimum amount of morbidity and mortality. The patient with significant metastatic burden and a relatively unobtrusive primary tumor seems to benefit from the initiation of chemotherapy without further surgical therapy. Complications necessitating surgery are quite rare in this group of patients. However, symptomatic patients with significant burden of disease require a multidisciplinary team consisting of a surgeon, medical oncologist, gastroenterologist, and/or a radiation oncologist, to develop the most efficacious palliative intervention, to achieve the best goal-directed outcome for patients and family members.

Abstract

The treatment of locally advanced rectal cancer including timing and dosage of radiotherapy, degree of sphincter preservation with neoadjuvant radiotherapy, and short and long term effects of radiotherapy are controversial topics. The MEDLINE, Cochrane Library databases, and meeting proceedings from the American Society of Clinical Oncology, were searched for reports of randomized controlled trials and meta-analyses comparing neoadjuvant and adjuvant radiotherapy with surgery to surgery alone for rectal cancer. Neoadjuvant radiotherapy shows superior results in terms of local control compared to adjuvant radiotherapy. Neither adjuvant or neoadjuvant radiotherapy impacts overall survival. Short course versus long course neoadjuvant radiotherapy remains controversial. There is insufficient data to conclude that neoadjuvant therapy improves rates of sphincter preserving surgery. Radiation significantly impacts anorectal and sexual function and includes both acute and long term toxicity. Data demonstrate that neoadjuvant radiation causes less toxicity compared to adjuvant radiotherapy, and specifically short course neoadjuvant radiation results in less toxicity than long course neoadjuvant radiation. Neoadjuvant radiotherapy is the preferred modality for administering radiation in

locally advanced rectal cancer. There are significant side effects from radiation, including anorectal and sexual dysfunction, which may be less with short course neoadjuvant radiation.

INTRODUCTION

Colorectal cancer is the third most frequent cancer in men and women. In 2009, in the United States 40000 new cases of rectal cancer alone were diagnosed^[1]. The past 2 decades have seen many advances in the treatment of patients with rectal cancer. Surgery remains the mainstay. The standard of surgical care now includes total mesorectal excision (TME), which was shown to significantly decrease local recurrence rates^[2]. Evolution of Combined Modality Treatment (CMT) revolutionized care of locally advanced rectal cancer with the most considerable change the introduction of pelvic radiation. Improvements in preoperative staging with endorectal ultrasound and magnetic resonance imaging have allowed experimentation with different regimens of neoadjuvant (preoperative) and adjuvant (postoperative) radiotherapy (RT).

The goals of this review are to provide a critical over-

view of the most relevant clinical trials, and to evaluate the advantages and disadvantages of different RT regimens, in the adjuvant and neoadjuvant setting, for patients with locally advanced rectal cancer (stages II B and C, III A through C).

ADJUVANT RADIATION

RT for rectal cancer was first introduced in the 1980s, in an attempt to decrease rates of local recurrence in patients with locally advanced rectal cancer; at that time, the local recurrence rates after surgical resection were as high as 50%^[3].

One of the first randomized controlled trials (RCTs) to demonstrate success in control of local recurrence with the use of adjuvant therapy was published in 1985 by the Gastrointestinal Tumor Study Group^[4]. That study randomized 227 patients (data from 202 collected) to 4 arms: (1) no adjuvant therapy (the control arm) ($n = 58$); (2) adjuvant RT ($n = 50$); (3) adjuvant chemotherapy ($n = 48$); or (4) adjuvant CMT ($n = 46$). Patients in the CMT arm had significantly decreased local recurrence rates ($P < 0.009$), as compared with the control arm, but the overall survival rates did not significantly differ ($P = 0.07$). That 1985 publication ushered in the era of adjuvant therapy with RT for patients with locally advanced rectal cancer.

In the United States, the first official recommendation for the use of adjuvant chemoradiation in patients with rectal cancer came from the National Institutes of Health (NIH) consensus statement, published in 1990^[5]. The NIH set the standard of care for patients with stage II and III rectal cancer to include adjuvant chemoradiation without specifying the optimal regimen. Subsequently, extensive research has been conducted on the most advantageous timing and dosage of pelvic RT in patients with locally advanced rectal cancer (Table 1). In 1997, the Norwegian Adjuvant Rectal Cancer Project Group published the results of one of the early trials evaluating the chemotherapy dose in adjuvant chemoradiation for patients with locally advanced rectal cancer^[6]. Previous studies had shown improved locoregional control with adjuvant RT, but high toxicity and poor compliance with adjuvant CMT^[4,7]. The Norwegian trial addressed the important issue of clinically significant complications in the setting of adjuvant CMT for rectal cancer. In that trial, 144 patients were randomized to surgery alone or to adjuvant CMT (chemoradiation with long-course RT and short-term 5-fluorouracil (5-FU)-based chemotherapy). The short-term chemotherapy was tolerated by patients without sacrificing the benefits of improved local control. The minimum follow-up time was 4 years. The 5-year recurrence free rates significantly differed (64% in the CMT arm vs 46% in the surgery alone arm, $P = 0.01$), as did the 5-year survival rates (64% in CMT arm vs 50% in surgery alone arm, $P = 0.05$). Further, a meta-analysis in 1988 reviewed all RCTs evaluating adjuvant therapy (8 RT vs surgery alone, 17 chemotherapy vs surgery alone) with the endpoint of overall survival and found only a small improvement in the adjuvant chemo-

therapy arm [odds ratio (OR), 0.83, 95% CI: 0.70-0.98]. No effect on survival was found in the RT arm^[8].

NEOADJUVANT RADIATION

Efforts aimed at improving local control and long term survival stimulated experimentation with adjuvant RT in the 1990s and gave birth to the concept of neoadjuvant RT. Initial reports from small studies suggested that efficacy with neoadjuvant RT was comparable or improved compared to adjuvant RT, and toxicity was less severe. Delineating the veracity of these small studies intrigued investigators over the subsequent decade. Specifically two different regimens of neoadjuvant RT were being assessed: (1) long course RT, used mainly in the United States; and (2) short course RT, used mainly in Europe.

The European Organization for Research and Treatment of Cancer (EORTC) designed a study to evaluate the efficacy and toxicity profile of neoadjuvant RT (long-course). Four hundred and sixty-six patients were enrolled: 175 were ultimately randomized to surgery alone, and 166 randomized to neoadjuvant RT followed by surgery. Patients in the neoadjuvant arm tolerated the treatment adequately, had significantly decreased local recurrence rates (15% vs 30%, $P = 0.003$), but had no improvement in overall survival^[9]. The Swedish Rectal Cancer Trial^[10] was the first major trial to demonstrate significant improvement in local control with short-course RT (25 Gy in 5 consecutive daily fractions) followed by surgery, compared with surgery alone (11% local recurrence rate with short-course RT vs 27% without, $P < 0.001$). In addition, the Swedish trial was the only trial to demonstrate improved 5-year survival rates for patients in the neoadjuvant arm (58% with short-course RT vs 48% without, $P = 0.004$). The patient population included those with stage I rectal cancer as well as locally advanced disease. Note that the results of that trial, published in 1997, preceded surgical standardization to TME; hence, one of its drawbacks was the lack of standardization in surgical technique.

In response, the Dutch colorectal group performed a similar investigation, with the notable exception of standardizing surgery to TME^[11]. Again, patients were randomized to either short course neoadjuvant RT followed by surgery within 1 wk ($n = 695$) or surgery alone ($n = 719$). A significant decrease in local recurrence rates was found at 2 years in the neoadjuvant RT arm (2.4% vs 8.2%, $P < 0.001$), but no difference in overall survival (82% vs 81.8%, $P = 0.84$). An additional variable examined in this study was the import of a positive circumferential margin (CRM). Positive CRM was significantly correlated with an increased risk of local recurrence; and patients with positive CRM received post operative long course RT. The Dutch colorectal group confirmed the findings of the Swedish rectal trial in terms of local control, contradicted findings of improved survival, and raised a new question regarding the role of selective adjuvant RT with positive CRM. That question was addressed with the Medical Research Council (MRC) CR07 trial, whose results were

Table 1 Randomized control trials evaluating timing and dose of radiation therapy

Trial (year results published)	Study design	Patients	Follow-up (mo)	Treatment	Outcome: overall survival	Outcome: local recurrence
Swedish Rectal Cancer Trial (1997) ^[10]	RCT	1168	60	Neoadjuvant short-course RT vs surgery alone	58% vs 48% ($P = 0.004$)	11% vs 27% ($P < 0.001$)
Dutch TME Trial (2001) ^[11]	RCT	1861	24	Neoadjuvant short-course RT (standard TME) vs surgery alone	82% vs 81.8% ($P = 0.84$)	2.4% vs 8.2% ($P < 0.001$)
German Rectal Cancer Study Group (2004) ^[14]	RCT	799	60	Neoadjuvant long-course RT + chemotherapy vs adjuvant long-course RT + chemotherapy	76% vs 74% ($P = 0.80$)	6% vs 13% ($P = 0.006$)
Polish Colorectal Group (2006) ^[16]	RCT	312	48	Neoadjuvant short-course RT vs neoadjuvant long-course RT	67.2% vs 66.2% ($P = 0.96$)	14.2% vs 9% ($P = 0.17$)
MRC-NCIC (2009) ^[17]	RCT	1350	60	Neoadjuvant short-course RT vs selective adjuvant long-course RT + chemotherapy	70% vs 67.9% (HR 0.91, 95% CI: 0.73 to -1.13, $P = 0.40$)	4% vs 11% (HR 0.39, 95% CI: 0.27 to 0.58, $P < 0.0001$)
NSABP R-03 (2009) ^[18]	RCT	267	60	Neoadjuvant long-course RT + chemotherapy vs postoperative long-course RT + chemotherapy	74.5% vs 65.6% ($P = 0.065$)	10.7% vs 10.7% ($P = 0.69$)
Stockholm III (2010) ¹	RCT	303	Ongoing	Neoadjuvant short-course RT + surgery within 1 wk vs neoadjuvant short-course RT + surgery 4 to 8 wk later vs neoadjuvant long-course RT + surgery 4 to 8 wk later		Ongoing

¹Interim results. RCT: Randomized control trial; RT: Radiotherapy; TME: Total mesorectal excision; MRC-NCIC: Medical Rectal Council-National Cancer Institute of Canada; NSABP: National Surgical Adjuvant Breast and Bowel Project; HR: Hazard ratio.

published in 2009 (see below).

As more data became available, two meta-analyses were published in 2000 and 2001 asking two important questions. First, what is the efficacy of neoadjuvant RT in improving survival, and decreasing local recurrence rates^[12] and second, what is superior in improving survival and decreasing local recurrence: adjuvant or neoadjuvant therapy^[13]? Cammà *et al*^[12] addressed the first question; their analysis included 14 RCTs and found that neoadjuvant RT significantly improved the 5-year survival rates (OR, 0.84, 95% CI: 0.72-0.98, $P = 0.03$), the cancer-related mortality rates (OR, 0.71, 95% CI: 0.61-0.82, $P < 0.001$), and the local recurrence rates (OR, 0.49, 95% CI: 0.38-0.62, $P < 0.001$). The Colorectal Cancer Collaborative Group evaluated 22 RCTs (involving a total of 8507 patients) to determine the answer to the second question. The RCTs compared neoadjuvant therapy, adjuvant therapy, or surgery alone and included both short-course and long-course RT. The group found a significant improvement in the yearly local recurrence rate in the neoadjuvant RT arm (a 46% decrease vs surgery alone, $P = 0.00001$) and in the adjuvant RT arm (a 37% decrease vs surgery alone, $P = 0.002$). But the 5-year survival rate (45% with RT vs 42.1% with surgery alone) and the overall survival rate (62% with RT vs 63% with surgery alone, $P = 0.06$) did not significantly differ. Of note, 30 Gy was identified as the biologically active dose of RT.

The issue of neoadjuvant vs adjuvant RT is further clouded by the inclusion of chemotherapy into treatment regimens. In 2004, the German Rectal Cancer Group compared neoadjuvant CMT with adjuvant CMT in patients with locally advanced rectal cancer^[14]. Patients were randomly assigned to 2 arms: (1) neoadjuvant CMT

($n = 421$); and (2) adjuvant CMT ($n = 402$). All patients received long-course RT and 5-FU-based chemotherapy. The 5-year survival rates (76% with neoadjuvant CMT vs 74% with adjuvant CMT, $P = 0.8$) did not significantly differ. But the local recurrence rates significantly improved in the neoadjuvant arm (6% with neoadjuvant CMT vs 13% with adjuvant CMT, $P = 0.006$). The adjuvant arm had higher rates of acute and long-term toxicity (acute: 27% with neoadjuvant CMT vs 40% with adjuvant CMT, $P = 0.001$; long-term: 14% vs 24%, $P = 0.01$). Another important finding was that overstaging of patients resulted in unnecessary administration of neoadjuvant CMT.

In 2005, Law *et al*^[15] contributed to the controversy surrounding overstaging and overtreatment by suggesting that low risk stage II patients do not benefit from neoadjuvant therapy. They reported data on 224 patients with stage II disease who underwent TME surgery without neoadjuvant or adjuvant CMT. They hypothesized that the benefit of treating stage II disease with adjuvant therapy was less than the risk of complications or toxicity from CMT. Median follow up was 43 mo. Five years recurrence rate was reported as 6% which is comparable to previously reported values for patients undergoing neoadjuvant RT and surgery (2.4%-14.2%, Table 1)^[10,11,14,16-18]. Overall survival was reported as 71% which is also similar to data from previous trials for patients undergoing neoadjuvant RT and surgery (58%-82%, Table 1)^[10,11,14,16-18]. They conclude that there is no advantage to treating low risk stage II rectal cancer patients with negative margins with neoadjuvant therapy. There was an emphatic response to this statement from many authors who felt that that not treating stage II patients with neoadjuvant CMT was egregious^[19].

Once short-course neoadjuvant RT was established to

be safe and effective, the next step was to compare its efficacy with that of long-course neoadjuvant RT. In 2006, the Polish Colorectal Study Group randomized 312 patients to either (1) neoadjuvant short-course RT, surgery within 1 wk, and optional adjuvant chemotherapy or (2) neoadjuvant long-course RT, neoadjuvant chemotherapy, and surgery 6 to 8 wk later. Early RT toxicity was higher in the long-course RT arm (18.2% with long-course RT vs 3.2% with short-course RT, $P < 0.001$), but the 5-year survival rates (66% vs 67%, $P = 0.96$) and the local recurrence rates (9% vs 14%, $P = 0.17$) did not significantly differ. The study concluded that short-course and long-course RT had comparable efficacy, but short-course RT remains the standard of care in Poland because of the lower toxicity distribution and higher compliance rates. In 2009, Guckenberger *et al*^[20] introduced a new regimen for short-course RT, administering twice-daily doses of 2.9 Gy for 1 wk (total dose, 29 Gy) to 118 patients. That regimen lowered the single dose and allowed a 6-h tissue recovery period between treatments, but the daily dose was the same as with standard short-course RT (5 Gy daily \times 5 d). The 188 patients had clinical stage II (50%), III (41.5%), and IV (8.5%) rectal cancer; they all received adjuvant 5-FU-based chemotherapy. The median follow-up time was 46 mo. Late toxicity (grade II) occurred in 11% of the patients. The local control rate was 92%. The 5-year survival rate of 67% compared favorably with previously reported rates in randomized trials that also evaluated daily dosing of short-course RT (58%-82%, Table 1)^[10,11,16].

In the United States, the National Surgical Adjuvant Breast and Bowel Project (NSABP) R-03 trial also compared neoadjuvant CMT and adjuvant CMT in patients with locally advanced rectal cancer^[18]; the NSABP R-03 trial was similar to the German rectal cancer group trial published in 2004^[14]. Both arms of the NSABP R-03 trial used long-course RT, and the chemotherapy regimen was 5-FU-based with leucovorin. The study was initially powered for a sample size of 900, but had to close early due to poor accrual. In all, 123 patients were randomized to neoadjuvant CMT and 131 to adjuvant CMT. The surgical technique was not standardized, but rather left to the discretion of the surgeon. Primary endpoints were the disease-free survival and overall survival rates. The overall survival rates (74.5% with neoadjuvant CMT vs 65.6% with adjuvant CMT, $P = 0.065$) and the locoregional recurrence rates [Hazard ratio (HR), 0.86, 95% CI: 0.41-1.81, $P = 0.693$] did not significantly differ - in contrast to the 5-year disease-free survival rates (64.7% vs 53.4%, $P = 0.011$). Of note, the rate of complete pathologic response was 15% in the neoadjuvant CMT group but the rates of sphincter preservation (48% with neoadjuvant CMT vs 39% with adjuvant CMT) did not significantly differ, per the opinion of the operating surgeon. It is difficult to draw conclusions from the NSABP R-03 trial, because it was underpowered and not standardized in operating technique.

In 2009, the MRC and National Cancer Institute of

Canada (NCIC) combined CR07/CTG C016 trial^[17] addressed the issue of selective adjuvant CMT based on operative margins. The trial randomized 1 350 patients to 2 arms: (1) neoadjuvant short-course RT; or (2) initial surgery with selective adjuvant long-course RT and 5-FU-based chemotherapy based on circumferential (CRM) involvement. The surgical technique was not standardized. Median follow-up time was 4 years; the primary outcome measure was local recurrence. In the selective adjuvant arm, 12% of the patients had a positive CRM, 78% of whom then underwent adjuvant RT. In the neoadjuvant arm, a 61% relative risk reduction (HR, 0.39, CI: 0.27-0.58, $P < 0.0001$) was found for local recurrence, and a 24% improvement (HR, 0.76, CI: 0.62-0.93, $P = 0.013$) was found for disease-free survival. But the 2 arms did not significantly differ in overall survival rates. The MRC CR07/NCIC-CTG C016 investigators concluded that neoadjuvant short-course RT was effective therapy in patients with operable rectal cancer.

BENEFITS OF NEOADJUVANT RT

With the advent of neoadjuvant therapy, reliable methods to evaluate its efficacy and to determine the significance of response to treatment have been necessary. Pathologic tumor response has risen to the forefront, although several tumor grading systems are currently in use. Two recent prospective studies evaluated the impact of tumor response on overall survival in patients with locally advanced rectal cancer^[21,22]. Both studies concluded that tumor downstaging was the only variable that significantly and independently correlated with improved survival.

Most significantly the addition of neoadjuvant radiation has resulted in significant downsizing and downstaging of low locally advanced rectal cancers making sphincter preserving procedures feasible and with good oncologic outcomes. Weiser *et al*^[23] performed a retrospective analysis of 148 patients with locally advanced rectal cancer (within 6 cm of the anal verge) who were treated with neoadjuvant CMT (long-course RT) and selective adjuvant chemotherapy. The decision to perform sphincter-preserving surgery was made intraoperatively. The likelihood of sphincter-preserving surgery was associated with significant tumor downstaging. They concluded that neoadjuvant CMT facilitated sphincter-preserving surgery in addition to intersphincteric resection.

However, short course neoadjuvant radiation does not seem to offer the same results. Sauer *et al*^[14] did not find a significant difference in the rates of sphincter-preserving surgery between their neoadjuvant and adjuvant treatment arms. However, they did note that, within the subgroup of patients deemed to require abdominoperineal resection preoperatively ($n = 194$), the number of abdominoperineal resections actually performed was significantly lower in the neoadjuvant arm ($P = 0.004$). Bujko *et al*^[24] specifically looked at whether neoadjuvant short-course RT offered a benefit for sphincter preservation over neoadjuvant CMT in 316 patients and found no significant difference:

61% of patients in the RT arm and 58% in the CMT arm underwent sphincter-preserving surgery ($P = 0.57$). In conclusion, although short-course RT improves local control, no strong evidence exists that it also improves rates of sphincter-preserving surgery indicating short-course neoadjuvant RT does not have a significant effect on preoperative tumor downsizing or downstaging.

A significant benefit of neoadjuvant RT is patient compliance with treatment. Adjuvant RT has been associated with higher rates of treatment interruption. Lebowitz *et al*^[25] assessed for principle factors associated with treatment interruption in 113 RT patients. Patients in the adjuvant arm had a significantly increased chance of RT interruption, as compared with the neoadjuvant RT arm (OR, 14.08, CI: 1.55-127.87). Development of an adverse event was also significantly correlated with RT interruption (OR, 20.66, CI: 1.76-242).

ANORECTAL FUNCTION OUTCOMES

One of the most important variables evaluating quality of life in rectal cancer is anorectal function, specifically bowel function and sexual function^[26]. This is affected by both chemoradiation and surgical technique. The Dutch colorectal group assessed anorectal functional outcomes after short-course preoperative RT and TME and found significant differences between patients who did vs did not undergo RT^[27]. RT patients had higher rates of fecal incontinence (62% with RT vs 38% without, $P < 0.001$), pad wearing as a result of incontinence (56% vs 33%, $P < 0.001$), and anal blood loss (11% vs 3%, $P = 0.004$). RT patients also reported significantly lower satisfaction with bowel function.

A second prospective study randomized 316 patients to (1) short-course neoadjuvant RT or (2) long-course neoadjuvant chemoradiation^[26]. The goal was to evaluate anorectal and sexual dysfunction and quality of life. Early complications were more common in the chemoradiation arm, but no significant differences were found in the degree of anorectal and sexual function or in quality of life.

In addition to bowel and sexual dysfunction, RT patients may experience acute and late RT toxicity, including nausea/vomiting, postoperative hernia, femoral neck fracture, skin problems (nonhealing perineal wounds), ileus, anastomotic stricture, and fistula. The Dutch colorectal group assessed RT toxicity, intraoperative and postoperative complications, and other variables in patients who underwent short-course neoadjuvant RT vs TME alone^[27]. No differences were found in operative time, intraoperative complications, or hospital stay; however, the amount of intraoperative blood loss was higher in the RT arm ($P < 0.001$). Rates of perineal complications were also higher (29% with RT vs 18% with TME alone, $P = 0.008$). But no significant differences were found in the rate of abdominal wound complications (4.0% with RT vs 3.3% with TME alone) or in the overall postoperative mortality rate.

Frykholm *et al*^[28] looked at long-term complications

(minimum follow-up time, 5 years) after either neoadjuvant short-course RT ($n = 255$) or adjuvant long-course RT ($n = 127$), as compared with surgery alone (control group, $n = 82$). Long-term complications (defined as occurring at least 6 mo postoperatively) included recurrent abdominal pain, diarrhea, fecal incontinence, ileus, cystitis, paresthesias, delayed wound healing, and any neurologic dysfunction. The percentage of patients with small bowel obstruction did not significantly differ between the neoadjuvant RT group and control group. In the adjuvant RT group, the risk of developing a small bowel obstruction was significantly higher ($P < 0.01$). Overall, the frequency of complications possibly related to RT in the neoadjuvant group was 20%; in the adjuvant group, 41%. However, in the control group, the percentage of similar complications was 23%. In addition to finding a significant decrease in local recurrence after neoadjuvant short-course RT (13% in the neoadjuvant group vs 22% in the adjuvant group, $P = 0.02$), the cumulative risk of bowel obstruction was significantly higher in the adjuvant group.

Minsky *et al*^[29] also demonstrated significantly lower rates of adverse events and improved compliance in patients treated with neoadjuvant CMT compared to patients treated with adjuvant CMT. Despite receiving higher doses of chemotherapy, the neoadjuvant arm experienced a 13% incidence of acute grade 3 or 4 toxicity compared to a 48% incidence in the adjuvant arm ($P = 0.045$). A meta-analysis by Birgisson *et al*^[30] found that the most common late adverse effects of RT were bowel obstruction, bowel dysfunction (fecal incontinence), and sexual dysfunction. Several different RT regimens were included in the meta-analysis, offering some insight into how complications correlated with dosage. Overall, in the more recent studies which used lower doses and better techniques, the rates of adverse events were lower. Unfortunately, to date, no specific markers have been identified that might help predict which patients have a higher risk of acute RT toxicity. Further work is needed in this important area of ongoing research.

CONCLUSION

Patients with locally advanced rectal cancer clearly benefit, in terms of locoregional control, from both neoadjuvant and adjuvant RT; and patient compliance is better with neoadjuvant RT. No definitive evidence demonstrates the superiority of using short vs long-course RT.

The current standard treatment for patients with locally advanced rectal cancer in the United States consists of neoadjuvant radiation (45 to 55 Gy administered over 5 to 6 wk), followed by neoadjuvant chemotherapy (5-FU-based infusion + leucovorin), surgery 6 to 8 wk after completion of chemotherapy, and additional adjuvant chemotherapy after surgery^[31]. In contrast, the standard regimen in most of Europe is now neoadjuvant short-course RT. The most recent European Rectal Cancer Consensus Conference concluded that neoadjuvant short-course RT (25 Gy administered over 1 wk), especially when combined with

5-FU-based chemotherapy, improved local control for patients with locally advanced rectal cancer^[32].

Several important trials are currently in progress. The next interim analysis from Stockholm III should provide some clues in the debate concerning short-course neoadjuvant RT and timing of surgery. Given the lack of data supporting improved overall survival rates with neoadjuvant or adjuvant RT, treatment failure in patients with stage II and III rectal cancer likely arises from distant metastases.

Current research trials focus on evaluating the impact of chemotherapy regimens on systemic disease in patients with locally advanced rectal cancer. The NSABP R-04 trial (radiation therapy and either capecitabine or fluorouracil with or without oxaliplatin before surgery in treating patients with resectable rectal cancer is designed to compare capecitabine (with or without oxaliplatin) vs 5-FU (with or without oxaliplatin) in patients with operable rectal cancer who undergo neoadjuvant RT. The EORTC is also currently enrolling patients in a similar trial comparing neoadjuvant CMT and adjuvant chemotherapy with (1) capecitabine and oxaliplatin vs (2) capecitabine alone in patients with locally advanced rectal cancer (PETACC-6).

Abstract

To assess the merits of currently available treatment options in the management of patients with low rectal cancer, a review of the medical literature pertaining to the operative and non-operative management of low rectal cancer was performed, with particular emphasis on sphincter preservation, oncological outcome, functional outcome, morbidity, quality of life, and patient preference. Low anterior resection (AR) is technically feasible in an increasing proportion of patients with low rectal cancer. The cost of sphincter preservation is the risk of morbidity and poor functional outcome in a significant proportion of patients. Transanal and endoscopic surgery are attractive options in selected patients that can provide satisfactory oncological outcomes while avoiding the morbidity and functional sequelae of open total mesorectal excision. In complete responders to neo-adjuvant chemoradiotherapy, a non-operative approach may prove to be an option. Abdominoperineal excision (APE) imposes a permanent stoma and is associated with significant incidence of perineal morbidity but avoids the risk of poor functional outcome following AR. Quality of life following AR and APE is comparable. Given the choice, most patients will choose AR over APE, however patients following APE positively appraise this option. In striving toward sphinc-

ter preservation the challenge is not only to achieve the best possible oncological outcome, but also to ensure that patients with low rectal cancer have realistic and accurate expectations of their treatment choice so that the best possible overall outcome can be obtained by each individual.

INTRODUCTION

In the management of patients with rectal cancer, sphincter preservation is a priority and regarded a marker of surgical quality. Technical and technological advances have led to an increase in sphincter preserving surgery and a fall in the rate of abdominoperineal excision (APE)^[1]. Furthermore, the recognition of the oncological importance of the circumferential, rather than distal resection margin, has allowed an increasingly aggressive surgical approach. The knowledge that a distal margin of 1 cm will safely allow complete tumor removal affords an ever greater proportion of patients the opportunity of sphincter preserving surgery for low rectal cancer^[2]. In addition, our ever increasing understanding of tumor behaviour gives patients new options in the form of non-operative

treatment (following complete response to neo-adjuvant treatment), or transanal excision in selected circumstances. On the other hand, tumor down-staging following neo-adjuvant chemoradiotherapy has not led to the expected increase in sphincter preserving surgery.

Thus, for patients with low rectal tumors, and for whom APE would formerly have been the only option, a number of sphincter preserving options are now available. However, while it may be technically possible to reconstruct (or avoid radical surgery altogether) an increasing majority of patients with rectal cancer, we should pause to consider the overall merits of this approach and consider the patient's overall outcome (both oncological and functional), while remembering that there remain acceptable non-reconstructive alternatives (APE or low Hartmann's procedure). In doing so, a number of factors must be considered and the 'costs' of sphincter preservation evaluated.

ONCOLOGICAL OUTCOME IN THE TREATMENT OF RECTAL CANCER

The oncological outcome is of paramount importance whether anterior resection (AR), APE, transanal excision, or a non-operative approach is adopted in the treatment of low rectal cancer.

High rates of circumferential resection margin (CRM) positivity (up to 40%) following APE in some series and consequent high local recurrence rates have led to suggestions that the outcome following APE is inherently worse than that following AR. It does appear that rectal tumors in patients who undergo APE are often more locally advanced, more poorly differentiated, and show a lesser response to neo-adjuvant chemoradiotherapy^[3]. However, with meticulous surgery and the avoidance of tumor perforation and margin positivity, results following APE can be similar to those after AR^[4]. Indeed, local recurrence rates in the order of 5% can be achieved following the application of a standardised approach^[5,6].

Undoubtedly the technique of APE has drifted from that originally described by Miles^[7] in which a wide dissection of the rectum was performed to produce a cylindrical specimen. Application of TME principles and evolution in technique have resulted in an APE in which the specimen tapers (Morson's waist) at the level of the pelvic floor with a consequent narrow circumferential resection margin and risk of CRM positivity and tumor perforation. Recourse to originally described principles *via* an extra-levator approach avoids "waisting" of the specimen^[8] and reduces the rate of CRM involvement^[9]. Nonetheless, rates of CRM involvement may still lag behind those seen in AR^[10] and there remains a need to further examine surgical technique in APE and develop a standardised approach with appropriate training if needed.

Inter-sphincteric resection represents the most extreme form of sphincter preserving surgery in which part, or all, of the internal sphincter is resected. This approach may be applied to tumors within 2 cm of the sphincter

complex and is made feasible by the recognition that distal intramural tumor spread beyond 1 cm is uncommon. Thus, inter-sphincteric resection becomes an option for patients with tumors within 2 cm of the sphincter complex, in whom pre-operative continence is intact, and for whom the tumor, at least in its distal part, is confined to the rectal wall. Follow-up suggests that local (6.6%) and distant (8.8%) recurrence rates^[11] are comparable to those in published series of APE. Patients with locally advanced (T3-T4) tumors may become candidates for inter-sphincteric resection if a favourable down-staging response to neo-adjuvant chemoradiotherapy is demonstrated^[3]. Those who are not suitable for inter-sphincteric resection and require APE are likely to self-select as they have locally advanced tumors, that are poorly differentiated and show poor response to neo-adjuvant treatment^[3].

Laparoscopy is increasingly employed as a less invasive approach in the management of rectal cancer. While the initial results from the UK MRC CLASSIC trial highlighted increased rates of margin positivity following laparoscopic rectal cancer surgery (when compared to conventional, open TME)^[12], the long-term oncological outcomes do not appear to be compromised^[13,14]. This study remains the only randomised controlled trial to assess the role of laparoscopy in rectal cancer, however results from prospective series of laparoscopic resection have also demonstrated similar oncological outcomes to those reported following open TME^[15].

Transanal surgery for rectal cancer represents an attractive approach that may allow the morbidity and functional sequelae of total mesorectal excision (TME) to be avoided. Better surgical results with lower margin positivity are achieved following transanal endoscopic microsurgery (TEMS) than conventional transanal (TA) excision (2% *vs* 16%)^[16], however outcomes are generally inferior to those following radical resection with a 3-5 fold increased local recurrence risk^[17]. TEMS appears to be a reasonable option (LR < 5%) in selected patients with favourable pathological features (pT1 Sm1; well or moderately differentiated; < 3 cm diameter; no lymphovascular invasion)^[18]. For tumors with less favourable features, the oncological result following TEMS is inferior to that seen after TME. Difficulty in reliably predicting the T-stage pre-operatively remains an obstacle to patient selection. Likewise, prediction of N-stage is problematic as up to 18% of T1 tumors will have associated nodal disease. However, in patients with adverse pathological features after TEMS, subsequent conversion to radical surgery does not appear to be associated with significantly increased LR rates^[18]. In reality, the decision to adopt a transanal approach is frequently based upon the fitness of the patient.

One-fifth to one-quarter of patients following neo-adjuvant chemoradiotherapy will show a complete pathological response. Predicting those likely to respond and those who have had a complete pathological response remains difficult - up to 40% of patients who appear to have had a complete clinical response have residual disease following

resection^[19]. Conversely, approximately 10% of patients who have an incomplete clinical response will show a complete pathological response^[20]. Observation alone may be a viable alternative in selected patients who show a complete clinical response to neo-adjuvant therapy^[20]. Local recurrence has been reported in 11% of those who had a sustained complete clinical response. These patients appear amenable to salvage therapy without adverse oncological outcome in the event of local recurrence^[21].

There may also be a role for full thickness transanal excision of tumor in selected patients with T3 tumors who show an excellent response to neo-adjuvant chemoradiotherapy and who are deemed unfit for or refuse TME, or who had a perceived complete response to neo-adjuvant treatment. The limited available data point to local recurrence and survival figures that are comparable to those achieved with radical surgery^[22]. This approach requires further validation.

Finally, endoscopic submucosal dissection is an evolving technique that may represent an alternative sphincter preserving approach in the management of rectal tumors. This technique has been reported with low complication rates and in patients in whom complete resection is achieved (approximately 70%) recurrence rates at short-term follow-up are low^[23]. Further studies are required to establish the role of this technique.

FUNCTIONAL OUTCOME AND QUALITY OF LIFE FOLLOWING SURGERY FOR RECTAL CANCER

Functional outcome

Frequency, urgency, and soiling (anterior resection syndrome) are common problems after anterior resection that reflect loss of the capacitance and compliance of the rectal reservoir. Approximately 60% of patients experience some degree of incontinence, while one-third experience frequent symptoms of urgency and frequency. Post-operative studies suggest that anorectal dysfunction after low anterior resection is more a factor of reduced compliance and capacity, than diminished sphincter function^[24,25]. Furthermore, reflexes of the anal sphincter that help to maintain continence are preserved after low anterior resection^[26].

Patients undergoing inter-sphincteric resection have the additional insult of reduced internal sphincter function^[24]. Inter-sphincteric resection is associated with a fall in resting anal canal pressures^[27] and continence when compared to conventional anastomosis, but not with a worsening of stool frequency (typically averaging 2/24 h^[28]) and urgency^[29]. Long-term satisfactory continence rates are achievable in 75% of patients^[11]. Outcomes, particularly in the first post-operative year, can be improved by performing only a partial or subtotal resection of the internal sphincter and through construction of a colonic J-pouch^[27,30,32]. Pre-operative radiotherapy significantly worsens the functional outcome following inter-sphincteric resection^[11].

Following straight anastomosis progressive dilatation

of the neorectum can allow some improvement in compliance^[33] and function over time. Colonic reservoirs (J-pouch or coloplasty) may allow early preservation of function by providing a neorectum functionally comparable to the resected rectum. It is technically possible to create a J-pouch in the majority of patients (95%)^[34]. With optimum pouch size (5 cm)^[35,36] and level of anastomosis (< 8 cm from the anal verge)^[37], there appear to be functional advantages to the creation of a colonic J-pouch. Patients undergoing low anterior resection with J-pouch reconstruction have less stool frequency and urgency when compared to those with a straight anastomosis, however this benefit is not maintained beyond two years^[34]. Surprisingly, this functional gain may not impact positively on quality of life after surgery^[38]. Evidence would suggest that there is no significant advantage to coloplasty over straight anastomosis^[38]. Side-to-end anastomosis using a short side limb may represent an alternative to colonic pouch with the limited available data suggesting comparable functional and surgical outcomes, however further studies are needed^[39-41].

The benefits of the colonic pouch may not be attributable to an increased capacity when compared to straight anastomosis, but rather due to the interruption of normal propulsive motility^[42,43].

Pre- or post-operative irradiation has a significant negative impact on function following anterior resection. In the Dutch TME study, pre-operative radiotherapy was associated with a significant increase in bowel frequency and incontinence (62% *vs* 38% for surgery alone) and this had a significant negative impact on patient satisfaction and daily activity^[44]. Incontinence was worst in patients with lower tumors^[44]. These findings have been replicated in other studies with long-term follow-up showing an approximate doubling of symptoms of faecal incontinence, soiling and bowel frequency when compared to patients treated with surgery alone^[45]. Anorectal manometry has shown irradiated patients to have significantly lower resting and squeeze pressure, while endoanal ultrasound has shown increased scarring of the anal sphincter when compared to non-irradiated patients^[24,45]. Short course pre-operative radiotherapy and pre-operative long-course chemoradiotherapy appear to impact similarly on anorectal function^[46]. The functional outcome following post-operative radiotherapy is worse than following pre-operative treatment with patients experiencing increased frequency of defecation and clustering^[47].

While reduced following pre-operative radiotherapy, the functional result in patients undergoing low anterior resection with colo-anal anastomosis appears to better with a colonic J-pouch rather than straight anastomosis or coloplasty at 24 mo follow-up^[48].

Despite increased tumor down-staging, pre-operative conventionally fractionated radiotherapy does not appear to confer an advantage with respect to sphincter preservation over short-course radiotherapy^[49].

Extended pelvic lymphadenectomy is frequently performed in Japan as an adjunct to TME, and often without neo-adjuvant treatment. This approach does not appear to confer an oncological advantage when compared to

TME alone (with neoadjuvant treatment) and is associated with an increased incidence of urinary and sexual dysfunction^[50-52].

Quality of life

There is an absence of randomised studies comparing outcomes following APE and AR for low rectal tumors (due to presumption that AR is superior). As a result, inferences as to their comparative quality of life outcomes can only be drawn from individual studies. None-the-less, the available data challenges the presumption that a permanent stoma automatically renders an inferior quality of life outcome when compared to that following restorative surgery. A meta-analysis of over 1400 patients from 11 studies showed no difference in general quality of life scores between patients who underwent APE and AR. While APE was associated with better emotional and cognitive function scores and superior future perspectives (patients' understanding of disease stage), vitality and sexual function scored better in patients undergoing AR^[53]. These findings were consistent with those of an earlier meta-analysis^[54], however, their interpretation must be tempered by the poor quality of a number of individual studies, and the limited follow-up duration which fails to allow for the progressive functional improvement patients often experience following AR.

MORBIDITY

The argument in favour of observation (and/or trans-anal excision) in complete responders to neo-adjuvant treatment is the avoidance of the morbidity and functional loss associated with TME, with or without a temporary or permanent stoma. Anorectal dysfunction, sexual dysfunction, difficulty voiding, and urinary incontinence are seen in up to one-third of patients following TME. Furthermore, these problems are exacerbated by pre-operative radiotherapy. Post-operative morbidity following laparoscopic and open rectal resection appears to be similar^[12], while a benefit to the laparoscopic approach with respect to long-term complications such as adhesion small bowel obstruction and incisional hernia remains to be proven^[55]. Laparoscopic resection appears to impact similarly on bladder function when compared to open TME, but may be associated with a worse outcome with regard to male sexual function^[56].

For patients undergoing TME, larger studies have shown overall rates of early morbidity of approximately 40%. This figure increases to almost 50% following pre-operative radiotherapy. Of patients undergoing APE, approximately one-fifth develop perineal wound problems^[57]. The incidence of perineal wound problems rises to 30% following radiotherapy^[57] and doubles following extralevator APE (38%)^[10]. Eleven percent of patients undergoing AR developed clinical anastomotic leaks in the Dutch TME trial. The leak rate was not affected by pre-operative radiotherapy, but was reduced with proximal defunctioning stoma (8% *vs* 16%)^[57]. The mortality rate for non-irradiated patients was 3.3% in the same study.

Again, from the Dutch study we know that approximately 50% of patients undergoing AR will have a de-functioning stoma. It is worth noting that at long-term follow-up (median 48 mo) 21% of patients in one study who had undergone sphincter preserving surgery still had a stoma^[58]. Loop ileostomy closure is associated with 17% morbidity, however the majority (80%) of patients can be managed non-operatively^[59].

PATIENT PREFERENCE

The limited available evidence suggests that a majority (65%) of patients with rectal cancer are willing to defer decision making about their surgery to their surgeon^[60].

What is not known, unlike for breast cancer, is the role that patients with rectal cancer would like to adopt in decision making, and how their given role influences their satisfaction with decision making and outcomes. We do know however that the relative importance that surgeons place on various outcomes such as permanent stoma and incontinence is often not matched by their patients^[61]. Surgeons may in particular underestimate their patients' concerns. Furthermore, surgeon's choices may frequently be at odds with their patient's inherent and perhaps unrecognised true preference^[62]. Patients, for example, express a stronger desire to avoid chemotherapy than to avoid permanent stoma, while doctors express the opposite view.

Multimedia decision aids (incorporating patient values into evidence based data) have been used to assess and quantify the relative importance patients with rectal cancer place on different quality of life outcomes. Patients who have had surgery place greater emphasis on the avoidance of incontinence post-operatively than the avoidance of a permanent stoma^[61].

Trade-off techniques are another useful means of gauging patient's true preferences and will often highlight disparity between patients' preferences and those of their physicians^[62]. Using this technique, the strength of a preference is measured by determining the degree of risk of a particular (poor) outcome that the patient would be willing to accept in order to have the treatment. When patient preferences are assessed using time-trade methods, patients strongly express a desire to avoid a stoma with 65% willing to trade a mean of 34% of their life expectancy to avoid this outcome^[63]. Furthermore, patients expressed a stronger desire to avoid the option of APE and thus permanent stoma than their treating physicians. Again, in patients who have had surgery for rectal cancer, the majority of those without a stoma would be willing to trade frequent (monthly) episodes of incontinence in order to avoid a permanent stoma^[64]. APE patients would however hypothetically trade fewer years of remaining life to be without a stoma, than AR patients would to be without incontinence^[65].

While patients may often be happy to defer decisions as to the type of surgery to their surgeons, the majority of those patients who do choose, would favour AR over APE^[60]. More patients who have had AR would choose

that option again, than patients who have had APE (69% vs 46%)^[60]. Interestingly, at longer term follow-up 80% of patients who had APE indicate that they would choose the same option given the benefit of their experience^[60].

CONCLUSION

Sphincter preservation in rectal cancer - a goal worth achieving at all costs? The answer must be no. While we should strive toward sphincter preserving options, we must recognize the limitations of currently available approaches and accept that sphincter preservation may not be the best overall option for each individual patient.

Oncological outcomes following AR and APE should be equivalent, however there remains room to uniformly improve and standardise approaches and outcomes in APE. If equivalence for oncological outcome is achieved, then functional outcome, quality of life, and ultimately patient preference become of paramount importance in decision making for the treatment of low rectal cancer. Anorectal dysfunction and poor functional outcome are common following AR. The alternative of APE or low Hartmann's procedure imposes a permanent stoma. Quality of life following APE appears to be similar to that following AR. Given the choice, most patients would choose AR over APE. It is doubtful however that patients appreciate fully the functional outcome following AR, and also likely that patients harbour excessively negative misconceptions about life with a permanent stoma. Patients must be informed that function may not be as good as they expect after AR, and also that patients who have undergone APE positively appraise this option at follow-up. The morbidity associated with stoma reversal (following AR), and the significant risk of perineal wound problems following APE must also be considered. Non-radical and even non-operative approaches are increasingly an option in the management of selected patients with low rectal cancer that obviate the morbidity and outcomes following TME. Ultimately we must ensure that patients with low rectal cancer have realistic expectations of their treatment options and that their decisions are truly informed.

Abstract

Laparoscopic colon surgery for select cancers is slowly evolving as the standard of care but minimally invasive approaches for rectal cancer have been viewed with significant skepticism. This procedure has been performed by select surgeons at specialized centers and concerns over local recurrence, sexual dysfunction and appropriate training measures have further hindered widespread acceptance. Data for laparoscopic rectal resection now supports its continued implementation and widespread usage by experienced surgeons for select patients. The current controversies regarding technical approaches have created ambiguity amongst opinion leaders and are also addressed in this review.

INTRODUCTION

The benefits of laparoscopic colon surgery compared to the open approach are well established^[1-4]. Furthermore, laparotomy has been associated with an increased morbidity when compared to minimally invasive techniques for colorectal disease^[5]. More recently, the implementation of enhanced care programs coupled to laparoscopic resection has also resulted in a significant reduction in length of stay after both colon and rectal resection^[6,7]. Laparoscopic colon surgery for select cancers is slowly evolving as the standard of care but minimally invasive approaches for rectal cancer have been viewed with significant skepticism.

Laparoscopic rectal resection for cancer is performed by select surgeons at specialized centers. The variability in anatomic definitions of the rectum, technique, selection criteria, and need for neoadjuvant therapy amongst this group of surgeons have made parallel comparisons difficult and ambiguous. Concern over local recurrence, sexual dysfunction and appropriate training measures have further hindered widespread acceptance of this approach. This opinion addresses short-term and oncological outcomes for laparoscopic resection of rectal cancer, the aforementioned obstacles, and current controversies regarding technical approaches.

ONCOLOGICAL OUTCOMES

There are many potential endpoints for determining success for laparoscopic rectal resection. Undoubtedly, the

most significant is ensuring oncologic equivalence when compared to the open technique. This variable can primarily be measured by the adequacy of circumferential radial margins, recurrence rates, and both disease free and overall survival. Furthermore, the incidence of sexual dysfunction and other complications after laparoscopic pelvic dissection should approximate that with the open approach.

Circumferential radial margin

A positive circumferential resection margin (CRM) is a known marker for increased risk of future recurrence^[8]. Strict adherence to the principles of “total mesorectal excision” is essential to preserve the mesorectal envelope, obtain an adequate circumferential margin and therefore reduce local recurrence rates. The first randomized trial for laparoscopic rectal resection showed a trend towards increased CRM positivity (6% open *vs* 12% laparoscopic, $P = 0.19$) for anterior resection^[3]. Although this was initially alarming, several surgeons involved were on their learning curve, and preoperative chemoradiotherapy (CRT) was not standardized. Fortunately, three year outcomes showed that the difference in CRM positivity between laparoscopic and open approaches for anterior resection did not influence local recurrence rates. More recently, five year outcomes revealed no difference between groups in survival, disease-free survival, and local and distant recurrence^[9,10]. Wound/port-site recurrence rates in the laparoscopic arm were 2.4% and also unchanged^[10]. Conversion was associated with significantly worse outcomes overall but not disease-free survival.

In the largest retrospective review to date, Ng *et al*^[11] reported 579 laparoscopic rectal resections for cancer with a CRM positivity of 2.14%. These encouraging results were further substantiated by two recent randomized controlled trials that reported CRM positivity rates of 2.9% (open) *vs* 4% (laparoscopic)^[12] and 1.4% (open) and 2.6% (laparoscopic)^[13].

In 2006, the Spanish Association of Surgeons started an audited teaching program to both make known the results of rectal cancer treatment and improve the outcomes by the teaching process. The quality of the pathologic specimens for laparoscopic and open rectal resection patients was scored and the circumferential radial margin was positive if tumor was located 1 mm or less from the surface of the specimen. No differences between groups for the completeness of the mesorectum or distance of the tumor from the CRM were observed^[14]. Although laparoscopic TME amongst this experienced group approximates that for their open resection for select tumors, the results may not be as favorable for low bulky lesions or those in an obese male or narrow pelvis.

Local recurrence

As highlighted above, the five year results of the MRC CLASSIC trial reported similar regional recurrence for laparoscopic *vs* open resection of rectal cancer. Several other studies have also shown acceptable regional recurrence rates. In their retrospective review, Ng and colleagues reported two port site recurrences and a pelvic recurrence rate of 7.4%^[11]. Similarly, ten year outcomes from a pro-

Table 1 Overall survival for laparoscopic rectal resection with minimal 5 yr follow-up

Authors	Survival (laparoscopic)	Survival (open)	Follow-up (yr)
MRC CLASSIC (Jayne <i>et al</i>)	57.9%	58.1%	5
Sartori <i>et al</i>	75.4%	NA	5
Ng <i>et al</i>	63.9%	55.0%	10
Lam <i>et al</i>	64.0%		5
Laurent <i>et al</i>	82.0%	79.0%	5
Ng <i>et al</i>	70.0%	NA	5
Siami <i>et al</i>	80.2%	NA	5
Bianchi <i>et al</i>	81.4%	NA	5
Tsang <i>et al</i>	81.3%	NA	5

NA: Not applicable.

spective randomized trial for the laparoscopic resection of upper rectal cancers demonstrated a regional recurrence rate of 7.1% with no port-site recurrences^[13]. Laurent and colleagues aimed to assess long-term oncologic outcomes after laparoscopic versus open surgery for rectal cancer from in a retrospective comparative study^[15]. 471 patients had rectal excision for invasive rectal carcinoma during the trial period: 238 were treated by laparoscopy and 233 by open procedure. At 5 years, there was no difference of local recurrence (3.9% *vs* 5.5%, $P = 0.371$) between laparoscopic and open surgery^[15].

The multi-institutional series from Japan reported 1057 selected patients with rectal cancer that underwent laparoscopic surgery^[16]. All the data regarding the patient details and operative and postoperative outcome were collected retrospectively. At thirty months recurrence was found in 6.6% of the 1011 curatively treated patients. Specifically, local recurrence occurred in 11 patients (1.0%) and there was no port-site metastasis (Table 1)^[15].

FUNCTIONAL OUTCOMES

Laparoscopic rectal surgery proponents argue that the view in the pelvis is superior compared to the open approach. This magnification theoretically provides better visualization of the pelvic nerves. However, in the first randomized trial for laparoscopic rectal cancer male sexual function, erection and ejaculation were all significantly reduced with laparoscopic surgery. This should be interpreted with caution considering the aforementioned learning curve and that more patients in the laparoscopic group underwent a full TME, as compared to the open group. Bladder function remained similar between groups.

In a prospective evaluation of sexual function Stamopoulos and colleagues^[17] used the international index of erectile function (IIEF) for 56 patients who underwent rectal cancer surgery (38 open *vs* 18 laparoscopic procedures, 38 low anterior *vs* 18 abdominoperineal resections). Rectal cancer resections were associated with a significant reduction in IIEF scores and high rates of sexual dysfunction at 3 and 6 mo. The IIEF and domain scores at different assessment points were comparable between the laparoscopic and open surgery groups^[17].

Morino *et al.*^[18] also analyzed male sexual and urinary function after laparoscopic total mesorectal excision. They found that sexual desire was maintained by 55.6%, ability to engage in intercourse by 57.8%, and ability to achieve orgasm and ejaculation by 37.8% of the patients. The distance of the tumor from the anal verge and adjuvant or neoadjuvant treatments were the significant predictors of poor postoperative sexual function. Seven patients (14%) presented transitory postoperative urinary dysfunction, all of whom were medically treated. Tumor stage and distance from the anal verge were independently associated with the postoperative global international prostatic symptom score (IPSS). No differences were observed in urinary quality of life. The authors concluded that laparoscopic resection did not reproduce or improve on sexual and urinary dysfunction outcomes obtained in the best open TME series^[18].

In another series with investigators well beyond their learning curve, urinary dysfunction was reported by 6 (6%) patients and 6 (6%) patients had sexual dysfunction, manifesting as retrograde ejaculation in four patients and erectile dysfunction in a further two patients. The low rates of sexual dysfunction in this unit may be attributable to pelvic dissection only being undertaken by experienced, dedicated laparoscopic colorectal surgeons. Previous studies reporting poorer functional outcomes have probably included a significant number of patients on the surgeons' learning curve.

CONVERSION

The conversion rate for laparoscopic rectal resection is variable between centers and levels of expertise. The MRC CLASSIC randomized trial had a conversion rate of 32% for rectal cancer^[3], yet a previous experience of only 20 laparoscopic colon and rectal cases was sufficient to participate. A similar conversion rate (30%) was realized by Ng *et al.*^[11] in their ten year experience with laparoscopic rectal resection. After the inception of this trial significant improvements in energy devices, ports, cameras, and stapling devices have occurred that, combined with their experience, would likely decrease their current conversion rate.

Further analysis has shown that factors associated with conversion are BMI, male sex, and locally advanced tumors^[19].

More recently, conversion rates reflect the beneficial impact of extensive experience. Three large retrospective series (2008-2010) have reported conversion rates as low as 5.4%^[11], 15%^[15], and 4.9%^[20]. The multi-center retrospective series from Japan also demonstrated a reasonable conversion rate of 7.3%^[16].

Conversion rates are as dependent on a reasonable inclusion or selection criteria as surgeon experience. Very low bulky tumors, anterior lesions in men with previous intervention for prostate cancer, T4 lesions, reoperative pelvic dissections and morbidly obese patients should be reserved for the open approach in most cases.

DEFINING THE RECTUM

There has been considerable debate as to the exact length

of the rectum, the site of transition from sigmoid to rectum and most importantly the point of reference from where measurements are made. Within the surgical literature, numerous series have reported rectal cancer as being within 15, 16 and even 18 cm from the verge, although several other series use the dentate line as the reference point. Currently, the variability of these definitions not only impacts surgical decision making between centers but also the timing and need for neoadjuvant therapy, which in turn impacts oncologic outcomes and morbidity rates.

There are also significant differences in practice internationally with respect to the selection criteria used for CRT. In the United States, most practitioners adhere to the NCCN guidelines that recommend neoadjuvant CRT for patients with T3 or N1 disease with tumors within 10 cm of the dentate line^[21]. The Mercury study group^[22] has provided evidence that pre-operative MRI can accurately predict surgical resection margins. This report has led to a paradigm shift in the preoperative investigation and treatment of rectal cancer in the UK. With this approach, CRT is predominantly used when the tumor threatens or involves the mesorectal fascia and in all low rectal cancer where there is an inherent increased risk of involving the CRM.

Despite these apparent discrepancies most surgeons and oncologists generally agree that rectal cancer consists of extraperitoneal and intraperitoneal lesions. Tumors at or below the anterior reflection should be grouped together in investigations and are the real subject of this and other discussions surrounding laparoscopic rectal cancer.

TECHNICAL ISSUES

The most important variable being assessed with laparoscopic vs open rectal resection for cancer is the pelvic dissection. Surgeons must analyze their own ability to perform a laparoscopic total mesorectal excision with the same precision achieved by their open technique. Although this fact seems obvious it cannot be understated. Several studies continue to populate the literature describing a "hybrid" technique. With this approach the mobilization of the left colon is performed laparoscopically and the pelvic dissection and transection of the rectum are performed through a Pfannenstiel or lower midline incision. Outcomes with this technique have been favorable and it certainly has inherent advantages but unquestionably it is not laparoscopic rectal surgery. Therefore, although published results substantiate its role, ideally it should not be included in trials or case series for laparoscopic rectal resection and should not be billed or coded as such. If this procedure continues to demonstrate favorable outcomes and has a shorter learning curve it may require its own procedure code in the future.

Internationally, the straight laparoscopic approach with three or four abdominal trocar sites and a left lower quadrant or periumbilical extraction incision is preferred. Outcomes with this approach (outlined in previous section) were initially concerning but have now more consistently been favorable. As discussed above, the protracted opera-

tive times and concerns over both local recurrence and sexual function have been diminished with increased operative experience. This may be the most technically demanding method and surgeons preferring this technique recognize its limitations. Dividing the lower rectum, providing adequate traction low in the pelvis, and teaching trainees how to perform an appropriate total mesorectal excision are the current challenges. This procedure is less daunting for patients requiring an abdominal perineal resection. They are left without the morbidity of an abdominal wound as the specimen is routinely removed through the perineum.

Proponents of hand-assisted laparoscopy in the United States continuously have demonstrated equivalent outcomes for laparoscopic colon resection with reduced operative times. More recently results with hand-assisted methods for rectal cancer have also been reported with success^[23,24]. When the hand-assisted device is left in place and the pelvic dissection is performed laparoscopically these cases should be included with other minimally invasive approaches to rectal cancer. This approach may be favorable in patients with a bulky mesorectum or when additional tension is required to facilitate accurate transection of the low rectum.

Dividing the rectum laparoscopically is not always technically feasible. The limited angulation of the stapler and physical limitations of working in the bony confines of the pelvis are common deterrents^[25]. In this situation, having an assistant apply perineal pressure may elevate the pelvic floor enough to allow the first cartridge of the stapler to reach the anorectal junction. Furthermore, utilizing a suprapubic port or medicalizing the right lower quadrant port may help. Lastly, if these techniques are unsuccessful a limited lower midline or Pfannenstiel incision can be made and a 30 mm open stapler can be introduced. If an appropriate distal margin is not obtainable with these methods a mucosectomy with partial inter-sphincteric resection and hand-sewn coloanal anastomosis is performed.

In addition to the difficulty with transection, very low anteriorly based and bulky lesions are often challenging. Entering the appropriate plane anterior to Denonvillier's fascia laparoscopically, respecting the need for an adequate radial margin, and maintaining meticulous hemostasis is essential. In this location, tissue planes can be more ambiguous and any bleeding further obscures the appropriate anatomy. If there is considerable doubt that the correct tissue plane is being violated, immediate conversion is warranted. Ideally these tumors are approached by surgeons who are well past their learning curve for laparoscopic pelvic dissection.

The recognition of these technical limitations and the ongoing development of advanced technology led to the introduction of robotic applications for low pelvic dissection. Data for robotic approaches to rectal cancer have recently been published and presented in national and international forums. The advantage of operating with more degrees of freedom for low rectal cancer is apparent and is of particular benefit in a narrow male pelvis. However, concerns over significantly increased cost, operative times, and training have limited its widespread adoption. Furthermore, proponents seem to be employing this

approach *carte blanche* and looking for opportunities to expand its indications rather than using it as a tool. In the era of economic constraints and limited resident exposure to cases a costly technique with ill defined training methods should be used for select cases only.

CONCLUSION

Technical advances in the field of coloproctology have unquestionably improved patient outcomes. However, it is essential that we continue to strive to define the appropriate inclusion criteria for new approaches in regards to patient, disease, and surgeon experience. Historically, new technology, such as the PPH stapler, robotics, and laparoscopy, has become more than an optional approach or "tool". Surgeons inherently develop extraordinary comfort with the technology and tend to expand its indications, often illogically. Creativity and "pushing the envelope" should not be discouraged but when it becomes apparent that new approaches become simply a "means to an end" patients outcomes may be less than ideal.

The abundance of data for laparoscopic rectal resection for cancer supports its continued implantation and widespread usage by experienced surgeons for select patients. Until we become more adept at operating in the low narrow pelvis and transecting the rectum we must recognize that this approach is complementary to our open technique. To ensure the best outcomes we must continue to recognize the difference between the questions, "can you?" and "should you?" in regards to minimally invasive surgery.

Abstract

Several advances in genetics, diagnosis and palliation of pancreatic cancer (PC) have occurred in the last decades. A multidisciplinary approach to this disease is therefore recommended. PC is relatively common as it is the fourth leading cause of cancer related mortality. Most patients present with obstructive jaundice, epigastric or back pain, weight loss and anorexia. Despite improvements in diagnostic modalities, the majority of cases are still detected in advanced stages. The only curative treatment for PC remains surgical resection. No more than 20% of patients are candidates for surgery at the time of diagnosis and survival remains quite poor as adjuvant therapies are not very effective. A small percentage of patients with borderline non-resectable PC might benefit from neo-adjuvant chemoradiation therapy enabling them to undergo resection; however, randomized controlled studies are needed to prove the

benefits of this strategy. Patients with unresectable PC benefit from palliative interventions such as biliary decompression and celiac plexus block. Further clinical trials to evaluate new chemo and radiation protocols as well as identification of genetic markers for PC are needed to improve the overall survival of patients affected by PC, as the current overall 5-year survival rate of patients affected by PC is still less than 5%. The aim of this article is to review the most recent high quality literature on this topic.

Advances in diagnosis, treatment and palliation of pancreatic carcinoma: 1990-2010. *World J Gastroenterol* 2011; 17(7): 867-897 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i7/867.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i7.867>

INTRODUCTION

The vast majority (90%) of pancreatic cancers (PC) are malignant tumors originating from pancreatic ductal cells^[1]. Anatomically, 78% of PCs are located in the head, and the remaining 22% are equally distributed in the body and in the tail^[2]. The most common clinical presentations are progressive weight loss and anorexia, mid abdominal pain and jaundice^[3-5]. Over the past two decades many advances in the diagnosis, therapy and palliation of PC have taken place although the overall survival of affected patients has not improved significantly. The aim of this article is to review the most recent high quality literature on this topic.

SEARCH STRATEGY AND SELECTION CRITERIA

The literature search was targeted at studies that reported at least one of the following aspects of PC: epidemiology, diagnosis, therapy (e.g. surgery, radiotherapy, chemotherapy) and palliation. Randomized controlled trials (RCT) and prospective observational studies were given preference. Each of the topics was searched in MEDLINE, Ovid MEDLINE In-process, Cochrane Database of Systematic Reviews, Database of Systematic Reviews, Database of Abstracts of Review of Effects, EMBASE, PubMed, National Library of Medicine Gateway by established systematic review methods (Jadad Scale for RCT, as well as Downs and Black checklist for observational studies)^[6-8]. Articles from the authors' libraries and reference lists were further reviewed. We limited our search to English-language articles published from January 1990 to September 2010. We then developed a comprehensive and current database to catalog the medical literature on PC. To identify all potential papers, we searched the medical subject headings reported in Table 1. Three authors (Sharma C, Eltawil KM and Molinari M) independently performed the selection of the articles based on the content of titles and abstracts. When in doubt, each article was reviewed entirely. The decision to include articles in this review was reached by consensus. For conciseness, a full list of search strategies, search results, and quality assessment for each included study are available on request from the corresponding author.

EPIDEMIOLOGY

PC is the fourth leading cause of cancer related mortality in the United States with an estimated 42500 new cases and 35000 deaths from the disease each year^[9]. In industrialized countries, the incidence of PC (11 per 100000 individuals) ranks second after colorectal cancer among all gastrointestinal malignancies^[10]. While the mortality rate for males has decreased by 0.4% from 1990 to 2005, the mortality rate for females has increased by 4.4%^[9]. More than 80% of PCs are diagnosed in patients older than 60 and almost 50% have distant metastases at the time of presentation^[10-12]. Men are more frequently affected than women [relative risk (RR) = 1.3] and individuals of African American descent in comparison to Caucasians (RR = 1.5)^[10]. Analysis of overall survival shows that the prognosis of PC is still quite poor despite the fact that 1-year survival has increased from 15.2% (period between 1977-1981) to 21.6% (period between 1997-2001) and 5-year survival has increased from 3% (period between 1977-1986) to 5% (period between 1996-2004)^[10].

RISK FACTORS

Smoking

The risk of PC in smokers ranks second to lung cancer^[13] and it is proportionate to the frequency [≥ 30 cigarettes per day: odds ratio (OR) = 1.75], duration (≥ 50

years: OR = 2.13) and cumulative smoking dose (≥ 40 pack/years: OR = 1.78)^[14]. A meta-analysis of 82 studies from 4 continents has shown that cigarette smokers were diagnosed at significantly younger age and had a 75% increased risk of developing PC in comparison to the regular population^[15] and the risk persisted for 5 to 15 years after cessation^[16]. In a case-control study of 808 PC patients matched against 808 healthy controls, female smokers were at increased risk in comparison to males as they suffered from a synergistic interaction between cigarette smoking, diabetes mellitus (OR = 9.3) and family history of PC (OR = 12.8)^[17].

Diabetes

Nearly 80% of PC patients have either frank diabetes or impaired glucose tolerance^[18]. Diabetes is usually diagnosed either concomitantly or during the two years preceding the diagnosis^[19]. Several studies have assessed the role of diabetes in PC with conflicting results. A meta-analysis of 11 cohort studies found that the relative risk for diabetes was 2.1 [95% confidence interval (95% CI): 1.6-2.8]^[20]. These findings were supported by another cohort study of 100000 Danish diabetic patients which found a standardized incidence ratio of 2.1 (95% CI: 1.9-2.4) in a 4-year follow-up^[21]. A large prospective cohort study of 20475 men and 15183 women in the United States, has shown that the relative risk of PC mortality adjusted for age, race, cigarette smoking, and body mass index (BMI) was proportionate to the severity of abnormal glucose metabolism: RR was 1.65 for post load plasma glucose levels between 6.7 and 8.8 mmol/L; 1.60 for levels between 8.9 and 11.0 mmol/L, and 2.15 for levels equal or more than 11.1 mmol/L^[22]. Diabetes can be an early manifestation of PC as about 1% of new onset of diabetes in patients older than 50 is linked to PC^[23], but there is no evidence that screening for recent onset diabetes would reduce the mortality^[12] or lead to early diagnosis^[24].

The link between abnormal glucose and PC exists only for type II diabetes. A meta analysis of 36 studies has shown that the OR of PC for patients with type II diabetes for more than 5 years was 2.1^[25], while there are no reports on the association between PC and type I diabetes^[26].

Family history of diabetes does not appear to be a risk for PC. Compared to subjects with no family history, diabetics with a positive family history have an OR of 0.8 while non-diabetics with a positive family history have an OR of 1.0^[27].

A recent prospective study found that women with gestational diabetes have a relative risk of PC of 7.1 (95% CI: 2.8-18.0)^[28]. Gapstur and colleagues have proposed a mechanism to explain these findings^[22] by the fact that at high levels, insulin binds to the insulin-like growth factor I (IGF1) receptor^[24] and downregulates IGF binding protein 1^[25] causing an increase in cell growth in PC cell lines^[29,30].

Alcohol

The role of alcohol is controversial and several studies

Table 1 Summary of the terms used singly or in combination for evidence acquisition

Primary MeSH terms	Secondary MeSH terms (epidemiology, diagnosis)	Secondary MeSH terms (treatment, palliation)

have shown inconsistent findings. This might be attributed to multiple associations with confounding variables mainly smoking, socio-economic status^[31] and pancreatitis^[30]. A recent pooled analysis of 14 cohort studies with a sample of 862 664 individuals has shown a slight positive association between PC and alcohol intake only for consumption above 30 g/d (RR = 1.22; 95% CI: 1.03-1.45)^[32]. Contrasting findings were reported by a European epidemiological study with a smaller sample size ($n = 555$) that did not show any association between PC and alcohol consumption^[33].

Compared with light drinkers, men consuming large amounts of hard liquor suffered from a 62% increased risk of PC (95% CI: 1.24-2.10)^[16,34], but this was not observed for women or for beer and wine drinkers^[34].

Although moderate alcohol consumption is not a risk factor, African Americans were found to have a significantly higher OR when adjusted for their drinking habits, suggesting that racial differences might play a role in the development of PC^[35].

Pancreatitis

Several studies have shown a positive association between PC and history of pancreatitis, although the magnitude is still controversial^[36,37]. An international epidemiological study reported that both genders with chronic pancreatitis had an increased risk independently of the cause of pancreatitis^[37]. A large case-control study showed that chronic pancreatitis lasting more than 7 years was associated with a higher risk of PC (RR = 2.04; 95% CI: 1.53-2.72)^[38]. A large Italian study from 1983 to 1992 found similar results, as the risk increased after 5 or more years of chronic pancreatitis (RR in the first 4 years = 2.1, RR after 5 years = 6.9)^[34]. These findings have been challenged by an international study, as the risk was significantly increased only in the early years after diagnosis. This would suggest that pancreatitis might represent a manifestation of PC that becomes apparent only several years later, rather than a risk factor. The risk of PC in chronic pancreatitis has been shown to be especially true for patients affected by hereditary pancreatitis, who were found to have 53 times

the risk in comparison to normal individuals^[39]. This was confirmed by another study that estimated a 40% cumulative risk of PC in patients with hereditary pancreatitis by the age of 70. For patients with paternal inheritance, the cumulative risk of PC was even higher with risk up to 75%^[40]. Cytokines, reactive oxygen molecules and pro-inflammatory compounds seem to be responsible, as inflammation is a risk factor for many other solid tumors^[38].

Genetic predisposition for PC

Genetic predisposing factors have been a topic of intense research in the last decades. Case reports of families with multiple affected members suggest that PC might have a hereditary background^[41]. Yet, a large population study on twins identified hereditary factors for prostatic, breast and colorectal cancers, but not for PC^[42]. A Canadian study on patients with suspected hereditary cancer syndromes found that the standardized incidence rate of PC was 4.5 (CI 0.54-16.) when cancer affected one 1st degree relative, and increased to 6.4 (CI 1.8-16.4) and 32 (CI 10.4-74.7) when two and three 1st degree relatives were affected, respectively^[43]. This translates to an estimated incidence of PC of 41, 58 and 288 per 100 000 individuals, respectively, compared to 9 per 100 000 for the general population^[44].

Brentnall *et al.*^[45] and Meckler *et al.*^[46] described examples of autosomal dominant PC in individuals presenting at early age (median age 43 years) and with high genetic penetrance (more than 80%). A mutation causing a proline (hydrophobic) to serine (hydrophilic) amino acid change (P239S) within a highly conserved region of the gene encoding paladin (PALLD) was found in all affected family members and was absent in non-affected individuals of the same family (family X). Another study has shown that the P239S mutation was only specific for family X and was not a common finding in other individuals with suspected familial PC^[47]. Currently, genetic predisposition is thought to be responsible for 7% to 10% of all PC^[48]. Genetic factors including germline mutations in p16/CDKN2A^[49], BRCA2^[50-52] and STK 11^[53] genes increase the risk of PC. The combination of all these known genetic factors accounts for less than 20% of the familial aggregation of PC, suggesting the role of other additional genes.

A systematic review and meta analysis of studies that quantified familial risk of PC has shown that individuals with positive family history have an almost two-fold increased risk (RR = 1.80, CI 1.48-2.12)^[54]. Therefore, families with two or more cases may benefit from a comprehensive risk assessment involving collection of detailed family history information and data regarding other risk factors^[55]. A case-control study of PC in two Canadian provinces (Ontario and Quebec) assessed a total of 174 PC cases and 136 healthy controls that were compared for their family histories of cancer. Information regarding the ages and sites of cancer was obtained in 966 first degree relatives of the PC patients and for 903 first degree relatives of the control group. PC was the only malignancy in excess in relatives of patients with PC, compared to the control group (RR = 5, $P = 0.01$). The lifetime risk of PC was 4.7% for the first degree relatives and the risk was 7.2%

for relatives of patients diagnosed before the age of 60^[56].

Besides the isolated aggregation of PC in some families, several other hereditary disorders predispose to PC in known familial cancer conditions^[57]. These include hereditary pancreatitis, Puetz-Jeghers syndrome, familial atypical multiple mole melanoma, familial breast and ovarian cancer, Li-Fraumeni syndrome, Fanconi anaemia, Ataxia-telangiectasia, familial adenomatous polyposis, cystic fibrosis and possible hereditary non-polyposis colon cancer or Lynch syndrome^[11,55,58-60].

Familial PC registries

As the prognosis of PC is generally poor, there has been a strong interest in detecting genes or other markers that could help identify high risk patients at an early stage. Although a precise genetic marker for this scope is not currently available, geneticists and epidemiologists have been profiling traits of high risk families enrolled in registries established in North America and Europe^[61]. Even if there is no standardized definition for familial PC, most authors apply the term to families with at least two first degree relatives affected by PC in the absence of other predisposing familial conditions^[61]. The creation of familial PC registries has been used not only for identification of genetic mutations, but also for the screening of high risk individuals. In selected centers in North America and Europe, screening programs for high risk individuals have been implemented with the use of endoscopic ultrasound (EUS) and computed tomography (CT) scanning or magnetic resonance imaging (MRI). Such early diagnosis of PC within a comprehensive screening program is hoped to ultimately result in improved survival^[62]. The discovery of the genetic bases of inherited PC continues to be an active area of research, and in 2001 a multi-center linkage was formed to conduct studies aimed at the localization and identification of PC susceptibility genes (PAC-GENE)^[63]. The complex nature of pedigree data makes it difficult to accurately assess risk based upon the simple counting of the number of affected family members, as it does not adjust for family size, age of onset of PC, and the exact relationship between affected family members. Therefore, computer programs have been developed to integrate these complex risk factors and pedigree data. In April 2007, the 1st risk prediction tool for PC, PanaPro was released^[64]. This model provides accurate risk assessment for kindreds with familial PC as the receiver operating characteristic (ROC) curve was 0.75 which is considered good for predictive models.

Nutritional status

A number of studies have explored the relationship between BMI, lifestyle, diet and the risk of PC, but uncertainty regarding the strength of this relationship still exists. A recent case-control study of 841 patients and 754 healthy controls showed that individuals with a BMI of 25-29.9 had an OR of 1.67 (95% CI: 1.20-2.34) in comparison to obese patients (BMI of ≥ 30) who had an OR of 2.58 (95% CI: 1.70-3.90) independently of their diabetes status^[65]. The duration of being overweight was

significantly longer among patients with PC than controls. Being obese or overweight, particularly in early adulthood, resulted in earlier onset of PC (age at presentation of PC was 61 years for overweight patients and 59 years for obese) when compared to the median age of diagnosis (64 years) in the general population^[66]. A number of studies reported that central weight gain measured by waist circumference and/or waist-to-hip ratio had a statistically significant increased risk compared to those with peripheral weight gain (RR = 1.45, 95% CI: 1.02-2.07)^[67,68]. The known risk factors for PC are summarized in Table 2.

CLASSIFICATION

Anatomical classification

According to the location, PC can be divided in three groups: tumors of the head, body and tail. PCs of the head are at the right side of the superior mesenteric vessels, and tumors of the neck and body are located between the superior mesenteric vessels and the inferior mesenteric vein. PCs of the tail are located to the left of the inferior mesenteric vein.

A large epidemiological study^[2] of 100,313 patients in the United States has shown that 78% of PC presents in the head, 11% in the body and 11% in the tail (Figure 1).

Pathological classification

Recent advances in surgical pathology techniques integrated with molecular biology have allowed advances in the modern classification of PC. A summary of the clinico-pathological features of the different categories of PC is shown in Table 3.

Figure 1 Graphical representation of the pancreas and frequency of pancreatic cancer in the three anatomical sections: head, body and tail. PC: Pancreatic cancer.

Ductal infiltrating adenocarcinoma

Ductal infiltrating adenocarcinoma (DIA) represents the most common type (85%-90%) of PC originating from ductal epithelial cells. Most DIAs appear as whitish masses, hard at palpation and poorly defined from surrounding tissues, predominantly solid although cystic degenerations can be seen in larger tumors^[89]. The microscopic appearance of DIA ranges from well-differentiated neoplasms difficult to distinguish from reactive gland, to poorly differentiated. The majority of DIAs are moderately to poorly differentiated and develop a dense desmoplastic stroma^[89]. Mutations in the KRAS2 or p16/CDKN2A genes are observed in 90% of patients, TP53 gene abnormalities in more than 75% and more than 55% of cases have changes in MADH4/DPC4 genes. Tumors showing loss of DPC4 expression have a worse outcome than those with intact DPC4^[90], and immunolabeling for DPC2 protein can help to classify metastatic carcinomas of unknown primary etiology^[91].

Solid pseudopapillary neoplasm

Solid pseudopapillary neoplasms (SPPN) represent a small proportion of PCs (3%) and present as solid, or solid and cystic masses. They are malignant epithelial neoplasms made of poorly cohesive cells that form pseudo-papillae around the blood vessels^[91]. The majority of SPNN are grossly well demarcated, but typically do not have a well formed capsule. The majority are solid, yellowish and soft^[92]. Larger tumors usually develop cystic degeneration filled with blood and necrotic debris. Cases that are almost completely cystic without a solid component have also been reported^[91].

Molecular analyses have shown that SPNN are different from ductal adenocarcinomas as they do not harbor mutations in the Kras 2, p16/CDKN2A, TP53, MADH4/DPC4 genes^[93]. In contrast, 90% of SPNN have a mutation on chromosome 3p (CTNNB1) respon-

DIA: Ductal infiltrating adenocarcinoma; SPPN: Solid pseudo-papillary neoplasm; IPMN: Intraductal papillary mucinous neoplasm; NA: Not applicable.

sible for the metabolism of β -catenin protein causing its accumulation in the cytoplasm and nucleus of neoplastic cells^[94]. As a result alteration in β -catenin protein expression disrupts E-cadherin which is a key regulator of cell junctions causing poor adhesion of neoplastic cells^[95]. Although there is some histological overlap between SPNN and other tumors of the pancreas, immunolabeling for β -catenin protein may help establish the diagnosis.

Intraductal papillary mucinous neoplasm

Intraductal papillary mucinous neoplasms (IPMNs) represent 5% of all PCs and are papillary epithelial mucin-producing neoplasms arising in the main pancreatic duct or in one of its branches. IPMNs are relatively common with increasing age of the population^[91] and the mean age at presentation is 65 years^[96]. IPMN is a potential premalignant condition and the risks of developing invasive adenocarcinoma increase with tumor size and when originating in the main pancreatic duct.

Adenocarcinoma is present in up to one-third of patients with IPMN and current guidelines recommend surgical resection when IPMNs are greater than 3 cm, in the presence of main pancreatic duct dilatation and when mural nodules are detected^[97].

Neoplastic cells of IPMN are columnar with gene profiles similar to infiltrating ductal carcinoma. About 25% of patients show loss of heterozygosity of the STK11/LKB1 gene^[98,99]. Other frequent gene mutations are TP53, KRAS2, and P16/CDKN2A^[100].

Pancreatic intraepithelial neoplasia

Pancreatic intraepithelial neoplasia (PanIN) represents a

neoplastic proliferation of mucin producing epithelial cells confined to the smaller pancreatic ducts and is considered a precursor to invasive ductal carcinoma^[101].

PanINs are usually characterized by lesions too small to be symptomatic or to be detected by current imaging technologies^[89]. Microscopically, PanINs are classified into three grades (PanIN-1, PanIN-2 and PanIN-3) based on the progressive degree of architecture abnormality and cellular atypia^[102]. PanIN-1 shows minimum cellular atypia, PanIN-2 moderate changes and PanIN-3 is equivalent to PC-*in-situ*. The discovery of specific molecular changes present in both PanIN and PC has helped to establish that these small lesions are the precursors to DIA^[103]. Early abnormalities of IPMNs are telomerase shortening and activating point mutations in the KRAS2 gene while intermediate mutation is the activation of the p16/CDKN2A gene and late events are alterations in the TP53, MADH4/DPC4, and BRCA2 genes^[102]. The understanding that many DIAs arise from PanIN lesions has prompted screening efforts on the detection of these small and potentially curable lesions^[104].

Pancreatoblastoma

Pancreatoblastoma is a rare malignant tumor (0.5% of PC) usually presenting in the pediatric age group. Generally, it appears as a soft and well demarcated mass with epithelial or acinar differentiation, but often it has cells with endocrine and mesenchymal characteristics^[79]. Most pancreato-blastomas affect children with a mean age of 5 years and are frequently associated with elevated levels of serum alpha fetoprotein. The median survival of patients with pancreato-blastomas is 48 mo and the 5-year

survival rate after successful resection is 50% (95% CI: 37%-62%)^[80,105].

The majority of pancreato-blastomas have loss of heterozygosity of chromosome 11p from the maternal side^[106]. These molecular findings unite pancreatoblastoma with other primitive neoplasms such as hepatoblastoma and nephroblastoma^[107]. Genetic alterations in the adenomatous polyposis coli (APC)/ β -catenin pathway have also been detected in most pancreato-blastomas including mutations in β -catenin (CTNNB1) and APC genes^[107].

Undifferentiated carcinoma

Undifferentiated PC (UPC) lacks differentiation direction^[91] and presents with symptoms similar to patients with DIA, but has a worse prognosis as it has a more aggressive behavior and tends to metastasize and infiltrate surrounding organs in early stages^[82]. The average time from diagnosis to death is about 5 mo and only 3% of patients are alive at 5 years after undergoing surgical resection. UPCs can form large locally aggressive masses and may present with severe hemorrhage and necrosis. The majority of UPCs have KRAS2 gene mutation suggesting that they arise from pre-existing ductal adenocarcinomas that transform into poorly differentiated tumors during their progression^[108].

Medullary carcinoma

Medullary carcinoma (MC) is a variant of PC characterized by poor differentiation and syncytial growth that has been described and recognized only in recent years^[84]. Patients with MC have a better prognosis and are more likely to have a family history of any kind of cancer^[109]. MC does not differ significantly from other classes of PC in its clinical presentation, age and gender. These tumors tend to form well demarcated soft masses and microscopically they are usually poorly differentiated with pushing rather than infiltrating features^[110]. Focal necrosis and intratumoral lymphocytic infiltration can be prominent similar to MC of the colon and other tumors with microsatellite instability^[89]. MCs have been shown to have loss of expression of one of the DNA mismatch repair proteins (M1h1 and Msh2) and mutation in the BRAF gene, which is a downstream effector of the k-ras pathway^[111]. Patients with MC and their families may benefit from genetic counseling and more frequent screening for early detection of other common cancers. The prognosis of MC is better than adenocarcinoma, although it is not responsive to adjuvant chemotherapy based on fluorouracil (5-FU), similar to colon cancer with microsatellite instability^[112].

Other rare classes of PCs

Mucinous cystadenocarcinoma: Malignant cystic neoplasms are rare entities that account for only 1% of all pancreatic tumors^[113]. Both serous and mucinous cystic neoplasms are tumors of the exocrine pancreas with different biological behaviors. Serous cystadenomas are considered benign tumors with almost no malignant potential often managed expectantly unless symptomatic. However, the preoperative differentiation between a benign serous

cystadenoma and malignant serous cystadenocarcinoma remains difficult^[114]. Histologically, cystadenocarcinomas appear identical to serous cystadenomas and are distinguished only by the presence of lymphovascular invasion or metastases^[115]. Mucinous cystadenocarcinomas resemble DIAs although some cell populations can present with undifferentiated features and other histological characteristics such as osteoclast-like giant cells, adenosquamous carcinoma, choriocarcinoma, or high-grade sarcoma^[116-119]. Mucinous cystic neoplasms of the pancreas are slowly growing and only about 20% show invasive features^[120,121].

The prognosis of cystadenocarcinoma is favorable compared to DIA with 5-year survival rates of 56% after radical resection^[85]. There is limited evidence on the role of chemotherapy for cystadenocarcinomas of the pancreas as they appear to be unresponsive to current chemotherapy agents and radiation therapy^[122,123].

Adenosquamous carcinoma: Adenosquamous carcinoma has previously been referred as adenoachantoma, mixed squamous and adenocarcinoma, and mucoepidermoid carcinoma. Histologically, they are characterized by mixed populations of adenomatous cells and cells with varying amount of keratinized squamous features. Usually this tumor affects patients in their seventh decade of life, with symptoms and pancreatic distribution similar to DIAs. Although it is reported that adenosquamous carcinomas represents 4% of all PCs (range 3%-11%), the literature on the natural history and survival is limited to case series only^[86]. The prognosis seems to be worse than DIAs, with a mean survival of 5-7 mo even after surgical resection^[86,87]. Lymphovascular and perineural invasion appear to be common and early features of adenosquamous carcinomas and the role of adjuvant chemo and radiation therapy is still not clear^[124].

Acinar cell carcinoma: Acinar cell carcinomas (ACCs) represent less than 2% of all pancreatic malignancies^[87,88]. ACCs are predominantly constituted by neoplastic cells with immunohistochemical staining characteristic for exocrine enzymes such as trypsin, chymotrypsin or lipase, and they present in older patients than DIAs and the prognosis is slightly better, although the literature is somewhat limited^[125,126]. Symptoms at presentation are aspecific and include abdominal pain and weight loss that are similar to all other PCs^[125]. Very rarely, patients with ACC can develop subcutaneous fat necrosis secondary to exceedingly high concentrations of serum lipase and contrary to DIAs, bile duct obstruction causing jaundice is not as common^[125]. Median survival for ACC confined to the pancreas treated by surgical resection is 38 mo, whereas it is 14 mo for individuals with unresectable disease^[88]. For the majority of patients, surgical management is not curative as distant recurrent disease is more frequent than in DIA, suggesting the presence of early micrometastases even when the tumors are in the early stages^[88]. Because ACCs are rare, there is a lack of studies on the role of chemotherapy, although radiation therapy seems to provide good responses in patients with regional unresectable disease^[88].

DIAGNOSIS

Clinical presentation

Early symptoms of PC are notoriously difficult to measure as educational and economic factors influence their perception and reporting^[127,128]. Cholestatic symptoms are more common in early PC of the head, while abdominal and back pain are more common in patients with distal PC and in patients with tumors infiltrating peripancreatic nerve tissue^[129]. The appearance of these symptoms usually indicates advanced disease (Table 4)^[129,130].

Early symptoms are usually vague such as anorexia, moderate weight loss, and early satiety^[131]. Diabetes might be a sign of PC particularly when presenting during or beyond the sixth decade of life in the absence of risk factors and family history^[20]. Diabetes is detected in 60%^[132] to 81%^[133] of PC patients within two years of their diagnosis. Early detection is possible if symptoms raise clinicians' suspicion, as 25% of patients report upper abdominal discomfort up to 6 mo prior to their diagnosis^[134,135].

In two European studies^[128,130], weight loss was present in 66%-84% of patients, jaundice (bilirubin level > 3 mg/dL) in 56%-61%, recent onset of diabetes in 97% and distended palpable gall bladder in 12%-94%, energy loss in 86%, abdominal pain in 78%, back pain in 48%, nausea in 50%, clay-coloured stools in 54%, dark urine in 58%, jaundice in 56% and pruritis in 32% of patients.

Serum tumor markers

Several serum tumor markers are associated with PC, however, to date, no single marker has been found to be optimal for screening.

Carbohydrate antigen 19-9: Carbohydrate antigens have been used as markers for several cancers^[136,137]. The production of these antigens seems to be caused by the up-regulation of glycosyl transferase genes^[138]. Among these carbohydrate antigen epitopes, Sialyl Lewis^a (sLe^a) detected by the 1116NS19-9 monoclonal antibody is commonly called carbohydrate antigen 19-9 (CA19-9)^[139]. The serum levels of CA19-9 at the time of diagnosis and during follow-up of PC provide useful diagnostic and prognostic information^[140,141]. Its sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) are 70%-90%, 43%-91%, 72% and 81%, respectively^[142-145]. A worse survival was observed in patients with pre-operative CA19-9 levels above 370 U/mL (median survival 4.4 mo *vs* 9.5 mo if CA19-9 < 370 U/mL, *P* value < 0.01)^[146]. In another study, serum levels of CA19-9 > 200 U/mL were associated with a survival rate of 8 mo compared to 22 mo for patients with lower tumor antigen levels (*P* < 0.001)^[147]. In a prospective study of patients undergoing curative resection for PC, post-operative CA19-9 < 37 U/mL was associated with a longer median and disease-free survival compared to the control group^[148-150]. One of the limitations of CA19-9 is that high serum bilirubin can falsely increase its level and therefore the risk of false positive results in patients with jaundice. This is not observed for other markers such as carcinoembryonic antigen (CEA) and carbohydrate antigen 242 (CA 242)^[141].

Table 4 Presenting symptoms of advanced pancreatic cancer

Symptom	Percentage
Abdominal pain	78-82
Anorexia	64
Early satiety	62
Jaundice	56-80
Sleep disorders	54
Weight loss	66-84
Diabetes	97
Back pain	48
Nausea and weight loss	50-86

CEA: CEA is part of a subgroup of glycoproteins functioning as intracellular adhesion molecules. CEA was first detected in pancreatic secretions, and several studies have shown high levels of CEA in the pancreatic juice of patients with PC^[151-153]. A Japanese study found significantly higher CEA levels in the pancreatic juice of PC patients compared to those with benign pancreatic diseases. When the CEA cut off level in pancreatic juice was 50 ng/mL, the PPV, NPV, and the accuracy for diagnosis of carcinoma were 77%, 95% and 85%, respectively. CEA levels in pancreatic juice were higher in smaller tumors in comparison to advanced PC due to the incomplete obstruction of the pancreatic duct^[154]. A recent study examining single *vs* combined efficacy of tumor markers showed that CEA (> 5 ng/mL) alone had a sensitivity of 45% and a specificity of 75% in comparison to CA19-9 which had a sensitivity of 80% but lower specificity (43%) (*P* = 0.005)^[141,155]. The combination of CEA (> 5 ng/mL) and CA 19-9 (> 37 U/mL) decreased the sensitivity to 37%, but increased the specificity to 84%. Similarly, the combination of CEA (> 5 ng/mL) and CA242 (> 20 U/mL) decreased the sensitivity to 34% and increased the specificity to 92%. Yet, CEA and CA242 are currently not used as single tumor markers for PC, and the simultaneous use of CEA and CA19-9 provides the same information as CA19-9 alone^[156-158].

CA 242: CA 242, a sialylated carbohydrate was first defined by Lindholm *et al* in 1985 and has been used for diagnostic and prognostic purposes^[159,160]. For PC, its diagnostic sensitivity and specificity are 60% (*P* = 0.073) and 76% (*P* = 0.197), respectively, comparable to CEA. It also seems to be valuable in differentiating PC from benign pancreatic tumors as well as other hepatobiliary cancers and to predict outcomes as survival rates in CA 242 positive patients are lower than those with negative serum levels (*P* = 0.002)^[141].

In a study comparing CA 242 and CA19-9^[161], CA 242 appeared to be an independent prognostic factor for patients with resectable disease as serum levels of CA 242 < 25 U/mL were associated with a significantly better survival (*P* < 0.05). For patients with unresectable disease, poorer outcomes were observed when CA 242 levels were > 100 U/mL.

Similar results have been confirmed by Ni *et al*, who found that CA 242 is an independent prognostic factor

Table 5 Summary of the performance characteristics of serum tumor markers for the diagnosis of pancreatic cancer

in PC yielding more information than CA 19-9^[142,161]. In this study the use of combined tumor markers resulted in lower sensitivity, but higher specificity (Table 5). Despite these findings, CA 242 is not used in clinical practice as commonly as Ca 19-9 due to the limited number of laboratories equipped to run this test.

Other tumor markers

Recent studies have identified other serum molecules such as CA494^[168], CEACAM1^[169], PTHrP^[170], TuM2-PK^[171], CAM 17.1^[172] and serum beta HCG^[173] as potential markers for PC. Although preliminary results appear promising with sensitivity and specificity comparable and sometimes superior to CA19-9 and CEA, their clinical use has to be confirmed in larger studies and their role is currently confined to a limited number of medical centers and for research purposes.

Imaging modalities

Although PC may be detected with one particular diagnostic test, proper staging often requires the use of several imaging modalities^[174].

Abdominal ultrasound: Trans-abdominal ultrasound (US) is currently used as a screening test for patients with suspected PC^[175]. Its sensitivity ranges between 48%^[176] and 89%^[177], specificity between 40%^[178] and 91%^[179] and accuracy between 46%^[176] and 64%^[180]. PCs measuring less than 1 cm are detected by US in only 50% of cases, while the sensitivity increases to 95.8% for tumors larger than 3 cm^[177]. Other factors affecting the sensitivity of US are the operator's experience^[181] and the technical character-

istics of the machine. Newer US machines such as tissue harmonic imaging decrease artefacts and improve tissue contrast and therefore diagnostic accuracy^[182]. US has a relatively low performance profile for the staging of PC as its sensitivity for lymph node involvement only ranges between 8%^[159] and 57%^[177].

Color Doppler US has been used to assess the possible involvement of the portal vein and superior mesenteric vessels with a sensitivity ranging between 50%^[183] and 94%^[184], specificity between 80% and 100%^[183] and accuracy between 81% and 95%^[175].

The recent introduction of intravenous contrast has been shown to improve evaluation of the vascularity of pancreatic lesions allowing differentiation between PC and other conditions with 90% sensitivity, 100% specificity and 93% accuracy^[185]. Currently, US is considered a useful imaging modality for the initial screening of PC based on its ability to document unresectability (PPV = 94%)^[176]. However, the PPV for resectability is only 55%^[186], therefore, other imaging techniques are usually employed for better staging.

EUS: EUS provides high resolution images of the pancreas without interference by bowel gas^[187]. Despite the advancement of CT scans, EUS appears to have a higher sensitivity in detecting small PCs (98%) in comparison to CT (86%)^[188]. EUS has higher sensitivity compared to CT for local tumor staging (67% *vs* 41%), similar sensitivity for lymph node involvement (44% *vs* 47%) and potential tumor resectability (68% *vs* 64%)^[185]. EUS has a NPV of 100% for PC of the head^[186,189] and an accuracy of 90% for the assessment of portal and splenic vein inva-

sion^[178,190]. On the other hand, EUS does not appear to be accurate enough in assessing the invasion of SMA and superior mesenteric vein (SMV) with a NPV of 82% and sensitivity of only 50%^[191,192].

In order to improve EUS performance in PC staging, recent studies have assessed the benefits of using parenteral contrast agents. This technique has shown 92% sensitivity, 100% specificity, 100% PPV, 86% NPV and 95% accuracy^[193]. Although EUS is becoming a leading modality for staging and diagnosis of PC, drawbacks of this technique are the fact that it is invasive, highly operator dependent, costly and associated with a small risk of pancreatitis (0.85%)^[194], bleeding and duodenal perforation.

CT: On contrast CT, PC appears as an ill-defined, hypoattenuating focal mass with dilatation of the upstream pancreatic and/or biliary duct^[174]. Optimum visualization of the pancreas requires imaging acquisition obtained during both arterial and portal phases^[195]. Sensitivity and specificity of thin section triple phase helical CT is 77% and 100%, respectively, for lesions less than 2 cm^[196]. In a multicentric trial, the diagnostic accuracy of CT for resectability was 73% with a PPV for non resectability of 90%^[197].

With the advent of multi detector CT scanners (MDCT), the pancreas can be imaged at a very high spatial and temporal resolution^[198,199]. The dual phase pancreatic protocol MDCT using 1 to 3 mm slice collimation is one of the most sensitive techniques for metastatic disease to the liver and peritoneum^[186,200,201]. Recent studies have shown that MDCT has a NPV of 87% for tumor resectability compared to a NPV of 79% for conventional helical CT^[202] and with an accuracy between 85% and 95%^[203,204].

Images from MDCT can be used to visualize the biliary tree and normal vascular variants such as replaced hepatic arteries before surgical planning. Gangi *et al.*^[198] reported that pancreatic ductal dilatation in asymptomatic patients could be identified between 0 to 50 mo before PC diagnosis was confirmed. The sensitivity, specificity and accuracy of CT in the presence of hypo-attenuated pancreatic lesions, pancreatic ductal dilatation with cut-off, distal pancreatic atrophy, pancreatic contour abnormalities and common bile duct dilatation are reported in Table 6^[205].

Despite these improvements, interpretation of the CT scan is quite challenging in the setting of pancreatitis forming mass effects^[206] and in the presence of loco-regional lymph node involvement and small hepatic metastasis^[207].

Magnetic resonance imaging-magnetic resonance cholangiopancreatography: In most institutions, MRI is performed when other imaging modalities provide insufficient data for the clinical staging of the tumor, or when treatment planning can not be based on the images obtained by other techniques. Several studies have shown that MRI is superior to CT for the detection and staging of PC (100% *vs* 94%, respectively)^[208-211]. However, recent evidence has challenged this belief. The use of MRI-magnetic resonance cholangiopancreatography (MRCP) to better characterize PC is supported by a pro-

Table 6 Sensitivity, specificity and accuracy of computed tomography findings in pancreatic cancer patients

CBD dilatation	5	92	67

CT: Computed tomography; CBD: Common bile duct.

spective analysis that compared these two modalities in patients with periampullary cancers^[212]. MRI-MRCP was superior to CT in differentiating malignant from benign lesions (ROC = 0.96 *vs* 0.81, $P < 0.05$) and MRI-MRCP had better sensitivity (92% *vs* 76%), specificity (85% *vs* 69%), accuracy (90% *vs* 75%), PPV (95% *vs* 88%) and NPV (79% *vs* 50%) compared to CT. Another study confirmed the previous results with MRI-MRCP showing 97% sensitivity, 81% specificity and 89% accuracy^[213].

On the other hand, other studies comparing gadolinium-enhanced MRI with MDCT have shown that MRI and CT had equivalent sensitivity and specificity (83%-85% *vs* 83% and 63% *vs* 63%-75%, respectively). Both techniques had good to excellent agreement between radiologists, although MRI had a superior agreement for the evaluation of distant metastases (inter-observer agreement between MRI and CT scan; 0.78 *vs* 0.59 $P = 0.1$)^[214]. On the other hand, with the improvement in CT scan technology, recent studies have shown that MRI might have lower sensitivity in comparison to MDCT (82%-94% *vs* 100%)^[215]. This was confirmed by a recent meta-analysis comparing the accuracy of several imaging modalities which showed that helical CT had superior sensitivity compared to MRI (91% *vs* 84%) and transabdominal US (91% *vs* 76%)^[216]. Sensitivity for resectability of the tumor was equal for both MRI and helical CT (82% *vs* 81%, respectively)^[216].

Positron emission tomography: ¹⁸F-2fluoro-2-deoxy-D-glucose (FDG) accumulated by tumor cells provides positron emission tomography (PET) with the advantage of combining metabolic activity and imaging characteristics. Newly developed PET scanners can detect small PCs up to 7 mm in diameter and diagnose metastatic disease in about 40% of cases^[217,218]. A Japanese study found that the overall sensitivity of PET-CT was superior to contrast CT (92% *vs* 88%) and that PET was better at detecting bone metastases (100% *vs* 12%). However, CT scanning was superior for the evaluation of vascular invasion (100% *vs* 22%), involvement of para aortic regional lymph nodes (78% *vs* 57%), identification of peritoneal dissemination (57% *vs* 42%) and hepatic metastases (73% *vs* 52%)^[219]. Another Japanese study confirmed that PET had a sensitivity of 87%, a specificity of 67% and accuracy of 85%, and that tumors with metastatic

disease had significantly higher standardized uptake values [SUV = tissue concentration (millicuries/g)/injection dose (millicuries)/body weight (g)] than those without metastases^[220]. PET had superior sensitivity (100% *vs* 65%), specificity (77% *vs* 61%), NPV (100% *vs* 31%), PPV (94% *vs* 87%) and accuracy (95% *vs* 65%) in an American study comparing PET-CT with a SUV cut off of 2.0 *vs* contrast CT^[221]. A recent study enrolling 59 PC patients showed similar results, with 91% PPV and 64% NPV for PET-CT. One of the most interesting results was that the clinical management of patients undergoing PET was changed in 16% of cases deemed resectable after routine staging ($P = 0.031$) preventing unnecessary surgery because of distant metastases^[222].

Diffuse uptake of FDG is frequent in pancreatitis in comparison to PC (53% *vs* 3%, $P < 0.001$), and therefore PET is extremely useful in distinguishing these two conditions in controversial cases^[218,223]. Animal studies have shown that ¹¹C-acetate-PET appears to be superior to FDG PET for the detection of early PC and might be useful in differentiating inflammatory processes from malignancies as ¹¹C-acetate-PET is less affected by the presence of inflammation in human tissues^[224].

Another very important characteristic of PET-CT is its ability to provide useful information on tumor viability, and this technique also allows monitoring of tumor response to treatment^[217] and the metabolic features of PET help predict the prognosis as a SUV less than 3 appears to be a positive predictive factor^[222,225-229].

Similar results were found by Zimny *et al*^[230] who showed that better survival trends were noted in patients with PC and a SUV less than 6.0 in comparison to those with a higher SUV. Sensitivity and specificity of imaging modalities are summarized in Table 7.

STAGING

Pathological staging

In the 7th edition of the American Joint Committee on Cancer the different categories of PC are classified according to only one TNM staging system, even if neuroendocrine tumors have a different biology and a better prognosis than ductal carcinomas. Yet, the TNM system provides a reasonable discrimination and prognostic validity for these patients^[236].

The TNM system classifies PC into 3 clinically important categories: (1) patients with Tis-T2 PC have localized cancer within the pancreas; (2) patients with T3 cancer have locally invasive disease; and (3) patients with T4 tumors have unresectable PC^[237] (Table 8).

Prognostic features of PC include perineural and lymphovascular invasion, elevated serum CA19-9 levels and incomplete tumor resection. Therefore, gross and microscopic assessment of the resection margins is of major importance even if it is not included in the TNM staging system. Patients undergoing resections with grossly or microscopically positive margins have no survival benefits compared to individuals undergoing palliative chemo-radiation therapy alone.

Clinical staging

Surgery is the only chance of cure and the presence of negative resection margins of the primary tumor represent the strongest prognostic factor. Preoperative staging modalities include the combination of several imaging techniques such as CT scan, MRI, EUS, staging laparoscopy and laparoscopic ultrasound which aim to identify patients with resectable disease. There is consensus that patients with distant metastases (liver, lungs, peritoneum)

Table 8 American Joint Committee on Cancer staging of pancreatic cancer

AJCC 6th edition TNM staging system for pancreatic cancer		
TX	Primary tumor cannot be assessed

AJCC: American Joint Committee on Cancer.

or local invasion of the surrounding organs (stomach, colon, small bowel) are usually not surgical candidates.

The criteria for unresectability of PC include tumor encroachment (defined as tumor surrounding the vessel more than 180 degrees) of arteries such as the celiac artery, hepatic artery, superior mesenteric artery (SMA) or massive venous invasion with thrombosis. Portal or superior mesenteric venous invasion without thrombosis or obliteration of vessels can still be classified as resectable PC^[204,238]. A recent study comparing the roles of EUS, CT, MRI and angiography in the assessment of PC staging and resectability has shown that CT scanning was the most accurate in assessing the stage of the tumor (73%), loco-regional invasion (74%), vascular involvement (83%), distant metastases (88%), final TNM stage (46%) and overall tumor resectability (83%)^[239]. EUS appeared to be superior in detecting smaller tumors not visualized by CT. A decision analysis demonstrated that the best strategy to assess tumor resectability was based on CT as an initial test and the use of EUS to confirm the results of resectability by CT^[221].

Laparoscopic staging

Diagnostic laparoscopy for PC was first introduced as a staging procedure in the late 1980s by Cuschieri *et al.*^[240] and Warshaw^[241,242]. Staging laparoscopy is considered a simple, minimally invasive technique to identify radiographically occult distant metastatic disease and to prevent non-therapeutic laparotomies. Laparoscopic examination allows direct visualization of intra-abdominal contents and has been reported to identify hepatic and peritoneal metastases not shown by other modalities^[243] as reported in some studies where 20%-48% of patients considered resectable by CT were found to be unresectable during surgery^[244-246].

Diagnostic laparoscopy involves a general exploration

of the abdominal surfaces including palpation of the liver with two instruments when necessary. The hilum of the liver is visualized, the foramen of Winslow is examined and periportal lymph nodes are biopsied when enlarged. The transverse colon and omentum are reflected cephalad and the base of the transverse mesocolon is examined with particular attention to the mesocolic vessels. The gastrotocolic ligament/omentum is incised and the lesser sac is examined^[247].

Laparoscopic ultrasonography (LUS) has been introduced as an additional procedure to increase the detection of intrahepatic metastases, identify enlarged and suspicious lymph nodes and to evaluate local growth in the vascular structures^[248]. Some studies have demonstrated that LUS has improved the accuracy of predicting resectability up to 98%^[249-251].

Despite these results, the routine use of staging laparoscopy and LUS in patients with radiographically resectable PC remains controversial as imaging modalities have significantly improved, thus reducing the risk of discovering non-resectable disease at the time of surgery. In addition, staging laparoscopy adds costs and it can be time consuming. Sustainers of staging laparoscopy are supported by a study by Kwon *et al.*^[250], which revealed that staging laparoscopy was able to detect unsuspected metastases and changed the surgical approach in 37% of patients even when using CT, MRI, ERCP and angiography for preoperative staging. Another study by Conlon *et al.*^[247], supported the use of staging laparoscopy as only 67 out of 115 patients (58%) with PC had resectable disease after completion of the laparoscopic examination. On the other hand, a more recent study from the same group at the Memorial Sloan-Kettering Cancer Center has shown that the yield of staging laparoscopy was only 8.4% when good imaging modalities were obtained at the referral center^[252].

Based on the fact that minimally invasive approaches for the diagnosis of PC as well as radiological imaging techniques will continue to advance, the selective use of staging laparoscopy and LUS would play a role in cases where detection of unresectable disease is more likely. Factors which suggest a higher yield with diagnostic laparoscopy include a large primary tumor (diameter larger than 4 cm), a tumor in the body or tail of the pancreas, equivocal findings after imaging tests, severe weight loss, abdominal or back pain, hypoalbuminemia and significantly elevated tumor markers^[240].

TREATMENT

Patients with suspected or confirmed diagnosis of PC should be assessed by a multidisciplinary team and stratified as resectable (stage I or II), borderline resectable (stage IIa or IIb), locally advanced unresectable (stage III) or metastatic disease (stage IV). Treatment should be planned according to local expertise and established guidelines, as resectable and borderline patients should be referred to surgeons, unresectable and metastatic patients should be referred to medical and radiation oncologists and palliative care teams. A multidisciplinary approach to PC is necessary to improve the overall outcome of these patients, especially for borderline resectable or unresectable disease as neo-adjuvant chemo-radiation therapy may play a role in downstaging and the conversion to potentially curable disease^[253,254].

SURGICAL THERAPY

Surgical treatment is the only potential cure for PC^[255]. Although pancreatic surgery is considered challenging and technically demanding, improvements in surgical techniques and advances in perioperative supportive care have reduced the mortality rates to less than 5% in high-volume centers^[256-258]. According to the United States Surveillance and Epidemiology End Results registries, the 5-year relative survival for the period between 1999 and 2006 was 22.5% for localized and 1.9% for metastasizing PC (Table 9)^[259].

Because only 20% of patients with PC are candidates for radical resection at the time of diagnosis^[260], accurate staging is important in identifying surgical candidates and sparing the risk and cost of surgery for patients who are affected by advanced disease^[261]. Unresectable PC is commonly defined when there is tumor invasion of the SMA, inferior vena cava, aorta or celiac arteries; encasement or occlusion of the SMV-portal venous system or by distant metastasis (e.g. hepatic, extra-abdominal, peritoneum, omentum, lymph nodes outside the resection zone)^[262]. An Italian study has recently demonstrated that the duration of symptoms (mainly jaundice and celiac pain) of more than 40 d, CA 19-9 levels above 200 U/mL and G3-G4 histological grade of the tumor are poor prognostic parameters, even if the disease is resectable by preoperative staging^[263].

Table 9 Stage distribution of pancreatic cancer and 5-year relative survival by stage at diagnosis for 1999-2006, all races and both sexes (SEER registries)

Stage at diagnosis	Stage distribution (%)	5-yr relative survival (%)
Localized (confirmed to primary site)	8	22.5
Regional (spread to regional LNs)	26	8.8
Distant (cancer had metastasized)	53	1.9
Unknown (unstaged)	14	5

SEER: Surveillance Epidemiology and End Results.

Tumor of the head of pancreas

Preoperative biliary decompression vs immediate surgical resection: Obstructive jaundice is a common presentation for tumors located in the periampullary area or in the head of the pancreas. To reduce perioperative complications and mortality in patients with obstructive jaundice undergoing pancreaticoduodenectomy (PD), preoperative biliary drainage appears to have a positive impact supported by the findings of several observational studies^[264-266]. On the other hand, several other non-randomized studies failed to show any advantage of preoperative biliary decompression in these patients, as they developed a higher incidence of bacteriobilia and fungal colonization causing more wound infections, postoperative sepsis and longer hospital stay^[267-270]. Two meta-analyses of randomized controlled trials and a systematic review of descriptive series have shown that the outcome of patients undergoing biliary decompression prior to PD was inferior to early surgery as they had higher rates of infectious complications and perioperative mortality^[271,272]. These findings were confirmed by a recent multicenter randomized controlled study from the Netherlands which showed that the rates of serious complications were 39% for patients who underwent early surgical resection in comparison to 74% in the group that underwent pre-operative biliary decompression ($P < 0.001$)^[264]. Similarly, surgical complications occurred in 37% of patients undergoing early resection in comparison to 47% for individuals who had preoperative biliary decompression. Although the difference did not reach statistical significance ($P = 0.14$), the overall mortality and hospital stay were comparable between the two groups^[273].

During the last decade, there has been an increasing interest in treating patients with neo-adjuvant chemoradiotherapy to improve disease-free and overall survival in patients undergoing surgery. Although there are still no phase III randomized controlled studies to support the use of this strategy, several phase II randomized trials have shown that neo-adjuvant chemo and chemo-radiation therapy are relatively well tolerated, do not reduce the resectability rate and seem to increase the percentage of patients who undergo R0 resections^[274-283]. For jaundiced PC patients, candidates for neo-adjuvant therapy must undergo biliary decompression to prevent liver decompensation and stent patency is required for several months. Currently, the only study assessing the outcome

of patients undergoing chemo-radiation therapy prior to PD has shown that plastic stents do not provide patency of the biliary system for long enough to complete the preoperative protocols. In fact, 55% of cases required unplanned repeat ERCP with stent exchange for recurrence of jaundice or ascending cholangitis^[284]. For these patients, self expanding metallic stents should be used as the direct costs associated with repeating ERCP and hospital admissions for recurrent biliary obstruction and ascending cholangitis appear to be superior to the initial higher cost of using metallic stents^[285].

Standard vs pylorus preserving PD: Walter Kausch first described PD in 1912^[286], and Allan Whipple later popularized the procedure that bears his name^[287]. The classic Whipple (CW) operation consists of an *en-bloc* removal of the pancreatic head, the duodenum, the common bile duct, the gall bladder and the distal portion of the stomach together with the adjacent lymph nodes^[288]. This operation can lead to specific long-term complications such as early and late dumping syndrome, post-operative weight loss^[289] and post-operative acid and bile reflux^[290].

Pylorus preserving PD (PPPD) was first introduced by Watson in 1942^[291], and the procedure was popularized by Traverso and Longmire in 1978^[292]. Although it was originally described for the treatment of periampullary tumors, many surgeons nowadays perform PPPD for PC in the head of the pancreas. In order to retain a functioning pylorus, the stomach and the first 2 cm of the duodenum are preserved along with their neurovascular supply. The rationale behind preservation of the stomach is to improve long-term gastrointestinal function^[293]. There is still some controversy as to which is the best surgical treatment for PC of the head of the pancreas. In comparison to CW, PPPD has the advantages of reduced operative time^[294], less blood loss, better access to the biliary anastomosis for post-operative endoscopy in patients with recurrent biliary obstruction, improvement of post-operative weight gain and quality of life^[295]. On the other hand, some series have reported that PPPD has a higher incidence of delayed gastric emptying^[296,297]. Moreover, it has not been unequivocally shown that PPPD is oncologically equivalent to CW^[298]. A number of RCTs and meta-analyses have demonstrated that both perioperative morbidity and long-term outcome are equal in CW and PPPD^[263,299,300].

Pancreatic reconstruction: The most significant cause of morbidity and mortality after PD is the development of complications caused by leakage of pancreatic secretions and pancreatic fistulae observed in up to 20% in specialized centers^[301,302]. The meticulous reconstruction of pancreatico-enteric continuity is the key to preventing pancreatic fistulae^[303]. Pancreatico-jejunostomy and pancreatico-gastrostomy (PG) are the most commonly employed techniques for pancreatocenteric reconstruction. PG was believed to be an easier technique and less prone to ischemia as a result of the close proximity between the stomach and the pancreatic stump and the presence

of a better vascular supply in the stomach in comparison to the jejunum. However, RCTs have not demonstrated superiority of one technique over the other in terms of post-operative complication rates or incidence of pancreatic fistulae^[304,305].

Tumor of the body/tail of pancreas

Distal pancreatectomy: Distal pancreatectomy is the surgical procedure of choice for PC of the body and tail of the pancreas. It entails resection of the portion of the pancreas extending to the left of the superior mesenteric vessels and not including the duodenum and the distal bile duct^[306]. The spleen is conventionally removed in an *en-bloc* fashion^[307]. However, splenic preservation could be accomplished without an increased rate of complications, operative time or the duration of post-operative hospital stay^[295,308]. Several closure techniques have been introduced for the pancreatic remnant in an attempt to reduce pancreatic fistulae. They include hand-sewn suture techniques, staple closure techniques or a combination of both^[309-312], ultrasonic dissection devices^[313], pancreatico-enteric anastomosis^[314], application of meshes, seromuscular^[315] and gastric serosal patches^[316], or sealing the pancreatic stump with fibrin glue^[199].

Cancers of the body and tail of pancreas usually present at a later stage of the disease in comparison to PC of the head due to lack of early symptoms^[317]. There are no survival differences between resections for equal TNM stage tumors of the head vs tumors of the body and tail as shown by a retrospective study that reported a 5-year survival of 17% after resection of the pancreatic head vs 15% for left-sided tumors in stage I cancers^[318].

Laparoscopic pancreatic resection: Laparoscopic pancreatic surgery represents one of the most challenging abdominal operations^[319,320]. Gagner and Pomp were the first to describe a laparoscopic duodeno-pancreatectomy in 1994^[321]. Since then, the total number of laparoscopic duodeno-pancreatectomies has remained small due to technical difficulties associated with this operation^[322]. A recent study from the Mayo clinic with 65 patients who underwent total laparoscopic PD (TLPD) outlined that TLPD is safe, feasible and its results appear to be comparable to the open approach^[323] (Table 10).

Nevertheless, larger prospective studies are required in order to better assess the advantages of TLPD.

Laparoscopic distal pancreatic resection is currently the most frequently performed laparoscopic pancreatic surgery^[327]. Most of the studies on distal laparoscopic pancreatectomy are case series with a relatively small number of patients^[328]. Although recent studies have shown that laparoscopic distal pancreatectomy is feasible and safe^[329-331], the morbidity, mortality and hospital stay are similar to those after open surgery^[332]. This is probably due to the fact that morbidity after pancreatic surgery results from retroperitoneal dissection, length of the operation and pancreatic fistulae rather than the incision. In addition, a recent prospective observational study comparing 85 open vs 27 laparoscopic distal pancreatectomies has shown

Table 10 Published results on laparoscopic pancreaticoduodenectomies

Author	Yr	Patient No.	Morbidity (%)	Pancreatic fistula (%)	Mean hospital stay	Mortality (%)
Kendrick <i>et al</i> ^[323]	2010	62	42	18	7	1.6
Palanivelu <i>et al</i> ^[324]	2007	42	28.6	7.1	10.2	2.4
Dulucq <i>et al</i> ^[325]	2006	25	31.8	4.5	16.2	0
Pugliese <i>et al</i> ^[326]	2008	19	31.6	15.8	18	0

that the number of lymph nodes removed during the minimally invasive procedure was significantly inferior (mean number: 5.2) in comparison to the open approach (mean number: 9.4)^[333]. These findings suggest that at this time there is a lack of evidence to support oncological equipoise between laparoscopic and open resections for PC.

Total pancreatectomy: Total pancreatectomy has been employed in selected patients with chronic pancreatitis^[334], multifocal islet cell tumors or diffuse IPMN^[335]. Total pancreatectomy for PC was initially proposed to avoid the risk of pancreato-enteric leaks and to remove potential undetectable synchronous disease in other parts of the gland^[336]. However, the indication of total pancreatectomy to avoid the risks of pancreatic fistulae is still controversial^[337]. Improvement in operative techniques, advances in nutritional support, critical care and interventional radiology have significantly decreased the incidence of life-threatening sequels of pancreatoenteric leaks^[338]. In addition, the permanent endocrine insufficiency associated with total pancreatectomy impacts enormously on the quality of life and long-term outcome of these patients^[339]. Some studies have demonstrated a significant increased risk of perioperative morbidity and mortality associated with total pancreatectomy compared with PD^[318]. A recent study by Reddy *et al*^[335] showed that long-term survival rates were equivalent after total pancreatectomy and PD (19.9% *vs* 18.5%), supporting the fact that there is no oncological benefit of total pancreatectomy *vs* a more limited resection in PC. Currently, total pancreatectomy should be performed in patients with PC if it is the only oncologically sound treatment option^[335].

Vascular resections and extended lymphadenectomy:

With the advancement in operative techniques and perioperative management of patients with PC, more radical surgical procedures with vascular resection and extended lymphadenectomy have been proposed for selected cases^[340]. The results of extended vascular and lymphatic resections remain controversial.

The principal use of venous resection and reconstruction is to allow complete tumor clearance when precluded by tumor involvement of the superior mesenteric or portal vein, and when the surgeon expects to achieve a negative resection margin^[341]. Post-operative morbidity and mortality rates following portal or superior mesenteric vein resections seem to be similar to those of patients with standard PD (42%-48.4% *vs* 47.1%, 3.2%-5.9% *vs* 2.5%, respectively)^[342,343]. Another study showed that patients undergoing pancreatic resection with venous recon-

struction (VR) had a median survival of 22 mo compared to 20 mo for those who had classic PD ($P = 0.25$)^[344]. In another study, a slight survival benefit was noted in patients who did not require VR (33.5%) compared to those with VR (20%, $P = 0.18$), although this did not reach statistical significance^[345].

Pancreatectomies with major arterial resections (common hepatic artery/celiac axis and superior mesenteric artery) have been reported in recent years with acceptable outcomes. Nevertheless, arterial reconstruction during pancreatectomies remains a challenging procedure with increased risk of complications compared to classic PD and PD with VR. In addition, most PCs with arterial invasion are for the majority, advanced tumors with distant lymph node involvement and metastases, and therefore indicated only in a very select group of patients^[346]. Recent data on pancreatectomies requiring arterial resections at high volume tertiary centers have shown operative mortality rates of 4.3%^[346], peri-operative mortality rates (60 d) of 17%^[347], morbidity rates of 48%^[348] and 3-year survival rates of 17%-23.1%, which are much higher than for classic PD^[346,347].

It has been noted that lymph node involvement outside the standard PD specimens occurs in more than 30% of cases^[349]. This has led to the evaluation of the need for a more extended lymph node dissection (ELND) in the surgical management of PC. To date, the definitions of a standard lymphadenectomy as well as ELND are still not very clear^[341]. A number of Japanese studies have shown an increased survival rate in patients who have undergone ELND compared to conventional PD^[350-352]. However, these studies were not randomized and their data were not validated by other centers^[353].

The first RCT comparing standard PD and ELND was reported by Pedrazzoli *et al*^[354] in 1998. In this study, standard lymph node dissection was defined as the removal of lymph nodes from the anterior and posterior pancreatoduodenal region, pyloric region, biliary duct, superior and inferior pancreatic head and body. In addition to the above, ELND included removal of lymph nodes from the hepatic hilum and along the aorta from the diaphragmatic hiatus to the inferior mesenteric artery and laterally to both renal hila, with circumferential clearance of the origin of the celiac trunk and SMA. This study showed no difference in morbidity, mortality or 4-year survival rates between the two groups.

Recently, a meta-analysis on standard PD and PD + ELND for PC patients showed comparable morbidity and mortality rates with a trend towards higher rates of delayed gastric emptying in the ELND group. The weighted

Table 11 Survival data after resection of pancreatic cancer

NA: Not applicable.

mean log hazard ratio for overall survival was 0.93 (CI: 0.77-1.13), revealing no significant outcome differences between the standard and extended procedure ($P = 0.480$) suggesting that ELND does not benefit overall survival and has a trend towards increased morbidity^[355].

CLINICAL VOLUME AND OUTCOMES

During the last two decades, several large observational studies in the U.S., Canada and the Netherlands have shown that the institutional volume of pancreatic resections affects patients' outcomes. Higher perioperative morbidity, mortality and decreased use of multimodality therapy have been observed more frequently in low volume centers^[356-363]. In 1993, Edge and colleagues reported that case load did not correlate with mortality after pancreatic resection^[364]. However, surgeons who performed fewer than 4 resections per year had more complications. Recent studies have shown significant improvements in perioperative morbidity and mortality in patients undergoing pancreatic resections in high volume centers. For example, investigators at Memorial Sloan Kettering Cancer Center found that in a cohort of 1972 patients, high-volume centers defined as performing more than 40 cases per year in New York State had significantly less mortality (4% *vs* 12.3%) than low volume centers^[356].

The definition of high and low volume varied among all these studies, but the findings were consistent and were confirmed by Birkmeyer *et al.*^[365] who showed that very low volume centers (0-1 procedure per year), low volume hospitals (1-2 procedures per year) and higher volume hospitals (more than 5 procedures per year) had significantly different mortality rates (16% and 12% *vs* 4% respectively; $P < 0.001$). The largest difference in operative mortality between very low volume (17.6%) and high volume (3.8%) centers is even more significant for PD when compared to other major surgeries as shown in a retrospective analysis of data from the national Medicare claims database and the Nationwide Inpatient Sample^[257].

A recent study involving 301 033 patients with PC included in the National Cancer Database evaluated the treatment patterns of 1667 hospitals over a 19-year period^[366]. During that time the pancreatectomy rate as well as the use of multimodality adjuvant therapy for patients with stage I and II disease increased significantly (pancreatectomy rate increased from 39.6% to 49.3%; $P < 0.001$, and

the use of multimodality therapy increased from 26.8% to 38.7%; $P < 0.001$). Furthermore, patients were more likely to receive multimodality therapy at academic institutions, particularly those considered to be high volume hospitals. Despite these important advances, it appears that there is still a high percentage (71.4%) of patients with potentially resectable disease who are still not referred for surgical resection as reported by Bilimoria *et al.*^[367]. These findings would suggest that a persistent nihilism of clinicians towards PC and pancreatectomy may be the most significant correctable factor that contributes to the current poor long-term outcomes of PC.

ADJUVANT CHEMORADIATION THERAPY

Several single agent chemotherapeutic agents have been tried in the treatment of PC. 5-FU has been used in PC for more than 25 years with response rates of 8%-15%^[368]. The addition of Leucovorin to 5-FU doubled the response rate to 26%, however, it showed no benefit in terms of survival^[369]. The only chemotherapeutic agent that demonstrated prolonged survival in comparison to 5-FU and Leucovorin was Gemcitabine^[370].

After pancreatic resection, the 5 year survival rate is only 20% or less as PC has a high loco-regional recurrence rate and a tendency towards early liver metastasis (Table 11)^[258,371-376].

Based on these observations it appears necessary to employ adjuvant therapy in combination with surgical resection in order to improve survival. Only a few years ago there was no valid data on adjuvant chemoradiation therapy after curative surgical resection^[377].

The first RCT that showed benefit from adjuvant chemoradiation therapy in comparison to surgery alone was the Gastrointestinal Tumor Study Group (GITSG) trial, where patients receiving 40 cGy followed by 5-FU showed a mean survival of 18 mo in comparison to 11 mo for those who received surgery alone ($P = 0.05$). The two- and five-year survival rates of the two groups were 43% *vs* 18% and 19% *vs* 0%, respectively^[378].

The EORTC (European Organization for Research and Treatment of Cancer) study showed that patients undergoing chemoradiation therapy (5-FU protocol) had a median survival of 17.1 mo compared to 12.6 mo for the

controls ($P = 0.099$). The two- and five-year overall survival rates were 37% and 20% for the experimental arm and 23% and 10% for the control arm ($P = \text{NS}$)^[379].

The European Study Group for PC 1 trial (ESPAC-1) compared four groups of patients who underwent pancreatic resection; (1) surgery alone; (2) 5-FU and Leucovorin adjuvant chemotherapy; (3) combination of adjuvant radiation therapy and 5-FU chemotherapy; and (4) adjuvant chemoradiation followed by chemotherapy^[380]. In this study, the five-year survival rate for patients who received adjuvant chemotherapy was 21% compared to 8% for patients who did not ($P = 0.009$). Patients who underwent chemoradiation therapy had an inferior five-year survival rate (10% *vs* 20%) in comparison to patients who did not receive radiation ($P = 0.05$).

In 2006, the Radiation Therapy Oncology Group trial compared patients receiving adjuvant chemoradiation (5040 cGy in combination with continuous 5-FU) followed by 5-FU *vs* similar chemoradiation therapy followed by Gemcitabine. For patients affected by PC of the head, the arm treated with Gemcitabine had a superior median (18.8 mo *vs* 16.7 mo) and overall survival at 3 years [31% *vs* 21% ($P = 0.047$)], but with a higher incidence of toxicity (80% *vs* 60%)^[381].

In 2007, a RCT conducted in Germany and Austria (CONKO-1 [Charite Onkologie Clinical Studies in GI Cancer 001]) compared patients undergoing R0 or R1 pancreatic resection alone *vs* resection followed by Gemcitabine-based chemotherapy. The median disease-free survival for patients treated with Gemcitabine was 13.9 mo *vs* 6.9 mo in the observation arm ($P < 0.001$), although there was no difference in the overall survival between the two groups (22 mo *vs* 20 mo)^[382]. From the results of these studies, adjuvant chemotherapy has become the standard of care for patients who can tolerate the treatment after surgical resection.

NEOADJUVANT THERAPY

Neoadjuvant therapy is defined as the preoperative intervention aiming to convert unresectable PCs to resectable tumors or to increase the probability of complete microscopic tumor resection^[383]. One of the limitations of the role of neoadjuvant therapy for PC is the fact that there is no standardized definition for tumor resectability and there is no data from randomized phase three trials on the benefit of neoadjuvant therapy. In addition, data from prospective and retrospective studies have several biases due to heterogeneity of inclusion and exclusion criteria, preoperative quality of imaging tests, and surgical pathology reports on lymph node involvement and resection margin status.

A recent systematic review^[383] evaluating retrospective and prospective studies on neoadjuvant chemo and radiation therapy from 1966 to 2009 included a total of 111 studies and 4,394 patients. The results of this meta-analysis showed that the majority of patients were treated with Gemcitabine, 5-FU or oral analogue Mitomycin-c, and Platinum compounds. Patients undergoing neoadjuvant treatment received radiotherapy in the range of 24-63 Gy.

The analysis showed that neoadjuvant treatment in patients with unresectable tumor was able to convert 33.2% of patients to resectable candidates, providing a median survival of 20.5 mo which was equivalent to patients undergoing resection followed by adjuvant therapy who had median survival of 20.1 to 23.6 mo. On the other hand, neoadjuvant therapy for patients with resectable cancer did not seem to improve overall outcome.

RADIATION THERAPY

Persistent loco-regional disease after pancreatic surgery is a major determinant of recurrence^[384]. Although there is supportive evidence for the use of adjuvant chemotherapy^[380,385], the role of adjuvant radiation remains unresolved. Generally it is believed that external-beam radiotherapy (EBRT) alone is a suboptimal treatment for locally advanced PC as most patients will die of systemic disease^[386].

In the Mayo clinic clinical trial and the GITSG trial, patients who were randomized to receive EBRT only had a median survival of 5.3-6.3 mo which was inferior to EBRT plus 5-FU^[387,388].

Among 210 patients who underwent surgical resection for PC [PD (73%), total and/or distal pancreatectomy (25%), Appleby procedure (2%)] followed by intraoperative electron beam radiotherapy (IOERT), some patients received a single fraction of IOERT alone (25 Gy), whereas others (30%) received additional EBRT and 54% received various forms of adjuvant chemotherapy. The study demonstrated excellent local control with the addition of IOERT (75%). Despite the benefit in local control, the overall median survival was similar to other studies with adjuvant chemotherapy or chemoradiation (19 mo)^[389]. A combined study of extended resection and intraoperative radiation therapy (IORT) concluded that IORT contributed to local control; however, it provided no overall survival benefits (14.6% 5-year survival)^[390].

In the United States, chemoradiation with concurrent 5-FU followed by Gemcitabine continues to represent the standard for adjuvant therapy of tumor of the pancreatic head. A direct comparison of chemo-radiation therapy and chemotherapy alone seems to be difficult to achieve and additive chemotherapy before or after chemo-radiation-therapy will have to be tested in randomized studies in order to determine the optimal sequencing^[391].

PALLIATIVE MEASURES

Palliative treatment of patients with PC plays a very important role as 80% to 90% of newly diagnosed tumors are not resectable due to local invasion or presence of distal metastatic disease^[392]. Median survival for patients with unresectable PC located in the head and body of the gland is approximately 7 mo, while for PC located in the tail median survival is significantly less [3 mo ($P = 0.0002$)], as they are usually diagnosed in more advanced stages^[393]. For these patients, relief of symptoms secondary to gastric outlet obstruction, jaundice and pain are essential to

improve their quality of life and overall survival. In the past, surgical palliation was more common as the diagnosis of unresectable disease was frequently done in the operating room and patients underwent one or more of the following procedures: gastric bypass, hepatico-enteric decompression and celiac plexus neurolysis for pain relief during the same surgery. With the improvement in diagnostic imaging tests, the role of surgical staging has decreased as the vast majority of patients can be currently classified as suffering from unresectable disease by non-invasive modalities such as CT and MRI or by endoscopic US. Nevertheless, there are still controversies on the best palliative strategies for these patients as there is a lack of randomized controlled trials and abundant contrasting data from observational studies.

Gastro-duodenal decompression

There is still some controversy on the use of routine gastro-intestinal bypass for PC diagnosed as unresectable at the time of exploratory laparoscopy or laparotomy.

In a large observational study of 155 patients with unresectable PC staged by extended laparoscopy at the Memorial Sloan Kettering Cancer Center, only 4% of patients required surgical intervention for gastric outlet obstruction before their death: 2 patients required open gastro-jejunal anastomosis alone and 1 patient underwent a combined gastro and hepatico-jejunostomy a few days after laparoscopy^[393]. In addition, 1 patient required a percutaneous endoscopic gastrostomy for palliation of gastric outlet obstruction a few weeks before demise. The authors concluded that the routine use of gastric bypass in patients with unresectable PC is not indicated. On the other hand, several other retrospective studies^[394,395] have suggested that up to 25% of patients with unresectable PC would develop gastric outlet obstruction requiring surgical intervention.

A recent prospective randomized trial compared 44 patients who were found unresectable at the time of surgery and who underwent a retrocolic gastro-jejunostomy to 43 patients who did not^[396]. The two groups had similar morbidity (32% *vs* 33%), mortality (0%) and hospital stay. On the other hand, patients who had gastric bypass did not develop any gastric outlet obstruction, while 19% of patients in the control group did ($P < 0.01$). Although this study would suggest that gastric bypass should be performed in all patients found unresectable at the time of surgery, the introduction of metallic self-expanding intestinal stents has changed the options for palliation.

A prospective multicenter cohort study of 51 patients with malignant gastric outlet obstruction treated with self-expandable metallic stents showed that in 98% of cases the stent was successfully deployed and that the median duration of patency was 10 mo. Only 14% of patients had stent dysfunction, and migration was observed in only 2% of cases^[397]. Similar results were reported by another study from South Korea which showed a median stent patency of 385 d, and only 1% serious complications (gastrointestinal bleeding or perforation)^[398]. Other observational studies have shown that compared with palliative surgery,

stent placement provides a shorter hospital stay, earlier resumption of oral intake, fewer complications and lower hospital costs^[399,400]. The only randomized controlled study that compared duodenal stent and laparoscopic gastrojejunostomy favored endoscopic therapy as it was associated with less discomfort, shorter hospital stay and improved physical health scores at 1 mo^[401]. In this small study, only a third of patients were alive at 1 year and no cases of stent occlusion were observed. The two groups had similar overall survival supporting equipoise between endoscopic and surgical palliation. Nevertheless, surgical palliation can still play an important role when patients have a long life-expectancy, need biliary and gastric bypass in combination with celiac neurolysis for pain control.

Biliary decompression

The majority of PCs occur in the head of the pancreas and obstructive jaundice is one of the early symptoms for 50%-80% of patients^[396]. In the past, staging laparotomy and biliary bypass were frequently performed for unresectable PC of the head^[402,403]. During the last decades, the development of interventional radiology and endoscopy has allowed palliation of obstructive jaundice by the insertion of percutaneous or endoluminal stents with minimal morbidity and mortality. Currently, endoscopic biliary stenting is the treatment of choice for unresectable PC with obstructive jaundice. Percutaneous transhepatic stenting is reserved only for patients in whom endoscopic stenting has failed as it is associated with a higher complication rate than endoscopic palliation (61% *vs* 35%)^[404,405]. High risk surgical patients are best managed by biliary stenting, however, it is still unclear whether palliative surgical biliary decompression is superior to other interventions for patients who are fit for surgery or who have a longer life expectancy. A European randomized controlled study comparing surgical biliary decompression *vs* endoscopic plastic stenting showed that both interventions were equally successful in palliating jaundice (95% *vs* 94%, respectively) and provided equal overall survival. Nevertheless, major complications (29% *vs* 11%) and procedure-related mortality (14% *vs* 3%) were significantly higher for surgical patients^[406]. In addition, surgical decompression was more expensive than stenting, although recurrent biliary obstructions and late gastric bypasses were more common in patients undergoing endoscopic treatment even if that did not reach statistical significance. Similar results were reported in a more recent Brazilian study which found that endoscopic therapy with self-expandable metallic stents was more cost-effective than surgical decompression (US\$2832 *vs* US\$3821, $P = 0.031$) and provided better quality of life at 30 ($P = 0.04$) and 60 d ($P = 0.05$)^[407]. The only available meta-analysis of randomized controlled studies comparing surgery with endoscopic stenting included only 3 studies where none tested the use of metallic self-expanding stents^[408]. Although the reintervention rate was 3% (0%-16%) in surgically treated patients compared with 36% (28%-43%) in stented patients, because of the limited number of studies with a relatively small group of patients and heterogeneous quality, the authors

concluded that they could not identify which treatment was preferable.

The patency of biliary stents has greatly improved with the introduction of expandable metallic stents (EMS) as they offer a larger diameter for drainage and are associated with a lower occlusion rate than plastic stents^[409,410]. The concurrent use of chemotherapeutic agents in patients palliated with SEMS was thought to increase the risk for ascending cholangitis. However, a Japanese retrospective study has demonstrated that the combination of SEMS and palliative chemotherapy for unresectable PC did not change the incidence of biliary infectious complications^[411]. In patients with combined biliary and duodenal obstructions, concomitant biliary and duodenal stenting is now feasible and justified as the need to repeat endoscopic therapies is rarely required even in long-term survival patients^[412].

Currently, surgical biliary bypass is advocated only for patients with obstructive jaundice who fail endoscopic or percutaneous stent placement.

Pain control

About 70% of patients with unresectable PC develop clinically important pain during their lives^[413]. Pain is the main cause of the significant drop in quality and quantity of life of these patients and good palliation is necessary as pain incidence and severity increases with disease progression^[414].

For the majority of patients, pain from PC can be managed with opioid analgesics. However, approximately one third of patients experience inadequate control of pain with oral analgesics alone^[415]. For these patients, radiation therapy, chemotherapy and celiac plexus neurolysis have been used. Percutaneous neurolytic celiac plexus block with injection of 50%-100% ethyl alcohol under radiological guidance has become the most commonly recognized method of splanchnicectomy with a 70%-96% success rate^[416]. The celiac plexus block has several advantages as it has been proven to ease pain without the side effects of opioids and can be administered intraoperatively, percutaneously, or by endoscopic ultrasonography. Recent studies have shown that endoscopic ultrasonography-guided neurolysis is effective and has minimal risk of the potentially serious complications associated with surgical or percutaneous approaches^[417,418].

A recent double-blind randomized controlled study comparing patients treated with celiac plexus block *vs* systemic analgesic therapy showed that splanchnic neurolysis provided superior pain relief and quality of life scores, but overall opioid consumption, frequency of opioid adverse effects and overall survival did not reach statistical significance between the two groups^[419]. For the majority of PC patients, pain is still controlled pharmacologically even if other modalities such as surgical thoracoscopic splanchnicectomy, epidural anesthesia, subcutaneous injection with octreotide, hypofractionated-accelerated radiotherapy and more recently photodynamic therapy have shown some temporary success^[414,420-423].

Nutritional supportive care

The median survival of patients with unresectable PC is 33 wk and for advanced metastatic disease is only 10 wk^[424]. About 90% of patients with PC have significant weight loss at the time of diagnosis and all of them develop progressive cachexia due to neoplastic metabolic derangements. Secondary events such as pancreatic exocrine insufficiency due to pancreatic duct obstruction, fat malabsorption due to biliary obstruction and poor oral caloric intake caused by nausea or gastric outlet obstruction are also responsible for the progressive weight loss. Even if weight loss has been found to have a prognostic effect on survival, most of the palliative care interventions for PC are directed at correcting biliary obstruction, gastric outlet obstruction and pain, and relatively little attention has been paid to interventions that can prevent or reduce the progressive weight loss of these patients^[425]. Recently, a placebo-controlled trial comparing patients receiving enteric coated pancreatic enzyme supplements *vs* placebo showed that after 2 mo, patients receiving pancreatin had gained 1.2% of their body weight in comparison to controls who lost 3.7% ($P = 0.02$), and that they had higher daily total energy intake (8.4 MJ *vs* 6.6 MJ, $P = 0.04$)^[424]. Although the Karnofsky performance status between the two groups was not different and survival analysis was not performed to determine if body weight gain translates into better prognosis, this study was the first to show an effective palliative strategy able to increase the intestinal absorptive function of patients who suffer from steatorrhea.

CONCLUSION

In recent decades, diagnostic modalities, and the surgical and palliative treatments of PC have clearly progressed although the overall prognosis has barely changed. The management of patients affected by PC is complex and requires expertise in many fields. Multidisciplinary teams are necessary to optimize the overall care, and palliative techniques have to be mastered as the majority of PCs are diagnosed in advanced stages. Better outcomes are reached if PC patients are appropriately referred to tertiary centers for assessment by surgical, medical and radiation oncologists, gastroenterologists, palliative care specialists and other dedicated health care providers. Despite recent progress, there is still a very limited ability to detect PC at an early stage, and there is a need for more studies to better understand genetic predisposing factors and to discover new markers that could assist physicians in this task. Randomized controlled studies are necessary to explore the role of neo-adjuvant therapies and new protocols for adjuvant strategies in patients undergoing pancreatic resection.

Abstract

AIM: To investigate the effect of *Ginkgo biloba* extract on the enteric neurons in the small intestine of diabetic rats.

METHODS: Fifteen Wistar rats were divided into three groups: control group (C), diabetic group (D) and diabetic-treated (DT) daily with EGb 761 extract (50 mg/kg body weight) for 120 d. The enteric neurons were identified by the myosin-V immunohistochemical technique. The neuronal density and the cell body area were also analyzed.

RESULTS: There was a significant decrease in the neuronal population (myenteric plexus $P = 0.0351$; submucous plexus $P = 0.0217$) in both plexuses of the jejunum in group D when compared to group C. With regard to the ileum, there was a significant decrease ($P = 0.0117$) only in the myenteric plexus. The DT group showed preservation of the neuronal population in the jejunum submucous plexus and in the myenteric plexus in the ileum. The cell body area in group D increased significantly ($P = 0.0001$) in the myenteric plexus of

both segments studied as well as in the ileum submucosal plexus, when compared to C. The treatment reduced ($P = 0.0001$) the cell body area of the submucosal neurons of both segments and the jejunum myenteric neurons.

CONCLUSION: The purified *Ginkgo biloba* extract has a neuroprotective effect on the jejunum submucous plexus and the myenteric plexus of the ileum of diabetic rats.

INTRODUCTION

Diabetes mellitus (DM) is a group of metabolic diseases characterized by high levels of glucose due to the lack of insulin and/or the inability of insulin to properly exercise its effects^[1]. Long-term hyperglycemia induces morbid states in patients, resulting in macroangiopathy^[2] complications, microangiopathy (retinopathy and nephropathy)^[3] and neuropathies^[4].

Neuropathy is the most common late complication in diabetic patients^[5,6]. It compromises the sympathetic, parasympathetic and enteric nerves, causing a variety of abnormalities such as ulcerations of the lower limbs, sud-

den death by cardiac arrhythmia, gangrene, amputations, sexual dysfunction and gastrointestinal alterations^[6,7].

The gastrointestinal tract is seriously affected by DM. Nearly 75% of diabetic patients may suffer with disorders such as late gastric emptying, vomiting, nausea, diarrhea, abdominal pain, swelling and constipation^[8]. These disorders are usually correlated with enteric neuron lesions^[9-12].

Oxidative stress plays an important role in the development and progression of diabetic neuropathy^[13,14]. Hyperglycemia has been identified as the main cause in the development of oxidative stress by the production of reactive oxygen species (ROS) and reduction of endogenous antioxidants^[15] due to auto-oxidation of blood glucose, excessive formation of AGEs (advanced glycation end products) and activation of the polyol pathway^[13]. The excessive activation of the polyol pathway reduces the cytosolic NADPH, thus decreasing reduced glutathione (GSH), an important endogenous antioxidant. At the same time, this pathway produces an accumulation of sorbitol which causes cellular osmotic stress, also leading to oxidative stress^[16].

ROS or free radicals such as superoxide anion (O_2^-), hydroxyl radical (OH) or intermediate species such as hydrogen peroxide (H_2O_2), damage all classes of cell macromolecular components and organelles (e.g. mitochondria, endoplasmic reticulum, proteins, *etc.*), which can lead to cell death. These free radicals also degrade the cell membrane phospholipids through a process called lipid peroxidation^[17].

The use of antioxidants has beneficial effects in the treatment of diabetic complications^[17-19]. *Ginkgo biloba* extract, obtained from *Ginkgo biloba* leaves, has medicinal properties and is one of the most sold natural supplements in the world. This extract has antioxidant activity and neuroprotective effect, inhibiting cell death^[20,21]. Husstedt *et al.*^[22] noticed that treatment with *Ginkgo biloba* reduced symmetrical polyneuropathy when they analyzed clinical and neurophysiological parameters and the hemorheologic changes in patients with diabetes.

The immunohistochemical technique to identify protein myosin-V has been used to estimate the total neuronal population in different regions of the gastrointestinal tract^[11,12]. This technique confers specificity in the identification of enteric neurons, because this protein is located in neuronal cytoplasm, allowing visualization of cell bodies and their projections^[12].

Our aim was to analyze the effects of standardized extract of *Ginkgo biloba* (EGb 761) on neurons of the myenteric and submucous plexuses in the jejunum and ileum of streptozotocin-diabetic rats. To do so, a morphometric and quantitative study of enteric neurons after 120 d of treatment was carried out.

MATERIALS AND METHODS

Animals

Fifteen male *Wistar* rats (*Rattus norvegicus*) were used, obtained from the Central Vivarium of the Universidade

Estadual de Maringá (UEM). The animal procedures described in this work were conducted in accordance with the ethical principles of the Brazilian Academy in Animal Experimentation (COBEA) and approved by the Ethics Committee in Animal Experimentation of UEM.

The weight of animals at the beginning of the experiment was 400 g, corresponding to an approximate age of 150 d. The animals were kept for 120 d in groups of five per box in a room with a light cycle of 12/12 h (7:00 to 19:00) and at constant room temperature of 21-22°C. They were fed with Nuvilab standard diet and water *ad libitum*.

Experimental design

The animals were divided into 3 experimental groups, each group comprised of 5 animals: control group (C) (normoglycemic); diabetic group (D); diabetic-treated with *Ginkgo biloba* extract (EGb 761) group (DT).

To induce diabetes the rats in groups D and DT were weighed and fasted for 16 h. Then, they were injected intravenously with streptozotocin (Sigma, St. Louis, MO, USA) at a dose of 35 mg/kg of body weight.

Blood glucose levels were determined after 7 d by the glucose oxidase method to confirm the disease onset. Only animals with blood glucose higher than 200 mg/dL were kept in groups D and DT.

Besides their normal diet, the DT group animals were treated daily by gavage with the *Ginkgo biloba* (EGb 761) extract (Tebonin, Altana Pharma, Jaguariúna, São Paulo, Brazil) at a dose of 50 mg/kg of body weight throughout the experiment.

Collection and processing of material

At the end of the 120-d trial period, all animals were anesthetized intraperitoneally with thiopental (40 mg/kg body weight) (Abbott Laboratories, Chicago, IL, USA). Blood was collected through cardiac puncture to assess the glycemia. After a laparotomy, the jejunum and ileum segments were collected. These segments were washed with 0.9% saline solution, the ends tied up and inflated with a fixative solution [periodate-lysine-paraformaldehyde (10 mmol/L sodium periodate, 75 mmol/L lysine, and 1% paraformaldehyde in 37 mmol/L phosphate buffer, pH 7.4)]. They were kept in vials containing the same solution for one and half hours. Thirty minutes later, two small holes were made near each end, and the fixative content was drained.

In order to improve the antibody tissue permeability, fragments of the jejunum and ileum were dehydrated in increasing series of alcohols (50%, 70%, 80%, 90%, 95%, 100% I, 100% II), cleared in xylol and rehydrated in decreasing series of alcohol up to 70%.

The dissection procedures were performed by cutting transversely the cylindrical segments of the jejunum and ileum, which were then opened longitudinally at the mesenteric insertion in order to obtain rectangular pieces. The procedure was carried out under a stereoscopy microscope and samples handled with watchmaker tweezers to obtain myenteric plexus membrane whole mounts. The

mucosa and submucosal tunica were removed from the myenteric plexus, while the external muscular layer was kept. The mucosa was removed from the submucosal plexus with the aid of a wooden spatula.

Immunohistochemistry of the myenteric and submucosal plexuses

The myenteric and submucous plexuses were stained by the anti-myosin-V immunohistochemical technique as described by Buttow *et al.*^[23]. The final concentration of antibody was 0.89 mg/mL. The dilution used was 1:1000 (v/v). The membranes were first immersed in a blocking solution of 0.1 mol/L PBS containing 2% bovine serum albumin (BSA) and 0.5% Triton X-100 and normal goat serum at a ratio of 1:50 (v/v) for 3 h. The material was incubated with primary antibody for 48 h at room temperature (RT); this was performed in a solution of 0.1 mol/L PBS containing 1% BSA and 0.1% Triton X-100 and normal goat serum in the proportion of 1:50 (v/v). After the incubation, the material was washed twice for 15 min with PBS solution 0.1 mol/L and Triton X-100 0.1% and then also washed twice in PBS 0.1 mol/L and Tween 20 at a concentration of 0.05% for 15 min. The whole-mounts were then incubated with anti-rabbit secondary antibody produced in goat, peroxidase-conjugated [ImmunoPure® Goat Anti-Rabbit IgG, (Fc), Peroxidase Conjugated, brand Pierce] in a blocking solution containing 0.1 mol/LPBS, 1% BSA and 0.05% Tween 20 for 24 h at RT. Normal goat serum at 1:50 (v/v) was also added to this blocking solution. The material was washed 4 times for 15 min in a solution of 0.1 mol/L PBS containing 0.05% Tween 20. The membranes were developed with the use of a diaminobenzidine solution (Sigma, St. Louis, MO, USA) for approximately 10 min at a concentration of 0.14 mg/mL. After developing, the material was mounted on histological slides with glycerol-gel (containing 50% glycerol, 0.07 g/mL gelatin in PBS, and 2 μ L/mL phenol). The slides were then placed in refrigerator (4°C), in order to slowly dry the whole-mounts.

Density analysis of myosin-V immunoreactive neurons

Enteric neurons were counted on a BX 40 Olympus microscope under a 40 \times lens. Forty microscopy fields, randomly selected, were counted for each preparation. The area of each field was 0.229 mm². The results were expressed in number of neurons per cm².

Morphometric analysis of myosin-V immunoreactive neurons

Images of the ganglia were taken and then measured with the aid of the image analysis software Image Pro-Plus 3.0.1 (Media Cybernetics, Silver Spring, MD, USA) to study the area of neurons in different groups. The area (μ m²) of 100 cell bodies per animal was measured, for a total of 500 neurons (5 animals per group). Neurons were classified into the class interval of 10 μ m², and the percentage of each group was calculated for each interval.

Table 1 Final weight and glycemia in groups: control, diabetic and EGb 76-treated diabetic (mean \pm SE)

Group	Final weight (g)	Blood glucose (mg/dL)
C	445.6 \pm 63.04	78.97 \pm 5.12
D	264.6 \pm 22.88	253 \pm 64.97
DT	308 \pm 19.27	322 \pm 20.42

n = 5/groups. C: Control; D: Diabetic; DT: EGb 76-treated diabetic.

Statistical analysis

To compare the parameters of the studied groups we used analysis of variance (ANOVA). When there was a significant difference we used Tukey's test. For this study we used the Prism software version 3.0. Results were considered significant when *P* < 0.05. The results were shown as mean \pm SE, *n* indicating the number of samples in each group.

RESULTS

Streptozotocin caused diabetic syndrome onset in animal groups D and DT, as evidenced by the significant increase in blood glucose, as well as a significant reduction in body weight, when compared to group C (Table 1). Other typical symptoms of the disease (polyuria, polydipsia and polyphagia) were observed during the experimental period.

Neuronal density

There was a significant reduction (*P* < 0.05) in the neuronal density of myenteric neurons in the jejunum in group D when compared to C (Table 2). There was no significant difference in the DT group when compared to groups C and D. The neuronal density of submucosal neurons decreased significantly (*P* < 0.05) in group D when compared to C. No significant difference in the neuronal density was observed when group DT was compared to C (Table 2).

The neuronal density of myenteric neurons in the ileum decreased significantly (*P* < 0.05) in group D when compared to C (Table 3). No significant difference was seen when comparing group DT to C. There was no significant reduction in the neuronal density in the ileum submucous plexus when the three groups were compared (Table 3).

Areas of neuronal cell bodies

The results obtained with the measurements of 500 neurons per studied group were distributed according to the relative frequency of areas of neuronal cell bodies at intervals of 10 μ m² (Figures 1 and 2). The cell body area in the jejunum ranged between 81.33 and 538.9 μ m² for animals in group C; between 119.9 and 588.9 μ m² in group D; and between 101.0 and 609.2 μ m² in group DT. There were no significant differences in the mean areas of the jejunum myenteric neurons when comparing groups C and D. However, there was a significant reduction in the mean area (*P* < 0.05) of the DT group when compared to the other two groups (Table 2). The cell body area in the

$n = 5$ /myenteric plexus group; $n = 3$ /submucous plexus group. C: Control; D: Diabetic; DT: EGb 76-treated diabetic.

Figure 1 Neuronal behavior: area of cell body of myenteric (A) and submucosal (B) neurons, myosin-V immunoreactive in the jejunum, of control (C), diabetic (D) and diabetic-treated with EGb 761 (DT).

submucosal neurons in the jejunum ranged between 106.1 and 474.4 μ m² in group C, between 102.3 to 523.4 μ m² in group D and between 91.73 to 401.1 μ m² in group DT. There were no significant differences between the mean cell body areas in groups C and D ($P > 0.05$). However, there was a significant reduction ($P < 0.05$) in group DT when compared to groups C and D (Table 2).

Figure 2 Neuronal behavior: area of cell body of myenteric (A) and submucosal (B) neurons, myosin-V immunoreactive in the ileum, of control (C), diabetic (D) and diabetic-treated with EGb 761 (DT).

The cell body area of myenteric neurons in the ileum ranged between 97.70 and 725.7 μ m² in group C, between 101.5 and 595.5 μ m² in group D, and between 96.32 and 512.9 μ m² in group DT. There was a significant increase ($P < 0.05$) in group D when compared to C. No significant difference was observed when comparing group DT to groups C or D (Table 3). As for the ileum submucous

Figure 3 Myosin-V immunoreactive myenteric neurons in the jejunum (A-C) and myosin-V immunoreactive submucosal neurons in the jejunum (D-F). There is a significant reduction in the neuronal density in the myenteric (B) and submucous (E) plexus in group diabetic. The neuronal density in the submucous plexus (F) was preserved in group EGb 76-treated (DT) (F). There was a significant reduction in the neuronal cell body area in group DT of both plexuses (C and F).

plexus, the area ranged between 89.54 and 426.2 μm^2 , between 99.52 and 534.0 μm^2 in group D, and between 72.77 and 435.0 μm^2 in group DT. There was a significant increase in the mean cell body area in group D ($P < 0.05$) when compared to C. The DT group showed no significant difference in mean cell body area when compared to group C (Table 3). In the submucous plexus, reduction in neuronal profile area was greater than in the myenteric plexus; the values in the submucous plexus just below those of the control group.

The distribution of the relative frequency of areas of cell bodies in the jejunum showed a displacement curve to the right in the myenteric plexus; thus showing a higher relative frequency of neurons at about 160 μm^2 in both plexuses (Figure 1). There was a similarity in the curves of groups C and DT in both plexuses in the ileum (Figure 2). Group D showed a displacement to the right in both plexuses.

DISCUSSION

Streptozotocin (STZ) is widely used in experimental animal models to induce DM. Its cellular action includes irreversible changes in genetic material causing lethal alterations in the metabolism of β cells^[24]. There is a reduction in overall myenteric plexus neuron population in animal models with chronic STZ-diabetes^[11,12,25,26]. There are no studies of changes caused by diabetes in the overall neuronal population of the submucous plexus. Our study showed that the 120-d treatment with purified *Ginkgo biloba* extract (EGb 761) has a neuroprotective effect on the ileum myenteric plexus and on the jejunum submucous plexus of STZ-diabetic rats.

Characteristic diabetic symptoms (polydipsia, polyuria

and polyphagia) were observed in animals of D and DT groups. These data support the experimental model of streptozotocin-induced diabetes^[27-29]. The immunohistochemical technique, anti-myosin-V (Figures 3 and 4), was used to assess the effect of *Ginkgo biloba* extract (EGb 761) on the enteric neuronal population. The protein myosin-V is present in cell bodies and projections of enteric neurons^[30] and is being used as a pan-neuronal marker.

The reduction of the myenteric neuron density in the jejunum was 15.12% in group D when compared to C ($P < 0.05$). The submucosal neuron density was 9.61% lower in group D when compared to C ($P < 0.05$). A reduction of 11.83% in myenteric neuron density was observed in the ileum in group D when compared to C ($P < 0.05$). The submucosal neuron density in the ileum was similar among the three groups. Several authors report the reduction of myenteric neuron density in rats with STZ-diabetes in different regions of the gastrointestinal tract, including the cecum^[31], ileum^[11,26], jejunum^[25] and proximal colon^[12]. There are no studies in the submucosal plexus of the total neuronal population in STZ-diabetes models. Pereira *et al.*^[26] reported a 24% reduction in the number of myosin-V myenteric neurons in the ileum (after 120 d) of diabetic rats when compared to non-diabetic ones. De Freitas *et al.*^[25] observed a 37.9% neuronal loss of myosin-V myenteric neurons in the jejunum of diabetic rats when compared to non-diabetic animals, also after 120 d. These studies used 90-d-old animals at the beginning of the experiment and our study was carried out with 150-d-old rats, which may have contributed to the neuronal loss variation due to age.

The degenerative changes that affect the enteric nervous system seen in DM are due to metabolic disorders. High oxidative stress, resulting from the imbalance be-

Figure 4 Myosin-V immunoreactive myenteric neurons in the ileum (A-C) and myosin-V immunoreactive submucosal neurons in the jejunum (D-F). There is a significant reduction in the neuronal density in the myenteric plexus (B), but the neuronal density was preserved in this plexus in group EGb 76-treated (DT) (C). There is a significant increase in the neuronal cell body area in group diabetic in the myenteric (B) and submucous (E) plexuses. There was a significant reduction in the neuronal cell body area in group DT in the submucous plexus (F).

tween ROS production and neutralization, is a well established mechanism of diabetic neuropathy pathogenesis and other complications^[32,33]. The levels of endogenous and exogenous antioxidants are reduced in this condition. New studies have confirmed the destruction of endogenous antioxidants in peripheral nerves and the increased production of free radicals in the vasa nervorum^[4].

Ginkgo biloba extract is widely used for its neuroprotective and antioxidant activity in several cardiovascular and neurologic disorders^[34,35]. The *Ginkgo biloba* extract (EGb 761) was given at a daily dose of 50 mg/kg body weight for 120 d in this experiment. This standardized extract contains 24% flavonoid glycosides (quercetin, kaempferol, isorhamnetin) and 6% terpene lactones (ginkgolides, bilobalides). The EGb 761 extract components eliminate free radicals such as the hydroxyl radical and the superoxide anion^[36]. Quercetin is a powerful antioxidant within the flavonoid family due to its molecular configuration which is capable of eliminating free radicals^[37].

The myenteric neuronal density in the jejunum in the DT group was 9.17% lower when compared to C, though this reduction is not significant. On the other hand, the submucosal neuronal density in DT had very similar values to those of group C. The treatment with EGb 671 resulted in the preservation of the neuronal population in the ileum, represented by very similar values to those of the control group (Table 2), thus demonstrating a neuroprotective effect on this complex. The submucosal neuronal density in this segment was similar in all three groups. The *Ginkgo biloba* extract reduces the oxidative stress in diabetic rats by increasing the activity of antioxidant enzymes^[38]. Wu *et al.*^[39] reported that this extract may be vital to postpone diabetic cataract, since their studies showed that, besides inhibiting aldose reductase activity, *Ginkgo biloba* also inhibits apoptosis induced by high glu-

cose levels by reducing the Bax/Bcl2 ratio. This high ratio harms the mitochondria which release apoptosis-inducing proteins, such as the apoptosis-inducing factor, leading to the activation of caspase-3 *via* caspase 9. The myenteric plexus neuroprotection, seen only in the ileum, is similar to results in aging models^[40] where 120-d treatment of rats with the same dose of *Ginkgo biloba* extract was more efficient in the ileum myenteric plexus than in the jejunum.

Few studies have been carried out in the submucous plexus due to the difficulty of dissection. Some authors have reported changes in neuronal subpopulations through the neurotransmitter immunoreactivity. Belai *et al.*^[41] observed an increase in VIP and neuropeptide Y immunoreactivity when analyzing the submucous plexus in the ileum of STZ-diabetic rats aged 8 and 16 wk. They also observed a reduction in calcitonin gene-related peptide (CGRP) immunoreactivity. However, no change in substance P immunoreactivity or dopamine beta hydroxylase was seen. VIP-ergic neurons of diabetic rats show increased immunoreactivity in the jejunum^[42] and ileum^[43] submucous plexus.

The mean cell body areas of myenteric neurons in the jejunum were similar in groups C and D. These results are similar to those observed by De Freitas *et al.*^[25], who did not observe an increase in the mean area of the cell body of immunoreactive myosin-V neurons in the jejunum of diabetic rats when compared to non-diabetic rats. The mean areas of cell bodies of submucosal neurons in the jejunum were similar in groups C and D. Studies on morphometric changes in the submucosal plexus caused by diabetic syndrome report an increase in the mean area of the cell body of neuronal subpopulations. Defani *et al.*^[42] observed an increase in the mean area of the cell body of submucous VIP-ergic neurons in the jejunum. The technique used to stain the total population showed no change

in the mean area of submucosal neurons in the jejunum. The mean area of the cell body of myenteric neurons in the ileum was 7.44% ($P < 0.05$) higher in group D than in group C in our study. This increase was also observed by Zanoni *et al.*^[11] and Pereira *et al.*^[26] in Wistar rats after a 120-d experimental period. The mean area of the body cell of submucosal neurons in the ileum showed a statistically significant increase of 9.2% ($P < 0.05$) in group D when compared to C. Zanoni *et al.*^[43] reported an increase in the mean area of the body cell of submucous VIP-ergic neurons in the ileum.

The increase in the neuronal cell body area in rats with chronic diabetes may be the result of neuronal edema^[11]. The aldose reductase hyperactivity observed in diabetes is associated with increased levels of sorbitol^[44] which increases the intracellular osmolarity, resulting in edema and neuronal lesions^[43].

The EGb 761 treatment induced a reduction of 6.8% in the mean area of the cell body in the jejunum myenteric neurons in DT when compared to C ($P < 0.05$). The mean area of the cell body of submucosal neurons decreased 6.2% in group DT when compared to C ($P < 0.05$). The mean area of the cell body of myenteric and submucosal neurons in the ileum in DT was reduced to values similar to group C. Schneider *et al.*^[40] observed that the EGb 761 treatment reduced the mean area of myenteric neuronal cell bodies in the jejunum and ileum of aging rats. However, studies by Perez *et al.*^[45] in the large intestine treated with EGb 761 at a dose of 50 mg/kg of body weight observed that the EGb 761 extract promotes an increase in the mean area of myenteric neurons in rats in the aging process. These results show that the response to the use of antioxidants such as the *Ginkgo biloba* extract may be different according to the segment evaluated.

This study showed that treatment with *Ginkgo biloba* extract reduced the area of the cell body of myenteric and submucosal neurons in the jejunum and ileum of diabetic-treated rats (group DT) when compared to non-treated diabetic rats (group D). However, the reduction in the mean area of the cell body of myenteric neurons in the ileum was not significant. The inhibitory action of *Ginkgo biloba* on aldose reductase^[19] enzyme activity may be responsible for the reduction in the mean area of neuronal cell bodies observed in rats treated with EGb 761 (DT group).

In conclusion, our results show that the 50 mg/kg of body weight dose of standardized *Ginkgo biloba* extract (EGb761) has a neuroprotective effect on the ileum myenteric plexus and on the jejunum submucous plexus of STZ-diabetic rats.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Enilza Maria Espreafico (USP-Ribeirão Preto, Brazil) for her invaluable assistance and support in the production of the anti-myosin-V antibody, Maria Eurides do Carmo Cancino, Maria dos Anjos Fortunato, Valdir Trombeli and José Antônio de Souza (UEM, Brazil) for their excellent technical support, and

Ali Suleiman Mahmoud for translating the text. We gratefully acknowledge Altana Pharma for supplying the *Ginkgo biloba* extract (EGb 761).

COMMENTS

Background

Ginkgo biloba extract possesses various biological activities and has been shown to be useful in diabetes treatment. Oxidative stress has been known to play an important role in the development and progression of diabetes mellitus (DM), and reactive oxygen species (ROS) production is a direct consequence of hyperglycemia. Chronic hyperglycemia in diabetes is involved in direct neuronal damage caused by intracellular glucose which leads to altered neurotransmitter functions and reduced motor activity. Oxygen free radicals are also thought to play an important role in the diabetic and hypoxic condition of cells. Success of *Ginkgo biloba* application is determined by its main active substances, flavonoids (flavone glycosides, primarily composed of quercetin) and terpenoids (ginkgolides and bilobalides). *Ginkgo biloba* can improve hemodynamics, scavenge ROS, suppress platelet-activating factor (PAF) and relax vascular smooth muscle.

Research frontiers

Gastrointestinal (GI) afflictions are not normally life threatening but do profoundly affect quality of life. Diabetic patients experience a wide range of GI discomforts including nausea, vomiting, heartburn, diarrhea, constipation, abdominal pain and fecal incontinence. The high morbidity, high socioeconomic costs and lack of specific treatments are key factors that define the relevance of DM for human health and the importance of research on neuronal protective agents. Some studies provide a strong case for the application of *Ginkgo biloba* in diabetic nephropathy therapy.

Innovations and breakthroughs

Ginkgo biloba has been ascertained to be protective against DM. However, there has been little in the literature reporting on the protective effects of *Ginkgo biloba* on the enteric nervous system of the small intestine of streptozotocin-induced diabetic rats *in vivo*.

Applications

This study indicated that standardized extract of *Ginkgo biloba* (EGb 761) could improve antioxidant ability and protect the enteric nervous system of the small intestine of streptozotocin-induced diabetic rats *in vivo*. These biological activities have considerable potential in diabetes mellitus treatment.

Peer review

The authors investigated the effect of *Ginkgo biloba* extract on the enteric neurons on the small intestine of diabetic rats. They found purified *Ginkgo biloba* extract has a neuroprotective effect on the jejunum submucous plexus and the myenteric plexus of the ileum of diabetic rats. This is a well written paper.

Abstract

AIM: To evaluate outcome of patients with Budd-Chiari syndrome after balloon angioplasty ± stenting or transjugular intrahepatic portosystemic shunt (TIPS).

METHODS: Twenty five patients with Budd-Chiari syndrome admitted to Ain Shams University Hospitals, Tropical Medicine Department were included. Twelve patients (48%) with short segment occlusion were candidates for angioplasty; with stenting in ten cases and without stenting in two. Thirteen patients (52%) had Transjugular Intrahepatic Portosystemic Shunt. Patients were followed up for 12-32 mo.

RESULTS: Patency rate in patients who underwent angioplasty ± stenting was 83.3% at one year and at end of follow up. The need of revision was 41.6% with one year survival of 100%, dropped to 91.6% at end

of follow up. In patients who had Transjugular Intrahepatic Portosystemic Shunt, patency rate was 92.3% at one year, dropped to 84.6% at end of follow up. The need of revision was 38.4% with one year and end of follow up survival of 100%. Patients with patent shunts showed marked improvement compared to those with occluded shunts.

CONCLUSION: Morbidity and mortality following angioplasty ± stenting and TIPS are low with satisfactory outcome. Proper patient selection and management of shunt dysfunction are crucial in improvement.

INTRODUCTION

Budd-Chiari syndrome (BCS) results from hepatic venous outflow obstruction at any level, from hepatic venules to the right atrium^[1]. If obstruction is due to endoluminal venous lesion like thrombosis, primary BCS is considered. In secondary BCS, the cause originates from neighboring structures like extrinsic compression or tumor invasion^[2].

Imaging studies combined with clinical information

are often essential for reaching a definitive diagnosis^[3].

The goals of treatment are to prevent extension of thrombosis in hepatic veins (HVs) and to alleviate venous obstruction in order to decrease hepatic congestion. Few patients respond to medical treatment (anticoagulation \pm thrombolytic therapy, diuretics). However, most patients need intervention to restore the hepatic blood flow^[4].

If there is a possibility of restoring hepatic venous outflow in one of the major HVs by balloon dilatation, recanalization, or stent insertion, then this is the procedure of choice as it is the most physiological method. However, in cases where blood flow cannot be restored or when the approach fails, transjugular intrahepatic portosystemic shunt (TIPS) is used as a decompressing non-surgical procedure^[5].

MATERIALS AND METHODS

Study Design & Sampling: This prospective follow-up study was conducted on twenty five patients with confirmed diagnosis of primary BCS and eligible criteria for radiological intervention, who were presented to the Budd-Chiari Study Group and admitted to the Tropical Medicine Department, Ain Shams University Hospitals.

Patients were subjected to: (1) Complete Clinical Evaluation; and (2) Radiological Assessment, with special stress on the patency of HVs, portal vein and inferior vena cava (IVC) by abdominal Duplex/US. Abdominal MRI, MR venography or multislice CT scan were done to confirm diagnosis and to delineate vascular anatomy before intervention.

They were divided into two groups: (1) Patients with short segment occlusion of any of HVs who were candidates for angioplasty \pm stenting; and (2) Patients with complete occlusion of all HVs who were candidates for TIPS.

Exclusion criteria: (1) Secondary BCS; (2) Retro or suprahepatic IVC obstruction; (3) Complete portal vein thrombosis; (4) Presence of comorbid etiology for liver disease in addition to BCS (e.g.: viral hepatitis); (5) Hepatocellular carcinoma; (6) Cardiac contraindications to TIPS (congestive heart failure and severe pulmonary hypertension); (7) Marked coagulopathy (INR > 5) and Thrombocytopenia (platelets $< 20\,000$)^[6]; (8) Biliary obstruction; and (9) Uncontrolled sepsis.

Details of the study and interventions were explained to recruited patients who signed a written consent form.

Pre-intervention assessment and preparation

Routine laboratory investigations and thrombophilia workup were done aiming at identification of etiology of BCS, in addition to assessment of liver disease severity.

Patients' general health was assessed according to WHO performance status scale^[7]: 0: patient is fully active, able to carry on all pre-disease performance without restriction; 1: patient is restricted in physically strenuous

activity but ambulatory and able to carry out work of a light or sedentary nature, e.g. light house work; 2: patient is ambulatory and capable of all self care but unable to carry out any work activities. Up and about more than 50% of waking hours; 3: patient is capable of only limited self care, confined to bed or chair more than 50% of waking hours; 4: patient cannot carry on any self care and totally confined to bed or chair.

Patients were classified as follows: According to Rotterdam prognostic classification^[8] into 3 classes with scores according to the equation: $1.27 \times \text{encephalopathy} + 1.04 \times \text{ascites} + 0.72 \times \text{prothrombin time} + 0.004 \times \text{bilirubin}$ [Ascites and hepatic encephalopathy were scored as present (1) or absent (0) and prothrombin time as higher (1) or lower (0) than 2.3 INR. Bilirubin was included as a continuous variable]. Where Class I (0-1.1): good prognosis; Class II (1.1-1.5): intermediate prognosis and Class III (> 1.5): poor prognosis.

According to Child-Pugh score into 3 classes (A, B and C)^[9].

All patients started anticoagulation therapy when diagnosis of BCS was evident; in the form of low molecular weight heparin (LMWH) or unfractionated heparin. Then oral warfarin was added till INR reached its target (2-3), then continued on oral therapy alone after withdrawal of LMWH or unfractionated heparin.

Five days before procedure, oral anticoagulation therapy was stopped with administration of LMWH or unfractionated heparin only; to be stopped (6-12 h) before intervention in case of unfractionated heparin and (12-24 h) in case of LMWH to avoid intra or postoperative bleeding^[10].

Antibiotic prophylaxis was administered for all patients (1-2 h) before intervention in the form of combination of ampicillin- sulbactam 1.5 gm IV and cefotaxime 1 gm IV^[11].

Technical considerations

All procedures were performed in an angiographic interventional room with high resolution C-arm fluoroscopy, and digital subtraction angiography.

Interventions were done under general anesthesia.

All cases of TIPS or angioplasty with stenting had self expandable non covered metallic stents.

Post intervention management

Patients were admitted to hospital for 1 wk after procedure for early detection and management of any procedure-related complications and adjustment of anticoagulation.

Antibiotics regimen taken before procedure was continued for 5 d after.

Oral warfarin was introduced together with parental anticoagulation (LMWH after 24 h or unfractionated Heparin after 6 h) till INR reaches (2-3) then oral therapy was continued alone for life^[12].

Duplex U/S was performed to detect shunt patency at days 1, 3, and 7 after the procedure.

Follow up

Patients were followed up clinically, by laboratory investigations (mainly liver profile and PT and PTT for monitoring of anticoagulation) and radiologically by duplex U/S.

Follow up after intervention was every three mo or when indicated (e.g.: clinical manifestations suggestive of angioplasty or TIPS dysfunction). Follow up was intended to be at least one year (Minimum: 12 mo, Maximum: 32 mo).

Aims of follow up were

(1) Assessment of patients' survival and shunt survival (i.e.; shunt patency and function) (at one year interval and at the end of follow up); (2) Description of procedures related complications and their management; and (3) Assessment of patients' improvement after intervention by comparison of clinical, laboratory and performance status criteria before intervention and one year after.

Statistical analysis

Descriptive statistics: (1) Quantitative data: mean, standard deviation (\pm SD); and (2) Qualitative data: frequency and percentage.

Analytical statistics: (1) Quantitative data: Wilcoxon Signed Ranks Test; and (2) Qualitative data: McNemar Test.

Levels of significance: (1) $P > 0.05$ = non significant (NS); (2) $P < 0.05$ = significant (S); (3) $P < 0.01$ = highly significant (HS); and (4) $P < 0.001$ = very highly significant (VHS).

Survival: (1) Patient Survival was *defined* as the duration between diagnosis of BCS, and patient death or loss to follow up. Survival rates were Kaplan-Meier estimates; (2) Shunt Survival was *defined* as the duration between shunt application, and shunt occlusion or loss to follow up. Survival rates were Kaplan-Meier estimates.

RESULTS

Descriptive data

This study was conducted on twenty five patients with BCS who underwent non surgical hepatic decompression procedures in the form of either angioplasty \pm stenting or TIPS. They were 16 females (64%) and 9 males (36%) with a mean age of 28.28 ± 8.93 years (range 14-57 years). BCS was chronic form in 21 patients (84%), acute in three patients (12%), and fulminant in 1 patient (4%). When tested for underlying thrombophilia, 8 were negative (idiopathic), 4 primary antiphospholipid antibody syndrome (APS), 4 protein C deficiency, 3 Antithrombin III deficiency, 1 myeloproliferative disorder, 1 combined protein C, S deficiency, 1 combined protein C, S, Antithrombin III deficiency, 1 combined Antithrombin III deficiency + factor V Leiden mutation (FVLM), 1 combined protein S deficiency + FVLM and 1 was primary APS + FVLM.

According to Child Classification, 5 patients (20%)

Table 1 Clinical manifestations and radiological criteria in studied patients

Radiological criteria were obtained using duplex ultrasound, magnetic resonance venography and/or multislice computed tomography scan. RHV: Right hepatic vein; MHV: Middle hepatic vein; LHV: Left hepatic vein.

were Child A, 16 (64%) were Child B and 4 (16%) were Child C. According to Rotterdam Classification, 7 patients (28%) were Class I, 15 (60%) were Class II and 3 (12%) were Class III. The Performance status score was "0" in none of the patients, "1" in 4 patients (16%), "2" in 5 patients (20%), "3" in 11 patients (44%) and "4" in 5 patients (20%).

Pre-intervention clinical and investigational data

Clinical manifestations and baseline radiological criteria of studied patients using duplex U/S, MRV and/or Multislice CT scan are shown in Table 1.

Intervention details: The main indications for intervention in the studied patients were ascites associated with large esophageal varices; uncontrollable ascites only; large esophageal varices only and fulminant hepatic failure in 56%; 36%; 4% and 4% of patients respectively.

Twelve patients (48%) were candidates for angioplasty; of those; 10 patients (40%) had stenting (5; 20% in MHV, 4; 16% in LHV and 1; 4% in RHV) and 2 patients (8%) had angioplasty without stenting (1 patient in both LHV and MHV and the other patient in both RHV and MHV, where they shared a common short stenotic segment at their entrance into IVC).

Thirteen patients (52%) were candidates for TIPS.

The need of revision was 41.6% (5 out of 12 patients) in cases of angioplasty \pm stenting and 38.4% (5 out of 13 patients) in cases of TIPS as shown in Table 2.

Table 2 Details of patients who needed revisions and their follow up (*n* = 10)

Patient	Intervention	Time of dysfunction	Action taken	No of revisions	1 yr patency	End of FUP patency
23 yr F	Angioplasty without stenting	Day 7 and Day 10	TIPS was done, occluded at day 10; then re-angioplasty was done ¹	2	Patent	Patent at 20th mo
27 yr M	Angioplasty and stenting	Day 7 and 2nd yr	Angioplasty was done-then angioplasty + thrombectomy	2	Patent	Patent at 24th mo
28 yr F	Angioplasty and stenting	4th mo	Angioplasty + local thrombolytic therapy	1	Patent	Patent at 12th mo
30 yr F	Angioplasty and stenting	1st, 4th, 6th and 9th mo	TIPS was done-then angioplasty (3 times)	4	Occluded at 9th mo	Occluded at 24th mo
28 yr M	Angioplasty and stenting	3rd mo and 14th mo	Angioplasty + stent was done-then mesoatrial shunt	1	Occluded at 1 yr	Dead ² at 17th mo
27 yr F	TIPS	Day 1	(stent occlusion and migration to portal vein) - Re (TIPS)	1	Patent	Patent at 20th m
33 yr F	TIPS	Day 3	Angioplasty + thrombectomy + systemic thrombolytic therapy	1	Patent	Patent at 32nd mo
37 yr F	TIPS	Day 7 and 1st mo	Angioplasty (2 times)	2	Patent	Patent at 12th mo
27 yr M	TIPS	Day 7, 3rd and 8th mo	Angioplasty (3 times)	3	Patent	Occluded at 20th mo
17 yr M	TIPS	1st mo	Patient refused intervention	0	Occluded	Occluded at 12th mo

¹Patient had angioplasty dysfunction at Day 7, so transjugular intrahepatic portosystemic shunt (TIPS) was done but was occluded at Day 10, so angioplasty of TIPS stent was done; ²Cause of death: Intraperitoneal bleeding. Follow up period: Minimum (12 mo), Maximum (32 mo). F: Female; M: Male; yr: Years old; FUP: Follow up.

Table 3 Patient survival *n* (%)

	Angioplasty	TIPS	Total
One year			
Alive	12 (100)	13 (100)	25 (100)
Dead	0 (0)	0 (0)	0 (0)
End of follow up			
Alive	11 (91.6)	13 (100)	24 (96)
Dead	1 (8.4)	0 (0)	1 (4)

Because of death of one patient only out of 25; Kaplan-Meier curve couldn't be drawn for patient survival. TIPS: Transjugular intrahepatic portosystemic shunt.

Figure 1 shows frequency of all complications in total procedures done [Twenty six angioplasty ± stenting procedures (12 as primary intervention and 14 as a trial for maintenance of previously occluded angioplasty or TIPS) and 16 TIPS procedures (13 as primary intervention and 3 in patients with occluded stents following angioplasty in whom redilatation was not possible)].

In total procedures done (whether primary or revision procedures), the frequency of angioplasty dysfunction was 53.85% (14 out of 26 procedures) and the frequency of TIPS dysfunction was 43.75% (7 out of 16 procedures).

Statistical analysis

The mean duration of follow up was 20.04 ± 7.817 mo (ranging from 12-32 mo). One year survival rate was 100% for all patients and at the end of follow up survival rate was 96% due to death of one patient at the 17th mo of follow up as shown in Table 3.

Figure 2A shows patency rate in patients who underwent angioplasty ± stenting procedures; it was 11/12 (91.7%) at 9 mo (due to persistent shunt occlusion in one

Figure 1 Procedure complications. Transient hepatic encephalopathy (HE): HE lasting 2-3 d after procedure with rapid response to treatment. Bleeding was either intra-peritoneal or hemobilia. TIPS: Transjugular intrahepatic portosystemic shunt.

patient). Patency rate dropped to 10/12 (83.3%) at one year and continued till the end of follow up at 32 mo. (There was persistent shunt occlusion in 2 patients in spite of repeated revisions and optimal anticoagulation therapy).

Figure 2B shows patency rate in patients who had TIPS procedures; it was 12/13 (92.3%) at one year (due to persistent shunt occlusion in one patient despite repeated revisions). Patency rate dropped to 11/13 (84.6%) at 20 mo and this continued till the end of follow up at 32 mo (due to persistent shunt occlusion in another patient).

At one year of follow up, only three patients of 25 (12%) had occluded shunts. Patients with occluded shunts showed no improvement regarding their clinical manifestations, laboratory profile and performance status. On the contrary, patients with patent shunts (22 of 25; 88%) showed marked improvement as shown in Tables 4 and 5.

Figure 2 Patency rate in patients who underwent angioplasty \pm stenting (A) and transjugular intrahepatic portosystemic shunt (B). A: Type of intervention: angioplasty \pm stenting of hepatic veins, it was 91.7% at 9 mo and dropped to 83.3% at one year till the end of follow up at 32 mo; B: Type of intervention: transjugular intrahepatic portosystemic shunt, it was 92.3% at one year and dropped to 84.6% at 20 mo till the end of follow up at 32 mo.

DISCUSSION

This is the first study that addresses the short term outcome of interventional radiology procedures in management of Egyptian patients with BCS. In this study, 12 patients (48%) had short segment occlusion that enabled us to perform angioplasty with stenting in ten cases and without stenting in two cases. Thirteen patients (52%) were not suited for angioplasty and had TIPS.

According to Xu *et al.*^[13], short-term results of balloon angioplasty alone without stenting were excellent but the sustained patency rate was only 50% at two years after the procedure. In this study, one of the cases that had angioplasty alone was still having patent shunt at 24 mo after the procedure without any need for shunt revision; the other one had occluded shunt on the seventh day that necessitated re-intervention in the form of TIPS which was still patent at 20 mo after procedure.

Patency rate in patients who underwent angioplasty \pm stenting procedures was 10/12 (83.3%) at one year and at the end of follow up due to persistent shunt occlusion in 2 patients in spite of repeated revisions and optimal

anticoagulation therapy. This is a more or less satisfactory outcome; however it might have been influenced by the relatively short follow up period (ranging from 12 to 32 mo) as well as most of the patients having good or intermediate prognosis according to Rotterdam score. The need of revision in cases with angioplasty \pm stenting was 41.6% (5 out of 12 cases). One year survival was 100% and at the end of follow up, survival dropped to 91.6% due to death of one patient who had occluded shunt after one year and was also referred for mesoatrial shunt due to occlusion of IVC.

Although angioplasty is considered a simple procedure; some complications were reported in the current study. Twenty six angioplasty \pm stenting procedures have been done (12 procedures as primary intervention and 14 procedures as a trial for maintenance of previously occluded angioplasty or TIPS); of these procedures, angioplasty dysfunction was reported in 53.85%. This is consistent with Senzolo *et al.*^[14] who stated that although long-term patency rates can reach 80%-90% in angioplasty \pm stenting procedures; angioplasty may later be required in 50% of these cases to overcome angioplasty dysfunction.

Table 5 Lab data and performance status of patients before and after intervention

	Before intervention		One year after intervention		P value	Sig
	mean	SD	mean	SD		
Patients with occluded shunts (n = 3)						
ALT (N = 7-40 IU/L)	70.33	75.070	29.66	24.66	> 0.05	NS

Table 6 Comparison of different transjugular intrahepatic portosystemic shunt studies in Budd-Chiari syndrome with the current study

Points of comparison	Mancuso <i>et al</i> ^[18]	Perelló <i>et al</i> ^[19]	Rössle <i>et al</i> ^[20]	Hernández-Guerra <i>et al</i> ^[21]	Current study
No. of patients	15	13	35	25 (9 covered stents)	13
Mean age in years (range)	40 (20-73)	36 (17-67)	43 (12-74)	40 (17-54)	29 (14-57)
Median child score	11	9	9	9	8
Acute, fulminant/chronic presentation	8/6	4/6	11/13	ND	2/11
Mean follow-up (mo)	24	48	37	20	18
Stent stenosis (%)	36	72	47	67 (19% covered stents)	38.4
Anticoagulation (%)	100	95	100	ND	100
Patients with acute presentation who died	4	ND	2	ND	0
Patients with chronic presentation who died	0	ND	1	ND	0
Death total (%)	30	10	9	0	0
Liver transplantation	0	1	2	0	0
Surgical portocaval shunt	0	2	0	0	0

ND: Not determined; Anticoagulation: Percent of patients who were adherent to anticoagulation therapy.

Stent migration, which is very rare, occurred in one angioplasty procedure (3.84%) where stent migrated to the heart just after insertion. However, no serious complications occurred and stent was embedded in the wall of right atrium and the patient was quite well.

Post procedure (angioplasty \pm stenting) bleeding was encountered in 3 procedures (11.53%), 2 of which were intraperitoneal and one of which was hemobilia. All 3 cases were managed conservatively by temporary stoppage of anticoagulation and blood transfusion when indicated. This complication could be attributed to the application of a transhepatic approach in these procedures. Beckett and Olliff^[5] stated that this approach has the merit of simplicity over a transjugular or transfemoral approach, as well as feasibility with major superior vena caval obstruction but with a potentially greater risk of bleeding.

Post procedure sepsis occurred in 3 procedures (11.53%) in spite of antibiotic prophylaxis with cefotaxime in combination with ampicillin-sulbactam. This could be due to infection from resistant organisms. According to McDermott *et al*^[15], pathogens that precipitated infection after angio-

plasty and stent were *Staphylococcus aureus* and *S. epidermidis*, which were sensitive to cefazolin.

In this study, the results of angioplasty \pm stenting agreed with Fisher *et al*^[16] who stated that, with appropriate case selection, many patients with BCS caused by short length HV stenosis or occlusion may be managed successfully by angioplasty \pm stenting with a good outcome following the procedure, provided that anticoagulation is maintained. According to the authors' comparative study between percutaneous angioplasty and operative shunt surgery; both groups had the same re-occlusion rate and both were related to suboptimal dose of anticoagulation.

In the current study, 13 patients (52%) were not candidates for angioplasty and underwent TIPS. The need for revision was 38.4% (compared to 41.6% in angioplasty \pm stenting). One year and end of follow up survival rates following TIPS were 100%. This could be attributed to the relatively short follow up duration (ranging from 12 to 32 mo) and good selection of cases, as most of our patients had good or intermediate predictable prognosis according to Rotterdam score.

Patency rate in patients who had TIPS procedures was 12/13 (92.3%) at one year due to persistent shunt occlusion in one patient despite repeated revisions. At the end of follow up; patency rate dropped to 11/13 (84.6%) due to persistent shunt occlusion in another patient.

The results of the current study are much better than what had been reported by Valla^[17], namely that secondary thrombosis or shunt dysfunction requiring revision occurs in about 70% of cases by 6 mo. However, the results of this study are more or less comparable to those reported by Senzolo *et al*^[14] who stated that 36%-72% of patients needed reintervention after TIPS. The authors also reported a long-term patency rate of about 50% despite of routine anticoagulation therapy.

Comparison between the results of the current study, regarding TIPS, with other studies is shown in Table 6.

Sixteen TIPS procedures have been done throughout the current study (13 as primary intervention and 3 in patients with occluded stents following angioplasty in which predilatation was not possible).

Post TIPS sepsis occurred in 3 procedures (18.75%), in spite of prophylactic antibiotics. According to Dravid *et al*^[22]; an infection rate of 13% following TIPS was reported.

According to Ryan *et al*^[11], acute infection related to TIPS placement appears to be uncommon. Whether or not prophylactic antibiotics are of value remains undetermined. Options for prophylactic antibiotics for TIPS are: (1) no prophylaxis; (2) 1 g ceftriaxone single dose intravenously before procedure; and (3) 1.5-3 g ampicillin/sulbactam single dose intravenously before procedure. We adopted the third strategy successfully in combination with cefotaxime 1 gm IV and completed the course of antibiotics for five days after intervention.

Hepatic encephalopathy after TIPS occurred in 2 patients (12.5%) and was transient, lasting only for 2-3 d and responded well to anti hepatic encephalopathy measures.

Post procedure bleeding was encountered in 4 procedures (25%), 2 intraperitoneal and 2 hemobilia; all were managed conservatively with temporary stoppage of anticoagulation and blood transfusion if indicated.

In the current study, the overall 1 year shunt patency of all procedures (angioplasty \pm stenting and TIPS) was 22/25 (88%) as 3 patients had occluded shunts in spite of repeated trials of dilatation and adherence to anticoagulation therapy. We compared clinical and laboratory characteristics before and after intervention in patients with patent shunts (22 patients) and in those with occluded shunts (3 patients) irrespective of the type of procedure performed. We observed that patients with occluded shunts showed no improvement compared to those with patent shunts even after multiple revisions in terms of clinical manifestations, laboratory profile and performance status.

These observations are consistent with Bachet *et al*^[23] who concluded that, in patients with BCS treated with portosystemic shunting, shunt dysfunction has a major impact on morbidity and mortality and maintenance of shunt patency is of major importance for better long-term outcome.

In conclusion; Budd Chiari syndrome is a potentially life-threatening disorder that requires a multidisciplinary approach with hepatologist, hematologist, interventional radiologist and vascular surgeon. Morbidity and mortality following both angioplasty \pm stenting and TIPS are low with satisfactory stent and patient survival. Proper selection of procedure candidates and maintenance of shunt patency by strict adherence to anticoagulation and early management of shunt dysfunction are crucial in clinical, laboratory and radiological improvement of BCS patients.

COMMENTS

Background

Budd-Chiari syndrome (BCS) results from hepatic venous outflow obstruction at any level from hepatic venules to the right atrium. Few patients respond to medical treatment (anticoagulation \pm thrombolytic therapy, diuretics). However, most patients need intervention to restore the hepatic blood flow. Restoring outflow in one of the major hepatic veins by balloon dilatation \pm stenting is the management of choice. When not possible or failed, Transjugular Intrahepatic Portosystemic Shunt is used.

Research frontiers

Follow up of patients after radiological intervention is crucial in order to assess patient improvement, shunt patency and function and to manage any procedure related complications. In this study, the authors demonstrate that morbidity and mortality following angioplasty \pm stenting and transjugular intrahepatic portosystemic shunt (TIPS) are low with satisfactory outcome.

Innovations and breakthroughs

This is the first Egyptian study that addresses the short term outcome of interventional radiology procedures in management of BCS.

Applications

This study may represent a future strategy for good selection of procedure candidates, maintenance of shunt patency by strict adherence to anticoagulation and early management of shunt dysfunction which are all crucial in clinical, laboratory and radiological improvement of BCS patients.

Terminology

Angioplasty means balloon dilatation of hepatic vein; it may be with or without stent insertion. This procedure is performed in BCS patients with short segment stenosis or occlusion of the hepatic veins with significant patent segments. This approach will re-establish hepatic venous outflow via the physiological route. In cases where blood flow cannot be restored or where the approach fails (usually because the remaining patent veins are too small or have insufficient flow), Transjugular Intrahepatic Portosystemic Shunt is used; in which the shunt connects the hepatic vein to the portal vein to bypass the obstruction.

Peer review

The authors evaluated the outcome of patients with BCS after non surgical hepatic decompression procedures (either balloon angioplasty \pm stenting or TIPS). It revealed that morbidity and mortality following both procedures are low with satisfactory stent and patient survival. Thus, proper selection of procedure candidates and maintenance of shunt patency by strict adherence to anticoagulation and early management of shunt dysfunction are crucial in clinical, laboratory and radiological improvement of those patients. Their results are excellent on managing a very challenging group of patients and their program should be commended for this outcome.

Abstract

AIM: To identify factors associated with the age at onset of hepatitis C virus (HCV)-related hepatocellular carcinoma (HCC).

METHODS: Five hundred and fifty-six consecutive patients positive for HCV antibody and treatment-naïve HCC diagnosed between 1995 and 2004 were analyzed. Patients were classified into three groups according to age at HCC onset: < 60 years ($n = 79$), 60-79 years ($n = 439$), or ≥ 80 years ($n = 38$). Differences among groups in terms of sex, body mass index (BMI), lifestyle characteristics, and liver function were assessed. Factors associated with HCC onset in patients < 60 or ≥ 80 years were analyzed by logistic regression analysis.

RESULTS: Significant differences emerged for sex, BMI, degree of smoking and alcohol consumption, mean bilirubin, alanine aminotransferase (ALT), and γ -glutamyl transpeptidase (GGT) levels, prothrombin activity, and

platelet counts. The mean BMI values of male patients > 60 years old were lower and mean BMI values of female patients < 60 years old were higher than those of the general Japanese population. BMI > 25 kg/m² [hazard ratio (HR), 1.8, $P = 0.045$], excessive alcohol consumption (HR, 2.5, $P = 0.024$), male sex (HR, 3.6, $P = 0.002$), and GGT levels > 50 IU/L (HR, 2.4, $P = 0.014$) were independently associated with HCC onset in patients < 60 years. Low ALT level was the only factor associated with HCC onset in patients aged ≥ 80 years.

CONCLUSION: Increased BMI is associated with increased risk for early HCC development in HCV-infected patients. Achieving recommended BMI and reducing alcohol intake could help prevent hepatic carcinogenesis.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most com-

mon cancer in men and the eighth most common cancer in women worldwide. The incidence and mortality associated with HCC have been reported to be increasing in countries in North America, Europe and Asia. Infection with hepatitis C virus (HCV) infection is likely to play an important role in the pathogenesis of HCC^[1-3]. In Japan, over 70% of cases of HCC diagnosed in the last 20 years are related to HCV infection^[3].

One report estimates that 3%-35% of patients progress to cirrhosis 25 years after infection with HCV and 1%-3% progress to HCC 30 years after infection^[4]. However, the factors that influence the development of HCC in patients infected with HCV remain largely unknown. Previous studies have suggested that host factors, such as sex, alcohol consumption, smoking, diabetes mellitus, and obesity, are important risk factors for HCC^[5-11]. In addition, recent studies have suggested that HCV infection causes insulin resistance and leads to oxidative stress, potentiating fibrosis and hepatic carcinogenesis^[12-14].

Therefore, we hypothesized that obesity influences the time to onset of HCC related to HCV infection, which is reflected in the patient's age at onset. To test this hypothesis, we investigated the relationship between body mass index (BMI) and lifestyle factors and age at onset of HCC in HCV-infected patients.

MATERIALS AND METHODS

Study participants

The study was conducted in accordance with the Helsinki Declaration. Written informed consent on the use of clinical records for research purposes was obtained from all subjects.

From January 1995 to December 2004, 656 consecutive patients positive for HCV antibodies and diagnosed with HCC for the first time at Saga Medical School Hospital and Saga Prefectural Hospital, without prior HCC treatment, were recruited for this study. Patients were excluded from the study if they were positive for hepatitis B surface antigen ($n = 8$), were previously treated with interferon ($n = 23$), had uncontrolled ascites ($n = 27$), or had an advanced tumor stage accompanied by tumor thrombus in portal tract or extrahepatic metastasis ($n = 42$). The remaining 556 patients (351 men, 205 women), with a median age at HCC onset of 67.8 years (range, 41-92 years) were enrolled in this study.

Diagnosis and staging of HCC

Diagnosis of HCC was confirmed by combined ultrasonography and dynamic computed tomography (CT), dynamic magnetic resonance imaging, or CT during angiography, demonstrating a hypervascular contrast pattern of the nodule in the arterial phase and a hypovascular pattern in the portal phase. If the nodule contrast patterns were not consistent with those typical for HCC, a needle biopsy of the tumor was taken for pathological diagnosis.

Tumor stage was classified according to the 5th Edition of the General Rules for the Clinical and Pathological Study of Primary Liver Cancer, 2008, published by

the Liver Cancer Study Group of Japan^[15]. This classification system assumes three conditions: (1) tumor diameter of ≤ 2 cm; (2) a single tumor is present; and (3) no vascular invasion of the tumor. If all three conditions are met, the tumor is classified as stage I; if two conditions are met, it is classified as stage II; if only one condition is met, it is classified as stage III; and if none of the conditions are met, it is classified as stage IV.

Exposure and laboratory data

At the time of HCC diagnosis, blood tests were performed and BMI was calculated as weight in kilograms divided by the square of the height in meters (kg/m^2). Prothrombin activity and serum albumin and total bilirubin levels were measured and used to determine the Child-Pugh status. Blood samples were also used to measure alanine aminotransferase (ALT) and γ -glutamyl transpeptidase (GGT) levels and other liver function tests.

Patients were classified according to the World Health Organization (WHO) BMI criteria: underweight, BMI < 18.5 kg/m^2 ; normal weight, BMI 18.5-25 kg/m^2 ; overweight, BMI 25-30 kg/m^2 ; and obese, BMI ≥ 30 kg/m^2 ^[16]. Diagnosis of diabetes mellitus was made either by reviewing medical history or by assessing glucose levels with fasting plasma glucose level of ≥ 7.0 mmol/L or a 2-h plasma glucose level of ≥ 11.1 mmol/L^[17]. Patients were questioned by nurses about their smoking and drinking habits during the last 10 years. We defined heavy drinking as > 60 g of alcohol consumed per day and habitual smoking as > 20 pack years.

Statistical analysis

To identify factors associated with age at onset of HCC in patients with chronic hepatitis C, we compared clinical factors in two groups of patients; those aged < 60 years at HCC onset and those aged ≥ 80 years. We then analyzed risk factors affecting earlier (onset age < 60 years) and later (onset age ≥ 80 years) development of HCC in patients with chronic HCV.

We used the Kruskal-Wallis test or the χ^2 test to compare clinicopathological variables between three groups of patients. The differences in age at onset of HCC between the two groups stratified by BMI were analyzed by the Tukey-Kramer method. Univariate and multivariate logistic regression analyses were performed to identify factors associated with earlier or later onset of HCC.

Data processing and analysis were performed by using the SAS (SAS Institute Inc.). Two-tailed P values of < 0.05 were considered significant.

RESULTS

Patient characteristics

A histogram showing age at onset of HCC in 556 HCV-infected patients is depicted in Figure 1. The median age of patients was 67.8 years, with a nearly normal age distribution for the study population.

The clinical characteristics were categorized into three groups according to age at onset of HCC; < 60 years

Continuous variables are expressed as mean ± standard deviation. Statistical analysis was done using a: the χ^2 test or b: the Turkey-Kramer test. HCC: Hepatocellular carcinoma; BMI: Body mass index; ALT: Alanine aminotransferase; GGT: γ -glutamyl transpeptidase.

Figure 1 Histogram showing age at onset of hepatocellular carcinoma in hepatitis C virus-infected patients (n = 556). Median age, 67.8 years; range, 41-92 years.

(n = 79), 60-79 years (n = 439), and ≥ 80 years (n = 38) (Table 1). Of those aged < 60 years, 88.6% were men, a much higher percentage than in those aged 60-79 years (60.1%) and those aged ≥ 80 years (44.7%). In terms of BMI, the mean value increased, and the percentage of patients with BMI < 25 kg/m² decreased while that of patients with BMI > 25 increased with decreasing age at onset of HCC. However, this is a normal phenomenon in the general population. Therefore, we compared the mean BMI values according to the age at onset of HCC for

patients in this study with BMI values of the general Japanese population in 2005 and 2006, which were published by the Ministry of Health, Labour and Welfare, Japan (<http://www.mhlw.go.jp/>). The mean BMI of male HCC patients aged > 60 years was lower whereas that of female HCC patients aged < 60 years was higher than those of the general population (Figure 2). This indicates that the association between BMI and age at onset of HCC observed in this study was affected by factors independent of natural aging. We found that there were significantly more heavy drinkers ($P < 0.0001$) and habitual smokers ($P = 0.0001$) among patients aged < 60 years, compared with the other two age groups. Although the three groups did not differ in terms of Child-Pugh status, total bilirubin, ALT, and GGT levels were higher, and prothrombin activity and platelet counts were lower in patients aged < 60 years at HCC onset. No differences emerged in terms of the prevalence of diabetes mellitus or the distribution of tumor stage among the three groups.

Factors associated with the development of HCC at < 60 years of age

We investigated risk factors associated with the development of HCC at a younger age (i.e. < 60 years of age) (Table 2). In univariate analysis, the following were found to be significant risk factors for earlier age at onset of HCC: male sex [hazard ratio (HR), 5.4; 95% CI, 2.65-11.12; $P < 0.0001$], BMI > 25 kg/m² (HR, 1.7; 95% CI, 1.04-2.85;

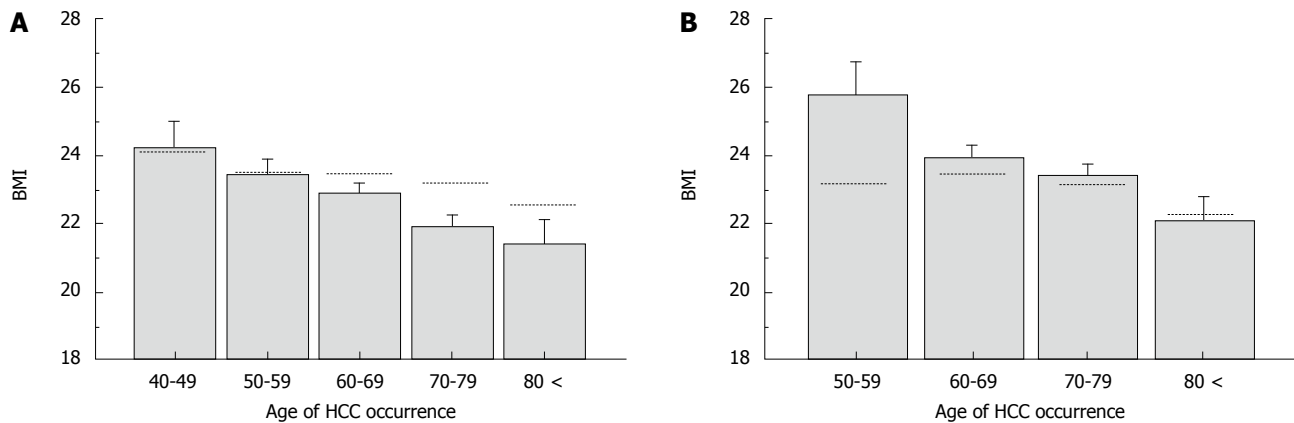

Figure 2 Mean body mass index in each age group at onset of hepatocellular carcinoma (A: Men; B: Women). The bars show the mean body mass index (BMI) \pm SD in patients with hepatocellular carcinoma (HCC). The dashed lines show the mean BMI for the general Japanese population in 2005 and 2006, which was surveyed by the Ministry of Health, Labour and Welfare, Japan.

ment of HCC at an older age (i.e. ≥ 80 years of age) (Table 3). In univariate analysis, the following were significantly and negatively associated with age at onset of HCC ≥ 80 years: male sex (HR, 0.45; 95% CI, 0.23-0.87; $P = 0.017$), diabetes mellitus (HR, 0.23; 95% CI, 0.05-0.96; $P = 0.043$), prothrombin activity $< 70\%$ (HR, 0.1; 95% CI, 0.01-0.76; $P = 0.025$), ALT > 80 IU/L (HR, 0.1; 95% CI, 0.02-0.43; $P = 0.002$), and GGT > 50 IU/L (HR, 0.51; 95% CI, 0.26-0.98; $P = 0.045$). In multivariate analysis, ALT > 80 IU/L was the only independent factor associated with age at onset of HCC ≥ 80 years (HR, 0.13; 95% CI, 0.03-0.57; $P = 0.007$).

Age at onset of HCC stratified by BMI in relation to sex or alcohol consumption

Differences in age at onset of HCC stratified by BMI were assessed in relation to sex or alcohol consumption. In men, age at onset decreased significantly with increasing BMI (mean age \pm SD; underweight, 71.1 ± 7.4 years; normal weight, 67.0 ± 8.5 years; overweight, 63.6 ± 8.1 years; obese, 57.0 ± 7.0 years) (Figure 3A). Although a similar trend was noted in women, this was not significant (underweight, 73.6 ± 7.8 years; normal weight, 70.4 ± 7.0 years; overweight, 68.9 ± 6.4 years; obese, 67.0 ± 7.5 years) (Figure 3B).

Although an association between BMI and age at onset of HCC was found among non-heavy drinkers (Figure 4A), no association was found among heavy drinkers (Figure 4B).

DISCUSSION

The results of this study revealed that higher BMI, heavy alcohol consumption, male sex, and high GGT levels are independent risk factors for younger age at onset of HCC in patients with chronic HCV infection. This study confirms the previously reported risk factors for HCC and is the first to investigate the relationship between age and HCC development.

It seems plausible that the duration of HCV infection plays a role in the age at which cirrhosis progresses to HCC. However, Hamada *et al.*^[18] reported a significant negative correlation between the time from HCV infection to onset of HCC and the patient's age at the time of infection, and as a result, the onset of HCC was considered to occur in patients during their 60 s regardless of their age at time of infection. This indicates that factors other than duration of HCV infection may be associated with the age at onset of HCC in HCV-infected patients.

Recent studies have shown that HCV proteins, such

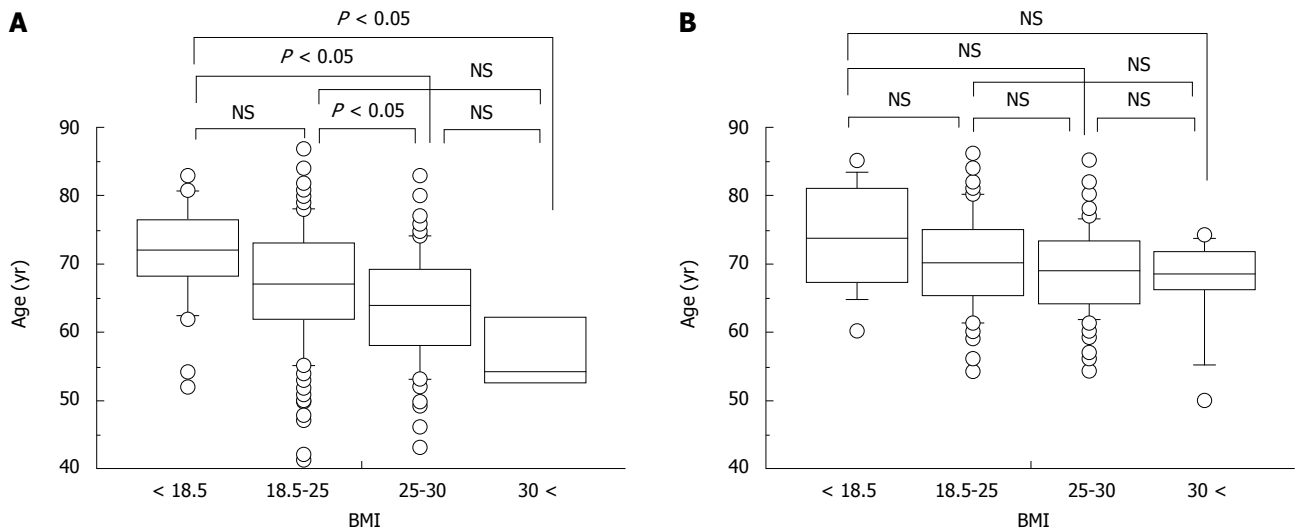

Figure 3 Differences in age at onset of hepatocellular carcinoma stratified by body mass index according to sex (A: Men; B: Women). Statistical analysis was performed using the Tukey-Kramer method. NS: Not significant; BMI: Body mass index.

Figure 4 Differences in age at onset of hepatocellular carcinoma stratified by body mass index according to degree of alcohol consumption (A: Non-heavy drinkers < 60 g/d; B: Heavy drinkers \geq 60 g/d). Statistical analysis was performed using the Tukey-Kramer method. NS: Not significant; BMI: Body mass index.

as the core protein, cause oxidative damage by exposing the endoplasmic reticulum to oxidative stress^[19-21]. Hepatic oxidative stress is strongly associated with increased risk for HCC in patients with chronic HCV^[22]. Because oxidative stress is also caused by various host-related factors, it is expected to be influenced more strongly by host-related factors in HCV-infected patients than in those with HCV-negative liver disease. Indeed, we have previously reported that visceral fat accumulation was associated with greater insulin resistance in chronic HCV patients than in those with non-alcoholic fatty liver disease^[23]. Therefore, it is plausible that the association between earlier onset of HCC and increased BMI is due to the generation of hepatic oxidative stress.

An interesting aspect of our results is that underweight patients, defined as those with a BMI of $< 18.5 \text{ kg/m}^2$, tended to be older at HCC onset than patients within the

normal weight range (BMI 18.5-25 kg/m^2). Recently, Ohki *et al.*^[11] reported that patients with a BMI $< 18.5 \text{ kg/m}^2$ had the lowest risk of developing HCC due to chronic HCV infection among all BMI groups. In general, the mortality rate associated with cardiovascular disease or cancer is higher in underweight patients than in normal weight patients^[24,25]. Clearly, a larger cohort study is needed to investigate whether leanness confers a protective effect against hepatocarcinogenesis in HCV-infected patients.

Excessive alcohol consumption is also known to exacerbate hepatic oxidative stress and evoke liver fibrosis or HCC^[20,26]. In this study, there was no association between BMI and age at onset of HCC in heavy drinkers. We speculate that this group may include some patients who are malnourished and possibly losing weight.

Sex modulates the natural history of chronic liver disease. Previous studies have suggested that chronic HCV

infection progresses more rapidly in men than women, and that cirrhosis is predominately a disease of men and postmenopausal women^[27]. Shimizu *et al* suggested that estrogens protect against oxidative stress in liver injury and hepatic fibrosis^[28]. In this study, the effect of BMI on age at onset of HCC was more remarkable in men than women. We speculate two mechanisms to account for this difference: (1) estrogens mitigate oxidative stress or insulin resistance associated with obesity; and (2) subcutaneous fat accumulation is more dominant in obese women than visceral fat, which is known to produce several adipokines that cause insulin resistance^[29].

In addition, we examined factors associated with onset of HCC at an older age (≥ 80 years). In this analysis, ALT level was the only independent factor associated with hepatocarcinogenesis in HCV-infected patients at an age ≥ 80 years. It is well known that ALT levels are associated with liver inflammation and fibrosis progression, and Ishiguro *et al* recently reported that elevated ALT levels were strongly associated with the incidence of HCC, regardless of hepatitis virus positivity, in a large population-based cohort study^[30]. Therefore, lower ALT levels might indicate a slow course of progression of hepatic fibrosis or carcinogenesis.

A limitation of this study is that it was a cross-sectional observation, rather than a cohort follow-up study. Further studies are needed to confirm our results.

In conclusion, the results of the present study indicate that higher BMI, excessive alcohol consumption, and male sex are independent risk factors for onset of HCV-related HCC at an age of < 60 years. These results suggest that interventions to promote changes in the lifestyle of patients with chronic HCV may slow the progression of HCV infection to HCC.

COMMENTS

Background

The incidence and mortality associated with hepatocellular carcinoma (HCC) have been increasing worldwide, and hepatitis C virus (HCV) infection plays an important role in the pathogenesis of HCC. However, the factors that influence the development of HCC in HCV-infected patients remain largely unknown. Previous studies have suggested that host factors, such as sex, alcohol consumption, smoking, diabetes mellitus, and obesity, are important risk factors for HCC. Meanwhile, it has been reported that HCV infection causes insulin resistance and leads to oxidative stress, potentiating fibrosis and hepatic carcinogenesis. Therefore, we hypothesized that body mass index (BMI) influences the onset age of HCC related to HCV infection.

Research frontiers

Many studies have indicated that obesity is an independent and a significant risk factor for HCC occurrence. Recently, several metabolic markers have been implicated in the development and progression of HCC.

Innovations and breakthroughs

This study indicated that higher BMI, heavy alcohol consumption, male sex, and high γ -glutamyl transpeptidase levels are independent risk factors for younger age at onset of HCV-related HCC. Interestingly, the underweight patients (BMI

$< 18.5 \text{ kg/m}^2$), tended to be older at HCC onset than patients within the normal weight range (BMI $18.5\text{--}25 \text{ kg/m}^2$).

Applications

The results of this study suggest that achieving an adequate body weight along with a reduction of alcohol intake in patients with chronic hepatitis C could help prevent hepatic carcinogenesis.

Peer review

The study was reasonably designed and well conducted, and the data support their conclusions.

Abstract

AIM: To examine the vitamin D status in patients with alcoholic cirrhosis compared to those with primary biliary cirrhosis.

METHODS: Our retrospective case series comprised 89 patients with alcoholic cirrhosis and 34 patients with primary biliary cirrhosis who visited our outpatient clinic in 2005 and underwent a serum vitamin D status assessment.

RESULTS: Among the patients with alcoholic cirrhosis, 85% had serum vitamin D levels below 50 nmol/L and 55% had levels below 25 nmol/L, as compared to 60% and 16% of the patients with primary biliary cirrhosis, respectively ($P < 0.001$). In both groups, serum vitamin D levels decreased with increasing liver disease severity, as determined by the Child-Pugh score.

CONCLUSION: Vitamin D deficiency in cirrhosis relates

INTRODUCTION

Patients with chronic liver disease have an increased risk for the development of osteoporosis and fractures, reduced muscle strength, an impaired inflammatory response, and malignancy^[1-3]. These conditions have also been associated with vitamin D deficiency^[4-6]. Vitamin D deficiency and osteomalacia have been described in chronic cholestatic liver disease, such as primary biliary cirrhosis (PBC)^[7]. However, the frequency of vitamin D deficiency, specifically in alcoholic liver cirrhosis (ALC), has not been well described. The limited available data suggest that there is a high frequency of vitamin D deficiency in patients with chronic liver disease^[8,9].

The main source of vitamin D in humans is the exposure of skin to sunlight. For further activation, vitamin D is hydroxylated in the liver to form 25-(OH) vitamin D

(25-OHD) and in the kidneys to form the active metabolite 1,25(OH)₂ vitamin D. The body stores of vitamin D are best reflected by the serum levels of 25-(OH)D^[10].

The aim of the present study was to describe the serum vitamin D status in a retrospective case series of patients with ALC compared to those with PBC. Patients with PBC were considered *a priori* to demonstrate a high incidence of vitamin D deficiency.

MATERIALS AND METHODS

We collected data from the medical records of all patients with a diagnosis of PBC or ALC who visited our outpatient clinic in 2005. A total of 205 patients were identified: 58 had PBC, and 147 had ALC. The study population comprised patients for whom vitamin D measurements had been completed and for whom the Child-Pugh status could be assessed (34 and 89 patients, respectively). In patients who had undergone serial vitamin D measurements, the first blood sample collected in 2005 was used. The vitamin D status was defined according to the following levels of 25-(OH)D: severe deficiency: 0-12.5 nmol/L, deficiency: 12.5-25 nmol/L, insufficiency: 25-50 nmol/L, and vitamin D replete: > 50 nmol/L^[11]. Data concerning previous and ongoing vitamin D supplementation were collected from the patients' medical records. To assess the severity of liver disease, the patients were scored according to the Child-Pugh classification. This score is based on the degree of encephalopathy, the presence of ascites, prothrombin time, and the serum levels of bilirubin, and albumin. The score ranges from 5 to 15 with increasing severity. Accordingly, the patients had either compensated liver disease (Class A, 5-6 points), moderate liver disease (Class B, 7-9 points), or severe liver disease (Class C, 10-15 points).

Techniques

Plasma 25(OH)D₂ and 25(OH)D₃ were analysed by isotope-dilution liquid chromatography-tandem mass spectrometry using an API3000 TM mass spectrometer (Applied Biosystems, Foster City, CA, USA) and a method adapted from Maunsell *et al.*^[12]. The interassay variation coefficients for plasma 25(OH)D₂ were 8.5% at 23.4 nmol/L and 8.0% at 64.4 nmol/L, and for plasma 25(OH)D₃ these values were 9.6% at 24.8 nmol/L and 8.1% at 47.7 nmol/L.

Statistics

Non-parametric statistics were used for the descriptions, and the Mann-Whitney *U* test was employed for comparisons between groups. The association between two variables was assessed by the contingency coefficient *C*, and statistical significance was determined using the χ^2 test.

RESULTS

In the patients with ALC, 18% had a severe vitamin D deficiency. In comparison, none of the patients with PBC had such a deficiency. Similarly, in a comparison of patients

Figure 1 Vitamin D levels in the study group. Vitamin D levels in 37 patients with primary biliary cirrhosis and 89 patients with alcoholic liver cirrhosis. Patients with alcoholic liver cirrhosis demonstrated significantly lower overall vitamin D levels in comparison to patients with primary biliary cirrhosis ($P < 0.0001$, Mann-Whitney *U* test). PBC: Primary biliary cirrhosis; ALC: Alcoholic liver cirrhosis.

Table 1 Study group stratified according to the Child-Pugh class and the degree of vitamin D deficiency

Vitamin D (nmol/L)	Child-Pugh group		
	A	B	C
< 25	17	15	21
25-50	14	16	12
> 50	18	6	4

with ALC and PBC, vitamin D deficiency was identified in 37% *vs* 16% and vitamin D insufficiency was identified in 30% *vs* 41% of patients, respectively. Only 15% of patients with ALC were vitamin D replete in comparison to 40% of patients with PBC. The median 25-OHD blood concentration in ALC patients was 24 nmol/L, or 53% of the median serum level of 45 nmol/L in PBC patients ($P < 0.001$, Mann-Whitney *U* test) (Figure 1).

Four patients with ALC and 13 patients with PBC were receiving vitamin D supplementation at the time of blood sampling. Their vitamin D levels did not differ from those determined in patients who did not receive supplementation.

The distribution of Child-Pugh groups A, B, and C differed between ALC and PBC patients. Patients with ALC demonstrated more advanced disease (16 A, 36 B, and 37 C) compared to those with PBC (33 A, 1 B, and no C). In all the cirrhotic patients, there was an association between the Child-Pugh score and vitamin D status (contingency coefficient $C = 0.29$, $P < 0.05$, χ^2 test) (Table 1).

DISCUSSION

The vast majority (85%) of patients with ALC presented a compromised vitamin D status. The same was found in fewer than half of the patients with PBC (47%). This finding is in contrast to the standard clinical knowledge that vitamin D deficiency is expected in PBC. Further-

more, this marked vitamin D deficiency has never been demonstrated in a study population of this size.

Our study group included 60% of the cirrhotic patients who were seen at our clinic during 2005. This distribution does not introduce a selection bias because the vitamin D measurements were ordered without physician knowledge of the study purpose. Because the intensity of sunlight changes throughout the year, there might have been a seasonal difference in the vitamin D levels according to when the blood samples were drawn. However, patients were recruited throughout the year in both groups, and therefore, seasonal changes should not affect comparisons between the two groups.

The observed deficiency in vitamin D might be related to several causes: an impaired hepatic hydroxylation of vitamin D, dietary insufficiency, malabsorption, reduced hepatic production of vitamin D binding protein, and an impaired cutaneous production due to either reduced exposure to sunlight or jaundice^[9,13]. The observation that the deficiency was less pronounced in PBC patients suggests that bile acid-related lipid malabsorption is not the only mechanism involved in vitamin D deficiency. It seems plausible that the mechanism of vitamin D deficiency is multifactorial and differs between the two groups of cirrhotic patients. When the results were stratified according to the Child-Pugh class, an association was observed between vitamin D deficiency and the severity of liver disease. This association has never been demonstrated in such a large study population. Thus, the better preservation of vitamin D status in patients with PBC might be ascribed to the diminished severity of their liver disease, as assessed by their Child-Pugh scores. Based on this finding, one could hypothesise that the risk for vitamin D deficiency or insufficiency might be influenced more by the degree of liver dysfunction than by the aetiology of the liver disease. However, our study was not designed to elucidate the exact mechanism underlying the vitamin D deficiency. The purpose of the study was to emphasise the importance of monitoring the vitamin D status in all patients with cirrhosis, especially those with ALC for whom nutritional status has been a relatively neglected area of study.

Our results imply that vitamin D deficiency is highly prevalent in patients with ALC. Because this was a retrospective study, we cannot extrapolate the results to the general population of cirrhotic patients. However, these results indicate that the frequency and severity of vitamin D deficiency in ALC patients warrant greater attention, similar to the usual clinical practice in patients with PBC.

Although 17 of the study patients received vitamin D supplementation, this supplementation was clearly insufficient, as their vitamin D concentrations remained low. Thus, it appears that the vitamin D deficiency in these patients should be treated with higher doses of vitamin D than that used in standard clinical practice for repletion.

The risk for bone disease in cirrhotic patients justifies the use of routine vitamin D therapy. Furthermore, the patients might also benefit from correction of their

vitamin D status with respect to reduced muscle function, cancer risk, and immune impairment.

COMMENTS

Background

Patients with liver cirrhosis have an increased incidence of cancer, infections, osteoporosis, and decreased muscle strength. Vitamin D deficiency is associated with these complications in other patient groups and could be partially involved in the clinical complications related to cirrhosis.

Research frontiers

Vitamin D deficiency is a well reported complication in chronic cholestatic liver disease such as primary biliary cirrhosis. While the prevalence and treatment of this deficiency has been addressed in many articles over the last decades, little is known of the vitamin D status in alcoholic liver cirrhosis.

Innovations and breakthroughs

Recent studies imply that vitamin D deficiency is frequent in all patients with cirrhosis. The current study shows that vitamin D deficiency is more frequent and severe in patients with alcoholic liver cirrhosis than in patients with primary biliary cirrhosis. Furthermore, it indicates that the degree of liver dysfunction, rather than the aetiology of cirrhosis, dictates the risk of vitamin D deficiency.

Applications

This study emphasizes the importance of monitoring vitamin D levels in all patients with cirrhosis. However, further studies are needed to find the most favourable form of vitamin D supplementation for these patients.

Terminology

Primary biliary cirrhosis and alcoholic cirrhosis are two different diseases that cause cirrhosis of the liver. While primary biliary cirrhosis is a cholestatic, autoimmune disease, alcoholic liver cirrhosis is an alcohol-induced liver disease usually without cholestatic features. The Child-Pugh score assesses the prognosis in patients with cirrhosis and is also used to quantitate the degree of liver dysfunction.

Peer review

This brief article nicely demonstrated the association of the liver damage severity with the level of 25-hydroxy vitamin D. This is a very important report, as many doctors do not realize that liver damage could cause significant vitamin D deficiency.

Abstract

AIM: To explore the feasibility of a water-jet hybrid knife to facilitate wedge hepatic resection using a natural orifice transluminal endoscopic surgery (NOTES) approach in a non-survival porcine model.

METHODS: The Erbe Jet2 water-jet system allows a needleless, tissue-selective hydro-dissection with a pre-selected pressure. Using this system, wedge hepatic resection was performed through three natural routes (trans-anal, trans-vaginal and trans-umbilical) in three female pigs weighing 35 kg under general anesthesia. Entry into the peritoneal cavity was *via* a 15-mm incision using a hook knife. The targeted liver segment was marked by an APC probe, followed by wedge hepatic resection performed using a water-jet hybrid knife with the aid of a 4-mm transparent distance soft cap mounted onto the tip of the endoscope for holding up the desired plane. The exposed vascular and ductal structures were clipped with Endoclips. Hemostasis was applied to the bleeding

cut edges of the liver parenchyma by electrocautery. After the procedure, the incision site was left open, and the animal was euthanized followed by necropsy.

RESULTS: Using the Erbe Jet2 water-jet system, trans-anal and trans-vaginal wedge hepatic resection was successfully performed in two pigs without laparoscopic assistance. Trans-umbilical attempt failed due to an unstable operating platform. The incision for peritoneal entry took 1 min, and about 2 h was spent on excision of the liver tissue. The intra-operative blood loss ranged from 100 to 250 mL. Microscopically, the hydro-dissections were relatively precise and gentle, preserving most vessels.

CONCLUSION: The Erbe Jet2 water-jet system can safely accomplish non-anatomic wedge hepatic resection in NOTES, which deserves further studies to shorten the dissection time.

INTRODUCTION

Liver resection, a surgical procedure consisting of he-

patic parenchymal dissection as well as precise identification followed by control of intra/extra-hepatic vascular and biliary anatomy, is technically challenging due to the risk of massive bleeding during operation. Since excessive hemorrhage and subsequent blood transfusion are strongly associated with increased peri-operative morbidity and mortality, technical innovations have mainly focused on minimizing blood loss^[1]. Besides inflow occlusion and low central pressure used to prevent bleeding from inflow vessels and hepatic veins in the transaction surface since the early 20th century, the development of specific devices for separating hepatic parenchyma, such as the ultrasonic dissector, water jet, Harmonic scalpel, Ligasure, and Tissue-Link dissecting sealer, has also contributed to bloodless transection. A meta-analysis^[2] assessing the benefits and risks of current techniques of parenchymal transection showed that there were no significant differences in terms of the mortality, morbidity, markers of liver parenchymal injury or liver dysfunction in pairwise comparisons including cavitron ultrasound surgical aspirator, radiofrequency dissecting sealer, sharp dissection and hydro-jet. Among them, the water-jet dissector employs a pressurized jet of water to fragment the liver parenchyma tissue, with intact vascular and ductal structures, which can be ligated with staplers or clipped with titanium hemoclips, resulting in reduced blood loss, transfusion requirement, and biliary leak^[3].

High-pressure water-jet dissection technology was originally developed in the steel and glass industries, where ultra-precise cutting and engraving were considered as professional demands^[4]. Since introduced to medical application in 1982^[5], this technology (Hydro-Jet[®]; ERBE, Tuebingen, Germany) has been successfully employed in open and laparoscopic operations, achieving favorable results in precise, controllable tissue-selective (indicating water-rich tissue such as liver parenchyma) dissection with excellent visualization and minimal injury to the surrounding fibrous structures (such as ductal and vessel systems with a high content of collagen and elastin)^[6]. The above-mentioned Helix Hydro-Jet device with a rigid hand-held applicator is not designed with sufficient flexibility for natural orifice transluminal endoscopic surgery (NOTES) procedures, and can not be passed through a standard working channel of the current flexible endoscope because its outer-diameter is larger than the endoscopic operative channel. Now a new water-jet hybrid knife^[7] incorporating with high-pressure water-jet and radiofrequency may overcome this drawback. It has a smaller size, being easy to handle, and showing more preciseness, with almost linear correlation of pressure and dissection depth, and less foaming compared with the precursor model Helix Hydro-Jet^[5].

As is known, trans-luminal liver resection is technically demanding and its expansion has been lagged behind other NOTES procedures. Phee *et al*^[8] demonstrated for the first time how a dexterous master and slave trans-luminal endoscopic robot could efficiently perform the wedge hepatic resection without laparoscopic assistance. Unfortunately, this technology is still an unexplored field

in China. The aim of our study was to explore the safety and efficacy of a water-jet hybrid knife to facilitate wedge hepatic resection using a NOTES approach in a non-survival porcine model.

MATERIALS AND METHODS

Experimental design

This non-survival study evaluated the performance of the water-jet hybrid knife during NOTES procedure in a live porcine model. A pilot experiment in an isolated liver was conducted first, and followed by an open procedure in a 35-kg female porcine model. The formal study included three operations of wedge hepatic resection using NOTES and water-jet technology through three respective natural routes (trans-anal, trans-vaginal and trans-umbilical). The outcome measures were the time spent in performing a trans-visceral incision, the time spent in excising the liver segment, and the blood loss including oozing and brisk vascular hemorrhage, determined as blood accumulation in the suction device.

This study was conducted with prior approval by the Institutional Animal Care and Use Committee of Tongji University of China.

Experimental animal and instrument

Transluminal hepatic wedge hydro-dissection was performed in three 35-kg female pigs. The pigs were food deprived but allowed liquids for 24 h before the procedure. Urethral catheterization and warm saline enema were conducted immediately before surgery. The animals were then transferred to an operating table, and placed in supine position.

The water-jet hybrid knife (Erbe Elektromedizin) used in this study is a stainless-steel tube that incorporates a microcapillary with a diameter of 150 μm ^[7]. The flexible instrument has an outer diameter of 2.1 mm and a length of 2.20 m so that it can pass through the operating channels (diameter, 2.8 and 3.7 mm) of a forward-viewing dual-channel therapeutic endoscope (GIF-2T160; Olympus Medical Systems Corporation, Tokyo, Japan). The hybrid knife can be used for hydro-dissection, rinsing blood clot and rinsing for a better endoscopic view by water-jet application, as well as coagulation by radiofrequency application. The foaming with the use of the hybrid-knife can be scavenged by the suction mechanism of the endoscope. In NOTES procedure, a 4-mm transparent distance soft cap was mounted onto the tip of the endoscope for holding up the desired surface, subsequently avoiding the deviation in the direction of the water-jet. However, it was not used in the previous open procedure, because distraction (with surgical retractors) could allow the water-jet hybrid knife to effectively dissect the tissue by exposing the base of the cutting plane.

Rau *et al*^[6] found that a pressure of 30-40 bar was very effective to dissect normal human liver tissues, and the long-distance transmission attenuation was about 10%. Therefore, we set the pressure at 45 bar, which was proved to be effective in our pilot experiment and open operation.

Figure 1 Colostomy on anterior wall of rectal junction and sigmoid colon. At the beginning of trans-anal natural orifice transluminal endoscopic surgery procedure, entry into the peritoneal cavity was via a 15-mm linear incision using the hook knife (cutting width set at 6 units and cutting interval set at 1 unit). The ideal access point was the junction of rectum and sigmoid colon at a distance of 15-20 cm away from the anus.

Figure 2 Hydro-dissection of liver segment in natural orifice transluminal endoscopic surgery procedure. Hepatic parenchyma dissection was performed using the water-jet hybrid knife kept away from the tissue in a no-touch fashion and perpendicular to but not tangentially against the predetermined surface, keeping in a smooth, reproducible, back-and-forth waving motion. A 4-mm transparent distance soft cap was mounted onto the tip of the endoscope for holding up the desired surface, subsequently avoiding the deviation in the direction of the water-jet.

Other instruments used were as follows: a flexible sterile overtube (MD48618, Sumitomo Bakelite, Tokyo, Japan), a transparent distance flat soft cap (D-201-13404, Olympus), a hook knife (KD-620LR, Olympus), endoscopic hemostatic forceps (FD-410LR, Olympus), endoclips (HX-610-135L OLYMPUS, Olympus), a foreign forcep (FQ-46L-1, Olympus), APC probe (argon plasma coagulation, APC) (ERBE Elektromedizin), and the modular VIO generator (VIO 300D; Erbe Elektromedizin, Tübingen, Germany).

Experimental procedure

Anesthesia was induced with 5% isoflurane administered intravenously. The animal was then intubated with endotracheal tube, followed by general anesthesia with 1%-2% isoflurane. Throughout the operation, oxygen was administered to the animal at a flow rate according to oxygen saturation, and both pulse rate and oxygen

Figure 3 Hydro-dissection of liver segment in open procedure. Hepatic parenchyma dissection was performed using the water-jet hybrid knife in a similar natural orifice transluminal endoscopic surgery procedure, except that the 4-mm transparent distance soft cap was not used.

saturation were monitored continuously using the pulse oximeter clamped to the animal tongue. Then normal saline enema was administered to each animal. Residual stool would be removed with aggressive washing, and suctioning during endoscopic inspection.

At the beginning of the procedure, entry into the peritoneal cavity was *via* a 15-mm linear incision made by the hook knife (a cutting width was set at 6 units and cutting interval was set at 1 unit). The ideal access point was the abdominal site 1 cm away from the umbilicus in trans-umbilical route, the bottom of the vagina in trans-vaginal route, the junction of rectum and sigmoid colon at a distance of 15-20 cm away from the anus in trans-anal route (Figure 1). Then the endoscope with a 4-mm transparent distance soft cap mounted onto the tip of the endoscope beforehand was passed through the access to reach the peritoneum using the air inflation mechanism of the endoscope.

After the target liver segment was identified, hepatic parenchymal dissection with the water-jet hybrid knife was performed in the following steps (Figure 2), which were generally similar to those in the previous open operation except the assistance of manual retraction (Figure 3). The range to be separated was marked by an APC probe. The Glisson's capsule was scored 2-3 mm deep along the demarcated plane of transaction with the hook knife. Then hepatic parenchyma dissection was performed using the water-jet hybrid knife kept away from the tissue in a no-touch fashion. The tip of the knife was perpendicular to but not tangentially against the predetermined surface (this was achieved with a 4-mm transparent distance soft cap mounted onto the tip of the endoscope for holding up the desired surface, subsequently avoiding the deviation in the direction of the water-jet). A smooth, reproducible, back-and-forth waving motion was used. Minor slow oozing from the cutting surface was controlled using the same knife, the hook knife or APC probe to initiate bursts of coagulation. Visible intra-hepatic vascular and ductal structures were clipped with endoscopic hemoclips. Once the liver segment was completely free and after checking for hemostasis, the incision was slightly enlarged, then an

Table 1 Comparisons of three routes for natural orifice transluminal endoscopic surgery procedure

Items	Trans-umbilical route	Trans-anal route	Trans-vaginal route
Access position	Visually inspected at para-umbilical region	Verified by finger pressing	Located by surrounding anatomic landmarks
Time to complete a trans-visceral incision		About 1 min	
Time to reach peritoneum		About 2 min	
Liver exposure	Antero-lateral segments could be easily detected, while posterosuperior segments were hard to be explored		
Working platform	Unstable		Relatively stable
Time to hydro-dissection	Abandoned 1 h later	2 h	2 h and 40 min
Size of resected liver segment	No resected specimen was obtained due to failure in trans-umbilical hepatic resection	50 mm × 25 mm × 5 mm	45 mm × 30 mm × 7 mm
Bile leak		Not found	
Blood loss	100 mL	200 mL	250 mL
Injury to surrounding organs		Not occurred	

Figure 4 A resected liver segment compared with the reserved part. A resected liver segment was picked out with white gauze.

Figure 5 Microscopic findings of water-jet dissection in liver tissues (HE stain, ×40). A smooth and gentle cutting margin was presented. The cutting width at the bottom of the cut was similar to the dissection width at tissue surface, with little vessel damage.

endoscopic retrieval net was inserted through the endoscopic working channel and the specimen was introduced into the net and was retrieved intactly. After the procedure, the incision site was left open, and the animal was euthanized followed by necropsy.

Histopathological examination

Histologic examination was performed for all dissected specimens. The results were observed under microscope after hematoxylin and eosin staining based on the characteristics of the dissection margins, vessel preservation and dissection impact on the surrounding tissues. Thermal alterations such as edema and structural changes of different layers of the specimen were also microscopically analyzed.

RESULTS

It took 20 min to complete the excision of a liver segment 50 mm × 30 mm × 10 mm in size during the pilot experiment, and 45 min to complete the excision of a liver segment 45 mm × 25 mm × 10 mm in size during the open procedure. The blood loss was 100 mL in the open operation.

As for the NOTES procedure, using the Erbe Jet2 water-jet system, trans-anal and trans-vaginal wedge hepatic resections were successfully performed in two pigs without

laparoscopic assistance. Trans-umbilical attempt failed due to an unstable operating platform. Each incision for peritoneal entry took 1 min, and 2 h was spent on excision of the liver tissue, indicating a hugely time-consuming part of the entire procedure. There was neither hemodynamic nor pulmonary instability throughout the NOTES procedure, and target visualization within the peritoneum was always kept clear. No untoward incident such as injury to surrounding organs occurred, and the whole intra-operative blood loss ranged from 100 to 250 mL. Parenchymal bleeding from resection could be adequately controlled by electrocautery with the hybrid knife itself, the hook knife or the APC probe (Table 1, Figure 4). Since all the exposed ductal structures were successfully clipped with Endoclips, no bile leak from the remnant liver occurred.

There were relatively smooth and precise cutting margins in all histological preparations. The cutting width at the bottom of the cut was similar to the dissection width at tissue surface, with little vessel damage (Figure 5). Some thermal alterations were obtained due to intra-operative electrocautery (Figure 6).

DISCUSSION

To the best of our knowledge, this is the first study in

Figure 6 Thermal alterations due to intra-operative coagulation (HE stain, $\times 100$). Removal of the liver capsule could be seen in an example of thermal damage.

a non-survival porcine model evaluating the feasibility and safety of wedge hepatic resection merely using a NOTES approach, Erbe Jet2 water-jet technology and endoscopic instrument.

Since first described by Kalloo *et al*^[9], natural orifice transluminal endoscopic surgery (NOTES) has become the newest minimally invasive surgical procedure in contrast to open and laparoscopic technology. It involves passing flexible endoscopic systems through natural orifices (per-oral, trans-vaginal, trans-anal, trans-umbilical or trans-vesical routes), approaching target organs and performing intra-abdominal procedures. For the entry into the peritoneal cavity, a trans-luminal incision is mostly created by endoscopic needle knife followed by balloon dilation. However, in our study, it was achieved just in about 1 min *via* a hook knife, with the same desirable effect. The air-inflation mechanism of the endoscope was used to induce and maintain peritoneum, and the suction mechanism of the endoscope was used intermittently to avoid a high intra-abdominal pressure. Overall, there was neither hemodynamic nor pulmonary instability during NOTES, as described elsewhere^[10].

Similar to laparoscopic liver resection, NOTES hepatic procedures must confront one and the same Achilles' heel, difficulty in obtaining hemostasis. Given the facts that protection of blood vessels is essential to minimize hemorrhage and blood transfusion, and smooth dissection margins might minimize adhesion formation^[11], the water-jet hybrid knife was taken into consideration. Hydro-dissection was accomplished with the hybrid knife kept away from the tissue in a no-touch fashion and perpendicular to but not tangentially against the predetermined surface. Minor slow oozing from the cutting surface was controlled using the same knife, the hook knife or APC probe to initiate bursts of coagulation. Visible intra-hepatic vascular and ductal structures were clipped with endoscopic hemoclip. Certainly, the need for coagulation or clipping of individual vessels led to a prolonged operative time.

Current flexible endoscopes have significant limitations when used for complex therapeutic procedures. Stable platform and off-axis operation are often necessary for the NOTES. However, standard endoscopic shafts are too

flexible and prone to looping, if these unfavorable factors caused the failure in transumbilical endoscopic hepatic resection. As for triangulation of endoscopically deployed instruments to approach the same target, internal double channels are small and in close proximity, producing parallelism and limiting possible triangulating interactions^[12]. The operator interface parallelism does not allow satisfactory traction/countertraction for effective dissection of tissue and organs. To counteract the negative impact on dissection efficiency, a 4-mm transparent distance soft cap was mounted onto the tip of the endoscope for holding up the desired plane, subsequently avoiding the deviation in the direction of the water-jet. Unfortunately, its effect was limited due to the heavy weight of the porcine liver and the restricted field of view. As a result, excision of one piece of the same size from the porcine liver was more difficult in NOTES than in open procedure (more than 2 h was spent in NOTES, but only 45 min spent in open procedure).

Notably, non-anatomic wedge hepatic resection by a NOTES approach in either our or Phee's^[8] study is still at a primary stage. As NOTES using current endoscopic instruments is technically difficult to realize pedicle control with an intrahepatic Glissonian approach^[13], it is suitable only for superficial lesions of the liver mostly with the fine trabecular infrastructures and medium caliber structures. In order to achieve the same level of segment-based laparoscopic liver resection^[14], advance in NOTES technology still has a long way to go.

In conclusion, the water-jet hybrid knife with the capacity of selective vessel-sparing tissue dissection can safely accomplish non-anatomic wedge hepatic resection through a NOTES approach. At the same time, its efficiency may be discounted by endoscopic deficiencies: lack of surgical triangulation, unstable operating platform as well as transmission attenuation caused by long distance and endoscopic looping. Although this technology is only at its beginning stage, as the old saying goes: well begun is half done.

ACKNOWLEDGMENTS

We thank Dr. Jiang-Fan Zhu for his editorial assistance.

COMMENTS

Background

Liver resection is technically challenging due to the risk of massive bleeding during operation. Since the early 20th century, the development of specific devices for separating hepatic parenchyma has contributed to bloodless transection. Furthermore, trans-luminal liver resection is technically demanding and its expansion has been lagged behind other natural orifice transluminal endoscopic surgery (NOTES) procedures.

Research frontiers

Phee described for the first time how a dexterous master and slave transluminal endoscopic robot could efficiently perform the wedge hepatic resection without laparoscopic assistance. This technology is still an unexplored field in China.

Innovations and breakthroughs

This is the first study to evaluate the feasibility and safety of non-anatomic wedge hepatic resection in a non-survival porcine model using a NOTES approach, Erbe Jet2 water-jet technology and endoscopic instruments. The

study demonstrated that the water-jet hybrid knife with the capacity of selective vessel-sparing tissue dissection can safely accomplish non-anatomic wedge hepatic resection through a NOTES approach.

Applications

Currently, non-anatomic wedge hepatic resection using NOTES approach and water-jet technology is suitable only for superficial lesions of the liver mostly with the fine trabecular infrastructures and medium caliber structures.

Terminology

High-pressure water-jet dissection technology was originally developed in the steel and glass industries, where ultra-precise cutting and engraving were considered as professional demands^[4]. Since introduced to medical application in 1982^[5], this technology has been successfully employed in open and laparoscopic operations, achieving favorable results in precise, controllable tissue-selective dissection with excellent visualization and minimal injury to the surrounding fibrous structures (such as ductal and vessel systems with a high content of collagen and elastin).

Peer review

This is the study in a non-survival porcine model evaluating the feasibility and safety of wedge hepatic resection by using pure NOTES approach.

Abstract

AIM: To analyze the upregulated CD133 expression in tumorigenesis of primary colon cancer cells.

METHODS: Upregulated CD133 expression in tumorigenesis of colorectal cancer cell lines (Lovo, Colo205, Caco-2, HCT116 and SW620) was analyzed by flow cytometry. Human colon cancer tissue samples were stained with anti-human CD133. SW620 cells were sorted according to the CD133 expression level measured by fluorescence-activated cell sorting. Spheroids of colorectal cancer cells were cultured with the hanging drop. Expression of CD133 and Lgr5 in spheroids of colorectal cancer cells and monolayer culture was detected by RT-qPCR. Spheroids of colorectal cancer cells were analyzed using anti-human CD133 with immunohistochemical staining.

RESULTS: CD133 antigen was expressed in colorectal cancer cell lines (Lovo, Colo205, Caco-2, HCT116 and SW620) as well as in primary and metastatic human colon cancer tissues. However, the CD133 was differently expressed in these cell lines and tissues. The expression levels of CD133 and Lgr5 were significantly

higher in spheroids of parental, CD133^{hi} and CD133⁺ cells than in their monolayer culture at the mRNA level ($P < 0.05$). Immunohistochemical staining of spheroids of CD133⁺ cells showed that CD133 was highly expressed in colorectal cancer cell lines.

CONCLUSION: Upregulated CD133 expression plays a role in tumorigenesis colorectal cancer cells, which may promote the expression of other critical genes that can drive tumorigenesis.

Yang ZL, Zheng Q, Yan J, Pan Y, Wang ZG. Upregulated CD133 expression in tumorigenesis of colon cancer cells. *World J Gastroenterol* 2011; 17(7): 932-937 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i7/932.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i7.932>

INTRODUCTION

CD133, also known as prominin-1, a transmembrane pentaspan protein, is originally described as a surface antigen specific for human hematopoietic stem and progenitor cells^[1,2]. Later, CD133 is recognized as a stem cell marker for other normal tissues of brain^[3], kidney^[4], prostate^[5], liver^[6], pancreas^[7], and skin^[8]. It has been increasingly reported that CD133 is a marker of putative cancer stem cells (CSC) in brain tumor^[9,10], prostate cancer^[11], colon cancer^[12-14], lung cancer^[15], hepatocellular carcinoma^[16], melanoma^[17], ovarian cancer^[18], and pancreatic cancer^[19]. Accordingly, CD133 has been referred to as "the molecule of the moment"^[20].

It has been recently shown that CD133 expression is broadly distributed in primary colon cancer cells including cancer stem cells, both CD133⁺ and CD133^{hi} metastatic colon cancer cells initiate tumors^[21-23]. However, whether CD133 expression plays a role in tumorigenesis of colorectal cancer cells is unknown.

In the present study, upregulated CD133 expression in several colorectal cancer cell lines as well as in human primary and metastatic colon cancer tissue samples was analyzed. SW620 cell line was sorted using CD133 antigen. Spheroids of parental, CD133⁺ and CD133^{hi} cells were cultured with the hanging drop. Expressions of CD133 and Lgr5 were detected in spheroids of colorectal cancer cells. CD133 was widely expressed in human colorectal cancer cell lines as well as in primary and metastatic colon cancer tissues and upregulated CD133 expression was detected in spheroids of colorectal cancer cells, indicating that upregulated CD133 expression may promote the expression of other critical genes that can drive tumorigenesis.

MATERIALS AND METHODS

Cell lines and cell culture and tissue samples

Human colorectal cancer cell lines (Lovo, Colo205, Caco-2, HCT116 and SW620) were cultured in RPMI1640 medium containing 10% fetal bovine serum (FBS), 2 mmol/L L-glutamine, 10 μ mol/L thioglycerol, 12.5 U insulin, 0.5 mg hydrocortisone, and 30mg penicillin G/0.05 g streptomycin. Colorectal cancer cells were cultured at 37°C in a humidified atmosphere containing 10% CO₂. CD133 expression was detected in formalin-fixed, paraffin-embedded primary and metastatic colorectal cancer tissue samples from Affiliated Sixth People's Hospital of Shanghai Jiaotong University. The study was approved by the Ethics Committee of Affiliated Sixth People's Hospital of Shanghai Jiaotong University.

Fluorescence-activated cell sorting

Single-cell suspensions were stained with antibodies against human CD133 (AC133, 1:40) and human CD133/1 and CD133/2(1:10, APC conjugated, Miltenyi Biotech, Germany). Dead cells, cell debris, doublets and aggregates were excluded by forward and side scattering and pulse-width gating. Colorectal cancer cells (1×10^5) were stained in an eppendorf tube. Primary antibody was incubated for 45 min on ice and second antibody (anti-mouse Alexa488, 1:400) was incubated for 30 min on ice in the dark. Flow cytometry analysis was carried out on a fluorescence-activated cell sorting (FACS) caliber (BD). Colorectal cancer cells (1×10^6) were prepared for sorting, stained with human CD133/1 (1:10, APC conjugated, Miltenyi Biotech) and 1 μ g/mL propidium iodide (PI) to exclude dead cells during sorting. The cells were sorted using FACS Aria (BD). Matched isotype antibodies were applied in parallel as controls.

Colon spheroids were culture with hanging drop

SW620 colorectal cancer cells and their sorted CD133⁺ and CD133^{hi} cells were prepared as a single cell suspension. The cells were counted and diluted in RPMI1640

containing 20% FBS and antibiotics to a concentration of 500 cells per 20 μ L/drop in a sterile basin. The lid was lifted, inverted and placed on top of the dish containing 10 mL PBS. An 8-channel pipette was used to make rows of 20 μ L drops on the up-turned inner surface of the tissue culture dish lid. The drops were incubated at 37°C in an atmosphere containing 10% CO₂ for 10 d.

Immunohistochemistry

Frozen sections of the spheroids of colorectal cancer cells were fixed in acetone at -20°C for 10 min and rehydrated in PBS. Endogenous peroxidase was inactivated by immersing the sections in 0.3% hydrogen peroxide for 20 min. The primary antibody for frozen sections of the spheroids of colorectal cancer cells and paraffin-embedded sections of colorectal cancer tissue samples was a mouse anti-human monoclonal CD133/2 (1:40, Miltenyi Biotech, Germany) and a rabbit anti-human polyclonal CD133 (1:100, Abcam, England), respectively. The sections were incubated overnight at 4°C in a humidified chamber, then with biotinylated secondary antibody (VECTASTAIN ABC kit, Vector Laboratories) for 30 min at room temperature. Each section was incubated with the VECTASTAIN ABC reagent for 30 min at room temperature. The sections were developed using the DAB (Vector Laboratories) as the substrate and then counterstained with hematoxylin. The negative control was performed by incubating samples with PBS.

Quantification of CD133 expression by quantitative polymerase chain reaction

Total RNA was isolated from cultured colorectal cancer cells and their spheroids using the RNeasy extraction kit (GE Healthcare) and reverse transcribed using high-capacity cDNA reverse transcription kit (Applied Biosystems) according to their manufacturer's instructions, respectively. Relative quantitative polymerase chain reaction (PCR) was performed on a 7300 fast real-time PCR system (Applied Biosystems) using SYBR green PCR master mix (Applied Biosystems). The human-specific intron spanning primer pairs for CD133 were provided by QIAGEN (Catalog number: QT00075586). The sequences of primer pairs used for GAPDH and Lgr5 are CAATGACCCCTTCATTGACC (forward) and TGATGACAAGCTTCCCGTTC (reverse), and CTTTCAACCTCAGCGTCTTC (forward) and TTTCCCGCAAGACGTAAGTTC (reverse), respectively. PCR was performed for 1 cycle at 50°C for 2 min and 1 cycle at 95°C for 10 min, followed by 40 cycles at 95°C for 15 s and 60°C for 1 min. Specificity of PCR products was tested according to the dissociation curves. Relative values of transcripts were calculated using the equation: $2^{-\Delta\Delta C_t}$, where ΔC_t is equal to the difference in threshold cycles for target and reference.

Statistical analysis

Results were expressed as mean \pm SD for three repeated individual experiments in each group. Statistical analyses were conducted using the SPSS software (version 10.0).

Figure 1 Fluorescence-activated cell sorting showing CD133 expression in different colorectal cancer cell lines (A), CD133 staining of human primary colorectal cancer tissue (B) and metastatic colorectal cancer tissue (C) (Original magnification $\times 100$). Brown indicates positive staining.

Correlation between sample groups and molecular variables was assayed with paired *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

CD133 expression in colon cancer cell lines and human colon cancer tissues

CD133 antigen was expressed in all colorectal cancer cell lines with a difference of 30%-95% (Figure 1A). CD133 in human colorectal cancer tissue samples was stained with polyclonal antibody. CD133 expression was detected in 18 of the 20 primary cancer tissue samples, exclusively on the membrane of the vast majority of colorectal cancer gland cells (Figure 1B), and in 9 of the 10 metastatic colorectal cancer tissue samples with positive staining in cytoplasm of cancer cells (Figure 1C).

CD133 expression in spheroids of sorted colorectal cancer cell subpopulations

To minimize the contamination between the sorted CD133⁺ and CD133⁻ cells, a high CD133 expression cell subpopulation (CD133^{hi}) and a CD133⁻ cell subpopulation sorted from the SW620 cells could be persistently passed. CD133 antigen was stably expressed in the monolayer culture (Figure 2A). To mimic the tumorigenesis of colorectal cancer cells *in vivo*, spheroids of the sorted cells were cultured with hanging drop. The parental, CD133^{hi} and CD133⁻ cells could grow into spheroids. CD133 expression was upregulated in spheroids of CD133⁻ cells. Although the CD133 expression rate was not changed,

the mean fluorescence intensity (MFI) was significantly increased in spheroids of CD133^{hi} cells, and the CD133 expression rate and MFI were significantly increased in spheroids of parental cells detected by FACS assay (Figure 2B). Immunohistochemical staining of CD133 antigen was observed in spheroids of CD133⁻ cells (Figure 2C). The CD133 gene expression level was significantly higher in spheroids of SW620, CD133^{hi} and CD133⁻ cells than in their monolayer culture at the mRNA level (4.224 ± 0.063 *vs* 2.680 ± 0.117 , 3.653 ± 0.061 *vs* 1.325 ± 0.044 , 8.746 ± 0.029 *vs* 3.761 ± 0.065 , $P < 0.05$) (Figure 2D).

Lgr5 expression in spheroids of sorted colorectal cancer cell subpopulations

Lgr5 expression was analyzed by RT-qPCR in order to observe the role of the expression of other colon stem cell genes in tumorigenesis of colorectal cancer cells. The results showed that the Lgr5 expression level was significantly higher in spheroids of parental, CD133^{hi} and CD133⁻ cells than in their monolayer cells (5.942 ± 0.091 *vs* 4.003 ± 0.039 , 6.611 ± 0.214 *vs* 3.645 ± 0.046 , 5.910 ± 0.035 *vs* 3.903 ± 0.083 , $P < 0.05$) (Figure 3).

DISCUSSION

Whether CD133 antigen can be used as a marker of colorectal cancer stem cells is still controversial. The focus is that CD133 expression is not restricted to just a small number of colorectal cancer cells. In this study, the CD133 expression was upregulated in colorectal cancer cell lines and primary or metastatic colorectal cancer tissue

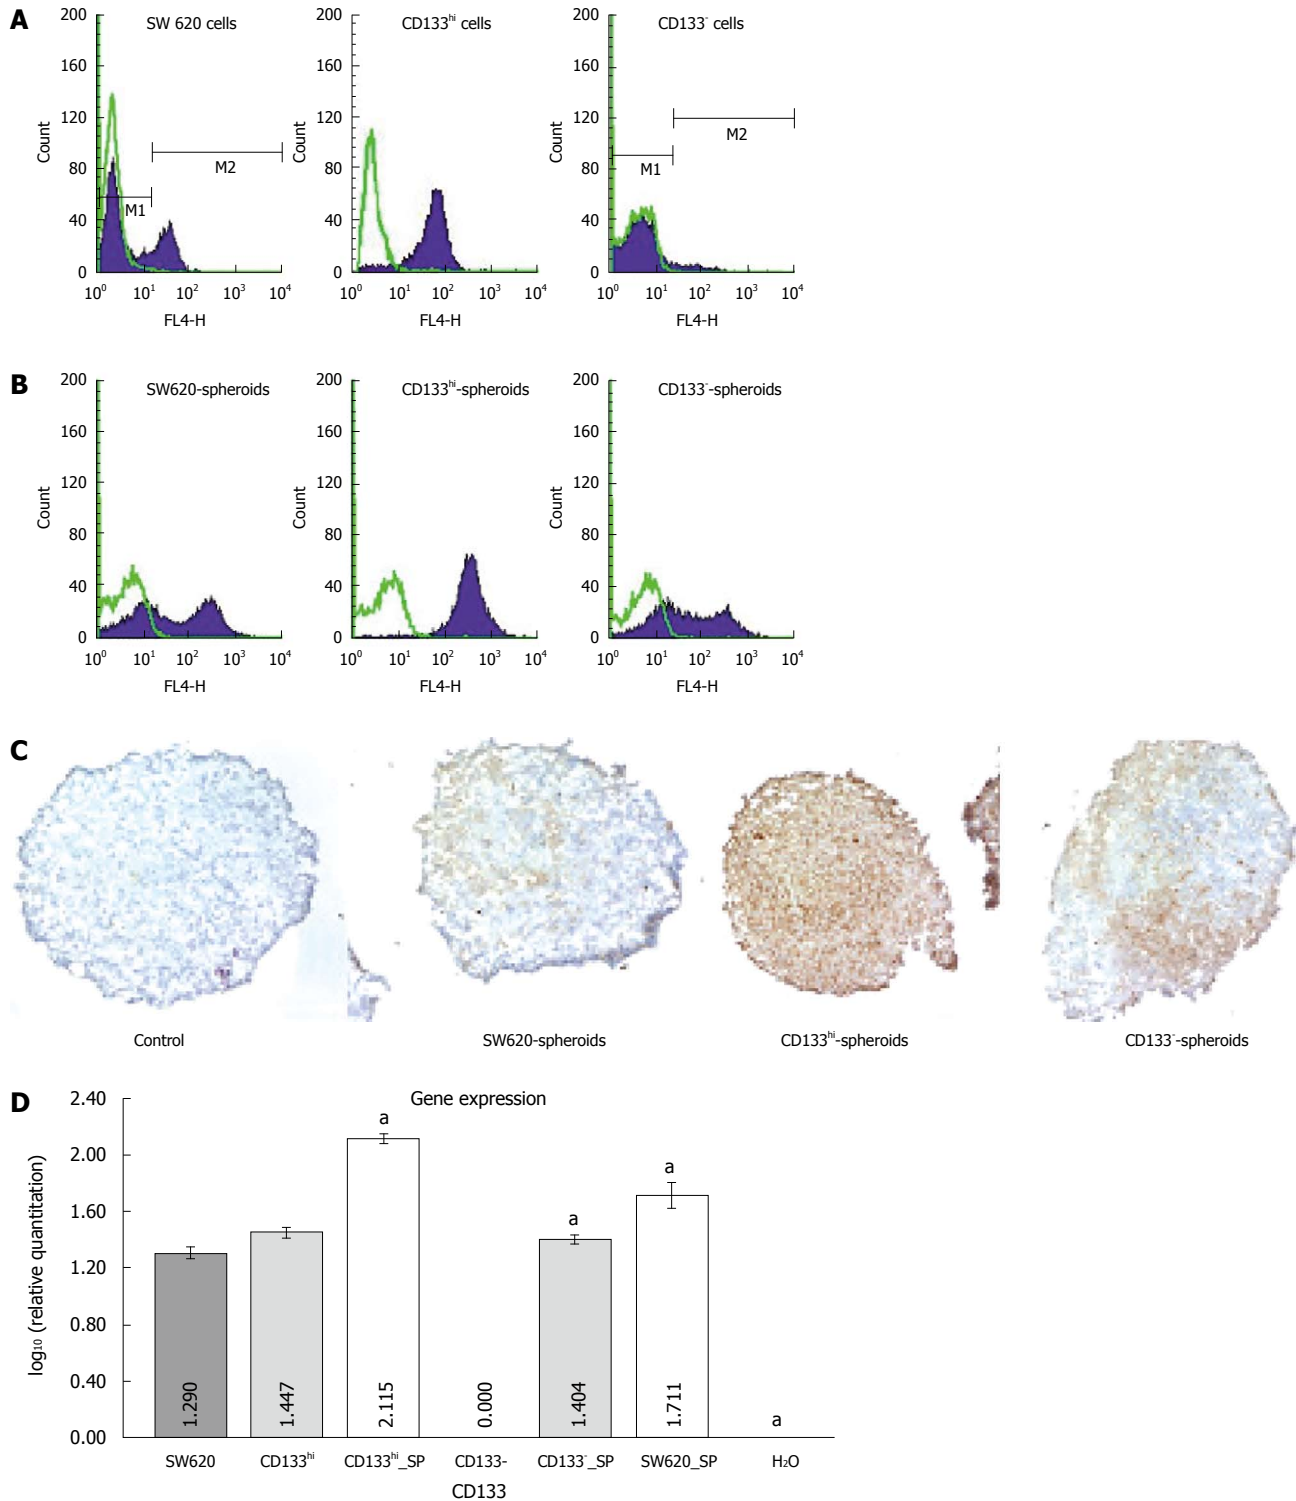

Figure 2 Fluorescence-activated cell sorting showing CD133 expression in SW620, CD133⁻ and CD133^{hi} cells (A) and in their spheroids (B), CD133 staining in spheroids of SW620, CD133⁻ and CD133^{hi} cells (original magnification $\times 100$, brown indicates positive staining) (C), and reverse transcription-polymerase chain reaction showing CD133 expression in SW620, CD133⁻ and CD133^{hi} cells and their spheroids. ^a $P < 0.05$ vs monolayer cells. SP: Spheroid.

samples, showing that CD133 antigen can be expressed in colorectal cancer cell lines with a difference of 30%-95%. CD133 expression was detected in 18 of the 20 primary colorectal cancer tissue samples, exclusively on the membrane of a large number of colorectal cancer gland cells, and in 9 of the 10 metastatic colorectal cancer tissue samples with a positive staining in cytoplasm of colorec-

tal cancer cells, which is consistent with the reported findings^[21-23]. The different CD133 expression levels in colorectal cancer cell lines may be related to the different glycosylation to the mask specific epitopes of CD133 antigen in colorectal cancer cell differentiation^[24]. Therefore, our data indicate that CD133 is commonly expressed in colorectal cancer cells.

Figure 3 Quantitative reverse transcription-polymerase chain reaction showing Lgr5 expression in SW620, CD133^{hi} and CD133^{hi} cells and their spheroids. ^a*P* < 0.05 vs monolayer cells. SP: Spheroid.

To investigate whether the upregulated CD133 expression plays a role in tumorigenesis of colorectal cancer cells, SW620 cell line containing two cell subpopulations (CD133^{hi}, CD133⁻) was selected and sorted using CD133 antigen, the spheroids of parental, CD133^{hi} and CD133⁻ cells were cultured with the hanging drop *in vitro*, which is based on the natural disposition of cells to aggregate without the need for polymer scaffolds such as matrigel, polyglycolic acid or microporous supports to achieve homogeneous multicellular tumor spheroids^[25]. The spheroids represent a popular *in vitro* 3D tissue structure that mimics *in vivo* tumor tissue organization and microenvironment^[26,27]. In the present study, CD133^{hi} and CD133⁻ cells could be cultured into their spheroids, CD133 expression was upregulated in spheroids of CD133⁻ cells. Although the CD133 expression was not changed, the mean fluorescence intensity (MFI) was significantly increased in spheroids of CD133^{hi} cells as detected by FACS assay. Immunohistochemical staining of CD133 antigen was observed in spheroids of CD133⁻ cells, indicating that CD133 antigen expression is upregulated in spheroids of CD133⁻ and CD133^{hi} cells. Further analysis revealed that the CD133 gene expression level was significantly higher in spheroids of SW620, CD133^{hi} and CD133⁻ cells than in their monolayer culture at the mRNA level, suggesting that the upregulated expression of CD133 including protein and gene plays a role in tumorigenesis of colorectal cancer cells.

Since the upregulated CD133 expression plays a role in tumorigenesis of colorectal cancer cells, whether CD133 protein supports the growth of colorectal cancer is a subject that should be actively studied. As CD133 by itself may lack of a functional role in initiation of tumors and metastasis of human colorectal cancer^[28,29], it has an impact on the survival of colorectal cancer patients^[22,29]. It has been recently demonstrated that prominin 1 (also called CD133)-marked mouse intestinal stem cells are susceptible to neoplastic transformation^[30], possibly due to the fact that upregulated CD133 expression may promote the expression of other critical genes that can drive tumorigenesis of colorectal cancer cells. In this study, the expression level of Lgr5 (leucine-rich-repeat-containing G-protein-coupled receptor 5), also known as Gpr49, a colon stem cell marker

gene^[31], was significantly higher in spheroids of parental, CD133^{hi} and CD133⁻ cells than in their monolayer cells.

In conclusion, the upregulated CD133 expression plays a role in tumorigenesis of colorectal cancer cells, which may be related to the expression of other critical genes that can drive tumorigenesis of colorectal cancer cells. Further study is needed to confirm the present results *in vivo*.

COMMENTS

Background

It has been recently shown that CD133 expression is broadly distributed in primary colorectal cancer cells, and not restricted to cancer stem cells. Whether the upregulated CD133 expression plays a role in tumorigenesis of colorectal cancer cells is unknown.

Research frontiers

It has been increasingly reported that CD133 is a marker of putative cancer stem cells (CSC) in some cancers. However, it has been recently shown that CD133 expression is broadly distributed in primary colon cancer cells and not restricted to cancer stem cells, and both CD133⁻ and CD133^{hi} metastatic colorectal cancer cells initiate tumors. Whether the upregulated CD133 expression plays a role in tumorigenesis of colorectal cancer cells is unknown. In this study, the upregulated CD133 expression was found to play a role in tumorigenesis of colorectal cancer cells.

Innovations and breakthroughs

Recent reports have shown that whether CD133 antigen can be used as a marker of colorectal cancer stem cells is controversial. This is the first study to report the role of upregulated CD133 expression in tumorigenesis of colorectal cancer cells. Furthermore, our *in vitro* studies suggested that the upregulated CD133 expression may promote the expression of other critical genes that can drive tumorigenesis of colorectal cancer cells.

Applications

Whether the upregulated CD133 expression plays a role in tumorigenesis of colorectal cancer cells was studied, the results may help to solve the controversy on CD133 antigen as a marker of colorectal cancer stem cells.

Terminology

CD133, also known as prominin-1, a transmembrane pentaspan protein, is originally described as a surface antigen specific for human hematopoietic stem

and progenitor cells. Lgr5 (leucine-rich-repeat-containing G-protein-coupled receptor 5), also known as Gpr49, is a colon stem cell marker gene.

Peer review

The authors detected the expression of CD133 in a panel of colorectal cancer cell lines and human colorectal cancer tissue samples. The expression of CD133 and Lgr5 in spheroids of the sorted colorectal cancer cell subpopulations suggests that the upregulated expression plays a role in tumorigenesis of colorectal cancer cells, which may promote the expression of other critical genes that can drive tumorigenesis. The results are interesting.

Abstract

AIM: To investigate intraperitoneal transplantation of microencapsulated hepatic-like cells from human umbilical cord blood for treatment of hepatic failure in rats.

METHODS: CD34⁺ cells in umbilical cord blood cells were isolated by magnetic cell sorting. In the *in vitro* experiment, sorted CD34⁺ cells were amplified and induced into hepatic-like cells by culturing with a combination of fibroblast growth factor 4 and hepatocyte growth factor. Cultures without growth factor addition served as controls. mRNA and protein levels for hepatic-like cells were analyzed by reverse transcription-polymerase chain reaction, immunohistochemistry and immunofluorescence. In the *in vivo* experiment, the hepatic-like cells were encapsulated and transplanted into the abdominal cavity of acute hepatic failure (AHF) rats at 48 h after D-galactosamine induction of acute hepatic failure. Transplantation with PBS and unencapsulated hepatic-like cells served as controls. The mortality rate, hepatic pathological changes and serum

biochemical indexes were determined. The morphology and structure of microcapsules in the greater omentum were observed.

RESULTS: Human albumin, alpha-fetoprotein and GATA-4 mRNA and albumin protein positive cells were found among cultured cells after 16 d. Albumin level in culture medium was significantly increased after culturing with growth factors in comparison with culturing without growth factor addition ($P < 0.01$). Compared with the unencapsulated group, the mortality rate of the encapsulated hepatic-like cell-transplanted group was significantly lower ($P < 0.05$). Serum biochemical parameters, alanine aminotransferase, aspartate aminotransferase and total bilirubin in the encapsulated group were significantly improvement compared with the PBS control group ($P < 0.01$). Pathological staining further supported these findings. At 1-2 wk post-transplantation, free microcapsules with a round clear structure and a smooth surface were observed in peritoneal lavage fluid, surviving cells inside microcapsules were found by trypan blue staining, but some fibrous tissue around microcapsules was also detected in the greater omentum of encapsulated group by hematoxylin and eosin staining.

CONCLUSION: Transplantation of microencapsulated hepatic-like cells derived from umbilical cord blood cells could preliminarily alleviate the symptoms of AHF rats.

J Gastroenterol 2011; 17(7): 938-945 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i7/938.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i7.938>

INTRODUCTION

Substantial efforts have been made with regard to cell transplantation as an effective supporting system for hepatic failure and assisted therapies. However, immunological rejection has always been an important problem for cell transplantation. Alginate-poly-L-lysine-alginate (APA) microcapsules have proven to be effective in protecting enclosed target cells from immune rejection following transplantation into experimental animals, thereby eliminating the problems of immunosuppressive therapy^[1-3].

Extensive studies have also been conducted on the core of this therapy, namely the cell sources. The investigated cells have included liver stem cells, embryonic stem cells, human umbilical cord blood (UCB) cells and bone marrow stem cells. Human UCB cells have some advantages that other cells do not have. The frequencies of UCB hematopoietic stem/progenitor cells exceed those from bone marrow and peripheral blood. In our previous study, we confirmed the differentiation of mononuclear cells (MNCs) from human UCB into hepatocytes in three different ways, namely co-culture with injured liver cells, growth factor-assisted culture, and MNC transplantation in animal models of liver injury^[4]. In the present study, we found that CD34⁺ cells derived from human UCB could be converted into hepatic-like cells that generate hepatocyte lineage cells. Furthermore, we encapsulated the hepatic-like cells using an alginate method and transplanted them into acute hepatic failure (AHF) rats to evaluate the effects of encapsulated hepatic-like cell transplantation.

MATERIALS AND METHODS

Isolation and identification of CD34⁺ cells

UCB (more than 80 samples) from full-term deliveries were obtained from the Obstetrics Department of Peking University Shenzhen Hospital. UCB cells were harvested after written informed consent was obtained. The study protocol was approved by the Ethics Committee of Peking University Shenzhen Hospital. MNCs were isolated from the UCB samples by density-gradient centrifugation at 2000 r/min for 35 min using Ficoll-Hypaque (Huaqing, Shanghai, China). CD34⁺ subpopulations were isolated using a Miltenyi Direct CD34 Progenitor Cell Isolation Kit (Miltenyi Biotec, Bergisch Gladbach, Germany). The specific steps were as follows: (1) isolated MNCs were resuspended in a final volume of 300 μ L of PBS that contained 5 g/L bovine serum albumin (BSA); (2) 100 μ L of FcR Blocking Reagent and 100 μ L of CD34 Micro Beads per 1×10^8 total cells were sequentially added, mixed well and incubated for 30 min in a refrigerator at 4°C; (3) cells were passed through a magnetic column twice and purified; and (4) CD34⁺ cells were collected, resuspended in

Gene	Primer (5'-3')		Amplicon (bp)
	Forward primer	Reverse primer	
ALB	CTTTCAAAGCAT-GGGCAGTAG	GCAGCAGCACGA-CAGAGTAA	411
GATA-4	ACCTGGGACTTG-GAGGATAG	GACAAGGACATCTT-GGGAAA	250
AFP	TGAGCACTGTTG-CAGAGGAG	CTGAGACAG-CAAGCTGAGGA	308

ALB: Albumin; AFP: α -fetoprotein.

100 μ L PBS, incubated with 10 μ L CD34-phycoerythrin for 10 min at 4°C and identified by flow cytometry.

Differentiation in vitro

Freshly isolated CD34⁺ cells were primarily cultured in Dulbecco's modified Eagle's medium - low glucose (DMEM-LG, Gibco, Carlsbad, CA, USA), amplified for 3-5 d with a combination of 12.5 μ g/mL thrombopoietin (TPO) (R&D Systems, Minneapolis, MN, USA), 50 ng/mL stem cell factor (SCF) (R&D Systems) and 50 ng/mL Flt-3 (R&D Systems); then induced into hepatic-like cells by culturing in DMEM-LG that contained 50 mL/L fetal bovine serum (Gibco), 100 U/mL penicillin, 100 μ g/mL streptomycin, 4.7 μ g/mL linoleic acid, 1×10^{-4} mol/L L-ascorbic acid 2-P supplemented with 100 ng/mL fibroblast growth factor (FGF)4 (R&D Systems) and 20 ng/mL hepatocyte growth factor (HGF; Sigma, St. Louis, MO, USA). CD34⁺ cells were incubated in 24-well plates at 37°C in a 5% CO₂ atmosphere. Culture medium was replaced every 3 d. Cultured cells were collected after 8 and 16 d. Cultures without growth factors served as controls.

Total mRNA isolation and reverse transcription-polymerase chain reaction

Total mRNA was extracted from collected cells using Trizol (Mrcgene, Cincinnati, OH, USA). mRNA was reverse-transcribed and the resulting cDNA was amplified using the primer sets shown in Table 1 and a RobusT I reverse transcription-polymerase chain reaction (RT-PCR) Kit (Finnzymes, Espoo, Finland). Reverse transcriptase reaction was run at 48°C for 45 min and PCR was initiated with pre-denaturation at 94°C for 2 min, followed by 35 cycles of 30 s at 94°C, annealing at 58°C for 30 s and extension at 72°C for 30 s, with 72°C for 7 min for final extension. The PCR products were separated on a 1.2% agarose gel.

Immunocytochemistry for CD34⁺ cells

Cytospins prepared from cells were fixed with 4% paraformaldehyde and 0.15% picric acid in PBS at room temperature for 20 min, then permeabilized and blocked with 10% goat serum and 0.1% Triton X-100 in PBS at room temperature for 10 min. The cells were sequentially incu-

bated with a mouse anti-human albumin antibody (R&D Systems) for 30 min, a biotinylated peroxidase-conjugated secondary antibody (Zymed, South San Francisco, CA, USA) for 10 min, and diaminobenzidine for 10 min. Between the above steps, cells were washed with 0.1 mol/L PBS that contained 1 g/L BSA.

Albumin determination

Culture media were collected for the quantitative determination of human albumin by ELISA using a Human Albumin ELISA Kit (Alpha Diagnostics International, San Antonio, TX, USA) according to the manufacturer's instructions.

Cell encapsulation

Cells collected after 16 d induction were washed with PBS and resuspended in the alginate. The alginate-cell mixture was passed through a microcapsule generator and extruded into 40 mL 1.1% CaCl_2 solution. The airflow rate was adjusted for the regulation of the microcapsule diameter between 300 and 800 μm . The capsules and CaCl_2 solution were then transferred to 50-mL conical tubes. After removal of the supernatant, the capsules were gently mixed with the wash solution and allowed to settle for 2 min. Before transplantation, a few drops of encapsulated cells were placed on a slide, stained with 0.4% Trypan blue, covered with a cover glass and lightly pressed to force cells out of the microcapsules. Numbers of living cells were counted and expressed as percentages.

Induction of AHF and cell transplantation

Sprague-Dawley rats were purchased from the Experimental Animal Center of Southern Medical University (Guangzhou, China). The Scientific Committee at Peking University Shenzhen Hospital approved the use of animals for experimental purposes. Forty-eight hours before transplantation, the Sprague-Dawley rats (weight: 180–250 g) were intraperitoneally injected at 1.4 g/kg with a 10% D-galactosamine solution in normal saline. On the day of the experiment, microencapsulated cells at a density of 2×10^6 cells/mL were prepared and transplanted into the abdominal cavity of rats. Transplantation with PBS only or unencapsulated hepatocyte-like cells were performed for the establishment of control groups. As UCB samples are not delivered on the same day, animal experiments were carried out by batch and the transplantation of cells performed also on different days. The mortality rate, hepatic pathological changes and serum biochemical indexes were determined.

AHF rats grouping

We obtained total 135 AHF rats 48 h after injection of D-galactosamine. They were divided into three groups on the day of the transplantation. Namely, encapsulated group (transplantation with encapsulated hepatic-like cells, $n = 55$), unencapsulated group (transplantation with unencapsulated hepatic-like cells, $n = 40$), PBS group (transplantation with PBS, $n = 40$). Among these, 76 AHF rats were determined for hepatic pathological changes and

serum biochemical indexes (encapsulated group, $n = 36$; unencapsulated group, $n = 20$; PBS group, $n = 20$). The remaining 59 rats were determined for mortality rate (encapsulated group, $n = 19$; unencapsulated group, $n = 20$; PBS group, $n = 20$).

Histology

The liver and greater omentum from all three groups were fixed in 4% buffered formaldehyde overnight. After paraffin embedding, 4–5- μm thick serial sections were stained with hematoxylin and eosin (HE) and observed under the light microscope.

Statistical analysis

Data were expressed as the mean \pm SD. Mortality rate analysis was determined by Fisher's exact test. Serum biochemical index statistical analysis was performed by ANOVA using SPSS version 13.0 (SPSS Inc., Chicago, IL, USA). Differences with P values < 0.05 were considered statistically significant.

RESULTS

Differentiation of CD34⁺ cells into hepatic-like cells

Approximately 3×10^5 – 9×10^5 /mL sorted cells were obtained using the CD34 immunomagnetic bead method, and 91% of them expressed CD34 by flow cytometry analysis (Figure 1). CD34⁺ cells were firstly amplified 20-fold by a combination of TPO, SCF and Flt-3, and then they were cultured with HGF and FGF4. At 16 d, they developed larger volumes, richer cytoplasts, and binucleated structures, as observed under a Hoffman microscope (Figure 2). The RT-PCR showed no human albumin, α -fetoprotein (AFP) and GATA-4 mRNA expression in CD34⁺ cells before the induction procedure. The expression of albumin and GATA-4 mRNA increased with the culture time after the addition of growth factors, whereas the amount of AFP mRNA expression peaked after 8 d and reduced at 16 d (Figure 3). Cells that expressed albumin and AFP were verified by immunocytochemical staining and ELISA (Figures 2 and 4). The percentage of albumin- and AFP-positive cells at 16 d was 30% and 24%, respectively. The albumin product in culture medium was significantly increased after culturing with HGF and FGF4 in comparison with control groups ($P < 0.01$).

Cell encapsulation and transplantation

The APA microencapsulation technique was used to encapsulate hepatic-like cells. The percentage of living cells was $> 80\%$, as determined by trypan blue staining. The AHF animal model was successfully established using Sprague-Dawley rats by the injection of D-galactosamine. Pathological section of the AHF liver revealed that the structure of the hepatic lobules was destroyed and the hepatic cord was disordered, with large areas of denatured and necrotic hepatocytes, and infiltrating lymphocytes were found on the portal area at 48 h after injection. On the day of the experiment, microencapsulated cells at a density of 2×10^6 cells/mL were prepared and transplanted.

ed into the abdominal cavity of AHF rats. The mortality rate and hepatic pathological changes were determined. At 48 h after transplantation, HE staining of the encapsulated group revealed that the hepatic lobules were still intact; denaturation was the major change in hepatocytes and the area of necrosis nidus was small, and congestion and hemorrhage were almost undetectable (Figure 5). The mortality rate at 48 h after transplantation in three groups was 42.1% (encapsulated group), 65% (unencapsulated group) and 75% (PBS group), respectively. Compared with the unencapsulated group, the mortality rate of the encapsulated group was significantly lower ($P < 0.05$). In addition, the serum biochemical indexes of ALT, AST and total bilirubin in the microencapsulated group differed significantly from those in the PBS group ($P < 0.01$)

at 48 h after transplantation, but there were no differences between the encapsulated and the unencapsulated group (Table 2). At 1-2 wk post-transplantation, free microcapsules with a round clear structure and a smooth surface were observed in peritoneal lavage fluid, surviving cells in microcapsules were found by trypan blue staining, but some fibrous tissues around microcapsules were also detected in the greater omentum of encapsulated group by HE staining (Figure 6).

DISCUSSION

With the continued increase in people with hepatic failure from cirrhosis and hepatocarcinoma, cell transplantation as an effective therapy is becoming a matter of concern

Table 2 Changes in serum biochemical indexes at different times

	48 h after injection D-GaIN	48 h after transplantation			7 d after transplantation		
	All 3 groups	Encapsulated group	Unencapsulated group	PBS group	Encapsulated group	Unencapsulated group	PBS group
ALT (U/L)	3242.3 ± 2403.24	93.93 ± 63.45 ^b	126.1 ± 54.35	245.9 ± 67.87	42.25 ± 11.86	45.07 ± 10.56	47.27 ± 11.08

for more scientists. Cell transplantation could offer metabolic support when liver function is damaged, and extend the waiting time for a liver donor^[5,6]. Hepatic cell transplantation via the peritoneum or spleen has shown good prospects in clinical and animal experiments. However, the cell sources for transplantation and the requirement for long-term immunosuppression have caused stagnation in this field.

There have been some intriguing studies that have described adult stem cells displaying plasticity in recent years. These studies have led us to consider that using adult stem cells might cure diseases such as AHF^[7,8]. Human UCB cells are enriched in hematopoietic stem/progenitor cells that exceed those in the bone marrow and peripheral blood. In comparison with bone marrow stem cells, UCB stem cells are even more immature and with lower immunogenicity. In our previous study, we confirmed that the conversion of UCB MNCs into hepatocytes by three different ways, namely co-culture with injured liver cells, growth-factor-assisted culture, and MNC transplantation in AHF animal models^[4]. In the present study, we explored the possibility that CD34⁺ cells derived from human UCB could be converted into hepatic-like cells. At present, the curative effect of hepatic-like cells derived from CD34⁺ cells in the bone marrow has already been confirmed by *in vivo* animal experiments^[9-12]. This showed that an AHF model was initially set up using immunodeficient mice, and CD34⁺ cells enriched by immunobeads were injected through the tail vein or portal vein into the model animals. Expression of differentiation markers of donor cells in

recipient livers at different times after transplantation was determined by fluorescence *in situ* hybridization, immunohistochemistry and molecular biological techniques. It was found that stress-induced signals, such as increased expression of stromal-cell-derived factor 1, matrix metalloproteinase-9 and HGF, recruits human CD34⁺ progenitors with hematopoietic and/or hepatic-like potential to the liver of NOD/SCID mice^[13]. Furthermore, another study has confirmed that FGF, leukemia inhibitory factor, SCF, HGF, FGF4 and oncostatin M contribute to the proliferation and/or differentiation of hepatic cells in different ways, and that combinations of these factors, especially HGF and FGF4, are necessary for human UCB cells to convert into albumin-producing cells^[14].

With a combination of HGF and FGF4, we have established a 16-d culture system to induce CD34⁺ cell differentiation. The culture system with HGF and FGF4 displays the capability to convert the CD34⁺ cells from human UCB into cells with hepatocyte phenotypes, as confirmed by RT-PCR, immunohistochemical staining, and ELISA. Moreover, the positive ratio of albumin-containing cells by immunocytochemical staining was about 30%, which is consistent with the study of Kakinuma *et al*^[14]. All these indicate that after proliferation and differentiation, we could obtain many transplantable hepatic-like cells.

Although the lower immunogenicity of UCB stem cells has advantages in heterogenic transplantation, untreated UCB cells can sometimes cause serious immune rejection. How to resolve this problem is therefore a key point for further studies. Microencapsulation offers a

possibility to overcome the difficulty. This technique uses microcapsules such as APA microcapsules to coat target cells or organs, and is beneficial for heterogenic transplantation because its biocompatible and semi-permeable membranes are capable of intercepting substances with molecular weights above 11×10^4 . Since Lim *et al.*^[15] first presented the concept of bio-microcapsules in 1980, artificial cell microcapsules as an effective barrier system for immunoprotection have been successfully applied in diabetes, parkinsonism, spinal cord injury, and peripheral nerve regeneration^[15,16].

Our study examined coated hepatic-like cells derived from UCB by the APA microencapsulation technique. The obtained microcapsules exhibited a good smooth surface and integrated appearance. Furthermore, living cells inside the microcapsules were $> 80\%$ as determined by trypan blue staining. The mortality rate of AHF rats transplanted with microencapsulated hepatic-like cells significantly decreased in comparison with AHF rats transplanted with unencapsulated cells. In addition, there were significantly better outcomes in serum biochemical indexes such as ALT, AST and total bilirubin in the encapsulated group than in the PBS group, but no differences were observed between the encapsulated and the unencapsulated groups. Liver pathological staining supported these findings. The reason why the latter two groups showed no difference requires further exploration, although it is possibly related to the lower number of encapsulated cells. There have been some studies to support the notion that microcapsules provide the encapsulated cells with a good living space, and can significantly increase their survival time, therefore, we could theoretically reduce the number of transplanted cells^[17]. Our data suggest that the transplantation of microencapsulated hepatic-like cells could offer a metabolic support to AHF rats in the short term, but it is not sufficient to interrupt or repair the damage of the recipient hepatocytes.

In our study, the pathological staining clearly showed liver recovery at 7 d after induction of AHF with D-galactosamine. At 2 wk post-transplantation, the morphological form of free microcapsules could be observed in the peritoneal lavage fluid, and showed round clear structures and smooth surfaces, and some microcapsule fragments were observed as well. HE staining revealed that some microcapsules attached to the greater omentum exhibited lymphocyte invasion surrounded with fibrous tissues. Although transplantation of microencapsulated hepatic-like cells could preliminarily alleviate the symptoms of AHF rats, their short lifespan and varying stability are still problems for the further use of the technique. The improvement in the airflow encapsulation system might be considered to yield sufficient uniformity in the size of microcapsules^[18].

Transplantation of microencapsulated cells could provide a temporary metabolic support to AHF patients and/or be a transitional treatment, because its mechanism is not only related to the immunosuppressive and substitution effects of the transplanted cells, but is also associated

with liver repair promoted by the transplanted cells. This new approach could provide a potential alternative for severe liver diseases.

COMMENTS

Background

With the continued increase in people with hepatic failure from cirrhosis and hepatocarcinoma, cell transplantation could offer metabolic support when liver function is damaged, and extend the waiting time for a liver donor. However, the cell sources for transplantation and the requirement for long-term immunosuppression have caused stagnation in this field.

Research frontiers

Alginate-poly-L-lysine-alginate (APA) microcapsules have been proved effective in protecting enclosed target cells from immune rejection following transplantation into experimental animals. Many studies have been conducted on the cell sources such as liver stem cells, embryonic stem cells, umbilical cord blood (UCB) cells and bone marrow stem cells.

Innovations and breakthroughs

The research team led by Professor Yu has established an artificial cell microcapsules platform, which is based on APA microcapsule technology and stem cell differentiation, to study the therapeutic effects of intraperitoneal transplantation of microencapsulated hepatic-like cells derived from UCB cells on AHF in rats. The effective immunoprotectivity of artificial cell microcapsules has been observed in this study, which suggests that the transplantation of microencapsulated hepatic-like cells could offer a metabolic support to AHF rats in the short term, but it is not yet sufficient to interrupt or repair the damage of the recipient hepatocytes.

Applications

Transplantation of microencapsulated cells could provide a temporary metabolic support to AHF patients and/or be used as a transitional treatment. This new approach could provide a potential alternative for severe liver diseases.

Terminology

UCB was obtained from full-term deliveries at the Obstetrics Department of Peking University Shenzhen Hospital. Hepatic-like cells were induced from UCB CD34⁺ cells by culturing with FGF4 and HGF. Alginate-poly-L-lysine-alginate microcapsules have biocompatibility and semi-permeable membranes, and can intercept substances with molecular weights $> 1.1 \times 10^5$.

Peer review

Zhang *et al.* reported that CD34⁺ cells sorted from human UCB cells were cultured for 16 d in a specific medium and could differentiate into hepatocyte-like cells. When the hepatocyte-like cells were encapsulated by alginate and intraperitoneally transplanted into rats with galactosamine-induced AHF, the number of surviving rats increased compared to that of control rats at 2 d after transplantation. Although the differentiation of CD34⁺ cells derived from UCB to hepatocyte-like cells has been reported, it is interesting to use the peritoneal injection of alginate-encapsulated hepatocyte-like cells for the alleviation of AHF. If the preserved UCB cells are used for the treatment of AHF and related diseases, it will be beneficial to the patients.

Abstract

AIM: To retrospectively analyze the computed tomography (CT) and magnetic resonance imaging (MRI) appearances of primary clear cell carcinoma of the liver (PCCCL) and compare the imaging appearances of PCCCL and common type hepatocellular carcinoma (CHCC) to determine whether any differences exist between the two groups.

METHODS: Twenty cases with pathologically proven PCCCL and 127 cases with CHCC in the Second Affiliated Hospital of Sun Yat-sen University were included in this study. CT or MRI images from these patients were retrospectively analyzed. The following imaging findings were reviewed: the presence of liver cirrhosis, tumor size, the enhancement pattern on dynamic contrast scanning, the presence of pseudo capsules, tumor rupture, portal vein thrombosis and lymph node metastasis.

RESULTS: Both PCCCL and CHCC were prone to occur in patients with liver cirrhosis, the association rate of liver cirrhosis was 80.0% and 78.7%, respectively ($P >$

0.05). The mean sizes of PCCCL and CHCC tumors were (7.28 ± 4.25) cm and (6.96 ± 3.98) cm, respectively. Small HCCs were found in 25.0% (5/20) of PCCCL and 19.7% (25/127) of CHCC cases. No significant differences in mean size and ratio of small HCCs were found between the two groups ($P = 0.658$ and 0.803 , respectively). Compared with CHCC patients, PCCCL patients were more prone to form pseudo capsules (49.6% vs 75.0%, $P = 0.034$). Tumor rupture, typical HCC enhancement patterns and portal vein tumor thrombosis were detected in 15.0% (3/20), 72.2% (13/18) and 20.0% (4/20) of patients with PCCCL and 3.1% (4/127), 83.6% (97/116) and 17.3% (22/127) of patients with CHCC, respectively. There were no significant differences between the two groups (all $P > 0.05$). No patients with PCCCL and 2.4% (3/127) of patients with CHCC showed signs of lymph node metastasis ($P > 0.05$).

CONCLUSION: The imaging characteristics of PCCCL are similar to those of CHCC and could be useful for differentiating these from other liver tumors (such as hemangioma and hepatic metastases). PCCCLs are more prone than CHCCs to form pseudo capsules.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary malignant tumor of the liver. It can be classified according to its histological architecture or cytological features. HCC includes various cytological types; the less common ones are clear cell type, spindle cell type, giant cell type, small cell type and squamous cell type^[1,2]. Primary clear cell carcinoma of the liver (PCCCL) is rare, with a frequency varying between 2.2% and 6.7% among HCCs reported in the published literatures^[3,4]. Due to the accumulation of glycogens and/or fats, the PCCCL cell cytoplasm is clear to hematoxylin-eosin staining. PCCCL may pose a diagnostic dilemma even with histological evaluation because the morphology of PCCCL cells is similar to that of extrahepatic clear cell tumors, such as clear cell cancers of the kidneys, adrenal glands, ovaries, thyroid, endometrium, uterine cervix, and vagina^[5,6]. PCCCLs should be differentiated from metastatic clear cell cancer because their treatment strategies and prognoses are quite different. The prognosis of PCCCL is generally considered better than that of the common type of HCC (CHCC)^[3,7,8].

Computed tomography (CT) and magnetic resonance imaging (MRI) are important examinations for the detection and characterization of liver tumors^[9,10]. To our knowledge, the imaging features of PCCCL have rarely been reported in the English literature^[11]. The purpose of this study was to describe the CT and MRI findings of PCCCL and compare them to CHCC to determine whether any differences exist between the two groups.

MATERIALS AND METHODS

Patients

Between January 2005 and August 2009, a total of 570 patients with primary HCC underwent hepatectomy at the Second Affiliated Hospital of Sun Yat-sen University. Twenty (3.5%) of these patients had pathologically confirmed PCCCL. The participants of this study included 20 patients with PCCCL and 127 patients with CHCC (randomly selected from the other 550 cases of primary HCC). No patient had received preoperative treatment, such as interventional therapy or chemotherapy.

Of the 20 patients with PCCCL, 14 had right upper abdominal pain, two complained of fatigue and four were asymptomatic. All patients with PCCCL were positive for HBsAg, and two were positive for anti-hepatitis C virus-IgG. The serum concentration of α -fetoprotein (AFP) was 5.8-68 787.0 $\mu\text{g/L}$ for PCCCL patients, with a median of 149.9 $\mu\text{g/L}$. Of the 20 patients with PCCCL, 17 were AFP-positive ($> 25 \mu\text{g/L}$).

Pathologic examinations were retrospectively reviewed by an experienced pathologist. According to diagnostic criteria generally accepted by pathologists in China, PCCCL was diagnosed when clear cells accounted for more than 50% of the tumor^[1,3,4,12].

Imaging protocols

CT or MRI examinations were performed no more than 5

days before hepatectomy. Thirteen patients with PCCCL and 73 patients with CHCC underwent dynamic CT examination using a spiral CT scanner (HiSpeed NX/I; GE Medical Systems, Milwaukee, WI) or a multi-detector CT scanner (Sensation 64; Siemens Medical Solutions, Erlangen, Germany). The scan parameters were as follows: 5-7 mm slice thickness reconstructions, 120-kV, 220-400 mA current, 25 cm field of view, and 256×256 matrix. Scans began at the dome of the diaphragm and proceeded in a caudal direction. After pre-contrast CT scans, the patients underwent dynamic contrast-enhanced scans. A bolus injection of 80-100 mL of non-ionic contrast medium (Iopamidol, Bracco, Milano, Italy) with a concentration of 350 mg I/mL was given via the antecubital vein at a rate of 3.5 mL/s. Images of the hepatic arterial phase (HAP), portal venous phase (PVP) and equilibrium phase (EP) were obtained at 25 s, 70 s and 120 s, respectively, after the injection of contrast agent.

Seven patients with PCCCL and 54 patients with CHCC underwent MRI studies with a 1.5-T MR unit (Gyrosan Intera, Philips Medical System, Best, the Netherlands). Unenhanced MR images included T1-weighted images with a water-selective excitation technique (FFE, TR 218ms, TE 4.9 ms, flip angle of 80, one acquisition) and turbo spin-echo T2-weighted images with fat saturation (TR 1600 ms, TE 70 ms, TSE Factor 24, three acquisitions). Five patients with PCCCL and 43 patients with CHCC underwent dynamic contrast-enhanced MR scans using a high-resolution turbo spin-echo sequence (TR 5.3 ms, TE 1.4 ms, flip angle of 40, 3.0-mm slice thickness, no gap, one acquisition) via a power injector; contrast agent was administered at a rate of 2.5 mL/sec. HAP, PVP and EP scans were obtained at 20, 60, and 110 s, respectively. The other 13 patients (2 with PCCCL and 11 with CHCC) received manual injections of gadopentetate dimeglumine (Magnevist, Bayer Schering, Berlin, Germany) at a dose of 0.1 mmol/kg; post-contrast T1-weighted images were obtained at PVP (60-80 s after injection) with the same scanning parameters as the pre-contrast T1W scan. Regardless of the technique employed, axial and coronal images were acquired with 5.0-mm slice thickness.

Image interpretation

The CT and MRI images were retrospectively analyzed by two radiologists who have 10 and 15 years of experience in diagnosing abdominal diseases. Neither radiologist was aware of the patients' clinicopathological data. Reviews were performed jointly and by consensus. The presence of liver cirrhosis, tumor size, the enhancement pattern on dynamic contrast scanning, the presence of pseudocapsule, tumor rupture, portal vein thrombus, and lymph node metastasis were recorded. A typical HCC enhancement pattern was defined as early enhancement at HAP and rapid contrast medium washout at PVP or EP with hypo-attenuation/intense signal or iso-attenuation/intense signal^[9,10].

Statistical analysis

Differences in mean age and tumor size were assessed

with an independent-samples *t* test. Differences in the frequencies of liver cirrhosis, tumor capsule formation, tumor rupture, typical enhancement pattern, portal vein tumor thrombus and lymph node metastases between the two groups were compared using the Chi-squared test or Fischer's exact test. A *P* value of 0.05 or less was considered significant. Statistical analysis was performed using the SPSS 13.0 software package (SPSS Inc., Chicago, IL, USA).

RESULTS

The male-to-female ratio was 4.0:1 in the PCCCL group and 6.1:1 in the CHCC group. The mean age was 52.00 ± 10.09 years (range, 29-66 years) in the PCCCL group and 51.82 ± 13.20 years (range, 19-83 years) in the CHCC group. There were no statistical differences between the two groups regarding sex or age ($P = 0.733$ and $P = 0.953$, respectively).

Table 1 summarizes the imaging features observed in patients with PCCCL and patients with CHCC. Both PCCCL and CHCC were prone to occur in patients with liver cirrhosis, with a rate of 80.0% and 78.7%, respectively. The mean sizes of PCCCLs and CHCCs were 7.28 ± 4.25 cm (range, 2.0-15.9 cm), and 6.96 ± 3.98 cm (range, 1.0-17.0 cm), respectively. Small HCCs with diameters ≤ 3.0 cm were found in 25.0% (5/20) of PCCCL cases and 19.7% (25/127) of CHCC cases. No statistically significant differences in mean size or ratio of small HCC were found between the two groups ($P = 0.658$ and 0.803 , respectively). Compared with CHCCs, PCCCLs were more prone to form pseudo capsules, with a rate of 49.6% and 75.0%, respectively ($P = 0.034$). Pseudo capsules showed hypo-attenuation/intensity haloes on pre-contrast scans and rim enhancement after contrast administration (Figures 1 and 2).

A higher percentage of tumor rupture was found in patients with PCCCL (15.0%, 3/20) than in patients with CHCC (3.1%, 4/127); however, there was no significant difference between the two groups ($P > 0.05$). Of the 20 PCCCL cases, three showed tumor ruptures. The ruptured tumors were 15.9 cm, 10.9 cm and 9.3 cm in diameter and were located at the periphery of the liver with protruding contours. Two cases presented as discontinuities of the liver surface on CT scan (Figure 1). The remaining case presented a local hematoma at the rupture site on MRI, which appeared as mixed iso-/hypo-intense signals on T1WI and hypo-intense signals on T2WI with no enhancement after injection of contrast agent.

Typical HCC enhancement patterns were noted in 72.2% (13/18) of PCCCLs and 83.6% (97/116) of CHCCs; however, no significant difference was found between the two groups ($P > 0.05$) (Figures 1 and 3). The other five PCCCL cases showed atypical CT features on dynamic scan: two cases showed minimal enhancement and remained hypo-attenuated at HAP and PVP, while the other three cases showed gradual contrast enhancement during the portal phase.

Four patients (20.0%) with PCCCL had portal vein tumor thrombosis: one located at the left branch of the portal vein, one at the right branch, and one at the right

PCCCL: Primary clear cell carcinoma of the liver; CHCC: Common type of hepatocellular carcinoma.

anterior branch and main portal vein. Compared with CHCC patients, PCCCL patients showed a slightly higher incidence of portal vein tumor thrombosis (17.3% and 20.0%, respectively); however, there was no significant difference between the two groups ($P > 0.05$). No PCCCL patients and 2.4% (3/127) CHCC patients showed sign of lymph node metastasis ($P > 0.05$).

DISCUSSION

PCCCL is a specific and rare subtype of primary HCC. The reported incidence of PCCCL is 0.4%-37%; inconsistent diagnostic criteria may be responsible for the variable reports^[1,3,4,7,8,12,13]. Lai *et al*^[7] suggested that the diagnosis of PCCCL could be made even when the proportion of clear cells was $< 30\%$, while Buchanan *et al*^[8] suggested that PCCCL should be diagnosed when the proportion of clear cells was $> 30\%$. Most studies diagnosed PCCCL when the proportion of clear cells was $> 50\%$ ^[1,3,4,12]. Using this criteria, PCCCL only accounts for 2.2%-6.7% of all resectable HCCs in most reports^[3,4]. Among the 570 cases of primary HCC resected in our hospital, only 3.5% patients had PCCCL. The clear cell development is presumed to involve metabolic disorders and abnormalities of sugar metabolism^[14,15].

The clinicopathological presentations of PCCCL were different from those of CHCC. The rates of hepatitis C infection and capsule formation were higher in PCCCL patients than in those with CHCC; however, no remarkable differences in patients' age, sex, AFP-positive rate or

Figure 1 Primary clear cell carcinoma of the liver in a 47-year-old woman. A: On pre-contrast computed tomography scan, the mass shows slight hyper-attenuation with a hypo-attenuation halo (arrows); B: At hepatic arterial phase, the mass shows early enhancement; C: At the equilibrium phase, the mass presents hypo-attenuation with rim enhancement (arrows); D: At portal venous phase, the reconstructed coronal image shows the mass with a discontinuous liver capsule (arrows) at Segment VI, indicating tumor rupture, which was surgically confirmed; E: Pathologically, the mass shows a pseudocapsule (arrows) (HE, $\times 100$).

Figure 2 Primary clear cell carcinoma of the liver in a 29-year-old man. A: On T1WI, the mass shows slightly hypo-intense signals (arrows); B: At portal venous phase, the mass presents with rim enhancement (pseudocapsule); C: Pathologically, the mass is mainly composed of clear cells (HE, $\times 200$); D: Pathologically, the mass shows a pseudocapsule (HE, $\times 100$).

Figure 3 Primary clear cell carcinoma of the liver in a 62-year-old man. A: On pre-contrast computed tomography scan, the mass shows hypo-attenuation (arrows); B: At hepatic arterial phase, the mass shows early enhancement; C: At portal venous phase, the mass shows hypo-attenuation and thin rim enhancement (pseudo-capsule); D: Microscopically, the mass is mainly composed of clear cells (HE, $\times 200$).

the location, number, size and grade of tumors were observed between the two groups^[3]. Both tumor types were prone to occur in patients with hepatitis B, mostly on the basis of liver cirrhosis^[3]. PCCCL had a better prognosis than CHCC, mainly related to capsule formation, vascular invasion, preoperative liver function and clear cell proportion^[3,4,12]. Surgical resection is an effective treatment for patients with PCCCL^[3,4,7].

The presence of clear cells and fatty changes characterizes well-differentiated HCC in the early stage, and their ratio is presumed to decrease as the tumor enlarges^[15]. In 1999, Monzawa *et al*^[16] analyzed the pathologic and imaging changes of well-differentiated HCC; and found that some well-differentiated HCCs showed clear cell formation and/or fatty changes, which presented as high echo on ultrasound and hyper-intense signals on T1WI. However, in their study, the proportion of clear cells in the recruited HCC was less than 10%, or only 10%-50%, which did not meet the diagnosis criteria for PCCCL. In 2008, Takahashi *et al*^[11] described CT, MR and angiographic findings of PCCCL in a woman with a normal liver. To our knowledge, no further research on the imaging manifestations of PCCCL has been conducted.

Pseudocapsule formation (consisting mainly of peritumoral hepatic sinusoids and/or fibrosis) is an important gross pathologic feature of HCC. Pseudocapsule indicates a relatively positive prognosis after tumor resection^[17]. Liu *et al*^[3] found a higher ratio of pseudocapsule formation in PCCCL than in CHCC microscopically (88.4% *vs* 68.0%, $P < 0.05$); and pseudocapsule formation might be related

to a relatively lower degree of malignancy and a better prognosis for PCCCL. CT and MRI are reliable imaging examinations for the detection of HCC pseudo capsules. The pseudocapsule presents as rim enhancement on dynamic contrast scanning, and MRI is more sensitive than CT in identifying pseudocapsule^[17-19]. Among the 20 cases of PCCCL in our study, 15 (75.0%) had pseudocapsule, all of which were confirmed pathologically. The percentage of pseudocapsule formation was higher in PCCCL patients than in CHCC patients ($P < 0.05$).

Because of hypervascular blood supply, typical HCC showed early enhancement at HAP, and rapid contrast medium washout at PVP or EP with hypo-attenuation/intense signal or iso-attenuation/intense signal^[9,10]. Among the 18 PCCCL cases in our study that underwent dynamic contrast CT or MRI examination, 13 presented a typical HCC enhancement pattern, indicating that the tumor is rich of blood supply. The enhancement pattern of PCCCL is not different from that of CHCC ($P > 0.05$). This imaging characteristic may be useful in differentiating PCCCL from other liver tumors, such as hemangioma and hepatic metastases. The other five PCCCL cases presented atypical enhancement on dynamic CT scans: two cases showed minimal enhancement with hypo-attenuation at HAP and PVP, indicating hypovascularity, and three cases showed gradual contrast enhancement during the portal phase, which may be attributable to the difference in blood supply (such as existence of small arteriportal shunts), tumor differentiation or liver cirrhosis background^[20,21].

Spontaneous rupture of HCC is usually life-threatening

ing but relatively uncommon, with a reported incidence of 3%-15%^[22]. CT is a valuable imaging technique for diagnosing HCC ruptures. The imaging findings include: discontinuity or disruption of the liver capsule adjacent to the liver mass and hematoma with hyper-attenuation at the rupture site. The enucleation sign is a specific sign for diagnosing HCC rupture^[23,24]. To our knowledge, no report on PCCCL rupture is available for review. Among the 20 PCCCL cases in our study, only three had tumor rupture: two showed discontinuity of the liver capsule on CT scans, and the other showed a hematoma at the rupture site on MRI, with iso-/hypo-intense signals on T1WI and hypo-intense signals on T2WI.

Portal vein thrombosis, the characteristic growth pattern of HCC, occurs in 12.5%-39.7% of HCC patients^[25]. Liu *et al*^[3] reported that the microscopic vascular invasion rates are similar between PCCCL and CHCC (53.4% *vs* 65.0%, $P > 0.05$). In our study, the incidence of macroscopic portal vein tumor thrombus in PCCCL and CHCC detected on imaging examination was not significantly different ($P > 0.05$). Portal vein invasion was an independent risk factor for the prognosis of patients with PCCCL^[12].

Chemical shift imaging is valuable for characterizing lesions with a mixture of water and fat^[26]. Renal clear cell carcinomas usually contain fat, and present focal and diffused signal loss on chemical shift imaging. This imaging technique is helpful for differentiating renal clear cell carcinoma from other types of renal cancer^[27,28]. The cell morphology of PCCCL is similar to that of renal clear cell carcinoma, with cytoplasmic accumulation of glycogens and/or fat. The signal reduction of HCC during chemical shift imaging may help identify intratumoral fatty components and confirm a diagnosis of PCCCL^[2].

In summary, the imaging characteristics of PCCCL are similar to those of CHCC, including early enhancement and rapid washout of contrast agent on dynamic contrast scans, and presence of portal vein thrombus or tumor rupture. These imaging features may help differentiate PCCCL from other liver tumors, such as hemangioma and hepatic metastases. Pseudocapsule formation is more likely to occur in PCCCL than in CHCC and may be related to PCCCL's relatively lower degree of malignancy and better prognosis.

COMMENTS

Background

Primary clear cell carcinoma of the liver (PCCCL) is a specific and rare subtype of primary hepatocellular carcinoma (HCC), with a frequency varying between 2.2% and 6.7% among HCCs in the published literatures. PCCCL may pose a diagnostic dilemma even with histological sections because the morphology of PCCCL cells is similar to that of metastatic clear cell tumors. As a result of the paucity of cases, available data about its imaging findings are limited.

Research frontiers

Imaging modalities [computed tomography (CT) and magnetic resonance imaging (MRI)] are important for the detection and characterization of liver tumors. The imaging characteristics of common type hepatocellular carcinoma (CHCC) are well documented; for example, CHCC is usually associated with liver cirrhosis, typical enhancement pattern on dynamic contrast scanning (early enhancement at hepatic arterial phase and rapid contrast medium washout at portal venous phase or equilibrium phase) and the presence of pseudocapsule. However, the imaging features of PCCCL have not been unequivocally addressed. This study clarifies the CT or MRI findings of PCCCL.

Innovations and breakthroughs

The authors presented 20 surgically confirmed PCCCL cases and retrospectively analyzed their imaging findings. This study revealed that the imaging characteristics of PCCCL are similar to those of CHCC. PCCCLs are more likely to form pseudo capsules than CHCCs.

Applications

With a better understanding of the imaging features of PCCCL, further investigations should determine how to use imaging modalities, especially MRI, to differentiate PCCCL from CHCC or metastatic clear cell cancer. Chemical shift imaging with an MR scanner may help detect lipid component in the cytoplasm of clear cells in PCCCL.

Terminology

PCCCL is a rare variant of HCC. Due to the accumulation of large amounts of glycogen and/or lipids that are dissolved by routine histological processing (hematoxylin-eosin staining), the cytoplasm of PCCCL cells is clear. PCCCL can be diagnosed when the tumor cells are predominantly or wholly composed of clear cell cytoplasm (a proportion of clear cells > 50%). The prognosis of PCCCL is generally considered better than that of the CHCC.

Peer review

It is a well written paper, with interesting results.

Meetings

Events Calendar 2011

January 14-15, 2011
AGA Clinical Congress of
Gastroenterology and Hepatology:
Best Practices in 2011 Miami, FL
33101, United States

January 20-22, 2011
Gastrointestinal Cancers Symposium
2011, San Francisco, CA 94143,
United States

January 27-28, 2011
Falk Workshop, Liver and
Immunology, Medical University,
Franz-Josef-Strauss-Allee 11, 93053
Regensburg, Germany

January 28-29, 2011
9. Gastro Forum München, Munich,
Germany

February 4-5, 2011
13th Duesseldorf International
Endoscopy Symposium,
Duesseldorf, Germany

February 13-27, 2011
Gastroenterology: New Zealand
CME Cruise Conference, Sydney,
NSW, Australia

February 17-20, 2011
APASL 2011-The 21st Conference of
the Asian Pacific Association for the
Study of the Liver
Bangkok, Thailand

February 22, 2011-March 04, 2011
Canadian Digestive Diseases Week
2011, Vancouver, BC, Canada

February 24-26, 2011
Inflammatory Bowel Diseases
2011-6th Congress of the European
Crohn's and Colitis Organisation,
Dublin, Ireland

February 24-26, 2011
2nd International Congress on
Abdominal Obesity, Buenos Aires,
Brazil

February 24-26, 2011
International Colorectal Disease
Symposium 2011, Hong Kong, China

February 26-March 1, 2011
Canadian Digestive Diseases Week,

Westin Bayshore, Vancouver, British
Columbia, Canada

February 28-March 1, 2011
Childhood & Adolescent Obesity:
A whole-system strategic approach,
Abu Dhabi, United Arab Emirates

March 3-5, 2011
42nd Annual Topics in Internal
Medicine, Gainesville, FL 32614,
United States

March 7-11, 2011
Infectious Diseases: Adult Issues
in the Outpatient and Inpatient
Settings, Sarasota, FL 34234,
United States

March 14-17, 2011
British Society of Gastroenterology
Annual Meeting 2011, Birmingham,
England, United Kingdom

March 17-19, 2011
41. Kongress der Deutschen
Gesellschaft für Endoskopie und
Bildgebende Verfahren e.V., Munich,
Germany

March 17-20, 2011
Mayo Clinic Gastroenterology &
Hepatology 2011, Jacksonville, FL
34234, United States

March 18, 2011
UC Davis Health Informatics:
Change Management and Health
Informatics, The Keys to Health
Reform, Sacramento, CA 94143,
United States

March 25-27, 2011
MedicReS IC 2011 Good Medical
Research, Istanbul, Turkey

March 26-27, 2011
26th Annual New Treatments in
Chronic Liver Disease, San Diego,
CA 94143, United States

April 6-7, 2011
IBS-A Global Perspective, Pfister
Hotel, 424 East Wisconsin Avenue,
Milwaukee, WI 53202, United States

April 7-9, 2011
International and Interdisciplinary
Conference Excellence in Female
Surgery, Florence, Italy

April 15-16, 2011
Falk Symposium 177, Endoscopy
Live Berlin 2011 Intestinal Disease
Meeting, Stauffenbergstr. 26, 10785
Berlin, Germany

April 18-22, 2011
Pediatric Emergency Medicine:
Detection, Diagnosis and Developing
Treatment Plans, Sarasota, FL 34234,
United States

April 20-23, 2011
9th International Gastric Cancer
Congress, COEX, World Trade
Center, Samseong-dong, Gangnam-
gu, Seoul 135-731, South Korea

April 25-27, 2011

Bowel Diseases/Crohn's & Colitis
Foundation's Clinical & Research
Conference, Hollywood, FL 34234,
United States

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organizations]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *ggrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office**World Journal of Gastroenterology**

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com

Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interac-

tions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Knowledge on pancreaticobiliary reflux in normal pancreaticobiliary junction and its pathologic implications has experienced tremendous progress during the last few years. This editorial reviews the current knowledge on this condition and its pathological implications on gallbladder diseases. The following aspects were defined appropriate for discussion: (1) Evidence of carcinogenesis associated with pancreaticobiliary reflux; (2) Evidence of pancreaticobiliary reflux in normal pancreaticobiliary junction; and (3) Evidence of sphincter of Oddi (SO) dysfunction as a cause of pancreaticobiliary reflux in normal pancreaticobiliary junction. The articles reviewed were selected and classified according to five levels of evidence: Level I, meta-analysis double-blind randomized clinical trials, Level II, cohort non-blinded studies and non-randomized clinical trials, Level III, good quality case-control studies and non-randomized cohort studies, Level IV, case series and poor quality case-control studies, and Level V, case report articles and experts' opinion. Evidence levels II, III, IV and V were found to support biliary carcinogenesis associated with pancreaticobiliary reflux in normal and abnormal pancreaticobiliary junction. The same levels of evidence were found to support the common occurrence of pancreaticobiliary reflux in normal pancreaticobiliary junction, and SO dysfunction as the most plausible cause of

this condition. Although an important body of research has been published regarding pancreaticobiliary reflux in normal pancreaticobiliary junction and its clinical significance, the current evidence does not fully support what has been suggested. Studies with evidence level I have not been undertaken. This is a fascinating subject of study, and if finally supported by evidence level I, the importance of this condition will constitute a major breakthrough in biliary pathology.

Beltrán MA. Pancreaticobiliary reflux in patients with a normal pancreaticobiliary junction: Pathologic implications. *World J Gastroenterol* 2011; 17(8): 953-962 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i8/953.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i8.953>

INTRODUCTION

The reflux of pancreatic enzymes into the biliary tract has been associated with proliferative changes of the biliary epithelium, hyperplasia and carcinoma^[1-3]. This sequence of events, caused by pancreaticobiliary reflux (PBR), has been extensively studied in patients with biliary tract anomalies such as anomalous pancreaticobiliary junction and choledochal cysts^[4-19]. Recently, it has been recognized that PBR is a phenomenon occurring in normal pancreaticobiliary junction (NPBJ)^[20-29]. It has also been associated with gallbladder carcinoma^[30-38], and it has been suggested that it could play a role in gallstone formation through inflammatory changes in the gallbladder mucosa^[20,29,36]. The

pathophysiology and clinical importance of this phenomenon is now being elucidated, and attributes the occurrence of PBR to biliary tree motility disorders involving the sphincter of Oddi (SO), a theory which remains to be definitively proved^[27,29,36]. The purpose of this review is to discuss the current knowledge on PBR in NPBj and its pathologic implications.

SUBJECTS OF DISCUSSION

The following aspects were defined appropriate for discussion on the current knowledge and pathologic implications of PBR in NPBj: (1) Evidence of carcinogenesis associated with PBR; (2) Evidence of PBR in normal NPBj; and (3) Evidence of SO dysfunction as a cause of PBR in NPBj.

LEVELS OF EVIDENCE

The articles reviewed for this report were selected and classified according to five levels of evidence^[38,39]: (1) Level I, meta-analysis double-blind randomized clinical trials; (2) Level II, cohort non-blinded studies and non-randomized clinical trials; (3) Level III, good quality case-control studies and non-randomized cohort studies; (4) Level IV, case series and poor quality case-control studies; and (5) Level V, case report articles and experts' opinion.

OTHER SOURCES

In order to provide an adequate background, a PubMed search with the MeSH terms: pancreaticobiliary reflux in normal pancreaticobiliary junction and SO pathophysiology and dysfunction was performed. Articles in English language concerning pancreaticobiliary reflux in pancreaticobiliary maljunction, diagnosis and implications of a long common channel, and SO dysfunction were identified and reviewed regardless of their level of evidence.

CARCINOGENESIS ASSOCIATED WITH PANCREATICOBILIARY REFLUX: WHAT IS CURRENTLY KNOWN?

Most of the current knowledge on gallbladder carcinogenesis associated with PBR comes from studies on patients with anomalous pancreaticobiliary junction; consequently this part of the review deals with patients with gallbladder cancer and anomalous pancreaticobiliary junction. A good level of evidence has been collected on this subject and is detailed in Table 1. The reflux of pancreatic juice plays an important role in gallbladder carcinogenesis, and this fact has been recognized for more than 60 years^[2,9]. Gallbladder carcinoma associated with PBR was first described in patients with choledochal cysts^[2,4,40]. In these cases, the presence of an anomalous pancreaticobiliary junction in more than 96% of these patients^[42-46]; causes reflux of pancreatic juice into the dilated or non-

dilated cystic common bile duct and into the gallbladder, where active pancreatic enzymes concentrate leading to chronic inflammation with associated mucosal malignant changes: hyperplasia, metaplasia, dysplasia, and eventually carcinoma *in-situ* and invasive carcinoma^[6,9,12,16-19,40,43-45]. In patients with gallbladder cancer, an incidence of 8.7% to 16.7% of anomalous pancreaticobiliary maljunction has been found^[17,45]. Gallbladder carcinoma has an incidence of between 8.4% and 24.6% in patients with anomalous pancreaticobiliary junction^[14,17]. Gallbladder carcinoma has been reported to be more frequently associated with gallbladder carcinoma in pancreaticobiliary maljunction without dilatation of the biliary tract than in pancreaticobiliary maljunction with dilatation of the biliary tract, with a reported incidence ranging from 41% to 90%^[6,9,14,17,19], whereas in the dilated type the incidence is about 10%^[14]. In addition, the incidence of epithelial hyperplasia is significantly higher in gallbladders without common bile duct dilatation (91%) than in those with common bile duct dilatation (38%)^[7,19]. A plausible explanation for the differences between dilated and non-dilated common bile duct in anomalous pancreaticobiliary junction, is that refluxed pancreatic juice stagnates in the gallbladder in the non-dilated type consequently injuring the biliary mucosa, and in the case of the dilated bile duct, pancreatic juice stagnates in the dilated common bile duct injuring the ductal biliary mucosa. Pancreaticobiliary maljunction outside the duodenum causes two-way regurgitation: pancreatic juice refluxes into the bile duct, or bile regurgitates into the pancreatic duct^[44], however, pancreatic duct hydrostatic pressure is higher within the pancreatic

duct^[10,42], consequently the reflux of pancreatic juice into the common bile duct is a more frequent phenomenon^[10]. Refluxed bile, undergoes stasis in the gallbladder accumulating and causing inflammation of the mucosa which suffers multiple cellular and molecular changes finally leading to carcinoma^[6,13,15,16,47,48].

Epithelial changes

Metaplasia and hyperplasia are often found in gallbladder epithelia of patients with PBR, while they are seldom found in control epithelia^[7,14,17]. Hyperplastic and metaplastic changes in the gallbladder of these patients are commonly found^[9,17], and papillary hyperplasia, mainly low-grade hyperplasia, is commonly seen in patients with PBR, and has been associated with gallbladder cancer^[16]. However, others suggest that high-grade hyperplasia is more frequent in patients with pancreaticobiliary maljunction and a non-dilated common bile duct^[9,14]. Epithelial hyperplasia of the gallbladder is an early characteristic change of the gallbladder mucosa in patients with PBR, with an incidence ranging from 38.5% to 87%; higher than the incidence of epithelial hyperplasia in patients without PBR. Moreover, epithelial hyperplasia is more frequent in patients with non-dilated common bile duct and pancreaticobiliary maljunction (91%) than in patients with a dilated choledochus and pancreaticobiliary maljunction (38%)^[9,14]. Gallbladder carcinoma in patients with PBR is habitually found in people over 50 years-old^[36,46], more frequently in women than in men, occurring mainly in the gallbladder fundus, and with the atypia of the gallbladder epithelium becoming less marked nearest the common bile duct^[46]. The pathogenesis of epithelial hyperplasia of the gallbladder mucosa in PBR can be explained by an increased hydrostatic pressure in the biliary tract secondary to the reflux of pancreatic juice, and an increased concentration of bile cholesterol secondary to biliary stasis in the gallbladder acting as a stimulus for the development of hyperplastic epithelium^[14].

Cellular kinetics

The mixture of bile acids and pancreatic activated enzymes present in PBR contains carcinogens, which are mutagenic, and cause injury to DNA which shows aneuploid or polyploid patterns, accelerating the cell cycle of the biliary epithelium of patients with PBR^[14,17]. Other specific molecular changes demonstrated in the mucosal cells of patients with PBR related to increased cellular kinetics are: elevation of the labeling indices of bromodeoxyuridine demonstrating a significantly greater nuclear S-phase fraction; elevation of the proliferative cell nuclear antigen; elevation of Ki-67 labeling index (Ki-67LI); an increase in the mean number of argyrophilic nucleolar organizer regions per nucleus; an increase in the activity of the ornithine decarboxylase, the rate-limiting enzyme in the biosynthesis of polyamines; and increased expression of the transforming growth factor- α (TGF- α) which regulates cell proliferation^[9,14,17-19]. Of interest, was the finding of overexpression of mucin core protein (MUC1)

in hyperplastic and dysplastic epithelia of the gallbladder mucosa and carcinomatous lesions in PBR, this anomaly was found even in noncancerous epithelium reflecting an altered phenotype of epithelial cells, and suggesting that the PBR itself might be related to carcinogenesis^[9,47].

Gene mutations: K-ras, p53, and others

The prevalence of K-ras mutation ranged from 0% to 58% in gallbladder hyperplasia, and from 5% to 100% in gallbladder carcinoma in patients with PBR^[12-14,18,19]. Point mutations of the K-ras oncogene in codon 12 (specific point mutation of GGT -Gly- to GAT -Asp- transition, only found in gallbladder carcinoma with PBR), and codon 13 of exon 1 in the gallbladder epithelium have been identified^[7,9,13,14,17,19]. Gene mutations of K-ras range from 5% to 100% in invasive gallbladder carcinomas and from 15% to 73% in dysplastic gallbladder lesions associated with PBR^[13,18]. In addition, the overexpression of p53 tumor suppressor gene located on the short arm of chromosome 17 (17p) in 57.1% patients with gallbladder carcinoma has been identified^[9]. Specific point mutations were found at codons 207, 212 and 217 on exons 5 to 8 in 31% to 80% patients with gallbladder cancer and PBR^[8,9,15,17,18]; p53 overexpression or mutations have not been detected in the noncancerous hyperplastic or dysplastic region adjacent to the cancer region, these observations suggest that p53 overexpression or mutations may be related to the transition from premalignancy to malignancy in the carcinogenesis of gallbladder mucosa^[12,17-19]. However, p53 mutations have also been detected in noncancerous biliary epithelium (38.5%) in patients with PBR, supporting the involvement of p53 gene mutations in biliary epithelium carcinogenesis in PBR^[15]. Finally, loss of heterozygosity of p53 has been detected in 72% patients with gallbladder carcinoma and PBR^[8,9,15]. In patients with PBR, p53 overexpression was detected in cancer but not in hyperplasia, indicating that it may be a late event in gallbladder carcinogenesis^[9,14]. Within the gallbladder, and along the biliary tract, chronic severe inflammation from PBR destroys the protective mucin-producing epithelial cells, and this repeated process of destruction/regeneration of biliary epithelium, leads to the known sequence of hyperplasia, metaplasia, dysplasia and carcinoma^[16]. K-ras mutations and overexpression of p53, are present in malignant, precancerous dysplastic and chronically inflamed bile ducts in patients with choledochal cysts and abnormal pancreaticobiliary junction without choledochal dilatation, this suggests that the reflux of active pancreatic enzymes causes these cellular and molecular alterations and that the biliary epithelium of patients with PBR should be considered as an epithelium with high carcinogenic potential^[7,9,15,16,44]. Mutations in tumor suppressor genes p14ARF, p16INK4a, and p16INK4/CDK2 have been frequently found in gallbladder cancer in PBR, and also in PBR without gallbladder cancer^[9]. Other genetic changes described in patients with gallbladder cancer and PBR involve inactivation of the

CDKN2 gene (80%), allelic loss at 8p22 locus (44%), DCC (18q21) deletions (31%), allelic loss at 17q13 at the *TP53* gene, allelic loss at 9p21 at the *p16^{Ink4a}/CDKN2* gene, and 5q21 loss of heterozygosity near the APC gene (22%); these mutations are considered early events in the pathogenesis of gallbladder carcinoma^[18]. Overexpression of Bcl2, an inhibitor of apoptosis found in mitochondria membranes, has been found in the non-cancerous portion of gallbladders in PBR and in the gallbladder carcinoma of these patients; this was regarded as an early event causing carcinogenesis in PBR^[19,48]. Telomerase activity is increased in gallbladder cancer only in patients with PBR, but is also increased in the noncancerous gallbladder mucosa of these patients, and in the epithelia of noncancerous patients with PBR^[48]. Microsatellite instability (MSI) was detected in 80% of gallbladder cancerous lesions, in 87.5% of dysplastic lesions and 0% of hyperplastic lesions in patients with PBR, contributing to carcinogenesis in these patients^[9]. Finally, mRNA indices in metaplastic and hyperplastic gallbladder epithelia in PBR are significantly increased, signaling metaplasia and hyperplasia as precancerous lesions^[9].

Carcinogens

Some bile acid fractions such as lithocholic and deoxycholic acids, deconjugated bile acids and β -glucuronidase, and active pancreatic enzymes in bile such as amylase, lipase, trypsin, elastase I, and phospholipase A₂ promote carcinoma under conditions of infection, inflammation, bile stasis, decreased trypsin inhibitors, and the presence of enterokinase^[6,7,9,17,19]. Moreover, phospholipase A₂ hydrolyzes lecithin into lysolecithin which is harmful to the mucosal barrier injuring the cell membrane^[6,7,9,17,47]. Other secondary bile acids, mainly taurodeoxycholic acid, may play a role in carcinogenesis, although this hypothesis is not completely accepted^[9]. Also, some amino acids acting as mutagenic substances, such as glycine, tyrosine and phenylalanine, have been found in large quantities in PBR^[6,9,17].

Cytokines and growth factors

Akiyama reported high levels of serum interleukin-6 (IL-6), TGF- α , and hepatocyte growth factor in a patient with gallbladder carcinoma and pancreaticobiliary maljunction. Also high levels of IL-6 and TGF- α were found in the same patient, suggesting a relationship between these molecules and chronic inflammation of the biliary tract in PBR^[46]. Other investigators have found overexpression of TGF- α , β -catenin, cyclinD1 and COX-2 in hyperplastic gallbladder mucosa of patients with PBR^[8,9,12].

Gallbladder cancer in normal pancreaticobiliary junction

Recently, PBR in patients with NPBj has been identified and has been associated with gallbladder cancer. A good level of evidence was found in published articles dealing with this subject, and is detailed in Table 2. The first reports on patients with NPBj and PBR associated with

Table 2 Articles from "Carcinogenesis associated to pancreaticobiliary reflux: What is currently known?" – Levels of evidence in normal pancreaticobiliary junction

gallbladder cancer were almost anecdotal case reports or case series^[22,30,33,35]. The reported incidence of gallbladder cancer in reports of series of cases, ranged from 6.5% to 50%^[22,26,31,34,36]. The levels of pancreatic enzymes, mainly amylase, have been reported to be extremely high in patients with gallbladder cancer and PBR in NPBj, compared to patients with benign gallbladder diseases within the same study^[22,26,31,34,36]. Although there has been no explanation as to why amylase levels were highly elevated in these cases, a strong correlation was found between gallbladder cancer and higher levels of amylase in the gallbladder bile of patients with PBR and NPBj^[26,30,33,36]. In patients with higher amylase levels, thickening of the gallbladder mucosa was a significant manifestation, and histological examination showed a high incidence of metaplastic changes compared to patients with lower levels of amylase^[26,36,37]. Markers of increased cellular kinetics, such as Ki-67LI, were found to be highly elevated in patients with higher amylase levels compared to those with lower amylase levels in patients with gallbladder cancer^[26,36]. Moreover, studies on non-cancerous epithelium of patients with PBR and NPBj, have found an increased Ki-67LI, COX-2 expression and overexpression, and mutations of *K-ras* gene at codon 12 with an increased and statistically significant frequency in patients with higher amylase levels^[31,32]; and increased Li-67LI in patients with hyperplastic or dysplastic gallbladder epithelium without gallbladder cancer, with a higher mean Li-67LI in dysplastic epithelium compared to metaplastic epithelium^[31]. Dysplasia and hyperplasia are frequently found in patients with PBR and NPBj, the incidence has been reported to be between 46% and 50%^[31,34]; also, intestinal metaplasia has been found in 16.8% of patients with extremely high levels of amylase and NPBj^[37]. These findings suggest that besides PBR, higher levels of pancreatic enzymes in bile constitute a risk factor for gallbladder cancer, and that the sequence of hyperplasia–metaplasia–dysplasia–carcinoma seen in patients with abnormal pancreaticobiliary junction might be similar for patients with NPBj and PBR^[30–34,36]. Overexpression of *p53* gene has not been frequently found in gallbladder cancer of patients with PBR associated with NPBj^[32], while only a few articles have reported this genetic marker as positive in patients

with gallbladder cancer^[30]. This fact is in contrast with the frequent identification of *p53* abnormalities in gallbladder carcinoma of patients with pancreaticobiliary maljunction. It has been assumed that the pathophysiological changes leading to gallbladder carcinoma in patients with NPBJ and PBR parallel the pathophysiology described in studies on patients with anomalous pancreaticobiliary junction and gallbladder carcinoma^[22,31,33,34,36].

Summary

Gallbladder carcinogenesis, in patients with PBR, is a multifactorial and multistage dynamic process involving multiple genetic changes and proliferative inductions of the gallbladder mucosa induced by the reflux of active pancreatic enzymes into the biliary tree and pooling in the gallbladder lumen. After many years of investigation and multiple publications on the subject, the precise processes of gallbladder carcinogenesis secondary to PBR are not yet clear. Gallbladder cancer in anomalous pancreaticobiliary junction is associated with a non-dilated common bile tract, in which stasis of the refluxed pancreatic juice occurs in the gallbladder and causes the variety of changes previously reviewed, leading to gallbladder cancer. The pathophysiology of gallbladder cancer in NPBJ probably resembles this well-known condition.

PANCREATICOBILIARY REFLUX IN NORMAL PANCREATICOBILIARY JUNCTION: WHAT IS CURRENTLY ACCEPTED?

The reflux of pancreatic enzymes into the biliary tract and its role in gallbladder diseases has been studied since the first half of the twentieth century^[50]. However, despite some early elegant published studies^[20], PBR occurring in NPBJ has only recently become accepted^[21-24,27,29,36]. Normal pancreaticobiliary junction was defined as the union of the common bile duct and the main pancreatic duct inside the duodenal wall where the SO surrounds them with muscular fascicles which regulate the flow of bile and pancreatic juice^[50,51]. According to this definition, reflux of pancreatic juice into the biliary tract in patients with a NPBJ can only be explained by an improper functioning of the SO^[29,34,36,52]. Most studies on PBR in NPBJ have addressed the potential relationships with gallbladder cancer and have been previously discussed. In this section we will discuss other aspects referring to benign gallbladder diseases related to PBR, diagnostic methods and normal values (Table 3).

Methods employed to diagnose pancreaticobiliary reflux in normal pancreaticobiliary junction

A variety of methods has been employed to demonstrate PBR. Some investigators have used radioimmunoassay of biliary trypsin in bile samples taken directly from a T tube inserted directly into the common bile duct after sur-

gery^[20,52]. A widely used method has been the bile sample taken directly from the gallbladder at the time of cholecystectomy and pancreatic amylase and lipase determination by colorimetric or enzymatic methods^[20,23,24,29,36,53]. Many researchers have measured pancreatic enzymes in bile using samples taken directly from the bile duct in patients undergoing endoscopic retrograde cholangiopancreatography (ERCP) and analyzing the samples with enzymatic methods or Western-blotting tests^[24-28,30-34,36,54]. Others have employed magnetic resonance cholangiopancreatography (MRCP) with secretin injection to stimulate the SO to indirectly show reflux of pancreatic juice into the biliary tract^[21,22,24,25,27]. However, of these methods, the sampling of bile by ERCP seems to be an inadequate method to demonstrate PBR because in order to take the sample of bile, the SO must necessarily be disrupted, potentially causing reflux of enzymes into the bile duct and gallbladder and consequently invalidating the sample and the method. Secretin injection MRCP is an indirect and unspecific method with low sensitivity and specificity to prove PBR^[22,24], and in patients who should be submitted to surgery, it seems to be a rather unnecessary preoperative study. Taking bile samples from an indwelling T tube is probably an inadequate method to prove PBR because in order to insert the T tube, the biliary tract must have been manipulated and have suffered surgical trauma with instrumentation of the SO, consequently invalidating the method. We believe that the most accurate method to measure PBR is directly sampling the bile from the gallbladder during cholecystectomy, before any manipulation in the triangle of Calot area or over the common bile duct has been performed^[29,36].

WHICH ARE “NORMAL” LEVELS OF PANCREATIC ENZYMES IN BILE?

No one has determined and validated normal values or levels of pancreatic enzymes in bile^[1,27,36]. However, most researchers use as a reference the normal values of pancreatic enzymes in plasma to discriminate patients with PBR from those without the considered anomalous reflux of pancreatic juice into the biliary tract^[22-24,27,29,36,52,53]. The argument favoring this assumption is that any patient with bile levels of pancreatic enzymes within the normal plasma value does not have PBR, considering that the presence of pancreatic enzymes in bile within the normal plasma value depends on the normal hepatic filtration ratio which was determined at 0.30 to 0.70 for trypsin^[23,52]. In a recent investigation, we determined that patients without gallstones have minimal or no levels of pancreatic enzymes in their gallbladders^[29]. Consequently, we may argue that “normal” values of pancreatic enzymes in bile should be close to zero.

Acute cholecystitis

Anderson *et al*^[20] determined the concentration of pancreatic enzymes, amylase and lipase, in bile obtained from the gallbladder in 70 patients and found highly elevated levels of amylase in 87% cases and lipase in 66%, they concluded that the reflux of pancreatic enzymes may initiate chronic inflammatory changes in the gallbladder and could play a role in gallstone formation and in the pathogenesis of some cases of acute cholecystitis. This premise, was also followed by Josef Vracko who investigated the role of PBR in acute cholecystitis^[23,54]. Vracko *et al*^[23,54] postulated that endoscopic sphincterotomy releasing the common channel outlet obstruction could initially improve the course of acute cholecystitis in elderly patients, reducing the risk of biliary sepsis, and delaying surgery until their conditions were improved in order to undergo elective surgery at a later time and avoid emergency surgery. Pancreatic enzymes were found to be extremely elevated in patients with initial edematous acute cholecystitis compared with patients with late gangrenous cholecystitis and patients with chronic symptomatic cholelithiasis; suggesting that in some patients, acute cholecystitis could be initiated by the reflux of pancreatic enzymes into the gallbladder due to SO dysfunction or an obstructing gallstone in the papilla of Vater or both^[23]. Another interesting finding was that in patients with gangrenous cholecystitis, pancreatic enzymes were lower and comparable to patients with chronic cholecystitis; this phenomenon was explained as a consequence of the consumption of pancreatic enzymes by extensive damage of the gallbladder wall, including vascular damage, coagulation, fat necrosis, and intramural hemorrhage^[23]. Consequently, although not absolutely proven, the role of PBR in patients with acute cholecystitis might be related to a sudden functional or mechanical obstruction of the SO

leading to an excessive reflux of active injurious pancreatic enzymes into the common bile duct and gallbladder, initiating a cascade of events ultimately leading to acute cholecystitis. This theory might find its clinical application in the proposal of endoscopic sphincterotomy in the early course of acute cholecystitis within the first 72 h after the onset of symptoms, as an alternative to more invasive surgery in elderly frail patients, improving the clinical course and allowing time for conservative treatment or delayed elective surgery^[23,55].

Gallstone formation

Pancreaticobiliary reflux causes chronic inflammation and injury of the biliary tract mucosa, particularly of the gallbladder mucosa where bile concentrate and pancreatic enzymes pooling reaches high levels^[22,24,25,29,31,36]. High levels of pancreatic enzymes have been found within the whole spectrum of gallbladder diseases, benign and malignant, including acute and chronic cholecystitis, common bile duct stones, gallbladder polyps, and gallbladder cancer^[20,22,24,26,29,36,37]. This suggests that PBR has a role in the whole spectrum of gallbladder diseases^[20,24,27,29,36]. Initial and chronic inflammatory changes of the gallbladder mucosa induced by active pancreatic enzymes could play a role in gallstone formation^[20,27,29,36]. The reflux of pancreatic enzymes causes chronic inflammation of the gallbladder mucosa^[20-29,36,53,54]. Chronic inflammation of the gallbladder mucosa modifies the hepatic bile in ways other than the reabsorption of fluids and electrolytes, with the addition of total proteins such as mucin and albumin which increase the nucleation time leading to the formation of biliary sludge, microlithiasis and ultimately gallstones^[20,27,55]. It has been suggested that motility disorders of the gallbladder and biliary tree; including spastic episodes of the SO that could be influenced by gender, hormones and genetic predisposition, and associated with PBR leading to biliary tract and gallbladder mucosa chronic injury; could play a role in the etiology of gallstones, chronic gallbladder disease and ultimately gallbladder cancer, constituting only different continuous stages of a common pathologic entity^[29].

Summary

The occurrence of PBR in patients with a NPBJ seems to be a pathologic condition occurring in benign and malignant biliary diseases such as acute and chronic gallstone cholecystitis and gallbladder cancer. This reflux plays a role in acute and chronic inflammation of the gallbladder epithelium, gallstone formation, acute cholecystitis and carcinogenesis. To study PBR in normal pancreaticobiliary junction, a variety of indirect and direct methods have been employed; however, none seem to be the ideal method. A sample of bile directly from the gallbladder during surgery would be the best currently available method for this purpose. The so-called normal levels of pancreatic enzymes in bile would be close to zero.

PANCREATICOBIILIARY REFLUX IN NORMAL PANCREATICOBIILIARY JUNCTION: WHAT IS CURRENTLY SUSPECTED?”

This section will deal with the most plausible cause of PBR in patients with NPBJ (Table 4).

What is a normal pancreaticobiliary junction?

Pancreaticobiliary maljunction has been defined as a union of the pancreatic and biliary ducts which is located outside the duodenal wall forming a markedly long common channel^[56,57]. Consequently, NPBJ must, necessarily, be located inside the duodenal wall where the sphincteric mechanism provided by the muscular fascicles, of which the SO is composed, can influence the normal antegrade flow of bile and pancreatic juice.

Long common channel and its implications

A long common channel has been regarded as an intermediate variant of pancreaticobiliary maljunction, others have also named it a high confluence of pancreaticobiliary ducts^[58,59]. Some authors, argument that a long common channel is included within the SO^[27,57-60]; however, it is not plausible that this long common channel would be under the complete influence of the SO, consequently this would be the cause of PBR in these cases. Most authors agree that the normal length of the common channel generally tends to be less than 10 mm in adults and 4 mm in infants^[50,56], consequently a longer common channel should be considered an abnormal variant. However, other authors have suggested that a common channel should be considered long when it is equal or larger than 5 mm^[58]. A long common channel is not under the complete influence of the SO, no high-pressure area has been found in

the area of the common channel of the pancreaticobiliary junction in patients with anomalous pancreaticobiliary junction or a long common channel, which confirms that the SO does not fully extend to the area of the pancreaticobiliary junction in these cases^[41,60], consequently pancreaticobiliary and biliopancreatic reflux is a common occurrence^[60]. The most important clinical significance of a long common channel is that, as well as in patients with anomalous pancreaticobiliary maljunction, patients with a long common channel showed significant PBR related to gallbladder cancer^[22,58,59].

SO: Its role in pancreaticobiliary reflux in normal pancreaticobiliary junction

The human bile duct lacks a contractile muscle layer^[52]. Therefore, the flow of bile and pancreatic juice towards the duodenum is a consequence of gallbladder activity and intraductal bile and pancreatic duct pressures, which depend on the production of bile and pancreatic juice, respectively, and is regulated by the SO. The normal sphincter activity directs the flow of bile and pancreatic juice towards the duodenum by antegrade phasic contractions^[61], consequently, in patients with PBR and NPBJ, the only plausible explanation for reflux of pancreatic juice into the biliary tract is an anomaly in the normal function of the SO causing a functional obstruction to the normal flow and retrograde contractions favoring the reflux of pancreatic juice into the biliary tract^[23,27,29,34,36,52-54], because the intraluminal pressure of the pancreatic duct is higher than the intraluminal pressure of the common bile duct^[51,62,63].

SO: How it functions?

The SO is a smooth muscle structure measuring approximately 1 cm in length which is situated at the junction of the bile duct, pancreatic duct and duodenum^[51,66]. The SO normally produces high-pressure phasic antegrade contractions that are superimposed on a modest basal pressure, the phasic contractions propel small volumes of either bile or pancreatic juice into the duodenum^[51,56,65,66]. In man, most flow occurs between the phasic contractions^[51,65,66]. The SO function is influenced by a number of neural stimuli, circulating hormones such as cholecystokinin, and duodenal activity secondary to ingestion of food^[51]. During fasting, the SO demonstrates regular phasic contractile activity which alternates with the interdigestive motor activity of the duodenum^[51,65]. During duodenal phases I and II, the SO contracts at the rate of 2 to 4 contractions per minute without a quiescent phase; approaching duodenum phase III, the SO also increases its contractile activity concluding at the same time, this pattern repeats over the same period as duodenal activity^[51,65,66]. The fact that the SO continues to contract during the quiescence of duodenal phase I supports the independent nature of SO motility. This pattern of function demonstrated by the SO, supports indirectly the theory regarding the cause of PBR in NPBJ, which states that spasms of the SO not related to the migrating myo-

electric complex is the cause of this phenomenon^[23,27,36,65]. SO dysfunction is suspected clinically based on the established Rome II Diagnostic Criteria^[67,68]. To study SO dysfunction, less invasive procedures to rule-out other biliary tract conditions should be considered first, such as liver function blood tests and abdominal ultrasound^[67]. Other more specific, although non-invasive methods, such as the Morphine-Prostigmin Provocative Test or Nardi Test which has a low sensitivity and specificity, the Quantitative Hepatobiliary Scintigraphy Test which has not been fully accepted due to controversial and imprecise criteria to diagnose SO dysfunction, and Magnetic Resonance Cholangiopancreatography with secretin stimulation could also be employed^[67,68]. Other invasive methods such as endoscopic ultrasonography, intraductal ultrasonography, and endoscopic cholangiography have been used, and although they can give indirect evidence of the presence of SO dysfunction, their results are nonspecific^[67,68]. Currently, the gold standard to study and diagnose SO dysfunction is SO manometry^[51,61,62,64,66-68]. The cause of SO dysfunction is unknown at the present time; however, we suggest that this is probably due to congenital motility anomaly traits.

Summary

SO dysfunction is the most plausible cause of PBR in patients with NPBj.

CONCLUSION

Although an important body of research has been published regarding PBR in NPBj and its clinical significance, the current evidence does not fully support what has been suggested. Studies with evidence level I have not been undertaken. This is a fascinating subject of study, and if finally supported by evidence level I, the importance of PBR in NPBj will constitute a major breakthrough in biliary pathology.

Abstract

Rectovaginal fistula (RVF) continues to be the most difficult perianal manifestation of Crohn's disease to treat. This devastating and disabling complication has a significant impact on patients' quality of life and presents unique management challenges. Current therapeutic approaches include many medical therapeutics and surgical treatments with a wide range of success rates reported. However, current evidence is lacking to support any recommendation. The choice of repair depends on various patient and disease factors and basic surgical tenets. In this article, we review the current options to consider in the treatment of Crohn's-related RVF, and try to evaluate their effects on fistulae closure and quality of life.

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder with a variable clinical course that may occur anywhere in the alimentary tract, characterized by a tendency to form fistulas with adjacent structures. In addition, CD is the second most common cause of rectovaginal fistula (RVF) after obstetrical trauma. In general, the cumulative incidence of all perianal fistulas in CD is 50% after the age of 20, and up to 9% of these are RVFs. The incidence of Crohn's RVF is thought to be proportionate to the frequency and severity of large-bowel inflammation^[1,2]. Although representing less than 10% of anal fistulas, RVF may cause significant clinical distress and social embarrassment. Common symptoms include dyspareunia, perianal pain, vaginal irritation, and poor hygiene leading to recurrent genitourinary infections^[3].

Accurate assessment is essential for planning management. The treatment of fistulas is based on the severity of symptoms, the anatomic location, the number and complexity of tracts and the presence of stricturing intestinal disease. Treatment options range from observation to medical therapeutics to the need for surgical intervention. Various surgical options have been suggested for RVF repair with a wide range of success rates, such as direct repair, fistulotomy, fibrin glue instillation, endorectal or vaginal advancement flap, abdominal procedures with colorectal or coloanal anastomosis, and epiploplasty. However, none has been universally accepted as the procedure of choice. The recurrence rates ranged from 25% to 50%^[2-4]. In this article, we review the current options to consider in the treatment of Crohn's-related RVF and their effects on quality of life.

TREATMENT CHOICE

The management involves an organized and detailed workup to accurately make the diagnosis and then implement the appropriate treatment. Only a combination of advanced imaging, physical examination, and clinical experience will afford the surgeon the opportunity to precisely identify the location and cause of this problem. There are no evidence-based randomized controlled trials for the appropriate management of RVFs. More focused studies targeting these patients with the use of combined medical and surgical therapy are necessary^[1,4].

Medical treatment of Crohn's RVF

Treatment of RVF is mainly surgical. However, medical therapy does have a role in the treatment of Crohn's RVF. Over the years, attempts at healing Crohn's RVF by medical treatment have been met with failure. The principles of medical therapy have been aimed at the treatment of the underlying active disease and include the use of antibiotics, corticosteroids, immunosuppressives and infliximab.

Up to now, there have been no randomized, double-blind, placebo-controlled studies to support the use of antibiotics and corticosteroids in healing Crohn's RVF. These treatments are not favorable, with low rates of long-term symptomatic control and unacceptable high rates of recurrence. Besides, some local therapies, including warm sitz baths, antidiarrheal medications and so on, might provide minor relief from symptoms but are not curative measures^[5]. More and more surgeons used them as adjuncts to surgical treatment of Crohn's RVF, despite the lack of clinical trials to establish their efficacy.

Antibiotics were found to display only short-term benefit for patients^[6]. Some studies reported that more than 80% RVFs required complete fistula closure when cyclosporine was used in high doses intravenously. However, about one third of patients relapsed when therapy was switched from intravenous to oral. Furthermore, cyclosporine was associated with toxicity, especially nephrotoxicity in long-term therapy. Tacrolimus had a mechanism similar to cyclosporin, and preliminary reports showed fistula healing rates of up to 64% when combined with azathioprine, but further studies should be done to evaluate the efficacy^[7]. The introduction of anti-tumor necrosis- α (TNF- α) therapy has been a major advance in the treatment of fistulizing CD, and has completely altered treatment strategies for perianal disease^[8,9]. About 25 women with Crohn's RVF were enrolled in the *post hoc* subset analysis of the ACCENT II (A CD Clinical trial Evaluating infliximab in a New long-term Treatment regimen in patients with fistulizing CD). After infusions of infliximab at weeks 0, 2, and 6, 60.7% and 44.8% of RVFs were closed at weeks 10 and 14. The duration of RVF closure was longer in the infliximab 5 mg/kg maintenance group than in the placebo group. They concluded that infliximab was effective in short-term closure of RVF, and maintenance treatment was more effective than placebo in prolonging RVF closure^[10]. Parsi and his colleagues^[11] studied the differences in response to infliximab among

patients with different types of Crohn's fistulas. The total closure rate for all external Crohn's fistulas was 78%, but the closure rate for Crohn's RVF was only 14% at 4 to 6 wk follow-up. Higashi *et al.*^[12] reported that the frequency of neoplasia did not differ according to whether infliximab was used or not, but it was necessary to be careful in terms of long-term administration and to select patients in whom efficacy could be expected.

So far, medically induced fistula healing is rare with basic therapeutic approaches and is only short lived, with no challenging results of infliximab treatment for Crohn's RVF, which might due to a poorly vascularized rectovaginal septum^[4,10].

Surgical treatment of Crohn's RVF

RVF in CD continue to be a challenging problem. A multistep approach has been recommended to treat patients with Crohn's-related RVF, in which medical treatment and drainage of local sepsis are the first initial steps to alleviate their discomfort before definitive surgical intervention is attempted^[1,13,14]. Many reports believed that the presence of acute perianal sepsis needed to be separately addressed prior to any attempts to repair RVF. This may require surgical drainage accompanied by placement of a loose draining seton^[15-17]. Subsequently, various surgical options have been suggested for RVF repair. Among them are direct repair, fistulotomy, fibrin glue instillation, endorectal or vaginal advancement flap, abdominal procedures with colorectal or coloanal anastomosis, and epiplooplasty^[18-20]. There are no guidelines concerning optimal therapeutic approaches. Endoanal mobilization techniques such as the advancement flap technique were considered the therapy of choice for many years, but are now regarded ever more critically^[21,22]. Surgical skill is very important and adherence to principles of hemostasis, gentle tissue handling and complete debridement of diseased tissue are imperative to success. The technique of repair will vary depending on the location of the fistula and extent of local and distant disease activity^[23-25].

Rectal advancement flap surgery is the most frequently used approach. A flap consisting of mucosa, submucosa, and some circular muscle fibers is elevated. The fistula tract is curetted and oversewn with synthetic absorbable suture. The distal end of the flap is then trimmed and sutured distal to the fistula opening. The repair is undertaken from the high-pressure side of a high low-pressure shunt, the primary source of the fistula is excised and a layer of intact healthy tissue is interposed. Rectal advancement flaps are best suited for Crohn's RVF when the fistula is low, the rectum is relatively spared, and there is no significant anal stenosis. However, this technique is contraindicated in patients with extensive ulceration or stricturing of the anal canal and transitional zone^[26,27]. Alternative or additional surgical procedures include a rectal sleeve advancement flap and a vaginal advancement flap. An advancement sleeve flap may be a better option for those with circumferential anal canal or low rectal disease and a normal proximal rectum. This approach removes all diseased tissue in the anal canal and allows "normal"

rectal tissue to be sutured to the neodentate line^[28]. Compared with a rectal flap, a vaginal flap is easier to mobilize. Sher *et al*^[29] treated 14 patients using a transvaginal flap with excellent results, with complete healing in 13 patients. The authors believed that the success of this technique was to be attributed to the fact that they used healthy tissue from the vagina. Unfortunately no other authors have published their experience with this interesting technique and further conclusions are impossible to draw.

Tissue interposition methods were intended to interpose normal healthy tissue between suture lines and bring well-vascularized tissue into the area. The use of a gracilis muscle transplant is one of the various options and has been proposed for failed previous RVF repair. In Lefevre's study, for patients with CD, four of five (80%) presented no recurrent rectovaginal fistula after a median follow-up of 28 mo. They concluded that gracilis muscle transposition was a useful and effective method for the treatment of recurrent RVF, especially in patients with CD, providing a viable tissue flap between the rectum and the vagina. This procedure is associated with minor morbidity and a good success rate, especially in patients with CD^[30]. However, despite healing, postoperative quality of life and sexual activity remained altered. Zmora *et al*^[31] reported that the important technical features of the gracilis transposition procedure were fecal diversion, meticulous hemostasis, tension-free primary repair of the rectum after dissection and mobilization to a level of at least 3 cm above the fistula site, and a viable, tension-free, well-vascularized muscle pedicle. So they recommended it for Crohn's RVF, especially after failed previous repairs.

Advanced improvements in medical treatment and expert surgical management have decreased the need for proctectomy. However, recurrence has a major negative impact on the quality of life. The suboptimal quality of perianal tissues that are affected by CD is probably the origin of the failure to heal. As we know, adult stem cells extracted from certain tissues, such as adipose tissue, can differentiate into different tissues, such as muscle. García-Olmo *et al*^[32] first reported a case of a young patient with CD who had a recurrent rectovaginal fistula that was treated by autologous stem cell transplantation with a lipoaspirate as the source of stem cells. Three months later the RVF still remained closed. The patient has not experienced vaginal flatus or fecal incontinence through her vagina. In any case, cell transplantation to overcome healing problems is a new surgical tool, and careful evaluation of this new modality might provide an opportunity to define a new era in the treatment of surgical challenges associated with healing disorders.

Failure, reoperations and recurrences of rectovaginal fistulas have a major impact on anal continence and quality of life. The technical feasibility of closing rectovaginal fistulas using new bioprosthesis such as SurgisisTM mesh has already been demonstrated. SurgisisTM is a biocompatible mesh generated from lyophilized porcine small intestinal submucosa, which allows host cells to replace and repair damage or defective tissue. The mesh is gradually replaced as the host cells rebuild and remodel

weakened tissue. Its sterile, acellular properties enable it to be used without the complication of rejection. There is a significant reduction in fibrosis during the healing process, because the mesh supports the patient's own connective tissue and smooth muscle growth^[33]. Schwandner *et al*^[34] reported that 21 patients with RVFs were performed with mesh procedures, the majority of them had Crohn's RVFs (nine). After a mean follow-up of 12 months, the success rates in relation to the presence of CD or not were 78% and 83% after primary mesh procedure separately. Besides, the success rates of RVF with only one prior attempt or at least two prior attempts were 88% and 62% respectively. Authors believed that this technique could potentially be an effective alternative or enrichment to "traditional" procedures such as advancement flap repair as the main procedure, or closure with muscle transposition. Further analysis is needed to assess the definitive role of this innovative technique in comparison to traditional surgical technique.

Complex RVFs are uncommon but difficult therapeutic problems. Local repair and flap advancement techniques have a high incidence of recurrence with poor functional outcomes. Transperineal repair with anal sphincter reconstruction, when indicated, and placement of a Martius flap result in improved rates of repair and better functional outcomes. A consecutive series of patients were retrospectively reviewed from a prospective database between 2002 and 2006 in McNevin's study^[26]. They concluded that selected complex RVF can be reliably repaired with good functional outcomes using the Martius flap with anal sphincter reconstruction. Persistent or recurrent fecal incontinence and dyspareunia are common sequela of the underlying perineal injury and repair. However, the number of patients is small. Prospective randomized trials are lacking. Therefore, it remains questionable whether addition of a Martius flap improves outcome after rectovaginal fistula repair^[27].

The protective or definitive stoma (proximal fecal diversion) may be taken into consideration to control the symptoms before proceeding to a more definitive operation. Results are equivocal when a stoma is used in conjunction with repair of a Crohn's perianal fistula. Fecal diversion alone is not successful in healing the fistula despite an improvement of the anorectal Crohn's fistula. Stoma does not ensure success and is probably used in most complicated cases. Creating a stoma remains a controversial subject. Currently the decision to use a stoma is up to the surgeon's judgment at the time of operation with valuable results of physical and laboratory examinations.

RESULTS OF VARIOUS TREATMENTS

A retrospective study reported by Athanasiadis^[35] was concerned on a comparison of different techniques for recovery rates and functional results after repair for RVF in CD. The operations comprised 56 procedures performed in 37 women presenting with RVF. The follow-up period was 7.15 years. Several techniques were performed: transverse transperineal repair ($n = 20$), endoanal direct closure multilayer without flap ($n = 15$), anocutaneous

Table 1 Current reports for different repairs for rectovaginal fistulas with Crohn's disease

Authors	Patients/repairs	Procedure	Primary/overall healing (%)	Recurrence (%)	Follow-up (mo)
Joo <i>et al</i> ^[38] , 1998	20	RAF	-/75		17

Ruffolo <i>et al</i> ^[36] , 2009	52/71	different	56/81	10	109
	-/36	RAF	56		
	-/23	VAF	57		

RAF: Rectal advancement flap; VAF: Vaginal advancement flap.

flap ($n = 14$), and advancement mucosal or full-thickness flap ($n = 7$). The success rates for each of the techniques in the above group were 70, 73, 86, and 29%, respectively. The transperineal repair led to decreased postoperative resting pressures. In the advancement flap technique, the resting and squeezing pressure decreased significantly. The risk of developing a suture line dehiscence leading to a persisting fistula was higher in the advancement flap procedure with 43%. Authors concluded that techniques with a low degree of tissue mobilization such as the direct closure and anocutaneous flap show higher success rates without significant postoperative changes in continence and manometric outcome. Impaired continence was observed only in the advancement flap group, resulting in significant changes in manometric values and recovery rates. The authors preferred to apply the direct multilayer closure technique without flap.

The research studied by Ruffolo evaluated the outcome of surgical repair of RVF in patients with Crohn's disease over a 14-year period and assessed the effect of therapy with antibody against TNF on healing^[36]. The surgical techniques included ileocecal interposition, coloanal anastomosis, perineoproctotomy with sphincter repair, levatorplasty and closure of the fistula, rectal advancement flap and vaginal advancement flap. After initial drainage of anal sepsis and optimization of medical therapy, fistula closure was achieved in 81% of 52 patients. Overall, cumulative closure rates after the first, second, third and fourth attempts were 56, 75, 78 and 81%, respectively. The primary healing rate was similar in patients who received anti-TNF treatment before the first operation (12 of 18 patients) and those who did not (19 of 34), even though the former patients probably presented with more extensive and/or aggressive disease at some stage. This observation supports the notion that anti-TNF- α does not interfere with wound healing^[37]. Furthermore, the current reports for different repairs for rectovaginal fistulas with CD are displayed in Table 1.

Crohn's-related rectovaginal fistulae have significant impact on quality of life including sexual function. El-Gazzaz^[40] and coworkers obtained long-term follow-up of Crohn's-related rectovaginal fistulae to assess variables that influence surgical success and determine its effects on

quality of life and sexual function. Sixty-five women were identified at median follow-up of 44.6 months, of which 30 patients (46.2%) were successfully healed. Methods of repair included advancement flap ($n = 47$), episio-proctotomy ($n = 8$), colo-anal anastomosis ($n = 7$), and fibrin glue or plug ($n = 3$). Twenty-eight women (43.1%) were sexually active at follow-up, and of those, nine complained of dyspareunia, all within the unhealed group of patients. Sexual function and quality of life scores were comparable between healed and unhealed groups. They believed that healing increased when immunomodulators were used within three months before surgery. Smoking and steroids were predictors of repair failure. Regardless of successful healing, quality of life and sexual function were similar. Dyspareunia appears to be higher for women with unhealed fistulas^[41]. Further research and multicenter studies should be performed.

CONCLUSION

Crohn's-related RVF continues to be difficult to treat. Up to now, there has been no ideal treatment option suitable for all patients, and many techniques have been reported with a wide range of success. The reasonable combination of medical and surgical treatments should be recommended. The surgical management of RVF is complex and the best results come in conjunction with individualized care within specialist units. The technique should be carefully chosen depending on the anorectal morphology. Hopefully, ongoing studies will help produce a universally accepted algorithm that may enhance long-term outcomes. Further multicenter studies should be needed to evaluate the long-term effects of various approaches. Besides, the prognosis and the quality of life for affected women should not be ignored.

Abstract

AIM: To develop and validate a transient micro-elastography device to measure liver stiffness (LS) in mice.

METHODS: A novel transient micro-elastography (TME) device, dedicated to LS measurements in mice with a range of measurement from 1-170 kPa, was developed using an optimized vibration frequency of 300 Hz and a 2 mm piston. The novel probe was validated in a classical fibrosis model (CCl₄) and in a transgenic murine model of systemic amyloidosis.

RESULTS: TME could be successfully performed in control mice below the xiphoid cartilage, with a mean LS of 4.4 ± 1.3 kPa, a mean success rate of 88%, and an excellent intra-observer agreement (0.98). Treatment with CCl₄ over seven weeks drastically increased LS as compared to controls (18.2 ± 3.7 kPa vs 3.6 ± 1.2 kPa). Moreover, fibrosis stage was highly correlated with LS (Spearman coefficient = 0.88, $P < 0.01$). In the amyloidosis model, much higher LS values were obtained, reaching maximum values of > 150 kPa. LS significantly correlated with the amyloidosis index (0.93, $P < 0.0001$) and the plasma concentration of mutant hApoA-II (0.62 , $P < 0.005$).

CONCLUSION: Here, we have established the first non-invasive approach to measure LS in mice, and have successfully validated it in two murine models of high LS.

INTRODUCTION

Transient elastography (TE) (FibroScan[®]) is a novel non-invasive bedside method to assess liver fibrosis *via* liver stiffness (LS)^[1,2]. In various liver diseases, LS was shown to be strongly associated with the degree of liver fibrosis^[2-8]. In these studies, cut-off values have been defined that allow the diagnosis of advanced fibrosis (F3/4). Despite some variability, cut-off values of 8.0 and 12.5 kPa are widely accepted to identify patients with F3 and F4 fibrosis, respectively. Although LS closely correlates with fibrosis stage, it also increases in patients with mild^[9,10] or acute hepatitis^[11], cholestasis^[12], and liver congestion^[13], independently of the degree of fibrosis. Thus, improved diagnostic algorithms require the exclusion of congestion and mechanic cholestasis by ultrasound and measurement of liver function tests prior to LS interpretation^[2].

Despite major efforts worldwide, the molecular mechanisms of liver fibrosis are still poorly understood^[14]. The appreciation of LS as physical parameter has not only improved fibrosis diagnosis, but has also stimulated our understanding of its pathophysiology. Thus, LS seems to directly affect matrix synthesis^[15] and precedes fibrosis progression^[16]. Two recent reports have highlighted the importance of hydrostatic pressure on LS^[12,13], leading to the formulation of the pressure-LS-fibrosis sequence hypothesis^[2]. However, no non-invasive and routinely exploitable methods exist to assess LS in mice, which is the standard animal model for studying fibrosis^[17] and antifibrotic strategies^[18].

Elastographic techniques seem to be the most promising approach to assess tissue stiffness *in vivo*. Although magnetic resonance elastography (MRE)^[19] has been successfully applied to quantify LS in rodents^[20,21], this technique sometimes requires the insertion of a needle to transmit a vibration to the liver^[20]. In addition, MRE techniques remain very expensive, limiting their routine use in animal laboratories. Likewise, alternative techniques, such as ultrasonic static elastography^[22], are restricted to *in vitro* or *in situ* studies in mice^[23], and they are not quantitative^[24]. Recently, acoustic radiation force impulse (ARFI) imaging^[25] has been successfully applied to quantify LS in a rat model of toxic liver fibrosis induced by carbon tetrachloride (CCl₄) injections^[26]. However, the probe had to be coupled to the rat's abdomen through a water-path and a layer of saran wrap. Alternative approaches, such as elasticity and atomic force microscopy^[15,27,28], yield stiffness values at the cellular level; however, how subcellular

stiffness parameters translate into overall organ stiffness and fibrogenesis remains under discussion. Finally, a direct rheological technique only allows the measurement of LS on the explanted organ *ex vivo*^[16].

Here, we introduce a novel miniaturized probe, based on the principle of vibration-controlled transient elastography. Significant changes in the physical parameters, such as vibration frequency, are required because of the small size of the murine liver. We demonstrate that the novel transient micro-elastography (TME) device reproducibly allows the measurement of LS in mice. We successfully validated the technique in two murine models of increased LS: the conventional CCl₄-induced fibrosis model and a transgenic model of systemic amyloidosis.

MATERIALS AND METHODS

Phantoms for stiffness measurements

A homogeneous copolymer-in-oil phantom, comprising Styrene-Ethylene-Butylene-Styrene (4%) and mineral oil, was used to compare the results obtained using TE and TME, as described recently^[29].

Animal models

Carbon tetrachloride fibrosis model: Toxic liver fibrosis was induced by carbon tetrachloride (CCl₄) injections over seven weeks, according to standard protocols (Sigma Aldrich, St. Louis, MO, USA)^[30]. Nine female CD1 mice were divided into three groups (Table 1): the first group ($n = 3$, aged 6 mo) received toxic injections (CCl₄, 5 mL/kg dissolved in paraffin oil, ratio 1:10), the second group ($n = 3$, aged 16 mo) received paraffin oil, and the third group ($n = 3$, aged 4 mo) was not treated. Intraperitoneal injections of CCl₄ or paraffin oil were performed twice a week over seven weeks. For LS measurements, mice were first anaesthetized with isoflurane (0.75%-1% in oxygen).

Mouse model of systemic amyloidosis: Transgenic mice with systemic amyloidosis were generated at the Cordeliers Research Center (UMRS 872, Paris, France) by microinjection of the 3-kilobase genomic clone of the human apolipoprotein A-II (hapoA-II) gene, bearing a stop codon serine mutation. In humans, this mutation results in a longer amyloidogenic protein^[31]. Normal apolipoprotein A-II (apoA-II) is a major protein of high-density lipoproteins, and its plasma concentration is measured by immunonephelometry using a commercial kit (DiaSys, Holzheim, Germany). Three transgenic lines (Y, K and F) with very low, moderate, and high expression levels, respectively, of mutant hapoA-II were obtained (X. Rousset, M. Lacasa, A.D. Kalopissis and M. Chabert, manuscript in preparation). Twenty-seven transgenic mice (9 Y, 8 K, and 10 F), aged between 4 and 12 mo, were included in the study (Table 2). This group comprised 13 males and 14 females (Table 2). Furthermore, four male C57BL/6 mice aged 4 mo were kept as controls (Table 1). The animals were anesthetized by intraperitoneal injection of avertin (tribromoethanol, 2% solution), and LS measurements were performed. Mice were then sacrificed to evaluate the stage of amyloidosis.

LSM: Liver stiffness measurement ; ND: Not determined.

The livers of 19 mice were removed and weighed. Animal use procedures were in accordance with the recommendations of the European Economic Community (86/609/CEE) and the French National Committee (decree 87/848) for the care and use of laboratory animals.

Amyloidosis staging

To determine the stage of amyloidosis, mice were sacrificed and their livers were subjected to macroscopic examination. Several parameters were considered, including the size of the liver, its apparent rigidity, and modifications of the lobes, such as hypertrophy, and included in an empirically established score from 0 to 4 (Table 3). Representative livers of a normal mouse and an amyloidosis mouse stage 3 are shown in Figure 1. All examinations were performed by M.C. in a blinded fashion, without knowledge of the TME data.

Histological analysis

Immediately after stiffness measurements, transgenic mice with amyloidosis were sacrificed for histological analysis. Their livers were quickly removed after intra-cardiac vascular washing with 0.1 mol/L phosphate buffer and then with 4% paraformaldehyde (PFA). The livers were then cut and immersion-fixed, successively, in 4% PFA and then in sucrose overnight. Small livers pieces were embedded in Tissue-Tek O.C.T. compound 4583 (Sakura Finetek, Torrance, CA, USA), frozen and stored at -80°C until analysis. Tissue sections of 20 µm were specifically stained for amyloidosis with Congo red. Amyloid fibrils consisted solely of hApoA-II; therefore, 5 µm thick liver sections were immunostained with a hApoA-II specific antibody and examined with an LSM-710 laser scanning confocal microscope (Carl Zeiss, Inc., Thornwood, NY, USA).

Livers of mice with toxic liver fibrosis were harvested, fixed in 4% neutral-buffered formalin, and embedded in paraffin. 5 µm thick sections were stained with hematoxylin and eosin (HE) or with picosirius red (Sigma Aldrich, St. Louis, MO, USA), as previously described^[32]. For morpho-

Figure 1 Representative livers from normal control mice (A), and mice with stage 3 amyloidosis (B).

metric analysis, 15 images per animal from at least two different lobes were taken at × 100 magnification. The areas of staining were quantitated using the software Image J 1.37v (National Institutes of Health, Bethesda, MD, USA). The histological results provided by the analysis of these 15 images are more reliable and representative than a mere biopsy.

Transient micro-elastography

TE measures shear wave velocity, and thus determines tissue stiffness using ultrasound to follow the propagation of a low frequency shear wave generated in a tissue by an external vibrator^[33,34]. In humans, TE uses a low frequency vibration of 50 Hz generated by an ultrasonic transducer 9 mm in diameter used as a piston. However, shear stiffness can be overestimated in the near field zone (i.e. under 25 mm for a 50 Hz excitation) because of diffraction effects^[35]. Due to the morphology of mice, measurements have to be performed very close to the vibration source, where diffraction effects are likely to occur. Our modified TME device allows the measurement of elasticity near the probe and is suitable for contact measurements of stiffness at the organ surface. TME comprises a microprobe, a high frequency electronic system (Echosens, Paris, France), and a laptop computer to control the ultrasound system and analyze the data. The microprobe contains an ultrasonic transducer (Imasonic, Besançon, France), used as both the receiver and emitter, which is mounted on a mechanical vibrator to generate a low frequency shear wave. The electronic system is fully programmable, and enables sampling of the radiofrequency data at a frequency up to 200 MHz with a 12-bit precision. Diffraction effects were reduced by increasing the frequency of vibra-

Table 3 Macroscopic liver amyloidosis index obtained by visual assessment and manual palpation

Index	Liver appearance
0	Normal
1	Slightly bigger and/or stiffer
2	Big and stiff (\pm whitish zones)
3	Very big and stiff, changes in the right lobe (\pm whitish zones)
4	Very big and stiff, right lobe transformed and very big (\pm whitish zones)

tion to 300 Hz and reducing the diameter of the piston (2 mm). To improve the performance of TME in mice, we also increased the ultrasound frequency (up to 12 MHz). These parameters allowed the calculation of displacements with better resolution. During the propagation of the low frequency shear wave, the radiofrequency (RF) data were acquired at a repetition frequency of 15000 Hz. The displacements induced in the medium were computed from the RF data using an autocorrelation method and derived *vs* depth to provide a strain image (Figure 2). Analysis of the strain image yields the shear wave velocity and thus elasticity, according to the formula $E = 3\rho V_s^2$ where E , ρ (1 kg/dm³), and V_s are the Young's modulus, the mass density, and the shear wave velocity, respectively. To compute the shear wave velocity, we used a time-of-flight algorithm, as previously described by Sandrin *et al*^[1]. The system enables the measurement of stiffness values (Young's modulus) between 0.5 kPa and 170 kPa. How-

Figure 2 Amplitude of the strains induced in the liver of a mouse with systemic amyloidosis (stage 1), as a function of depth and time. The shear wave velocity (V_s) is the slope of the wave pattern. The steeper the slope, the higher the velocity of the shear wave and the higher the Young's modulus (here $E = 79.3$ kPa).

ever, for high stiffness values (> 100 kPa), the computational step is larger and the measurement less accurate.

Liver stiffness measurement using TME

Anesthetized mice were placed in the spinal position. Abdominal hair was removed and gel was used to ensure the coupling. The best location for LS measurement was below the level of the xiphoid cartilage (Figure 3). We identified some conditions that could limit successful TME measure-

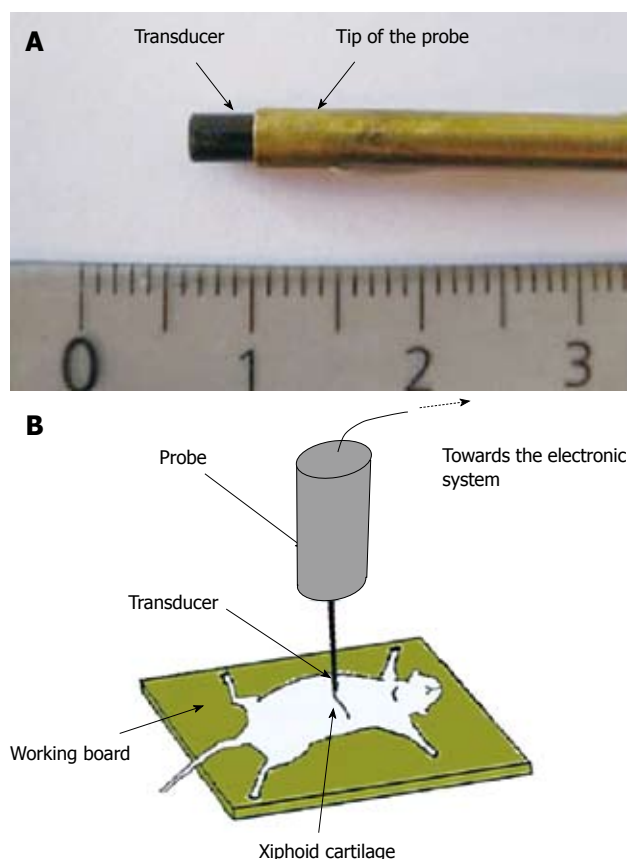

Figure 3 Transducer (A) and experimental setup (B) used in transient micro-elastography.

ments (very small mice, or mice with highly hypertrophic and misshapen livers, as in advanced amyloidosis). Measurements were routinely performed in the median liver lobe, between 2 mm and 5-6 mm below the skin surface, depending on the size of the animal. For each LS value, we performed at least 10 validated measurements, and used the median of the values recorded. The approximate duration of the examination was generally five minutes.

Statistical analysis

The relationship between LS and histology was investigated by computing p-values for the Spearman coefficient, and using Kruskal-Wallis nonparametric one-way analysis of variance (ANOVA) and one-sided Mann-Whitney tests. These nonparametric tests are particularly well suited to analyze data from small samples. Correlations with p-values less than 0.05 were considered significant. Bar plots were also used to estimate the stiffness distribution as a function of amyloidosis index. Intra-observer agreement was analyzed using the intraclass correlation coefficient (ICC). All statistical analyses were carried out using Matlab (The MathWorks, Natick, MA, USA).

RESULTS

TME studies on intra-observer agreement and reproducibility

A homogenous copolymer-in-oil phantom with a defined

Figure 4 Bar plot showing median liver stiffness in control (untreated vs oil-treated) and CCl₄-induced fibrosis. Liver stiffness is expressed in kPa. Whiskers indicate the extent of the data. The difference between the groups is significant (*P ≤ 0.05, Mann-Whitney).

stiffness was used to establish and compare TME with TE. In TE, the Young's modulus was measured in a region of interest (ROI) located between 25 and 65 mm from the source, whereas with TME, the ROI was located between 2 and 6 mm. TME yielded a slightly higher, but comparable, Young's modulus of 9.9 ± 0.3 kPa as compared to TE (8.2 ± 0.0 kPa). To evaluate the intra-observer agreement, we performed two consecutive series of 10 valid measurements in seven control mice (Table 1) and twelve transgenic mice exhibiting different amyloidosis stages (Table 2). Then, we computed the ICC, which was 0.98. In healthy control mice ($n = 7$), mean LS was comparable to human LS, at 4.4 ± 1.3 kPa. The mean success rate was 88%. Thus, we concluded that, using a vibration frequency of 300 Hz, TME allows for non-invasive and reproducible measurements of LS in mice over a wider stiffness range.

TME in a conventional fibrosis model

We next studied LS in a conventional fibrosis model using CCl₄ injections over seven weeks. Two controls were used (paraffin oil without CCl₄ and untreated controls). Fibrosis was assessed by picrosirius red staining, and stained areas were quantified (Table 1). As expected, fibrotic scars were only detected within the parenchyma of the CCl₄-treated mice, forming bridges between vessels with a very faint inflammatory reaction (not shown). TME showed a significantly higher LS (P -value ≤ 0.05) in the experimental CCl₄-treated group ($E = 18.2 \pm 3.7$ kPa) compared to oil-injected mice ($E = 6.8 \pm 2.2$ kPa) or control mice ($E = 3.6 \pm 1.2$ kPa) (Figure 4). A high correlation was also obtained between LS and CCl₄-induced liver fibrosis, as assessed by picrosirius red staining (Spearman coefficient = 0.88, $P < 0.01$).

TME in a systemic amyloidosis model

Hepatic amyloidosis is known to cause increased LS in humans^[36,37]. We therefore studied LS in a recently established murine amyloidosis model using TME. Amyloid deposits were detected in the livers of 6-mo-old transgenic mice by green birefringence in Congo red stained sections under a polarized microscope (Figure 5A and B).

Figure 5 Histological characterization of amyloidosis mice. Light microscopy of a liver section from a 6-mo-old K mouse stained with Congo red (A) and the same section under polarized light showing green birefringence (B); Confocal microscopy of liver sections with immunolocalization of mutant hapoA-II using an anti hapoA-II antibody and CY2 as the secondary antibody (green fluorescence): Control mouse, 8 mo old (C); K mouse, 2 mo old (D); K mouse, 6 mo old (E); F mouse, 8 mo old (F).

Figures 5C-F display liver sections immunostained with a specific anti-hapoA-II antibody (green fluorescence in confocal microscopy) detecting mutant hapoA-II forming amyloid fibrils. Amyloidosis was absent in a control C57BL/6 mouse (Figure 5C), and drastically increased in transgenic mice as a function of age (Figure 5D-F). Figure 6 shows bar plots of LS as a function of amyloidosis index. LS significantly correlated with the amyloidosis index established by macroscopic examination (Spearman coefficient = 0.93, P -value < 0.0001). Interestingly, significant differences in LS were observed between degrees of amyloidosis, and TME was able to clearly discriminate between amyloidosis indexes 0 and 1 (P -value < 0.005). Mice with amyloidosis indexes 3 and 4 exhibited very high stiffness values, very close to the upper detection limit of 170 kPa (Table 2); thus explaining the lack of discrimination between these two indexes by LS measurements. We also found a significant correlation between LS and the ratio of liver weight to body weight (Spearman coefficient = 0.84, P -value < 0.0001), which increases with the progression of the disease because of the progressive deposition of amyloid fibrils in the liver. In addition, the plasma concentration of mutant hapoA-II partly accounts for LS values (Spearman coefficient = 0.62, P -value < 0.005).

DISCUSSION

We here introduce TME for the assessment of LS in mice in a rapid and non-invasive manner. In addition, we successfully studied LS and validated TME in two mouse

Figure 6 Bar plot showing median liver stiffness as a function of amyloidosis severity. Liver stiffness is expressed in kPa, and amyloidosis severity is given according to the scoring system described in Materials and Methods. Whiskers indicate the extent of the data. The difference between index 0, 1, 2, and 3 is significant (aP < 0.005 and bP < 0.01; Mann-Whitney).

models with increased LS. With a success rate of 88% and an intra-observer variability of 0.98, TME offers the first approach to study LS in small animal models, a prerequisite condition for determining the role of LS in murine fibrosis models.

Interestingly, LS values of control mice (4.4 ± 1.3 kPa) were comparable to those of healthy humans, which should be below 6 kPa^[2]. These LS values are also consistent with those found in rodents using other techniques such as MRE or ARFI^[20,21,26]. These findings emphasize

that normal LS seems to be below 6 kPa, which is independent of liver size.

The investigation performed on mice with CCl₄-induced fibrosis showed the potential of TME for fibrosis quantification in mice. After seven weeks of fibrosis induction, LS had increased to 18.2 ± 3.7 kPa in all livers with a proven cirrhosis stage. Thus, murine LS had clearly passed typical cut-off values for F4 cirrhosis (12.5 kPa). The increase of LS in the CCl₄ model was also in good agreement with the recently reported storage shear modulus determined on explanted non-perfused livers^[16]. Previous MRE and ARFI studies reported much smaller LS values for fibrotic livers, using either CCl₄-induced fibrosis or knock-out models^[20,21,26]. However, the degree of fibrosis is known to vary considerably in the CCl₄ fibrosis model and significantly depends on the species used. Thus, LS of 5.4 and 6.9 kPa have been reported recently in CCl₄ rat models^[21,26], with a very small difference between control and treatment groups of less than 1.5 kPa. We observed a slightly higher LS in the control mice treated with the CCl₄ carrier solvent paraffin oil (6.8 ± 2.2 kPa), as compared to untreated mice (3.6 ± 1.2 kPa). This was most likely due to the older age (12 mo) of the oil-injected group: age has been recognized as factor that independently increases LS in humans^[38,39].

It has been recently demonstrated in humans that hepatic amyloidosis can drastically increase LS up to the detection limit of TE^[36,37]. Here, we reproduced these data in a transgenic murine model of amyloidosis using TME and showed significant correlation between histological and serum markers of amyloidosis. Thus, in contrast to visual assessment and manual palpation, TME allowed the detection of the early stage 1 of the disease. LS also significantly correlated with the amyloidosis index and plasma concentrations of mutant hApoA-II. Comparable to humans, amyloidosis showed the highest LS values reported so far in rodents, significantly exceeding 75 kPa.

In conclusion, TME allows the measurement of LS in mice in a fast, reproducible, and non-invasive manner. TME will be a powerful tool for studying fibrosis in murine models, and in transgenic and knock out mice in longitudinal studies. It will help in the better understanding of the determinants of LS, such as venous pressure^[13] or extrahepatic cholestasis^[12]. Finally, TME will also permit the exploration of anti-fibrotic strategies.

COMMENTS

Background

Transient elastography is a quantitative ultrasound elastography technique, which consists of following with ultrasound the propagation of a low frequency shear wave generated in a tissue by an external vibrator. Based on transient elastography, Fibroscan® (Echosens, Paris, France) is a novel non-invasive bedside method to assess liver fibrosis by measuring liver stiffness. This technique provides an average value of the Young's modulus in a region of interest, comprising an area between 25 and 65 mm below the skin. This device is non-invasive, fully automatic, and generates a result within a few minutes. Its main advantages are its ease of use, good reproducibility, and very good acceptance by patients. Clinical interest in liver stiffness measurement using Fibroscan® has been largely validated for adult patients with chronic liver diseases.

Research frontiers

Over the past decades, the mouse has emerged as one of the best model

organisms for experimental studies of human diseases and drug testing. For example, in liver pathologies, mice have been used in numerous investigations involving antifibrogenic substances. However, no non-invasive and routinely exploitable methods exist to assess liver stiffness in mice.

Innovations and breakthroughs

In the area of small animal experimentation, the use of elastographic techniques has been reported by several groups with magnetic resonance elastography (MRE) and static ultrasound elastography. However, the techniques proposed remain expensive (MRE) and are sometimes invasive and unsuitable for *in vivo* applications. The use of elastographic techniques on small animals is therefore a challenging area of investigation.

Applications

In this study, a novel transient micro-elastography (TME) device dedicated to liver stiffness (LS) measurements in mice was developed. The novel system was validated in both a classical fibrosis model (CCl₄) and a transgenic murine model of systemic amyloidosis. TME could be successfully performed in control mice below the xiphoid cartilage, with a mean LS of 4.4 ± 1.3 kPa, a mean success rate of 88%, and an excellent intra-observer agreement (0.98). Treatment with CCl₄ over seven weeks drastically increased LS as compared to controls (18.2 ± 3.7 kPa vs 3.6 ± 1.2 kPa). Moreover, fibrosis stage highly correlated with LS (Spearman coefficient = 0.88, $P < 0.01$). In the amyloidosis model, much higher LS values were obtained, reaching maximum values of > 150 kPa. LS significantly correlated with the amyloidosis index (0.93, $P < 0.0001$) and the plasma concentration of mutant hApoA-II (0.62, $P < 0.005$). Transient micro-elastography should make it possible to measure the evolution of pathologies such as fibrosis, in the same animal during longitudinal studies. Thus, TME could be a valuable non-invasive tool to assess the evolution of disease as a function of time and the response to treatment of fibrosis in *in vivo* murine models without proceeding to euthanasia.

Terminology

Elastography is a technique used to measure the elasticity of biological tissues. It has been introduced as a novel diagnostic tool in oncology and hepatology. Amyloidoses are a group of β -structure protein deposition diseases. Liver, kidney, spleen, heart, joints, muscles, and gastrointestinal tract are usually involved in the systemic forms of amyloidosis.

Peer review

This study is of interest because it introduces a method for successfully measuring liver stiffness in mice. Unlike previous methods, this method is noninvasive and quantitative. The method is illustrated in a model of CCl₄ induced liver fibrosis and also in an amyloidosis model.

Abstract

AIM: To investigate the anti-inflammatory effects of cinnamon extract and elucidate its mechanisms for targeting the function of antigen presenting cells.

METHODS: Cinnamon extract was used to treat murine macrophage cell line (Raw 264.7), mouse primary antigen-presenting cells (APCs, MHCII⁺) and CD11c⁺

dendritic cells to analyze the effects of cinnamon extract on APC function. The mechanisms of action of cinnamon extract on APCs were investigated by analyzing cytokine production, and expression of MHC antigens and co-stimulatory molecules by quantitative real-time PCR and flow cytometry. In addition, the effect of cinnamon extract on antigen presentation capacity and APC-dependent T-cell differentiation were analyzed by [³H]-thymidine incorporation and cytokine analysis, respectively. To confirm the anti-inflammatory effects of cinnamon extract *in vivo*, cinnamon or PBS was orally administered to mice for 20 d followed by induction of experimental colitis with 2,4,6 trinitrobenzenesulfonic acid. The protective effects of cinnamon extract against experimental colitis were measured by checking clinical symptoms, histological analysis and cytokine expression profiles in inflamed tissue.

RESULTS: Treatment with cinnamon extract inhibited maturation of MHCII⁺ APCs or CD11c⁺ dendritic cells (DCs) by suppressing expression of co-stimulatory molecules (B7.1, B7.2, ICOS-L), MHCII and cyclooxygenase (COX)-2. Cinnamon extract induced regulatory DCs (rDCs) that produce low levels of pro-inflammatory cytokines [interleukin (IL)-1 β , IL-6, IL-12, interferon (IFN)- γ and tumor necrosis factor (TNF)- α] while expressing high levels of immunoregulatory cytokines (IL-10 and transforming growth factor- β). In addition, rDCs generated by cinnamon extract inhibited APC-dependent T-cell proliferation, and converted CD4⁺ T cells into IL-10^{high} CD4⁺ T cells. Furthermore, oral administration of cinnamon extract inhibited development and progression of intestinal colitis by inhibiting expression of COX-2 and pro-inflammatory cytokines (IL-1 β , IFN- γ and TNF- α), while enhancing IL-10 levels.

CONCLUSION: Our study suggests the potential of cinnamon extract as an anti-inflammatory agent by targeting the generation of regulatory APCs and IL-10⁺ regulatory T cells.

INTRODUCTION

Oriental herbal medicines have been used for the treatment of various types of diseases for thousands of years^[1,2]. Herbal medicines have immunomodulatory effects through diverse mechanisms of action. They can enhance immunity and induce tolerance in specific disease conditions^[3,4]. For example, curcumin derived from *Curcuma longa* has potent anti-inflammatory activities by inhibiting nuclear factor- κ B activation and blocking interleukin (IL)-12 signaling^[5-7]. Andrographolide from *Andrographis paniculata* and herbkinase have potent immunostimulatory activities. They increase lymphocyte proliferation, production of pro-inflammatory cytokines, and the humoral response^[8-10].

Among many herbal medicines, *Cinnamomum cassia* bark is the outer skin of an evergreen tall tree belonging to the family *Lauraceae*. Cinnamon contains various active components including cinnamic aldehyde, cinnamyl aldehyde, tannin, mucus and carbohydrates. Previous studies have shown diverse biological functions of cinnamon extract such as antioxidant, antimicrobial and antidiabetic effects^[11-16]. It also has potent anti-inflammatory properties by inhibiting the production of NO, cyclooxygenase (COX)-2 and prostaglandin (PG)E2 in macrophage cell lines^[17,18]. However, it is still unclear how cinnamon modulates the function of immune cells, especially *in vivo*.

Antigen-presenting cells (APCs) process and present antigens on MHC molecules, and play pivotal roles in regulation of diverse immune responses. They can potentiate active immunity against pathogens while inducing immunotolerance to unharmed or self-antigens^[19]. Recently, many studies have suggested the important role of APCs for induction of immunotolerance by inducing regulatory T cells and desensitization of effector T cells^[20-22]. Regulatory APCs have potent therapeutic possibility to suppress various types of inflammatory immune disorders^[20,23,24]. Among the APCs, regulatory dendritic cells (rDCs) have potent anti-inflammatory activities through

diverse mechanisms of action. These include production of anti-inflammatory cytokines, induction of active cell death of effector T cells, inhibition of T-cell proliferation, and high level expression of indoleamine 2,3-dioxygenase (iDO)^[20]. These immunomodulatory properties of rDCs induce regulatory T cells through cell to cell contact^[23]. The potent anti-inflammatory properties of rDCs have been employed to treat several types of immune disorders including graft rejection, graft-versus-host disease and autoimmune disorders^[24]. Hence, development of immunomodulators to enhance generation of rDCs could be a good strategy for the treatment of diverse inflammatory immune disorders.

In the present study, we evaluated the effects of cinnamon extract on modulation of effector function of APCs *in vitro* and *in vivo*. Treatment with cinnamon extract enhanced generation of rDCs that inhibited APC-dependent T-cell proliferation, and converted CD4⁺ T cells into IL-10^{high} CD4⁺ T cells. Moreover, oral administration of cinnamon extract significantly suppressed experimental colitis by inhibiting expression of pro-inflammatory cytokines while enhancing IL-10 levels.

MATERIALS AND METHODS

Animals

Male C57BL/6 mice (6-8 wk old) and Do11.10 mice were purchased from SLC (Japan) or Jackson Laboratory (Bar Harbor, ME, USA), respectively. They were maintained under specific pathogen-free conditions in an animal facility at the Gwangju Institute of Science and Technology (GIST). All of the animal experiments were approved by the GIST Animal Care and Use Committee.

Preparation of cinnamon extract

Dried *Cinnamomum cassia* bark (Hwajin Distribution Co., Seoul, Korea) was pulverized and extracted in hot water for 3 h in a hot water extractor. The extract was filtered and the supernatant was concentrated with a rotary evaporator. The extract was then freeze-dried, resulting in a powder extract. The powder extract was suspended in sterilized distilled water at the appropriate concentrations. As we reported in our previous work^[25], HPLC analysis was performed by comparing the levels of trans-cinnamic acid (Sigma, St Louis, MO, USA) and cinnamic aldehyde (kindly provided by Dr. Ehren, Germany) as known standard markers for the quality control of composition of cinnamon extract in each experiment^[25]. Chromatography was carried out using 1% acetic acid (H₂O)/methanol (50:50 v/v) at room temperature on a Phenomenex Luna 5u C₁₈, 10-nm pore size, 250 × 4.60 mm I.D. column. The flow rate of the mobile phase was 2 mL/min. The amount of trans-cinnamic acid and cinnamic aldehyde was about 2.9 mg/g and 7.9 mg/g in each extract, respectively^[25].

Cell lines

Raw 264.7 cells were obtained from the Korean Cell Line

Bank (Seoul National University, Korea) and maintained in Dulbecco's Modified Eagle's Medium supplemented with 10% fetal bovine serum (Hyclone Laboratories, Logan, UT, USA), 100 U/mL penicillin (Sigma) and 100 U/mL streptomycin (Sigma). Cells were cultured with 0.2 mg/mL cinnamon extract for 24 h and harvested for further analysis.

RNA isolation, cDNA synthesis, quantitative RT-PCR

Total RNA was prepared using TRI Reagent (Molecular Research Center) according to the manufacturer's protocol. For reverse transcription, cDNA was generated using 1 µg total RNA, oligo(dT) primer (Promega, Madison, WI, USA) and Improm-II Reverse Transcriptase (Promega) in a total volume of 20 µL. One microliter of cDNA was amplified using the following RT-PCR primer sets: IL-1β (Forward 5'-GCAACTGTTCTGAACTCAACT-3', Reverse 5'-ATCTTTTGGGGTCCGTCAACT-3'), IL-2 (Forward 5'-CCTGAGCAGGATGGAGAATTACA-3' and Reverse 5'-TCCAGAACATGCCGCAGAG-3'), IL-4 (Forward 5'-ACAGGAGAAGGGACGCCAT-3' and Reverse 5'-GAAGCCCTACAGACGAGCTCA-3'), IL-6 (Forward 5'-GAGGATACCACTCCCAACAGACC-3' and Reverse 5'-AAGTGCATCATCATCGTTGTTC-3'), IL-10 (Forward 5'-ATAACTGCACCCACTTCCCA-3' and Reverse 5'-TCATTTCCGATAAGGCTTGG-3'), IL-12 p40 (Forward 5'-GGAAGCACGGCAGCAGAATA-3' and Reverse 5'-AACTTGAGGGAGAAGTAGGAATGG-3'), IL-17A (Forward 5'-TTCATCTGTGTCTCTGATGCT-3' and Reverse 5'-TTGACCTTCACATCTCTGGAG-3'), interferon (IFN)-γ (Forward 5'-TCAAGTGGCATAGATGTGGAAGAA-3' and Reverse 5'-TGGCTCTGCAGGATTTTCATG-3'), tumor necrosis factor (TNF)-α (Forward 5'-CATCTTCTCAAAATTCGAGTGACAA-3' and Reverse 5'-TGGGAGTAGACAAGGTACAACCC-3'), transforming growth factor (TGF)-β (Forward 5'-GAAGGCAGAGTTTCAGGGTCTT-3' and Reverse 5'-GGTTCCTGTCTTTGTGGTGAA-3'), HPRT (Forward 5'-TTATGGACAGGACTGAAAGAC-3' and Reverse 5'-GCTTTAATGTAATCCAGCAGGT-3'), B7.1 (Forward 5'-ACCCCAACATAACTGAGTCT-3' and Reverse 5'-TTCCAACCAAGAGAAGCGAGG-3'), B7.2 (Forward 5'-TGTTTCCGTGGAGACGCAAG-3' and Reverse 5'-CAGCTCACTCAGGCTTATGTTTT-3'), B7-DC (Forward 5'-GTGCGATTTTGACCGCAGAG-3', Reverse 5'-CTAGGGATGTGGAACAAAGCC-3'), MHCII (Forward 5'-CACCTCTCGTCTGTTCGGTGAC-3' and Reverse 5'-CCTCTCCCTGATGAGGGGTC-3'), ICOSL (Forward 5'-GACTGAAGTCCGGTGCAATGGT-3' and Reverse 5'-TGGGTTTTTCGATTTGCCAATAGA-3') and PD1L (Forward 5'-ATGCTGCCCTTCAGATCACAG-3' and Reverse 5'-TGTTGATTTTGCGGTATGGG-3').

Immunoblotting

Proteins were resolved by 10% SDS-PAGE, transferred onto PVDF membranes (Bio-Rad) and subjected to Western blotting analysis using anti-Cox-2 (Cayman) and peroxidase-conjugated secondary antibodies (DAKO). Proteins

were visualized with a chemiluminescence kit (Amersham Bioscience). β-tubulin antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) was used as a loading control.

TNBS-induced colitis model

Induction of experimental inflammatory bowel disease (IBD) was carried out as described previously with minor modification^[26]. To induce colitis, 1 mg TNBS in 50% ethanol was injected to slightly anesthetized mice through a catheter inserted into the rectum; 100 µL TNBS-ethanol mixture was carefully poured into the colon. The subsequent course of colitis was evaluated by assessing mortality, body weight decrease, and macroscopic and microscopic observations.

Macroscopic and histological evaluation of colitis

The intestines were removed from mice and evaluated as previously described (Marceau *et al.*, 2004). For histological scoring, intestines were fixed with 4% paraformaldehyde in PBS and embedded in paraffin. Paraffin sections were stained with hematoxylin and eosin (HE) and scored as previously described^[26]. To check the immunological changes, 5 d after IBD induction, mesenteric lymph nodes were obtained, suspended as single cells, and the expression level of cytokines and COX-2 were measured by quantitative real-time PCR or immunoblotting.

Isolation and activation of APCs and CD4⁺ T cells

For isolation of APCs (MHCII⁺ or CD11c⁺ DCs), spleens and lymph nodes isolated from C57BL/6 mice were ground with 30-µm pore meshes at the single cell level. Then, APCs purified with MHCII⁺ Isolation Kit (Miltenyi) or CD11c⁺ DC Isolation Kit (Miltenyi) were washed three times with ice-cold PBS and harvested for further analysis. CD4⁺ T cells from Do11.10 mice (Jackson Laboratory) were purified with CD4⁺ T cells Isolation Kit (Miltenyi).

Cell stimulation and treatment with cinnamon extract

Raw 264.7 cells were stimulated with lipopolysaccharide (LPS) (10 µg/mL) alone or in combination with cinnamon extract (0.2 mg/mL) for 24 h, and then washed three times with PBS. MHCII⁺ APCs or CD11c⁺ DCs were stimulated with LPS (10 µg/mL) alone or in combination with cinnamon extract (0.1, 0.3 and 0.5 mg/mL) for 24 h. After three washes, cells were harvested for further analysis.

Co-culture experiment

APCs (MHCII⁺ or CD11c⁺ DCs) were stimulated with LPS (10 µg/mL) alone or in combination with several doses of cinnamon extract (0.1, 0.3 and 0.5 mg/mL) for 24 h. The cells were incubated in mitomycin C (20 µg/mL) containing medium for 30 min at 37°C, and washed five times with ice-cold PBS. After 24 h stimulation, cells were co-cultured with CD4⁺ T cells obtained from Do11.10 mice in the absence or presence of ovalbumin peptide (Ova; 5, 20, 50 µg/mL) in 96-well plates for 56–72 h. After that, 0.5 µCi [³H]-thymidine (NEN) was added to each well and the cells were incubated for an additional 6 h.

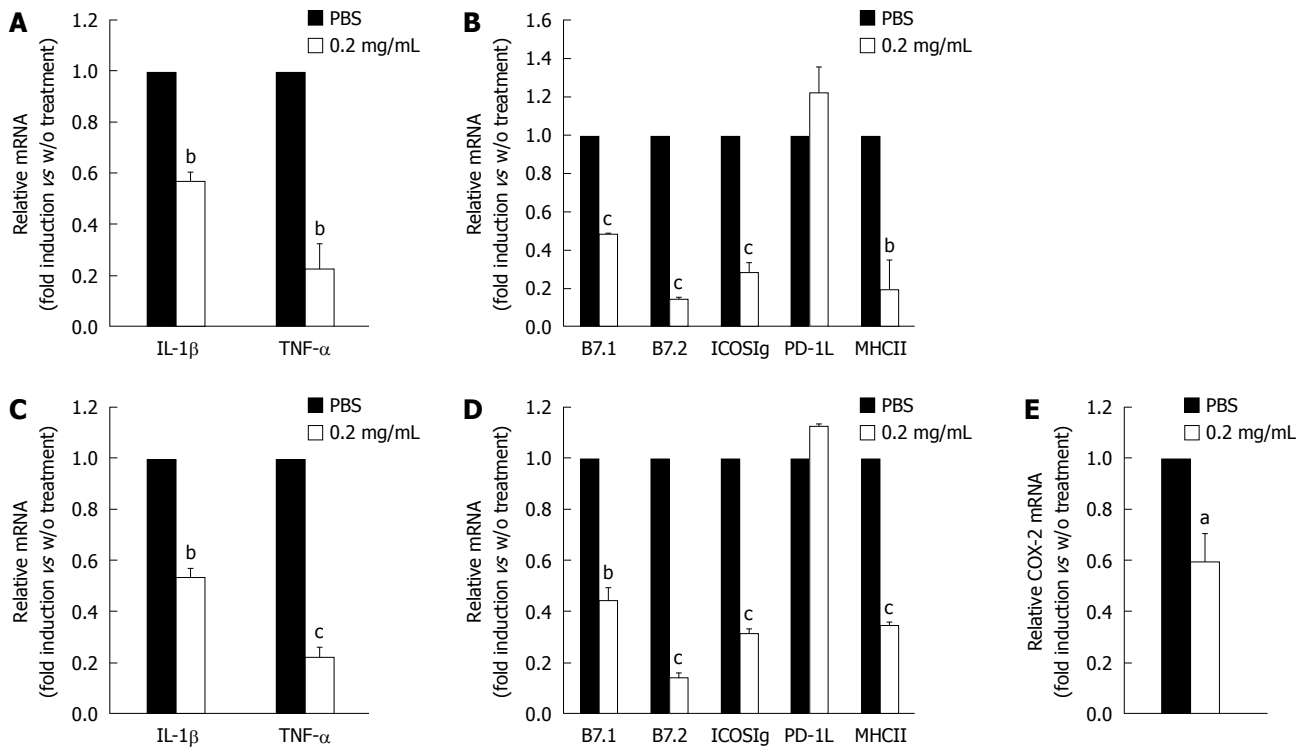

Figure 1 Treatment of cinnamon extract inhibits maturation of macrophage cell line. Murine Raw 264.7 macrophages were stimulated with PMA/ionomycin in the absence or presence of 0.2 mg/mL cinnamon extract. Expression levels of cytokines (A) and co-stimulatory molecules (B) were measured by quantitative real-time PCR. To mimic *in vivo* stimulation, cells were treated with lipopolysaccharide alone or in combination with 0.2 mg/mL cinnamon extract. Expression level of cytokines (C), co-stimulatory molecules (D) and cyclooxygenase (COX)-2 (E) was measured by quantitative real-time PCR. Error bars indicated SD. ^a $P < 0.05$, ^b $P < 0.005$, ^c $P < 0.001$. Data are representative of three individual experiments.

Cells were harvested and [^3H]-thymidine uptake was measured by liquid scintillation counting. For checking functional change of co-cultured CD4^+ T cells, CD4^+ T cells were re-isolated from co-cultured population and mRNAs were obtained to analyze the levels of cytokine expression by quantitative RT-PCR.

Intracellular cytokine staining

To detect intracellular TNF- α and IL-10 positive populations, cells were stimulated with LPS alone or in combination with cinnamon extract for 24 h, fixed with 2% paraformaldehyde (Sigma) for 10 min, permeabilized with permeabilization buffer (0.5% saponin, 1% BSA in PBS) for 30 min, and stained with anti-TNF- α -PE (BD Pharmingen) or anti-IL-10-PE (BD Pharmingen) for 20 min at 4°C. IgG isotypes were used as a control for all flow cytometry analysis. The IgG-positive population was shown to be < 0.2% (data not shown).

Statistical analysis

A two-tailed Student's *t* test was used, and $P < 0.05$ was considered to be statistically significant.

RESULTS

Treatment with cinnamon extract inhibits activation and maturation of APCs

Previous reports have shown that cinnamon components

have a potent anti-inflammatory role by inhibiting NO synthesis^[17,18] without providing any immunological evidence. In this study, we tested the anti-inflammatory efficacy of cinnamon extract and elucidated its working mechanisms by targeting APCs. To test the effect of cinnamon extract on activation and maturation of macrophages we used Raw 264.7 cells (Figure 1). Raw cells were stimulated with phorbol 12-myristate 13-acetate (PMA) and ionomycin for 24 h in the presence or absence of cinnamon extract at a concentration of 0.2 mg/mL, which did not induce any cell death or morphological change (data not shown). The expression levels of pro-inflammatory cytokines, co-stimulatory molecules and COX-2 were measured by real-time PCR. Raw cells upon activation produced a significant amount of IFN- γ and TNF- α . However, treatment with cinnamon extract significantly decreased expression levels of pro-inflammatory cytokine such as IL-1 β and TNF- α (Figure 1A). Expression level of COX-2, a key inflammatory mediator^[27], was also inhibited by cinnamon extract (Figure 1C). Next, to check the effect of cinnamon extract on maturation of Raw 264.7 cells, we analyzed the expression levels of activation markers for APCs such as MHCII and co-stimulatory molecules [B7.1, B7.2, ICOS ligand (ICOS-L) and PD1 ligand (PD-1L)] (Figure 1B). Consistent with inhibitory effects on pro-inflammatory cytokine expression, all the tested molecules were significantly reduced by treatment with cinnamon extract, except for PD-1L (Figure 1B). Since

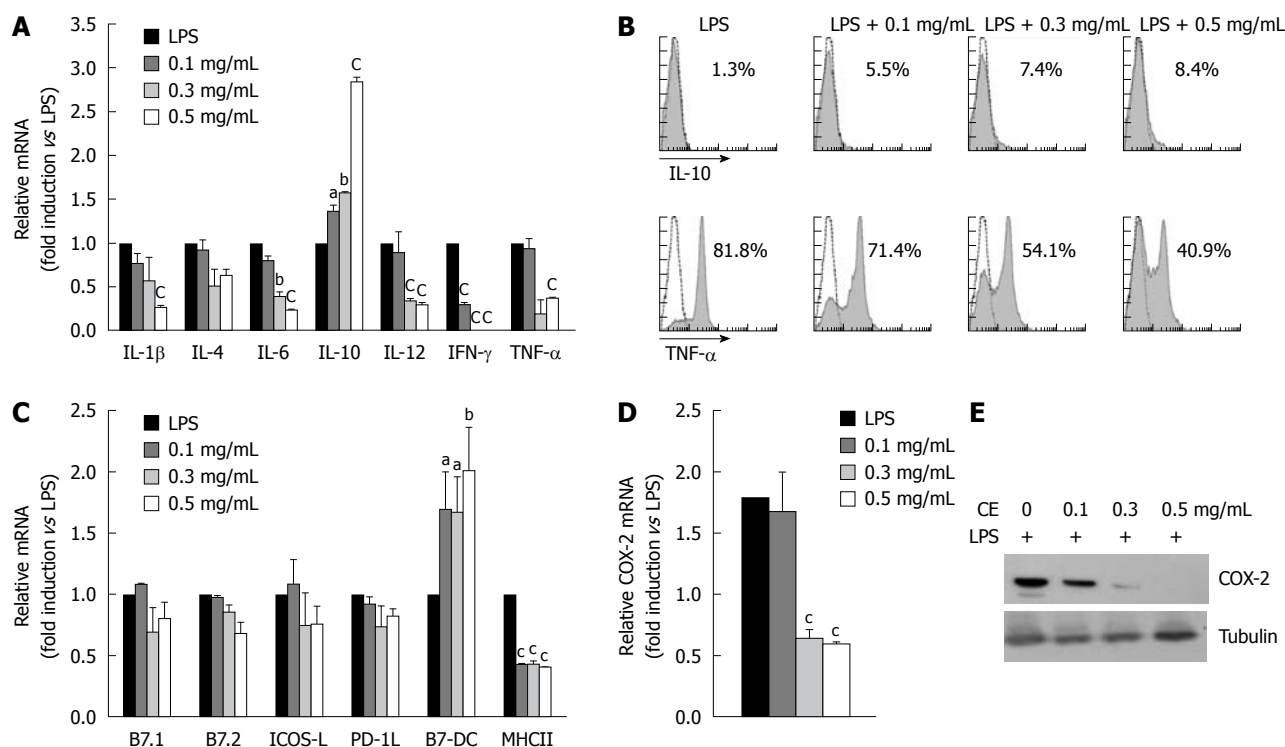

Figure 2 Treatment with cinnamon extract inhibits maturation of MHCII⁺ APCs. MHCII⁺ APCs were stimulated with lipopolysaccharide (LPS) alone or in combination with cinnamon extract (0.1, 0.3 and 0.5 mg/mL). Expression levels of cytokines (A) and co-stimulatory molecules (C) were measured by quantitative real-time PCR. B: Intracellular expression levels of interleukin (IL)-10 and tumor necrosis factor (TNF)-α proteins were analyzed by flow cytometry. Effect of cinnamon extract treatment on cyclooxygenase (COX)-2 expression at the mRNA (D) and protein (E) level was measured by quantitative real-time PCR and immunoblotting, respectively. Error bars indicated SD. ^a*P* < 0.05, ^b*P* < 0.005, ^c*P* < 0.001. Data are representative of three individual experiments. IFN: Interferon.

APCs can be activated by pathogen-associated molecular patterns^[28], to mimic the *in vivo* situation, we stimulated Raw 264.7 cells with LPS, a TLR4 ligand (Figure 1C-E). Cinnamon extract was added during LPS stimulation and its effect on APC maturation and expression of pro-inflammatory molecules was analyzed. LPS treatment significantly increased expression levels of inflammatory cytokines, cell surface molecules and COX-2 compared to non-stimulated cells. However, cinnamon extract strongly inhibited expression of pro-inflammatory cytokines (IL-1β and TNF-α) (Figure 1C), co-stimulatory molecules (B7.1, B7.2, ICOS-L and MHCII) (Figure 1D) and COX-2 (Figure 1E). These results suggest that cinnamon extract has potent anti-inflammatory properties by inhibiting activation and maturation of APCs *in vitro*.

To test further the effect of cinnamon extract treatment on primary APCs, first, we titrated the dose of cinnamon extract in primary MHCII⁺ APCs that did not induce cytotoxic characteristics such as growth inhibition and apoptosis. Up to 0.7 mg/mL cinnamon extract did not show any cytotoxicity (data not shown). Next, primary MHCII⁺ APCs were stimulated with LPS alone or in combination with cinnamon extract (0.1, 0.3 and 0.5 mg/mL) for 24 h, and then the expression levels of cytokines, co-stimulatory molecules and COX-2 were measured by quantitative real-time PCR (Figure 2A-C). Treatment of cinnamon extract significantly decreased LPS-induced expression of pro-inflammatory cytokines (IL-1β, IL-6, IL-12, IFN-γ and TNF-α) in a dose-dependent manner

(Figure 2A). Cinnamon extract significantly upregulated the expression level of IL-10, an immunomodulatory cytokine, in a dose-dependent manner (Figure 2A). To confirm whether cinnamon extract also modulates protein level, we compared IL-10 and TNF-α, as a representative anti- or pro-inflammatory cytokine, respectively, by flow cytometry (Figure 2B). Consistent with mRNA data, treatment with cinnamon extract significantly decreased the TNF-α⁺ while increasing the IL-10⁺ population. LPS-stimulated cells produced high levels of TNF-α⁺ (81.8%), whereas treatment with 0.5 mg/mL cinnamon and LPS significantly reduced its production (40.9%) in a dose-dependent manner (Figure 2B). However, treatment with cinnamon extract significantly increased the IL-10⁺ population from 1.3% (LPS alone) to 8.36% (LPS with 0.5 mg/mL cinnamon extract) in a dose-dependent manner (Figure 2B). In addition, treatment with cinnamon extract significantly decreased COX-2 mRNA (Figure 2D) and protein (Figure 2E) levels in a dose-dependent manner. Next, we tested whether cinnamon treatment also modulated activation stage of primary MHCII⁺ APCs. MHCII⁺ APCs were stimulated with LPS alone or in combination with cinnamon extract, and then expression levels of co-stimulatory molecules were analyzed (Figure 2C). Cinnamon treatment significantly decreased MHCII molecules that play critical roles in T-cell activation. However, cinnamon treatment did not induce significant alteration in expression patterns of co-stimulatory molecules including B7.1, B7.2, ICOS-L and PD-1L (Figure 2D). Cinnamon

Figure 3 Treatment of cinnamon extract inhibits maturation of CD11⁺ dendritic cells. CD11⁺ dendritic cells (DCs) were stimulated in the absence or presence of cinnamon extract (CE) and expression levels of cytokines [interleukin (IL)-1 β , IL-4, IL-6, IL-10, IL-12, interferon (IFN)- γ , tumor necrosis factor (TNF)- α and transforming growth factor (TGF)- β] (A) and co-stimulatory molecules (B7.1, B7.2, ICOS ligand, B7-DC and MHCII) (B) were measured by quantitative real-time PCR. Effect of cinnamon extract (CE) treatment on cyclooxygenase (COX)-2 expression at the RNA (C) and protein (D) level was measured by quantitative real-time PCR and immunoblotting, respectively. Error bars indicated SD. ^a $P < 0.05$, ^b $P < 0.005$, ^c $P < 0.001$. Data are representative of three independent experiments.

treatment significantly increased expression levels of B7 DCs that have regulatory roles in inflammatory immune responses^[29,30]. Hence, these data indicate that primary MHCII⁺ APCs upon treatment with cinnamon extract may gain immunoregulatory properties.

Cinnamon extract treatment inhibits maturation of DCs

Based on the finding that cinnamon extract inhibits activation and maturation of MHCII⁺ APCs, we further tested whether treatment with cinnamon extract exerted a similar effect on DCs. CD11c⁺ DCs were isolated and stimulated with LPS alone or in combination with cinnamon extract for 24 h. Expression levels of cytokines, co-stimulatory molecules and COX-2 were measured by quantitative real-time PCR (Figure 3). CD11c⁺ DCs stimulated with LPS significantly increased expression levels of pro-inflammatory cytokines such as IL-1 β , IL-6, IL-12, IFN- γ and TNF- α . However, expression levels of pro-inflammatory cytokines were markedly reduced in a dose-dependent manner upon cinnamon extract treatment (Figure 3A). Cinnamon extract treatment significantly upregulated the expression levels of immunomodulatory cytokines such as IL-10 and TGF- β ^[31,32] in a dose-dependent manner (Figure 3A). Moreover, treatment with cinnamon extract significantly downregulated COX-2 mRNA (Figure 3C) and protein (Figure 3D) levels in a dose-dependent manner. Cinnamon extract treatment also downregulated the expression levels of B7.1, B7.2 and MHCII (Figure 3B). These data indicate that cinnamon extract inhibited matu-

ration of CD11c⁺ DCs while inducing tolerogenic properties by increasing immunomodulatory cytokines.

Cinnamon extract treatment inhibits APC-dependent T-cell proliferation

One of the major roles of APCs is to process and present antigens in the context of MHCII to T cells, which is a key event for induction of adaptive immune responses. We tested whether cinnamon extract treatment affected APC-dependent T-cell proliferation. Two types of primary APCs were isolated: MHCII⁺ APCs and CD11c⁺ DCs. They were pre-stimulated with LPS alone or in combination with cinnamon extract for 24 h, and then co-cultured with naïve T cells obtained from Do 11.10 mice that specifically expressed Ova-specific T-cell receptors. In the presence of Ova peptide, co-culture was continued for 72 h. T-cell proliferation was mainly dependent on antigen presenting and co-stimulatory capacity of APCs (MHCII⁺ or CD11c⁺). APCs (MHCII⁺ (Figure 4A) and CD11c⁺ DCs (Figure 4B) pre-treated with cinnamon extract significantly lowered APC-dependent T-cell proliferation in a dose-dependent manner (Figure 4A). These results suggest that treatment with cinnamon extract negatively modulated antigen presenting capacity of MHCII⁺ APCs or CD11c⁺ DCs to stimulate T-cell proliferation.

DCs treated with cinnamon extract inhibit Th1 polarization while inducing IL-10^{high} CD4 T cells

DCs play important roles in regulating the activity and dif-

Figure 4 Treatment with cinnamon extract inhibits APC-dependent T-cell proliferation. APC-dependent T-cell proliferation was measured. MHCII⁺ APCs (A) and CD11c⁺ dendritic cells (DCs) (B) were pre-pulsed in the absence or presence of cinnamon extract for 24 h. Then, they were co-cultured with CD4⁺ T cells isolated from Do11.10 mice in the presence of Ova peptide. After 72 h co-culture, T-cell proliferation was measured by [³H]-thymidine incorporation assay. Error bars indicated SD. ^a*P* < 0.05, ^b*P* < 0.005, ^c*P* < 0.001. Data are representative of three independent experiments.

Figure 5 Cinnamon-extract-treated dendritic cells inhibit Th1 polarization. CD11c⁺ dendritic cells (DCs) were pre-pulsed with lipopolysaccharide (LPS) alone or in combination with cinnamon extract (CE) (0.2 mg/mL) for 24 h. Then, they were co-cultured with CD4⁺ T cells isolated from Do11.10 mice. A: After 72 h co-culture, CD4⁺ T cells were re-isolated from each treatment group and relative expression levels of cytokine mRNA were measured by quantitative real-time PCR; B: Intracellular protein levels of interleukin (IL)-10 and interferon (IFN)- γ in CD4⁺ T cells in each treatment group was analyzed by flow cytometry. Error bars indicated SD. ^a*P* < 0.05, ^b*P* < 0.005, ^c*P* < 0.001. Data are representative of three independent experiments.

ferentiation of naïve T cells into diverse T cell lineages such as Th1, Th2 and Th17 types^[33-35]. Since treatment with cinnamon lowered DC-dependent T-cell proliferation (Figure 4), we further tested the effects of cinnamon extract on DC-dependent T-cell polarization. T cells were co-cultured for 72 h with CD11c⁺ DCs pre-pulsed with LPS alone or in combination with 0.3 mg/mL cinnamon extract. Then, T cells were re-isolated and expression levels of T cell lineage-related cytokines were measured (Figure 5). T cells co-cultured with cinnamon-treated CD11c⁺ DCs produced much higher levels of IL-10 expression, while the levels of pro-inflammatory cytokines such as IL-6, IL-12, IL-17, IFN- γ and TNF- α were significantly decreased compared with control DCs (Figure 5A and B). No significant difference was observed in the levels of IL-2 and IL-4 between the treatment groups. These data indicate that CD11c⁺ DCs, upon treatment with cinnamon extract, could induce IL-10^{high} CD4 T cells while inhibiting Th1 polarization.

Oral administration of cinnamon extract ameliorates experimental colitis

To confirm the anti-inflammatory efficacy of cinnamon

extract *in vivo*, we tested whether oral administration of cinnamon extract could prevent progression of TNBS-induced experimental colitis, a typical Th1 type IBD^[36]. Mice were fed orally with PBS alone or in combination with cinnamon extract (50 μ g/g body weight) for 20 d, and experimental colitis was induced by intrarectal injection of TNBS. Clinical symptoms, weight loss and survival rate were monitored for 5 d. Both groups showed significant loss of body weight after 2 d of colitis induction. However, cinnamon-extract-treated mice began to recover weight loss starting from day 3, and almost restored their body weight at day 5, while PBS-treated mice continuously lost body weight during that period (Figure 6A). We also monitored survival rate. Cinnamon-extract-treated mice showed about 95% survival rate, while PBS-treated mice showed 50% survival on day 5 after colitis induction (data not shown). In accordance with weight loss and survival rate, colonic inflammation was significantly reduced in cinnamon-extract-treated mice compared with PBS-treated mice (Figure 6B). Tissue destruction and infiltration of mononuclear cells into the intestine, as shown by HE staining, were also significantly reduced by cinnamon

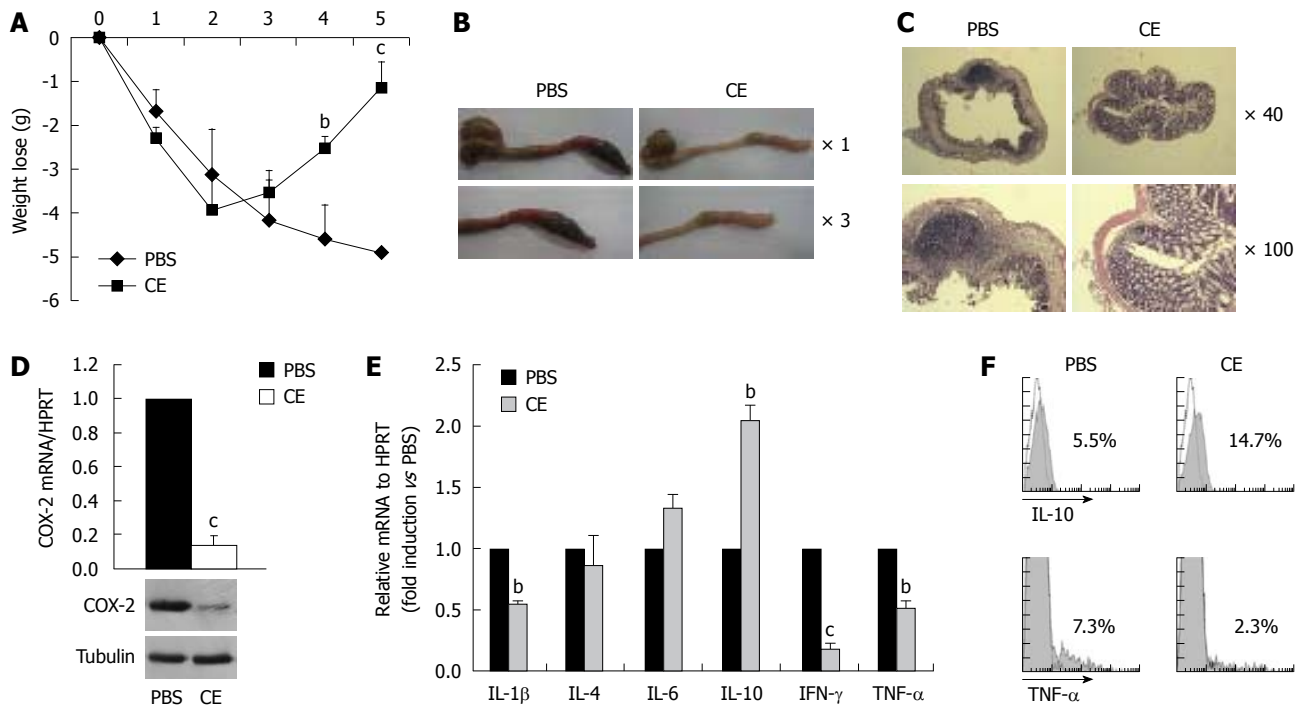

Figure 6 Oral administration of cinnamon extract ameliorates experimental colitis. Mice were orally fed with PBS or cinnamon extract (CE) (50 μ g/g per day) for 20 d, and intestinal colitis was induced by intrarectal injection of TNBS (50 μ g/g in 50% ethanol). A: A change in body weight was monitored for 5 d; B: Gross intestinal changes were analyzed with a magnifying glass 3 d after colitis induction; C: After HE staining, histological analysis was performed by comparing colon sections of treatment groups; D: After induction of inflammatory bowel disease, cyclooxygenase (COX)-2 expression in mesenteric lymph nodes was compared by quantitative real-time PCR and immunoblotting; E: Expression levels of cytokines in mesenteric lymphocytes were measured by quantitative real-time PCR; F: Intracellular protein levels of interleukin (IL)-10 and tumor necrosis factor (TNF)- α were measured by flow cytometry. Error bars indicated SD. $^bP < 0.005$, $^cP < 0.001$. Data are representative of three independent experiments. IFN: Interferon.

extract (Figure 6C). To investigate further the underlying mechanism of cinnamon-extract-mediated IBD protection, we measured the levels of pro- or anti-inflammatory mediators between the treatment groups. First, we measured the mRNA and protein levels of COX-2, an inflammatory mediator that is highly expressed in inflamed tissues and activated immune cells. In accordance with *in vitro* results (Figure 2D and E), oral administration of cinnamon extract significantly reduced the expression levels of COX-2 in mesenteric lymph nodes at both mRNA and protein levels (Figure 6D). We also compared expression level of various pathogenic or protective cytokines such as IL-1 β , IL-4, IL-6, IL-10, IFN- γ and TNF- α in cells isolated from mesenteric lymph nodes of cinnamon-extract-treated or non-treated mice. In agreement with clinical data, cells isolated from mesenteric lymph nodes of cinnamon-extract-treated mice expressed much lower levels of pathological cytokines such as IL-1 β , IFN- γ and TNF- α (Figure 6E). No significant difference in the expression levels of IL-4 and IL-6 was observed between the treatment groups. Oral administration of cinnamon extract significantly upregulated IL-10 expression levels (Figure 6E). To confirm these data at the protein level, IL-10 $^+$ or TNF- α $^+$ populations among total mesenteric lymph node cells were compared by flow cytometry. In accordance with mRNA level, oral administration of cinnamon extract significantly increased the IL-10 $^+$ population (PBS, 5.5% *vs* cinnamon extract, 14.7%) but decreased the TNF- α $^+$ population (PBS, 7.3% *vs* cinnamon extract,

2.3%). These data suggest that the prophylactic effect of cinnamon extract against colitis pathogenesis is mediated by its anti-inflammatory properties.

DISCUSSION

Treatment with cinnamon extract endowed APCs with tolerogenic characteristics resulting in inhibition of T-cell proliferation, T-cell polarization into Th1 type, while leading to IL-10 $^{\text{high}}$ CD4 T cells. Furthermore, oral administration of cinnamon extract significantly suppressed the progression of experimental colitis by increasing IL-10 production while suppressing the levels of pro-inflammatory cytokines.

APCs express high levels of MHC molecules on their surface to present antigen to adaptive immune cells, especially T cells^[19]. APCs are a heterogeneous population constituting various types of cells including DCs, B cells and macrophages^[19]. APCs play important roles in the initiation and enhancement of immune responses, and for induction of immunotolerance as well^[37-39]. DCs are key APCs that determine T-cell response and polarization into Th1 or Th2 cells^[33]. APCs also play pivotal roles in maintenance of immunological homeostasis through various action mechanisms^[20,24,40]. B cells have regulatory properties in modulating diverse inflammatory immune disorders such as IBD, collagen-induced arthritis, and autoimmune encephalomyelitis^[24,41-45]. The regulatory properties of B cells are mainly mediated by production of anti-inflam-

matory cytokines such as IL-10 and TGF- β , which are important to generate regulatory T cells.

rDCs promote immunotolerance rather than immune activation^[20,38,39]. rDCs usually express low levels of MHC molecules^[23], co-stimulatory molecules and pro-inflammatory cytokines (IL-1 β , IL-12 and TNF- α), while expressing high levels of IL-10, TGF- β and iDO. rDCs are resistant to maturation and help generation of regulatory T cells^[23]. Their potent anti-inflammatory functions have been successfully demonstrated in various types of inflammatory immune disorders^[23].

In this study, treatment with cinnamon extract significantly downregulated expression levels of MHCII and co-stimulatory molecules (B7.1 and B7.2) in macrophage cell lines (Figure 1D); primarily MCHII⁺ APCs (Figure 2C) and CD11c⁺ DCs (Figure 3B). Primary MCHII⁺ APCs significantly increased expression levels of B7-DC (PD-L2) upon cinnamon extract treatment in a dose-dependent manner (Figure 2C). B7-DC (PD-L2) is a ligand of PD1 which has potent anti-inflammatory properties to inhibit T-cell activation^[46]. Hence, an increase of B7-DC expression by cinnamon extract may mediate its anti-inflammatory properties.

One of the properties of tolerogenic APCs is to express high levels of immune regulatory cytokines (IL-10 and TGF- β) and iDO, while expressing low levels of pro-inflammatory cytokines^[23]. IL-10 and TGF- β are highly expressed in MCHII⁺ APCs, including B cells, macrophages and DCs, to suppress immune responses^[47,48]. MCHII⁺ APCs upon cinnamon extract treatment produced significantly reduced levels of pro-inflammatory cytokines, including IL-1 β , IL-6, IL-12, IFN- γ and TNF- α , while enhancing IL-10 levels (Figure 2A and B). Treatment with cinnamon extract also reduced NO production, a potent mediator of pro-inflammatory response in cinnamon-pulsed MCHII⁺ APCs (data not shown). In addition, cinnamon-pulsed DCs significantly decreased expression of pro-inflammatory cytokines, while upregulating IL-10 and TGF- β levels (Figure 3A). These results suggest that upregulated IL-10 and TGF- β levels in APCs by cinnamon extract may mediate downregulation of MHCII and co-stimulatory molecules^[47,48].

Tolerogenic APCs inhibit effector T-cell function by suppressing T-cell proliferation and cytokine expression^[23]. Upon LPS treatment, MCHII⁺ APCs and CD11c⁺ DCs strongly induced antigen-specific T-cell proliferation (Figure 4). However, cinnamon-pulsed MCHII⁺ APCs and CD11c⁺ DCs significantly reduced T-cell proliferation in response to antigen stimulation (Figure 4). Upon cinnamon extract treatment, how do APCs reduce their antigen-presenting capacity? An increased production of immunoregulatory cytokines (IL-10 and TGF- β) by cinnamon extract may reduce antigen-presenting capacity because increased levels of IL-10 and TGF- β suppress the expression of MHCII and co-stimulatory molecules on APC surfaces^[47,48]. Another possibility is that cinnamon extract may modulate DC properties. Tolerogenic APCs could generate IL-10^{high} (Tr1) or Foxp3⁺ regulatory T cells^[23]. These latter cells have pivotal roles to suppress ex-

aggerated immune responses in autoimmune, allergic and infectious diseases^[49,50]. Here, we found that T cells cultured with cinnamon-pulsed DCs significantly decreased expression levels of pro-inflammatory cytokines such as IL-6, IL-12, IL-17, IFN- γ and TNF- α , while increasing IL-10 levels (Figure 5), which indicates that cinnamon-pulsed DCs inhibit Th1 polarization of naïve T cells rather than generate IL-10^{high} regulatory T cells. Does cinnamon extract treatment increase Foxp3⁺ regulatory T cells? However, cinnamon extract treatment failed to increase Foxp3 expression within CD4⁺ T cells (data not shown).

COX-2 is a key mediator for PG synthesis. It promotes inflammatory immune response to exaggerate pathogenesis in rheumatoid arthritis, multiple sclerosis and cancer^[51]. In the normal state, expression of COX-2 is almost undetectable. However, many cell types including chondrocytes, macrophages, DCs and epithelial cells express high levels of COX-2 by various stimuli such as IL-1 β , TNF- α , phorbol esters, hypoxia, and LPS^[51,52]. COX-2 plays a pivotal role in inflammation and tumor progression^[53]. In our previous study, we have shown that cinnamon treatment effectively inhibits COX-2 expression in melanoma cell lines and in melanoma models^[25]. In this study, we found that treatment with cinnamon extract also significantly inhibited COX-2 expression in Raw macrophage cells (Figure 1), primary MCHII⁺ APCs (Figure 2), CD11c⁺ DCs (Figure 3), and in cells isolated from mesenteric lymph nodes in experimental colitis (Figure 6). IL-10 and TGF- β downregulate COX-2 expression in the immune system^[54,55], therefore, decreased expression of COX-2 levels (Figures 3, 4 and 6) may contribute to increased expression of IL-10 and TGF- β . However, we still do not know whether COX-2 inhibition by cinnamon is accomplished by intrinsic mechanisms such as active compounds of cinnamon, or extrinsic mechanisms mediated by immunomodulation. Currently, we are trying to identify active compounds from the cinnamon extract that have potent anti-COX-2 activities.

In summary, our study suggests a potent anti-inflammatory function of cinnamon extract that modulates effector function of APCs *in vitro* and *in vivo*. Cinnamon extract strongly inhibits maturation of APCs rather endows them with tolerogenic capacities that produce high levels of anti-inflammatory cytokines. Moreover, oral administration of cinnamon extract strongly ameliorated TNBS-induced experimental IBD by increasing IL-10 levels while downregulating pro-inflammatory cytokines. Further identification of the active components of cinnamon extract could lead to development of potent anti-inflammatory agents that target diverse inflammatory immune disorders.

COMMENTS

Background

Recently, the incidence of inflammatory immune disorders including inflammatory bowel disease, rheumatoid arthritis and allergic diseases has been growing fast. However, any conclusive medication for the treatment of these diseases is not available. Hence, oriental herbal medicines, which have been shown to

have various bioactive components, are regarded as a potent source of medication for the development of immunomodulators.

Research frontiers

Cinnamomum cassia bark contains various bioactive molecules, and has been shown to have diverse biological functions such as antioxidant, antimicrobial and antidiabetic effects. However, although little evidence suggests its immunomodulatory properties such as inhibiting the production of NO, cyclooxygenase-2 and prostaglandin E2 in macrophage cell lines, it is still unclear how cinnamon modulates the function of immune cells, especially *in vivo*. In this study, the authors demonstrated potent anti-inflammatory properties of cinnamon through modulating the properties of antigen-presenting cells (APCs) *in vitro* and *in vivo*.

Innovations and breakthroughs

The work has demonstrated the potent anti-inflammatory properties of cinnamon extract. It modulates the properties of APCs to endow them with immunoregulatory phenotypes. In particular, cinnamon extract treatment of APCs affected their maturation, to have tolerogenic immune function by upregulating expression patterns of tolerogenic marker molecules such as B7-DC and cytokines including interleukin (IL)-10 and transforming growth factor- β . Moreover, cinnamon-extract-treated APCs affected effector functions of T cells by inhibiting their proliferation, while increasing IL-10 production, resulting in potent therapeutic effects in an animal model of intestinal colitis. The data strongly suggest that cinnamon extract is a potent anti-inflammatory herbal medicine that can be used to treat inflammatory bowel disease.

Applications

The authors have provided scientific evidence that cinnamon extract has potent anti-inflammatory properties. Further identification of its active components could lead to development of potent anti-inflammatory agents that target diverse inflammatory immune disorders.

Terminology

Cinnamon is from *Cinnamomum cassia* bark, which is a small evergreen tree belonging to the family Lauraceae. APCs are cells that display foreign antigen complexes with the MHC on their surface, for the recognition of this complex by T-cells, using the T-cell receptors.

Peer review

This is an interesting study that showed the anti-inflammatory effects of cinnamon extract. The authors demonstrated that cinnamon extract acts on APCs and IL-10⁺ regulatory cells. Cinnamon administration ameliorated experimental colitis by inhibiting inflammatory cytokines.

Abstract

AIM: To investigate the effects of the Chinese herbal decoction, Yi-Qi-Zeng-Min-Tang (YQZMT), on insulin resistance in type 2 diabetic rats.

METHODS: Sprague-Dawley rats were divided into two dietary regiments by feeding either normal pellet diet (NPD) or high fat diet (HFD). Four weeks later, the HFD-fed rats were injected intraperitoneally with low-dose streptozotocin (STZ). Rats with non-fasting blood glucose level ≥ 16.67 mmol/L were considered type 2 diabetic and further divided into five subgroups: the type 2 diabetes model group, low-dose, medium-dose

and high-dose YQZMT groups, and rosiglitazone group. Age-matched NPD-fed rats served as controls. YQZMT or rosiglitazone were administered for 8 wk. Intraperitoneal glucose and insulin tolerance tests were performed before and after the treatment to measure the glucose tolerance and insulin sensitivity. Serum levels of biochemical parameters, adipocytokines, such as tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), as well as free fatty acids (FFAs), were also analyzed.

RESULTS: There was significant elevation of insulin resistance and serum levels of fasting glucose (12.82 ± 1.08 mmol/L vs 3.60 ± 0.31 mmol/L, $P < 0.01$), insulin (7197.36 ± 253.89 pg/mL vs 4820.49 ± 326.89 pg/mL, $P < 0.01$), total cholesterol (TC) (8.40 ± 0.49 mmol/L vs 2.14 ± 0.06 mmol/L, $P < 0.01$), triglyceride (2.24 ± 0.12 mmol/L vs 0.78 ± 0.05 mmol/L, $P < 0.01$), low-density lipoprotein cholesterol (LDL-c) (7.84 ± 0.51 mmol/L vs 0.72 ± 0.04 mmol/L, $P < 0.01$) and decrease in high-density lipoprotein cholesterol (HDL-c) (0.57 ± 0.03 mmol/L vs 1.27 ± 0.03 mmol/L, $P < 0.01$) in the low-dose STZ and high-fat diet induced type 2 diabetic group when compared with the control group. Administration of YQZMT induced dose- and time-dependent changes in insulin resistance, glucose and lipid profile, and reduced levels of FFA, TNF- α and IL-6 in the type 2 diabetic rats. After the treatment, compared with the diabetic group, the insulin resistance was ameliorated in the high-dose YQZMT (2.82 g/100 g per day) group, with a significant reduction in serum glucose (12.16 ± 1.00 mmol/L vs 17.65 ± 2.22 mmol/L, $P < 0.01$), homeostasis model assessment of basal insulin resistance (22.68 ± 2.37 vs 38.79 ± 9.02 , $P < 0.05$), triglyceride (0.87 ± 0.15 mmol/L vs 1.99 ± 0.26 mmol/L, $P < 0.01$), TC (3.31 ± 0.52 mmol/L vs 6.50 ± 1.04 mmol/L, $P < 0.01$) and LDL-c (2.47 ± 0.50 mmol/L vs 6.00 ± 1.07 mmol/L, $P < 0.01$), and a significant increase in HDL-c (0.84 ± 0.08 mmol/L vs 0.50 ± 0.03 mmol/L, $P < 0.01$). But the body weight was not changed significantly.

CONCLUSION: YQZMT, which ameliorates insulin resistance and does not cause increase in body weight, may be a suitable therapeutic adjunct for the treatment of type 2 diabetes.

INTRODUCTION

The prevalence of type 2 diabetes is dramatically increasing throughout the world. Pathogenesis of this disease involves abnormalities in glucose and lipid metabolism, including inadequate insulin secretion from pancreatic β -cells and insulin resistance^[1,2].

Insulin resistance is a hallmark of type 2 diabetes, characterized by a decreased response of the peripheral tissues to insulin action^[3,4], and it most often precedes the onset of hyperglycemia and predicts development of type 2 diabetes^[5]. Insulin resistance produces elevations in glucose and lipid levels^[6]. It has become increasingly evident that obesity and the concomitant development of inflammation are major components of insulin resistance. Studies have revealed a clear association between pro-inflammatory signaling pathways and decreased insulin sensitivity^[7]. Pro-inflammatory adipokines including tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), as well as free fatty acids (FFAs), have been implicated to play important roles in inflammation, insulin resistance, and type 2 diabetes^[8-11]. These inflammatory markers have been proposed to be risk factors for cardiovascular disease (CVD) in type 2 diabetes mellitus patients^[12].

Since insulin resistance both precedes and predicts type 2 diabetes, it is important to develop drugs to reverse insulin resistance^[13]. At present, thiazolidinediones (TZD), the agonists of the peroxisome proliferators-activated receptor (PPAR) γ , are the main agents to improve insulin sensitivity in the liver, adipose tissue, and skeletal muscle, thus improving glycaemic control in patients with type 2 diabetes^[14]. Despite the efficacy, some deleterious side effects of TZDs, including rosiglitazone and pioglitazone, have been noted, such as increasing body weight and aggravating heart failure through fluid retention^[15,16]. Therefore, development of new agents may help treat type 2 diabetic patients with insulin resistance.

Traditional Chinese Medicine (TCM) has a long history in the treatment of type 2 diabetes^[17]. Because of the supposedly less side effects when compared with modern medicine^[18], the use of traditional Chinese medicine and botanicals has been increasing rapidly^[19]. Yi-Qi-Zeng-Min-Tang (YQZMT), a traditional Chinese compound recipe of 10 medicinal herbs, is considered a useful medicine for the amelioration of insulin sensitivity of type 2 diabetic patients. *Radix Astragali* (Huangqi), the chief herb of YQZMT, has been shown to alleviate glucose intolerance and insulin resistance^[20]. It seems that this traditional Chinese herbal compound recipe is valued in the glucose homeostasis, and may be utilized as adjuvant therapy for the control of diabetes and its complications.

The high-fat diet and low-dose streptozotocin (STZ) induced type 2 diabetic rat model mimicking the natural history of the disease events (from insulin resistance to β cell dysfunction) as well as metabolic features of human type 2 diabetes, where the high-fat diet initiated a state of insulin resistance and followed by the addition of low-dose STZ, has been known to induce a mild impairment of insulin secretion characteristic of the later stage of type 2 diabetes mellitus^[21]. For this study, we aimed at investigating the effect of the Chinese herbal decoction YQZMT on insulin resistance in rats with type 2 diabetes.

MATERIALS AND METHODS

Composition and preparation of YQZMT

YQZMT was composed of 10 medicinal herbs, as shown in Table 1. The mixture was decocted for three times by refluxing with water (1:8, w/v) for 2 h, 1 h and 1 h, respectively. The solution obtained was concentrated to give an extract. The yield of YQZMT extract was 36.76% (w/w) compared with the original herbs. The process was manipulated by the National Engineering and Research Center for Traditional Chinese Medicine under internationally certified good manufacturing practice guidelines. Thin-layer chromatography and high-performance liquid chromatography identification was used to authenticate the plants. The YQZMT extract was stored at 4°C, and was diluted to the desired concentrations in distilled water before use.

Animal experiments

Sixty-five Sprague-Dawley rats (male, weight 180-220 g) were obtained from Shanghai Slaccas Laboratory Animal Company Limited, Shanghai, China. Animals were housed in standard polypropylene cages (three rats/cage) in a temperature- and humidity-controlled room with a 12 h light-dark cycle. All the rats were provided with rat normal pellet diet (NPD) (Shanghai Slaccas Laboratory Animal Company Limited, Shanghai, China) and water ad libitum, prior to the dietary manipulation.

After 1 wk of acclimatization, the rats were randomly divided into two dietary regiments consisting of 10 and 55 rats by feeding either NPD or high fat diet (HFD) (18% lard, 8% yolk powder, 2% cholesterol, 0.2% sodium cholate and 71.8% powdered NPD, as a percentage of

Table 1 Composition of Yi-Qi-Zeng-Min-Tang

Component	Part used	Amount used (%)
<i>Radix Astragali</i>	Root	16.0
<i>Mung bean coating</i>	Seed bark	16.0

<i>Phellodendron amurense</i> Rupr.	Bark	10.6
<i>Pollen Typhae</i>	Pollen	10.6
<i>Serissa foetida</i>	Whole strain	10.6
<i>Ramulus Cinnamomi</i>	Twig	6.4
<i>Radix Aconiti Lateralis Preparata</i>	Prepared root	6.4
<i>Coptis Chinensis</i> Franch	Root	6.4
<i>Rhizoma Alismatis</i>	Tuberous stem	6.4

total kcal, manufactured by Shanghai Slaccas Laboratory Animal Company Limited, Shanghai, China) ad libitum, respectively, for the initial period of 4 wk.

After the 4 wk of dietary manipulation, the 55 HFD-fed rats were injected intraperitoneally (ip) with low-dose STZ (35 mg/kg, Sigma), while the 10 NPD-fed rats were injected ip with vehicle citrate buffer (pH 4.4) in a dose volume 1 mL/kg 3 d after the STZ or vehicle injection, non-fasting blood glucose (NFBG) was measured in whole blood collected from the tail vein by a portable Glucometer (Accu-Check Active, Roche Diagnostics Limited, Germany). Rats with NFBG level ≥ 16.67 mmol/L were considered diabetic and selected for further studies. Fasting blood was collected from retro-orbital plexus of the rats under light ether anesthesia using capillary tubes at day 7 after the STZ or vehicle injection to measure biochemical parameters [fasting glucose level, triglycerides (TG), total cholesterol (TC), high-density lipoprotein cholesterol (HDL-c), low-density lipoprotein cholesterol (LDL-c), and insulin]. The rats were fed on their respective diets until the end of the study.

Fifty diabetic rats (the diabetic success rate was 90.9%) were further divided into five subgroups: type 2 diabetes model group (MOD, $n = 10$), low-dose YQZMT group (LDY, $n = 10$), medium-dose YQZMT group (MDY, $n = 10$), high-dose YQZMT group (HDY, $n = 10$), and rosiglitazone group (ROS, $n = 10$). The age matched NPD-fed rats served as control group (CON, $n = 10$). Administration of YQZMT or rosiglitazone lasted 8 wk. LDY, MDY and HDY rats were dosed orally with YQZMT 0.47, 1.41, 2.82 g/100 g per day, respectively. ROS rats were given by oral gavage (4 mg/kg per day), this dose was selected since it was found to rapidly induce PPAR γ -dependent genes^[22]. CON and MOD group rats were given with an equal volume of distilled water once a day for 8 wk. Fasting blood was collected from retro-orbital plexus of the rats under light ether anesthesia using capillary tubes at 4 wk and 8 wk after treatment. The experiments were approved by the ethics committee of our institution. All procedures were in accordance to the rules and guidelines of the Experimental Animal Center of Fudan University.

Intraperitoneal glucose and insulin tolerance tests

The intraperitoneal glucose tolerance test (IPGTT) and insulin tolerance test (ITT) were performed at day 7 after the STZ or vehicle injection in diabetic ($n = 5$) and con-

trol ($n = 5$) rats, also at the end of the experiment in various groups ($n = 5$ for each group). After an overnight fast (12–16 h), fasting blood was collected from retro-orbital plexus (time 0), and then 50% glucose solution (2 g/kg body weight) or neutral insulin (Novo Nordisk, Denmark) was injected intraperitoneally. Blood samples were collected from retro-orbital plexus at 30, 60, and 120 min for measurement of glucose. The areas under the glucose curves (AUC) were calculated for each parameter by the trapezoidal rule in IPGTT. In ITT, the value was presented as a percentage of initial glucose level.

Blood sampling and analysis

Blood sample of rats were collected from retro-orbital plexus under light ether anesthesia using capillary tubes. Samples were centrifuged at $2500 \times g$ for 10 min at 4°C, blood serum was removed and aliquot for the respective analytical determinations, stored at -80°C until analysis. The serum was analyzed for glucose, TG, TC, HDL-c, LDL-c, and insulin. Serum glucose concentration was measured by glucose oxidase method (Applygen Technologies Inc, Beijing, China). Insulin was analyzed by rat insulin enzyme-linked immunosorbent assay (ELISA) kit (Mercodia, Sweden). Levels of TG, TC, HDL-c and LDL-c were assayed with enzymatic assay kits (Shanghai Kexin Biotechnology Research Institute, Shanghai, China). Serum levels of FFA, TNF- α and IL-6 were measured by commercially available rat ELISA kits. The homeostasis model assessment of basal insulin resistance (HOMA-IR) = fasting glucose (mmol/L) \times fasting insulin (IU/L)/22.5. Lower HOMA-IR values indicated a greater insulin sensitivity, whereas higher HOMA-IR values indicated a lower insulin sensitivity (insulin resistance).

Statistical analysis

Data were presented as mean \pm SE. The unpaired Student's t test was used for analyzing the data between two groups. Statistical differences among more than two groups were determined using one-way analysis of variance. P value < 0.05 was considered statistically significant. The statistical SPSS Version 16.0 software was used for statistical calculations.

RESULTS

General characteristics of NPD-fed rats and HFD-fed/STZ induced diabetic rats

Type 2 diabetic rats induced by STZ (35 mg/kg, ip) after 4 wk of HFD feeding exhibited significant hyperglycemia, dyslipidemia and hyperinsulinemia compared with NPD-fed control rats injected with vehicle citrate buffer (1 mL/kg, ip) (Table 2). In addition, the feeding of HFD for 4 wk resulted in significant increase (data not shown) in body weight as compared with NPD-fed rats, and STZ produced reduction in the body weight of the HFD-fed rats, which was still considerably higher than NPD-fed control rats injected with vehicle citrate buffer (Table 2). The HOMA-IR score in the diabetic rats was 6.2-folds higher than in the control rats (Table 2).

Table 2 General characteristics of normal pellet diet-fed rats and high fat diet-fed/streptozotocin induced diabetic rats (mean \pm SE)

	NPD (<i>n</i> = 10)	HFD+STZ (<i>n</i> = 50)
Body weight (g)	411.30 \pm 2.74	457.90 \pm 2.43 ^b

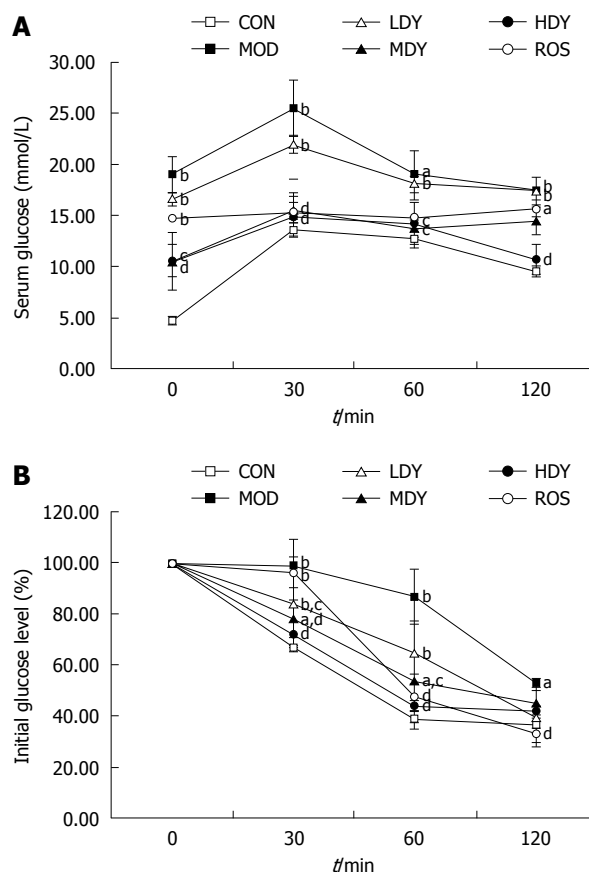

Figure 2 Intra-peritoneal glucose tolerance test and insulin tolerance test in diabetic rats after 8 wk of treatment. A: Serum glucose during intra-peritoneal glucose tolerance test (IPGTT) in diabetic rats (*n* = 5/group); B: Percentage of initial glucose level during insulin tolerance test (ITT) in diabetic rats (*n* = 5/group). YQZMT: Yi-Qi-Zeng-Min-Tang; CON: Control group; MOD: Type 2 diabetes model group; LDY: Low-dose YQZMT group; MDY: Medium-dose YQZMT group; HDY: High-dose YQZMT group; ROS: Rosiglitazone group. ^a*P* < 0.05, ^b*P* < 0.01 vs CON group; ^c*P* < 0.05, ^d*P* < 0.01 vs MOD group.

shows that HFD+STZ, as expected, led to glucose intolerance, since serum glucose concentrations increased from fasting levels of 12.41 ± 1.38 mmol/L to nearly 14.75 ± 0.2 mmol/L by 30 min and were still greatly increased over basal levels 2h after the glucose challenge. The NPD-fed control rats showed a significant elevation in serum glucose concentrations at 30 min but returned nearly to the basal levels within 2h after the glucose administration. Accordingly, the AUC was significantly greater in the HFD+STZ group than in the NPD group (1704 ± 40.05 mmol/L per minute *vs* 1315.2 ± 60.45 mmol/L per minute, *P* < 0.01). To investigate the differences in insulin sensitivity, we performed an ITT at different time points (Figure 1B). Insulin was given intra-peritoneally and blood was collected for the measurement of glucose. After insulin administration, the percentage of initial glucose level in HFD+STZ was shown to be significantly higher than in the NPD group during 120 min. These results indicated that HFD with STZ 35 mg/kg injection developed a diabetic model which was an analogue to type 2 diabetes mellitus with insulin resistance.

General characteristics of diabetic rats after treatment

After 4 and 8 wk of administration with YQZMT or rosiglitazone to the diabetic rats, body weight, serum glucose, insulin level, HOMA-IR value and lipids are shown in Tables 3 and 4. The levels of serum glucose, HOMA-IR, TG, TC, and LDL-c were significantly higher, while body weight and HDL-c were significantly reduced in the MOD group compared with that in the CON group, which again demonstrated that the disease animal model was established (Tables 3 and 4). At 4 wk, the MOD group had higher serum glucose levels with higher serum insulin levels compared with the CON group (Table 3), suggesting that the HFD+STZ caused insulin resistance. At 8 wk, serum insulin levels decreased in MOD group (Table 4). These results suggest that diabetes in HFD+STZ rats was the result of insulin resistance followed with relative insulin deficiency, as in human type 2 diabetes.

At 4 wk, the high-dose YQZMT (HDY) showed a significant reduction in serum glucose, HOMA-IR, TC and LDL-c, and a significant increase in HDL-c compared with MOD, while rosiglitazone (ROS) only reduced serum glucose and HOMA-IR (Table 3). After 8 wk of treatment, TG in HDY also showed a significant reduction (Table 4). The medium-dose YQZMT (MDY) also significantly reduced serum glucose and TG, and increased HDL-c. YQZMT of all oral dosage did not influence the body weight of diabetic rats. However, diabetic rats receiv-

ing rosiglitazone reduced TC and LDL-c, but without significant differences compared with the MOD group, and gained more body weight than the HDY group (Table 4). The HOMA-IR score in MOD group was 2.3 times higher than in the CON group, which markedly fell to 55.8% of ROS group and 58.5% of HDY group (Table 4).

IPGTT and ITT in diabetic rats after 8 wk treatment

IPGTT and ITT were carried out in diabetic rats after 8 wk of treatment to measure glucose tolerance and insulin sensitivity. Serum glucose levels were significantly elevated during the IPGTT in MOD compared with CON at all time points (Figure 2A). Accordingly, the AUC was roughly two-folds larger in MOD rats than in CON rats (2424.6 ± 372 mmol/L per minute vs 1340.1 ± 126.75 mmol/L per minute, *P* < 0.01). YQZMT and rosiglitazone attenuated the glucose intolerance, as the AUC was significantly smaller during the IPGTT in MDY (1674 ± 205.95 mmol/L per minute, *P* < 0.01), HDY (1567.8 ± 327.75 mmol/L per minute, *P* < 0.01), and ROS (1812.6 ± 134.55 mmol/L per minute, *P* < 0.01) compared with MOD rats. To investigate the differences in insulin sensitivity, we performed an ITT at different time points (Figure 2B). After insulin administration in CON group, glucose concentrations declined rapidly; however, the glucose concentrations declined slowly in MOD group. This demonstrated that MOD group presented insulin resis-

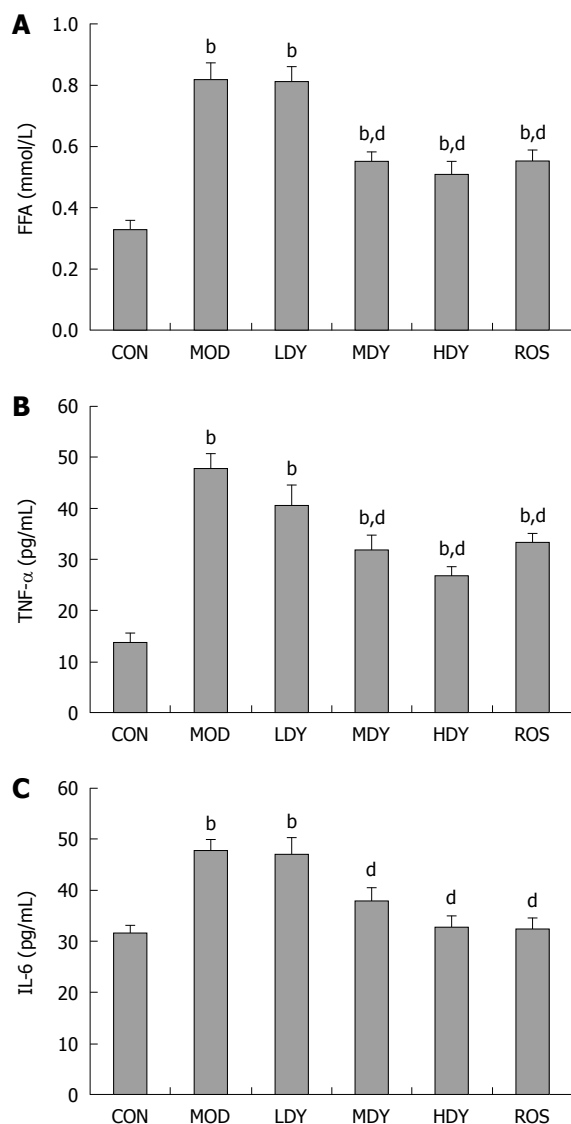

Figure 3 Free fatty acid and adipocytokines in diabetic rats after 8 wk treatment. A: Values of free fatty acid (FFA) in diabetes after 8 wk treatment; B: Values of tumor necrosis factor- α (TNF- α) in diabetes after 8 wk treatment; C: Values of interleukin-6 (IL-6) in diabetes after 8 wk treatment. CON: Control group; MOD: Type 2 diabetes model group; LDY: Low-dose Yi-Qi-Zeng-Min-Tang (YQZMT) group; MDY: Medium-dose YQZMT group; HDY: High-dose YQZMT group; ROS: Rosiglitazone group. Bar graphs indicate mean \pm SE. ^b $P < 0.01$ vs CON group; ^d $P < 0.01$ vs MOD group.

tance. YQZMT and rosiglitazone ameliorated the insulin resistance, since the percentage of initial glucose level in LDY, MDY, HDY and ROS was shown to be significantly lower than that of MOD group during 120 min.

FFA and adipocytokines in diabetic rats after 8 wk of treatment

The serum levels of FFA, TNF- α and IL-6 in diabetic rats after 8 wk of treatment are illustrated in Figure 3. When compared with CON group, the MOD group showed significant increase in serum levels of FFA (0.82 ± 0.05 mmol/L *vs* 0.33 ± 0.03 mmol/L, $P < 0.01$, Figure 3A), TNF- α (47.98 ± 2.75 pg/mL *vs* 13.91 ± 1.74 pg/mL, $P < 0.01$, Figure 3B), and IL-6 (47.77 ± 1.92 pg/mL *vs*

31.60 ± 1.45 pg/mL, $P < 0.01$, Figure 3C).

The diabetic rats treated with medium- and high-dose YQZMT (MDY and HDY group) and rosiglitazone (ROS group) showed significant reduction of the following parameters when compared with the untreated diabetic group (MOD group): serum levels of FFA (MDY *vs* MOD: 0.55 ± 0.03 mmol/L *vs* 0.82 ± 0.05 mmol/L; HDY *vs* MOD: 0.51 ± 0.04 mmol/L *vs* 0.82 ± 0.05 mmol/L; ROS *vs* MOD: 0.55 ± 0.04 mmol/L *vs* 0.82 ± 0.05 mmol/L, $P < 0.01$, respectively, Figure 3A), TNF- α (MDY *vs* MOD: 32.18 ± 2.88 pg/mL *vs* 47.98 ± 2.75 pg/mL; HDY *vs* MOD: 26.76 ± 1.94 pg/mL *vs* 47.98 ± 2.75 pg/mL; ROS *vs* MOD: 33.49 ± 1.75 pg/mL *vs* 47.98 ± 2.75 pg/mL, $P < 0.01$, respectively, Figure 3B), and IL-6 (MDY *vs* MOD: 37.84 ± 2.65 pg/mL *vs* 47.77 ± 1.92 pg/mL; HDY *vs* MOD: 32.74 ± 2.27 pg/mL *vs* 47.77 ± 1.92 pg/mL; ROS *vs* MOD: 32.54 ± 2.08 pg/mL *vs* 47.77 ± 1.92 pg/mL, $P < 0.01$, respectively, Figure 3C).

DISCUSSION

The therapeutic effects for type 2 diabetes are limited due to unavailability of effective medications. TCM has demonstrated a good practice in the treatment of diabetes mellitus and its complications^[17,20,23,24]. The present study was undertaken to investigate the effect of Chinese herbal decoction YQZMT on insulin resistance in high-fat diet and low-dose STZ-induced diabetic rats.

The chronic consumption of a high-fat diet is strongly associated with development of obesity^[25] and can induce insulin resistance in human and animals^[26-28]. The high-fat diet and low-dose STZ induced type 2 diabetic rat model mimicks the natural history of the disease events (from insulin resistance to β cell dysfunction) as well as metabolic features of human type 2 diabetes^[21,29]. In the present work, the model group of type 2 diabetes showed significant increase in serum levels of glucose, HOMA-IR value, TC, TG, LDL-c and decrease in HDL-c, coupled with impaired glucose tolerance and insulin sensitivity when compared with the normal control group. Insulin secretion of the model group rats, which was maintained initially, gradually declined but was not depleted at the end of the study. These results indicated the successful development of type 2 diabetes rat model with insulin resistance.

Administration of YQZMT induced dose- and time-dependent changes in biochemical parameters in the type 2 diabetic rats. In general, high-dose YQZMT exhibited the best effect. Treatment for 8 wk with high-dose YQZMT was found to significantly decrease the high serum glucose concentration, HOMA-IR, TC, TG, LDL-c, FFA, TNF- α , IL-6, and increase HDL-c compared with the model group, with a similar effect of rosiglitazone. However, rosiglitazone group reduced TC and LDL-c without significant differences. And a trend towards a decrease in serum insulin concentration could be found in the high-dose YQZMT group compared with the model group, while no change was seen in rosiglitazone group. IPGTT and ITT also verified that high-dose YQZMT

markedly improved glucose tolerance and insulin resistance. Like other studies^[30], we identified an increase in body weight in the group receiving rosiglitazone, and this was not found in groups administered with YQZMT.

Dyslipidemia contributes directly to development of type 2 diabetes mellitus as lipolytic products may induce gluconeogenesis in the liver, thus contributing to hyperglycemia^[31]. Well-established relationship of LDL-c levels with cardiovascular risk and the availability of proven treatments support LDL-c as the primary target^[32]. Furthermore, multiple epidemiologic studies have established a low level of HDL-c as an independent risk factor for CVD^[33]. While LDL-c-lowering strategies have consistently reduced cardiovascular risk, currently available options to increase low HDL-c levels are only moderately effective and associated with tolerance issues. In our study, reduction of serum TG (56.3%), TC (49.1%), LDL-c (58.8%) and increase of HDL-c (68%) were achieved after 8-wk treatment with high-dose YQZMT compared with the model group. However, diabetic rats receiving rosiglitazone treatment reduced TC and LDL-c, but without significant differences. It demonstrates that YQZMT may be a promising new strategy to address diabetic dyslipidemia and to reduce cardiovascular risk.

In accordance with the significant decrease of serum glucose, TG, TC and LDL-c, increase of HDL-c, amelioration of insulin resistance, and significant decrease of FFA, TNF- α and IL-6 levels were also observed in the high-dose YQZMT group compared with the model group. Chronically elevated FFA may impair insulin secretory function through the “lipotoxicity hypothesis” and can also induce or aggravate insulin resistance and contribute to the development of type 2 diabetes^[34-39]. The fact that TNF- α impairs insulin signaling, has been proven to be due to stimulation of serine phosphorylation of IRS (*via* activity of the serine kinase inhibitor of nuclear factor- κ B kinase), leading to both degradation of IRS and inhibition of tyrosine phosphorylation which is essential to insulin signaling and action^[8,40,41]. IL-6 plays a direct role in insulin resistance at the cellular level by inhibiting insulin receptor signal transduction through induction of suppressor of cytokine signaling-3^[42] and insulin metabolic actions including inhibition of insulin-induced glycogen synthesis^[43]. Our study confirmed again that the circulating FFA, TNF- α and IL-6 are elevated in established type 2 diabetes^[44-47] and rosiglitazone has the property of reducing levels of FFA, TNF- α and IL-6^[30,48,49]. Significant reduction of serum FFA, TNF- α and IL-6 was achieved after 8-wk treatment with medium- and high-dose YQZMT, similarly with rosiglitazone.

YQZMT may mediate glucose and lipid metabolism *via* ameliorating insulin resistance by down-regulating adipocytokines and fatty acids metabolism.

In conclusion, YQZMT has beneficial effects in insulin resistance, glycaemic control, dyslipidemia, FFA and adipocytokines in type 2 diabetes mellitus. Our findings demonstrate that YQZMT displays the insulin sensitization characteristic of rosiglitazone, but unlike rosigli-

tazone, does not cause any increase in body weight. Administration of YQZMT may be a suitable adjunct for the treatment of insulin resistance patients. Further studies will be required to identify the ingredients and chemicals in YQZMT responsible for the beneficial effects observed in the present study.

COMMENTS

Background

The prevalence of type 2 diabetes is dramatically increasing throughout the world. Insulin resistance is a hallmark of type 2 diabetes, and it most often precedes the onset of hyperglycemia and predicts development of type 2 diabetes. At present, thiazolidinediones (TZD), the agonists of the peroxisome proliferator-activated receptor γ , are the main agents to improve insulin sensitivity in the liver, adipose tissue, and skeletal muscle, thus improving glycaemic control in patients with type 2 diabetes. Despite the efficacy, some deleterious side effects of TZDs, including rosiglitazone and pioglitazone, have been noted, such as increasing body weight and aggravating heart failure through fluid retention. Therefore, development of new agents may be helpful in the treatment of type 2 diabetic patients with insulin resistance. Yi-Qi-Zeng-Min-Tang (YQZMT), a traditional Chinese compound recipe consisting of 10 medicinal herbs, is considered to be a useful medicine for the amelioration of insulin resistance of type 2 diabetes.

Research frontiers

Insulin resistance is a hallmark of type 2 diabetes, characterized by a decreased response of the peripheral tissues to insulin action. Insulin resistance produces elevations in glucose and lipid levels. It has become increasingly evident that obesity and the concomitant development of inflammation are major components of insulin resistance. Studies have revealed a clear association between pro-inflammatory signaling pathways and decreased insulin sensitivity. Pro-inflammatory adipokines including tumor necrosis factor- α , interleukin-6, as well as free fatty acids (FFAs), have been implicated to play important roles in inflammation, insulin resistance, and type 2 diabetes. The results of this study indicate that YQZMT has beneficial effect in insulin resistance, glycaemic control, dyslipidemia, FFA and adipocytokines, and does not cause any increase in body weight in high-fat diet and low-dose streptozotocin induced type 2 diabetic rats.

Innovations and breakthroughs

This study has established a model of type 2 diabetes with insulin resistance, and the beneficial effect of YQZMT was observed on insulin resistance, glycaemic control, dyslipidemia, FFA and adipocytokines in type 2 diabetes mellitus. YQZMT displays the insulin sensitization characteristic of rosiglitazone, but unlike rosiglitazone, does not cause any increase in body weight.

Applications

YQZMT, which ameliorates insulin resistance and does not cause increase in body weight, can be used as an adjunct for the treatment of type 2 diabetes.

Terminology

YQZMT, a traditional Chinese decoction, consisting of *Radix Astragali*, *mung bean coating*, *Folium Perillae*, *Phellodendron amurense Rupr*, *Pollen Typhae*, *Serissa foetida*, *Ramulus Cinnamomi*, *Radix Aconiti Lateralis Preparata*, *Coptis Chinensis Franch*, and *Rhizoma Alismatis*.

Peer review

Work by Zhang *et al.*, described in the present manuscript, generates data indicating a therapeutic effect of an herbal extract of Chinese medicinal plants in a rat model of insulin resistance and diabetes mellitus. The therapeutic effect is shown as changes in plasma markers of metabolic alterations and inflammation related to insulin resistance and diabetes, as well as whole body tests such as intraperitoneal glucose tolerance test and insulin tolerance test.

Abstract

AIM: To determine the expression of toll-like receptor 9 (TLR9) in pancreatic tumor and the effects of cytosine phosphate-guanosine oligodeoxynucleotides 2216 (CPG ODN2216) on biological behavior of pancreatic carcinoma cell line PANC-1 and explore their clinical significance.

METHODS: The immunohistochemistry and Western blot were used to determine the expression of TLR9 protein in pancreatic cancer tissues, and immunofluorescence staining was performed to detect the TLR9 protein expression in pancreatic carcinoma cell line PANC-1. To assess the effects of CPG ODN2216 on the invasive property of Panc-1 cells, *in vitro* cell adhesion, wound-healing scrape, and invasion and cell colony formation were evaluated.

RESULTS: TLR9 was highly expressed in pancreatic

cancer tissues and PANC-1 cells. The percentage of positive cells expressing TLR9 protein in human pancreatic tissues, paracancerous tissues and normal tissues were 73.3%, 33.3% and 20.0%, respectively, and the protein expression level of TLR9 was gradually descending ($P < 0.05$). *In vitro* tests in wound-healing scrape, cell adhesion, colony formation and matrigel invasion showed that the adhesion and motility of PANC-1 cells in CPG ODN 2216 treatment group were significantly lower than in the control group ($P < 0.05$). The cell growth assay showed that the proliferative ability of PANC-1 cells in treatment group was significantly decreased and CPG ODN2216 had an inhibitive effect in the growth of Panc-1 cells in a dose and time-dependent manner ($P < 0.05$).

CONCLUSION: The gene of TLR9 is correlated with the invasive and metastatic potential of human pancreatic carcinoma, and CPG ODN2216 induces the inhibition of migration and invasion of Panc-1 cells.

INTRODUCTION

Pancreatic cancer is a highly malignant tumor of digestive

system, with a very poor prognosis^[1,2]. In the developed countries, the pancreatic cancer ranks the fourth in the mortality of malignant tumors^[3]. The five-year survival rate is less than 5% and the median survival time is 5-6 mo. Although 10%-15% of patients have the opportunity for radical surgery, the median survival time is only 10-18 mo and the 5-year survival rate is about 17%-24%^[4,5]. The poor prognosis of pancreatic cancer patients is mainly due to local invasion and early metastasis^[6]. Most patients with pancreatic cancer are diagnosed when they are found to have local invasion or distant metastasis. Therefore, further studies of the molecular biological behavior of pancreatic cancer are necessary to improve the diagnosis of pancreatic cancer, prevention and treatment.

Toll-like receptors (TLRs) are pathogen receptors which have been recently discovered to have the ability of identifying specific types of micro-organisms, namely the pathogen-associated molecular patterns (PAMPs)^[7,8]. Recent studies found that the expression of TLRs occurred not only in immune cells, but also in normal epithelial cells and tumor cells^[9]. The activity of TLRs in tumor cells may delay the anti-tumor function of immune cells, interfere with the role of the immune response, leading ultimately to tumor progression^[10-12].

TLR9 is an important member in this family, with an ability to induce significant secretion of cytokine and chemotactic factors by B cells and dendritic cells, such as interleukin (IL)-12, IL-6, interferon- γ (IFN- γ), monocyte proinflammatory and matrix metalloproteinase^[13]. High-level expression of TLR9 was detected in a wide variety of tumors, however, it remains unknown whether TLR9 is expressed and what role it plays in pancreatic cancer. In order to investigate the role of TLR9 in the development of pancreatic cancer, the immunohistochemistry and Western blotting were used to determine the expression of TLR9 protein in pancreatic cancer tissues and immunofluorescence staining was also performed to detect the TLR9 protein expression in pancreatic carcinoma cell line PANC-1. And we employed TLR9-targeting ligand-synthetic CPG ODN2216 to stimulate pancreatic cancer cell Panc-1 and observe the changes in malignant phenotype of this cell line in terms of proliferation, growth, tumorigenic and invasive ability and the correlation between *TLR9* gene and the pancreatic cancer cells. All these will benefit the future research of the specific mechanism of TLR9 gene.

MATERIALS AND METHODS

PANC-1 cell line and cells culture

The pancreatic cancer cell line Panc-1 was supplied by the laboratory of the Department of General Surgery, Wuhan Union Hospital affiliated to Tongji Medical College of Huazhong University of Science and Technology. The cells were cultivated in Dulbecco's Modified Eagle Medium (DMEM) which contains 10% fetal bovine serum (FBS) and 100 μ mol/mL mycillin under 5% CO₂ at 37°C.

Tissue slices

Fresh human pancreatic cancer tissues ($n = 30$) and ho-

mologous peritumoral tissues (1-2 cm from the edge of cancer) were collected from pancreatic cancer patients. The normal human pancreatic tissues ($n = 30$) were obtained from non-cancer patients who had to be depancreatized for other reasons. All of the specimens were taken from patients with pancreatic cancer who were treated surgically in the Pancreatic Surgery Center of Wuhan Union Hospital and confirmed by post-operational pathology.

Main reagents and antibodies

CpG-ODN2216 (serial number: GGGGGACGATC-GTCGGGGGG) was synthesized, specifically phosphorothioate decorated and polyacrylamide gel electrophoresis (PAGE) purified by Sheng Gong Bio-engineering Company, Shanghai, China; TLR9 monoclonal antibody was provided by the Cell Signaling Company, USA; matrigel and dimethyl sulfoxide (DMSO) were purchased from Sigma-Aldrich Company, USA; and immunohistochemistry and immunofluorescence reagent kits were obtained from Boster Bio-engineering Co., Ltd., Wuhan, China.

Western blotting

Conventional methods were used to extract tissue proteins and the consistency of protein was measured by the method of Coomassie brilliant blue. Fifteen μ L protein was taken for 10% polyacrylamide gel electrophoresis and transferred to a nitrocellulose filter by electrolysis. To block the non-specific antigen, the sections were incubated with 5% skim milk added with 1:750 diluted rabbit anti-human antibody TLR9 monoclonal antibody, followed by overnight incubation at 4°C. Membranes were washed with Tris-Buffered Saline Tween-20 (TBST) containing 0.1% Tween20, added with goat anti-rabbit IgG antibodies (Boster Bio-engineering Co., Ltd., Wuhan, China) tagged with horseradish peroxidase (HRP) and incubated at room temperature for 2 h. After being washed and added with ECL Plus reagent, an enhanced chemiluminescence substrate, the membranes were exposed on X-ray films for 30 s, followed by routine development and fixation. Finally, the images were scanned and analyzed by an image analysis software for gel electrophoresis (Band scan v5.0).

Immunohistochemistry

The streptavidin peroxidase (SP) methods were used for the immunohistochemical studies. The staining step followed the routine process. The paraffin sections were prepared, dewaxed and hydrated by alcohol. After being immersed in 3% hydrogen peroxide for 10 min, the sections underwent antigen retrieval in 0.01 mol/L citrate buffer solution (pH 6.0) and then blocked at room temperature for 30 min by 5% goat serum albumin with subsequent removal of sealing solution. The appropriately diluted primary antibody was added, and the control antibody was replaced with phosphate buffer solution (PBS) and kept at 4°C overnight. They were rinsed with PBS for 3 times, 5 min each time; biotinylated secondary antibodies were incubated at room temperature for 30 min and washed with PBS for 3 times; and horseradish peroxidase (HRP)

labeled avidin was added and incubated at room temperature for 30 min. Finally, after PBS rinsing, DAB-staining, hematoxylin staining, dehydration, and septum pellucidum mounting, results were observed under microscope.

Immunofluorescence method

Pancreatin-digested pancreatic cancer cells were used to prepare single cell suspension and the cell suspension was dropped onto glass slides. Creeping plates were taken out after 24 h or longer according to the cell growth state and rinsed with PBS for 3 times (5 min each time), followed by 15 min fixation with 4% paraformaldehyde, PBS rinse and 20 min perforation by 0.5% Triton.

After rinsed with PBS for 3 times, the PANC-1 cell slides were blocked for 30 min by 5% bovine serum albumin (BSA). The first antibody dilution was added directly after dryness while PBS was used in the control group. Following overnight incubation at 4°C and rinsing with PBS for 3 times, the diluted second antibody was added and incubated for 1 h at 37°C. Finally, the slides were observed under a fluorescence microscope after PBS rinse for 3 times, and added with diluted Strept Avidin Biotin Complex - fluoresceine isothiocyanate (SABC-FITC) and incubated for 30 min at 37°C. PBS rinse was repeated for 3 times and sealed by water-soluble sheet.

Cell growth assay

Cell viability was measured using the Cell Counting Kit-8 (CCK-8) assay (Beyotime Bio., Shanghai, China) according to the method described previously^[14]. Pancreatic cancer cell suspension was transferred into 96-well tissue culture polystyrene (TCP) plates with 1×10^3 cells or 100 μ L per well. The cells were cultured at 37°C under 5% CO₂ and saturated humidity. After cell attachment at time point of 24 h, CPG ODN2216 of various concentrations (0.1, 0.5, 1, 5 and 10 mg/L) was added to act on Panc-1 cells, followed by addition of 20 μ L CCK8 of 5 mg/mL at time points of 24, 48 and 72 h, respectively and 4 h cell culture. Finally, after thorough shaking and mixing, absorbance values were determined by enzyme-linked immunosorbent assay (ELISA) reader. Inhibition rate (IC) = (A control group - A drug group)/A control group \times 100%. The curve of inhibited proliferation was plotted and IC50 was obtained.

Scratch adhesion test

Panc-1 cellular suspension at a concentration of 2×10^5 /mL was inoculated into a 6-well culture plate at 3 mL per well, and cultured for 24 h. In the next step, culture medium was removed and replaced by CPG ODN2216 culture medium at concentrations of 1 and 10 mg/L, respectively after the cell growth rate reached 80%. Supernatant was abandoned and scratches were carried out in the center of wells using a scraping cutter. Four marks were used as test sites at an equal distance along the scratch edge and the average value was obtained.

Cell adhesion test

Collagen gel overlays were prepared on 96-well TCP plates, followed by air dryness, BSA blocking and 60min

incubation. The cell concentrations of treatment group (interfered by CPG ODN at 1 and 10 mg/L for 24 h) and control group was adjusted to 5×10^5 /mL, and both cellular suspensions were inoculated in transwells, leading to 200 μ L/well. With 1h incubation, PBS rinsing, addition of 5 mg/ml methyl thiazolyl tetrazolium (MTT) and 4 h culture, the culture medium was abandoned and the remainder was dissolved in DMSO for 20 min. Lastly, absorbance values were measured at 490 nm wavelength. Cell adhesion inhibition rate = (A control group-A drug group)/A control group \times 100%. Each group contained 3 repeated wells and the average values were obtained.

In vitro invasion assay

Cell invasion *in vitro* was performed in Matrigel Invasion Chambers (Becton Dickinson Co., Franklin Lakes, NJ) in 24-well culture plates, as described previously^[15]. Thirty μ L synthetic basal membrane was added into transwell upper chamber and underwent air dryness. Then, 200 μ L of 24 h starvation-cultured cells was added respectively and the concentration of CPG ODN was adjusted to 1 and 10 mg/L. DMEM culture medium (500 μ L) containing 10% FBS as chemokine was added into the lower chamber of invasive cabinet. It was taken out of cabinet after 24 h culture at 37°C under 5% CO₂ and then cotton swab was used to rub away unigrated cells and superfluous liquid in upper chamber. After that, the cabinet was fixed for 10 min in 4% polyoxymethylene and dyed for 30 min with 1% crystal violet, followed by thorough membrane washing with deionized water. Finally, cells were observed and counted under microscope. Each group contained 3 repeated wells and the average values were obtained.

Cell cloning test

Panc-1 cells were digested with pancreatin and single cell suspension was prepared by blowing method, and then inoculated into a 6-well plate at about 200/well. Three groups were set up, one group without CPG ODN2216, the other two containing 1 and 10 mg/L CPG ODN2216, respectively. Each group contained two repeated wells. Then, the inoculated cells were cultured in the incubator till d 14. Cell culture was suspended when visible clone appeared and then culture medium was removed, rinsed by PBS, dyed for 30 min with hematoxylin and PBS rinse was repeated. Finally, the formation rate of cell clone was calculated and photographed by digital camera. The test was repeated 3 times.

Statistical analysis

Experimental data was analyzed by Statistical Package for Social Sciences(SPSS) software(SPSS, Inc., Version 16.0,USA), All of the data were represented by mean \pm SD and *T* test was performed for statistical analysis, and *P* values < 0.05 were considered statistically significant.

RESULTS

Western blotting test

As shown in Figure 1, the expression of glyceraldehyde-

Figure 1 Western blotting test for toll-like receptor 9 protein. 1: Normal human pancreatic tissue; 2: Human peritumoral tissue; 3: Human pancreatic cancer tissue. TLR-9: Toll-like receptor 9; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

3-phosphate dehydrogenase (GAPDH) protein was detected in cancer tissues, homologous peritumoral tissues and normal pancreatic tissues and protein band was located at 36 kDa. TLR-9 was expressed at 130 kDa. The expression level of TLR9 in cancer tissues was significantly higher than in both peritumoral tissues and normal pancreatic tissues.

Expression of TLR9 protein in pancreatic cancer tissues

Immunohistochemistry showed that TLR9 protein was mainly expressed in the cytoplasm of cancer cells, exhibiting yellowish and reddish brownness in an even manner. The expression of TLR9 protein was detected in both peritumoral tissues and normal pancreatic tissues, showing light yellowness and the expression level was lower than in the pancreatic cancer tissues. The total positive rates of TLR9 protein were 73.3% in human pancreatic cancer (22/30) and 33.3% (10/30) and 20% (2/10) in pancreatic peritumoral tissues and normal pancreatic tissues, respectively. There were statistical differences among the three groups ($\chi^2 = 13.99$, $P < 0.01$), (Figure 2).

Expression of TLR9 protein in Panc-1

The high expression of TLR9 in Panc-1 cells was found by immune fluorescence method. Upon excitation by ultraviolet, cytoplasm displayed green fluorescence whereas control group did not show the fluorescence (Figure 3).

Effects of CPG ODN2216 on proliferation of pancreatic cancer cell line Panc-1

CPG ODN2216 of different concentrations (0.1, 0.5, 5 and 10 mg/mL) showed inhibitory effects on Panc-1 cell line, and the growth inhibition rate increased markedly with concentration and time. Growth inhibition curve was plotted and the IC₅₀ at 24, 48 and 72 h was 65.1, 16.43 and 4.47 mg/mL, respectively. The inhibitory effect was time and dose dependant (Figure 4).

Cell scratch test

The results of scratch test showed that in contrast with control group, migration ability of Panc-1 cell was decreased with addition of CPG ODN2216 and higher CPG ODN2216 concentration led to significantly lower

Figure 2 Expression of toll-like receptor 9 protein. Brown color displays the positive expression. A: Human pancreatic cancer tissue ($\times 200$); B: Peritumoral human pancreatic cancer tissue ($\times 200$); C: Normal pancreas tissue ($\times 400$).

migration ability. Migration distance after 48 h was 20.20 ± 1.06 mm at 10 mg/L and 17.37 ± 0.70 mm at 1 mg/L and 13.27 ± 1.11 mm in the control group, the difference being statistically significant ($P < 0.05$), (Table 1, Figure 5).

Effects of CPG ODN2216 on the adhesion of pancreatic cancer cell line Panc-1 and its in vitro invasive ability

The adhesive inhibition rates were 12.5% and 2.5% respectively in 1 mg/mL CPG ODN treated group and 10 mg/L CPG ODN group, respectively. Cell adhesion strength was significantly lower than control group ($t = 25.4$, 14.9 $P < 0.01$) and the inhibitory effect appeared dose-dependent ($t = 6.32$, $P < 0.01$). The control group had higher invasive ability, and the higher the concentration of CPG ODN2216, the fewer cells crossed the membrane. Invasion inhibitory rates were 21.6% and 59.5%, respectively ($t = 6.59$, 13.79 $P < 0.01$), showing a dose-effect relationship ($t = 18.29$ $P < 0.01$), (Table 2, Figure 6).

Figure 3 Immunofluorescence staining test. The expression of toll-like receptor 9 (TLR9) was mainly detected in Panc-1 cell cytoplasm ($\times 200$). A: TLR9 was highly expressed in Panc-1 cells; B: TLR9 was negatively expressed in control group.

Cell colony formation

Hematoxylin stained cells in 10 mg/mL CPG ODN2216 treated group showed significantly fewer colonies per square centimeter ($0.27 \pm 0.13/\text{cm}^2$) than in group 1 mg/L (1.08 ± 0.11) and control group (1.17 ± 0.12), with statistical difference between the latter two groups ($t = 8.29$, 8.67 $P < 0.01$) but without significant difference between treatment group and control group ($P > 0.05$), (Figure 7).

DISCUSSION

Pancreatic cancer has a high degree of malignancy and develops stealthily, seriously threatening the human health. Therapeutic effects have been low by the available treatment methods and prognosis is poor. Epidemiological studies showed that both the incidence and mortality of pancreatic cancer are hiking in recent years^[16]. Currently, in China pancreatic cancer jumped from 16th to 6th in the death rate caused by a variety of cancer. Therefore, search for target of gene therapy for pancreatic cancer has always been the focus in this field. Substantial findings demonstrate that signaling pathway induced by TLRs and TLR9 may play an important role in the development of tumors and the up-regulation of TLRs expression may be closely connected with the stomach, lung, bowel cancers and so on^[17]. The expression of TLR9 in tumor is expected to provide new regimens for tumor chemotherapy and immunotherapy. In this study, we used Western blotting and immunohistochemical analysis to detect the expression

Figure 4 Inhibitory effect of cytosine phosphate-guanosine oligodeoxynucleotides 2216 of different concentrations on Panc-1 cell line with growth inhibition rate increasing remarkably with concentration and time.

Table 1 Migration width in different groups (mean \pm SE)

Time	Control group (mm)	1 mg/L group (mm)	10 mg/L group (mm)
0 h	23.98 \pm 1.71	24.02 \pm 1.67	22.52 \pm 1.43
48 h	13.27 \pm 1.11 ^b	17.37 \pm 0.70 ^b	20.20 \pm 1.06 ^b

Compared with control group, ^b $P < 0.01$.

Table 2 Mobility, adhesion and invasion ability of different groups ($n = 3$, mean \pm SE)

Group	Cell adhesion rate (%)	Cell number of invasion
Control group	0	198 \pm 13
1 mg/L	12.5 \pm 0.85 ^b	144 \pm 5 ^b
10 mg/L	22.5 \pm 2.62 ^a	80 \pm 6 ^a

of TLR9 gene in pancreatic cancer tissues and found that the expression of TLR9 gene in pancreatic cancer tissues was significantly higher than in pancreatic peritumoral tissue and normal pancreatic tissues. This is in agreement with Droemann's^[18] findings in lung cancer study. We also determined the expression of TLR9 gene in pancreatic cancer cells using immunofluorescence method and found high level expression of TLR9 protein in pancreatic cancer cells, mainly in endochylema. In order to investigate the significance of high expression of TLR9 gene in pancreatic cancer cells and clarify its effects, we applied specific ligands of TLR9, namely CPG ODN2216 and pancreatic cancer cell Panc-1, to study the function of CPG ODN and its influence on TLR9 gene in human pancreatic cancer cells.

In recent years it has been verified that CPG ODN has a strong immunoregulatory effect in Th1 direction, mainly through its combination with TLR9 and induction of secretion of Th1 polarizing cell factors such as IFN- γ , IL-12 and so on, promoting the differentiation of Th0 to Th1^[19,20]. For example, CPG DNA penetrates into dendritic cells (DCs) by means of sequence indepen-

Figure 5 Panc-1 cell scratch test at various time points ($\times 400$). Compared with control group, a higher cytosine phosphate-guanosine oligodeoxynucleotides 2216 concentration led to significantly lower migration ability ($P < 0.01$).

Figure 6 Invasion ability of Panc-1 in cabinet ($\times 200$). A: In control group, there are more Panc-1 cells penetrating through filter membrane; B: The cell number of 1 mg/mL cytosine phosphate-guanosine oligodeoxynucleotides (CPG ODN) treated group penetrating through filter membrane decreased significantly (A vs C, $P < 0.01$); C: The Panc-1 cell number of 10 mg/mL CPG ODN treated group penetrating through filter membrane further decreased (A vs B, $P < 0.01$).

dent, receptor-mediated endocytosis, then acts on TLR9 specifically in lysosomal area and finally activates signal transduction through interleukin-1 receptor associated kinase (IRAK1), interferon regulatory factor 7 (IRF7), TNF receptor-associated factor 6 (TRAF6), mitogen-activated protein kinases (MAPK) and nuclear factor κ B (NF- κ B) pathway and adaptor myeloid differentiation primary response gene (88) (MyD88)^[21-24]. However, at present, CpG ODN, which is used as an immunoadjuvant to induce Th1 immune response on human lung adenocarcinoma A549 cell by means of TLR9, may be adopted for monotherapy or supplement to immunization therapy to treat cancers^[25]. As for the direct effect of CPG ODN on pancreatic cancer, there has been no report in the literature so

far. We combined CPG ODN2216 and pancreatic cancer cell and found by CCK-8 assay that the growth and proliferation of pancreatic cancer cells were inhibited *in vitro* and the inhibitory effect was time-dose dependent.

One of the important biological characteristics of malignant tumor is its invasion into adjacent tissues and subsequent distant metastasis. Invasion is recognized as the foundation and precondition of distant metastasis and distant metastasis is the continuation and further development of invasion. Factually, they are two stages of the same process, and pancreatic cancer invasion and metastasis into adjacent tissues occur in the early stage. Only by preventing the two biological behaviors at proper time can we defeat pancreatic cancer. Like other tumors, invasion

Figure 7 Cell cloning test. A: More colonies are formed in the control group; B: The colony formed in the 1 mg/L cytosine phosphate-guanosine oligodeoxynucleotides (CPG ODN) treated group is the same as in the control group ($P > 0.05$); C: There are fewer colonies formed in the 10 mg/L CPG ODN treated group (A vs B, $P < 0.01$).

and metastasis of pancreatic cancer is a process characterized by polygenic participation, multi-steps and multi-stages^[26]. At the same time, the adhesion and invasion process increases the malignant tumor survival and metastasis ability, that is a committed step in the tumor transition process^[27]. To further investigate the role of TLR9 gene in the process of tumor invasion and metastasis, TLR9 specifically ligand-CPG ODN2216 and pancreatic cancer cell line Panc-1 were applied in the subsequent tests such as scratch adhesion test, adhesion test, Transwells *in vitro* invasion assay, cell clone test and so on. Scratch adhesion test is considered as one of the classic ways to determine cell immigration ability and adhesion and invasion test can relatively ideally simulate and reflect the invasion behavior and ability of tumor cells. Cell clone test can also be used to detect the proliferation ability of cancer cells. CPG ODN2216 had weakened *in vitro* migration, membrane anchor ability and clone proliferation ability of Panc-1 cells compared with the cells in the control group. Therefore, the expression of TLR9 can influence the degree of malignancy of human pancreatic cancer cell line.

In conclusion, there is high expression of TLR9 in both human pancreatic tissues and Panc-1 cells. TLR9 may increase the cell abilities of invasion, metastasis and adhesion to promote the occurrence and development of pancreatic neoplasm, and play an important role in invasion and metastasis of pancreatic cancer. However, the questions of how the gene regulates cell migration and invasion, and what transduction system ligand CPG ODN relies on to influence TLR9, remain to be answered and the specific mechanism need to be further studied.

COMMENTS

Background

Pancreatic cancer is a highly malignant digestive tumor with a very poor prognosis. Recently, an increasing number of studies reported that toll-like receptors (TLRs) were related to malignancies and involved in tumor progression, but whether TLRs, such as TLR9, is expressed in pancreatic cells remains unknown. Regulation of TLR9 signaling pathway in pancreatic cancer cells, and the relationship between the biological impact of behavior change are also unclear.

Research frontiers

Activating TLRs pathway in tumor cells could promote the proliferation and inhibit the apoptosis, leading to migration, invasion and angiogenesis of tumor, but it remains unknown whether TLR9 is expressed and what role it plays in PANC-1. There is no report about the direct effect of cytosine phosphate-guanosine oligodeoxynucleotides (CPG ODN) on pancreatic cancer in the literature so far. The authors demonstrate that the high expression of TLR9 exists in both human pancreatic tissues and Panc-1 cells. TLR9 may increase the cell abilities of invasion, metastasis and adhesion to promote the occurrence and development of pancreatic neoplasm, and play an important role in invasion and metastasis of pancreatic cancer.

Innovations and breakthroughs

This is the first study to report that TLR9 is expressed in both human pancreatic tissues and Panc-1 cells, and first demonstrate that TLR9 may increase the cell abilities of invasion, metastasis and adhesion to promote the occurrence and development of pancreatic neoplasm, and play an important role in invasion and metastasis of pancreatic cancer.

Applications

This study demonstrated that TLR9 may be a novel marker for the progression and prognosis of pancreatic cancer, and may provide a new strategy for the treatment of patients with pancreatic cancer.

Terminology

CPG ODN 2216 (cytosine phosphate-guanosine oligodeoxynucleotides 2216): the TLR9-targeting ligand-synthetic. It has a strong immunoregulatory effect in Th1 direction, mainly through its combination with TLR9 and induction of secretion of Th1 polarizing cell factors such as IFN-7 and IL-12, promoting the differentiation of Th0 to Th1.

Peer review

The authors examined the expression of TLR9 in both human pancreatic tissue and Panc-1 cells, and demonstrated a role for TLR9 in adhesion, migration and invasion of human Panc-1 cells. This is an interesting article in which the experimental design is well thought out and the results are intriguing.

Abstract

AIM: To determine the rate of use and non-use of prophylactic percutaneous endoscopic gastrostomy (PEG) tubes among patients with head and neck cancer (HNC) patients.

METHODS: All patients with HNC undergoing PEG between January 01, 2004 and June 30, 2006 were identified. Patients (or their next-of-kin) were surveyed by phone and all available medical records and cancer registry data were reviewed. Prophylactic PEG was defined as placement in the absence of dysphagia and prior to radiation or chemoradiation. Each patient with a prophylactic PEG was assessed for cancer diagnosis, type of therapy, PEG use, and complications related to PEG.

RESULTS: One hundred and three patients had PEG tubes placed for HNC. Thirty four patients (33%) could not be contacted for follow-up. Of the 23 (22.3%) patients with prophylactic PEG tubes, 11/23 (47.8%) either never used the PEG or used it for less than 2 wk. No association with PEG use *vs* non-use was observed for cancer diagnosis, stage, or specific cancer treatment. Non-use or limited use was observed in 3/6 (50%) treated with radiation alone *vs* 8/17 (47.1%) treated with chemoradiation ($P = 1.0$), and 3 of 10 (30%) treated with surgery *vs* 8 of 13 (62%) not treated with surgery ($P = 0.21$). Minor complications were reported in 5/23 (21.7%). One (4.3%) major complication was reported.

CONCLUSION: There is a high rate of unnecessary PEG placement when done prophylactically in patients with head and neck cancer.

INTRODUCTION

Significant weight loss and resultant malnutrition in patients undergoing radiation and or chemotherapy for head and neck cancer (HNC) are recognized clinical concerns^[1].

Impaired swallowing function may be further compromised by odynophagia resulting from therapy induced mucosal injury of the pharynx and esophagus. Morbidity related to poor nutritional intake during treatment may include dehydration, hospitalization, compromised treatment compliance, reduced quality of life and the potential for a negative impact on survival^[2]. Multiple interventions have been implemented to help ameliorate the impact of cytoreductive therapy on weight loss and nutritional status, including the use of percutaneous endoscopic gastrostomy (PEG) tube. Published studies suggest that HNC patients undergoing radiation and/or chemotherapy may benefit from prophylactic placement of PEG tubes^[3-9]. In our institution, many patients with newly diagnosed HNC scheduled to receive radiation and/or chemotherapy are offered a PEG tube before the start of treatment regardless of whether they have significant dysphagia. This practice is primarily in patients who are treated with combination chemotherapy and radiation based on the impression that there is added pharyngeal toxicity with this regimen.

We have observed anecdotally that a number of our HNC patients who received a prophylactic PEG tube in fact never used them. We performed a retrospective database study of all patients in whom PEG tube was placed for HNC to determine the prevalence of unused prophylactically placed PEG tubes. Data were also analyzed for possible factors predictive of unused PEGs or PEGs used for less than 2 wk.

MATERIALS AND METHODS

We performed a retrospective review of a prospectively maintained endoscopic database to identify all patients with HNC undergoing PEG between January 1, 2004 and June 30, 2006 at both the Oklahoma City Veteran Affairs and Oklahoma University Medical Center hospitals. Patients were surveyed by phone and all available medical records and cancer registry data were reviewed. If the patient was deceased, his or her next of kin was interviewed. Prophylactic PEG was defined as placement in the absence of dysphagia and prior to radiation or chemoradiation. A PEG was deemed definitely prophylactic if the patient's medical record was suggestive of prophylactic PEG placement and the patient confirmed a lack of pre-procedure symptoms by telephone survey. Possible prophylactic was defined as being when the patient's medical record indicated prophylactic PEG tube but the patient could not be contacted to confirm. Patients with definitely prophylactic PEG were assessed for: cancer diagnosis, type of therapy (radiation alone, chemoradiation, with or without surgery), whether the PEG was ever used, duration and extent of PEG use, and complications related to PEG. Patient demographics, including age, sex, and body mass index (BMI), were also recorded. Specific diagnoses and treatment modalities were examined for a correlation with PEG use *vs* non-use or limited use. For statistical purposes patients were grouped as early (Stage I or II) or late (Stage III or IV) HNC according to the American

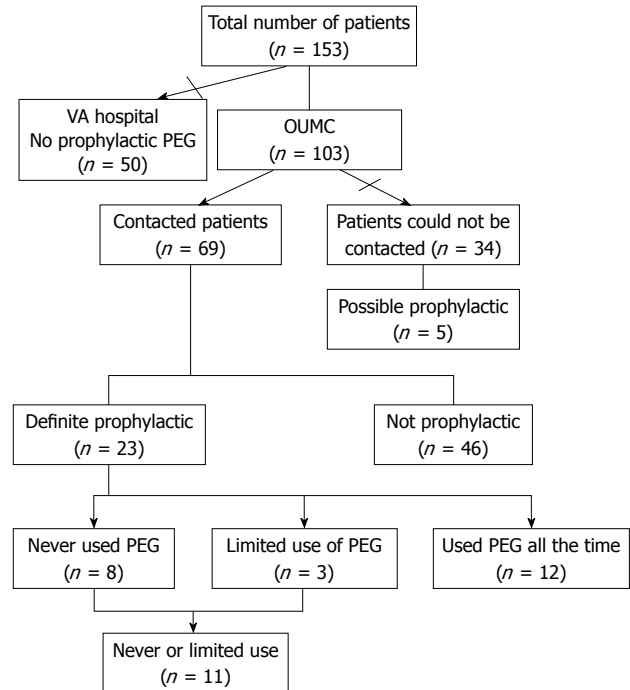

Figure 1 Patient selection. PEG: Percutaneous endoscopic gastrostomy; VA: Veteran Affairs; OUMC: Oklahoma University Medical Center.

Joint Committee on Cancer stage grouping for HNC^[10]. HNC was defined as any malignant tumor involving the lips, any region of the oral cavity, tongue, soft palate, pharyngeal wall, pyriform sinuses, supraglottic larynx, glottic larynx (true vocal cords and the mucosa of the anterior and posterior commissures) and subglottic larynx (extends to the inferior border of the cricoid cartilage).

Statistical analyses

Frequency and percentage of use (none or limited) by clinical parameters (tumor site, stage) or treatment modality (radiation, chemoradiation, surgery) are reported and graphically represented using bar charts. Fisher's exact test was employed to test for an association between nonuse of PEG and each variable.

RESULTS

One hundred and fifty three patients underwent PEG placement for HNC during the pre-specified period of time; of those, 50 patients were excluded because initial review of medical records revealed they did not meet the criteria for prophylactic PEG tube (Figure 1). Of the remaining 103 patients, 34 patients (33%) could not be contacted for follow-up. Chart review revealed that 5/34 patients not contacted likely had undergone prophylactic PEG. Of the 69 patients with available survey data it was established that 23 (22.3%) patients (19 males; 4 females; mean age 58 years) had definitely undergone prophylactic PEG. Ten patients (43.5%) had stage III HNC; seven patients (40.4%) had stage IV HNC. Fifty two percent (12/23) were classified as oropharyngeal; 39.1% (9/23)

PEG: Percutaneous endoscopic gastrostomy; XRT: Radiation therapy; CTX: Chemotherapy; N/A: Not available; NOS: No origin specified; HNC: Head and neck cancer. Staging is reported according to American Joint Committee on Cancer stage grouping for HNC.

were classified as laryngeal cancer, and one case was nasopharyngeal cancer. The treatment regimens of all patients are outlined in Table 1. All patients received various combinations of radiation, chemotherapy, and surgery. Four patients (17.4%) received radiation as the only treatment. Ten patients (43.5%) underwent surgical resection. Of these, 9 (90%) received preoperative radiotherapy and or chemoradiotherapy and one received chemoradiotherapy post operatively. Patients not using the PEG relied entirely on oral intake but the use of nutritional supplements could not be assessed (Table 1).

Of the 23 patients who underwent prophylactic PEG, 8 (34.7%) never used their PEG for feeding, and 3/23 (13%) used it for less than 2 wk. No association with PEG use *vs* non-use was observed for cancer diagnosis, stage, or specific cancer treatment (Figure 2).

Overall, complications occurred in 13/69 (18.8%). In the prophylactic PEG group, minor complications (pain and leaking at the PEG site) were reported in 5/23 (21.7%). One (4.3%) major complication (gastric perforation due to PEG tract disruption at time of tube removal) was reported. There was no difference in complication rates among patients who used the PEG for more than 2 wk *vs* those who never used it or used it for less than 2 wk; 17.4% (8/46) *vs* 21.7% (5/23), $P = 0.748$.

DISCUSSION

Not all cancer patients benefit from aggressive nutritional support as the pathophysiology behind weight loss and malnutrition is complex. HNC cancer patients are gener-

ally identified as a group of patients that may be helped by caloric supplementation^[3]. Many centers advocate prophylactic PEG tube placement in HNC cancer patients to prevent the rapid weight loss associated with aggressive cytoreductive treatments. In order to establish the practice of prophylactic PEG tube as an appropriate plan of care for these patients, certain end points need to be addressed, including: (1) effect on weight loss; (2) complication rates; (3) effect on quality of life; and (4) overall survival. With regard to weight loss prevention, multiple studies (retrospective and prospective) have demonstrated a benefit of prophylactic tube placement over on demand PEG tube placement. A retrospective study on 88 patients, found that the use of gastrostomy significantly reduced weight loss and the rate of hospitalization^[11]. Nguyen *et al*^[8] and Wiggeraad *et al*^[9] retrospectively evaluated the efficacy of prophylactic PEG tube. They found that the mean weight loss during treatment for all patients with prophylactic PEG was 8.5 kg and 2.3 kg, respectively, although no control group was available for comparison. Piquet *et al*^[6] prospectively compared patients selected for prophylactic PEG (i.e. age greater than 70, BMI less than 20, or recent weight loss greater than 10%) against comparable historical controls. Based on the criteria, 74% of patients qualified for prophylactic PEG. Patients prospectively evaluated for prophylactic intervention experienced significantly less weight loss and fewer hospitalizations for dehydration compared with a group managed with on demand PEG^[6].

PEG tube placement is considered relatively safe and has a low rate of significant associated complications but it is not an entirely benign procedure. Common complica-

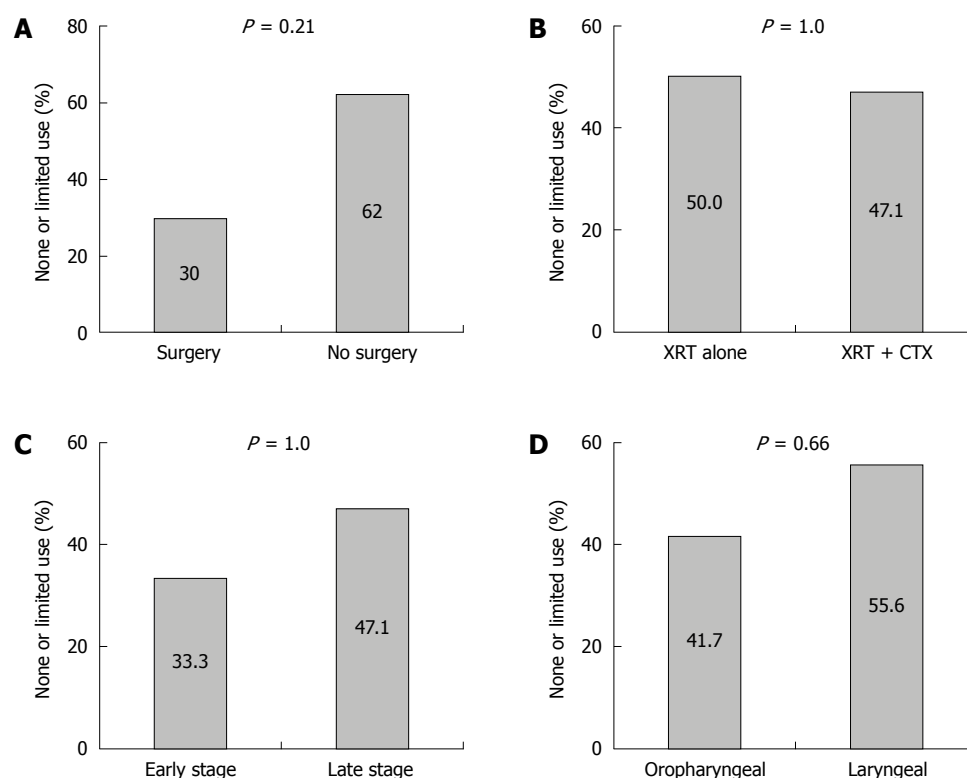

Figure 2 Percutaneous endoscopic gastrostomy use vs non-use observed for specific cancer treatment (A, B), stage (C), or cancer diagnosis (D). XRT: Radiation therapy; CTX: Chemotherapy.

tions associated with PEG tube placement include local site infection, tube blockage, and migration or dislodgement. Serious complications such as peritonitis, abscess, or fistula development are relatively uncommon^[12]. A recent systematic review of 2379 HNC patients found a PEG associated fatality rate of 2.2% and a pooled major complications rate of 7.4%^[13]. When reviewed in a meta-analysis of PEG placement in general mixed patient populations, PEG placement in HNC was associated with higher fatality rate (2.2% *vs* 0.33%) but similar overall major complication rate (7.4% *vs* 9.4%)^[14]. The frequency of complications observed following PEG tubes placement has varied in the literature depending upon the definition used and the population under study. In one study of 314 patients, 13% had minor complications and 3% had major complications^[15]. In our study, the overall complications rate observed (18.8%) is consistent with previously published rates.

Another rare but potential complication specific to this indication for PEG is metastasis of the primary tumor to the gastrostomy site, which has been described in multiple case reports^[16]. The balance between these risks and the potential benefits must be weighed. Overall quality of life should be considered. One study demonstrated that PEG placement prevented deterioration of the quality of life index during radiation therapy^[17]. On the other hand, a recent study was done to evaluate the impact of clinical predictors and other influences on long-term quality of life in patient with HNC, and found that patients with gastrostomy tubes had lower quality of life scores relative

to patients without a PEG ($P < 0.001$)^[18]. There has been no study done to evaluate the effect of prophylactic PEG tube in overall survival. Likewise the cost-effectiveness of this approach is undefined.

Limitations of our study include the inherent bias of retrospective studies in general, and the fact that one third of our patients were not available for phone survey yielding a small sample size. The study is a retrospective observational analysis on the use rates in patients with prophylactic tubes; hence temporally accurate nutritional parameters were not reliably available. There were a small number of patients with a possibly prophylactic PEG, but we choose to focus the analysis on patients that were definitely prophylactic. Inclusion of those five additional patients did not significantly alter the use rate or the overall conclusion.

Currently, there are no practice guidelines for patient selection regarding prophylactic PEG tube placement exist. Clinical judgment, in addition to patient and family preference, most commonly guides the decision on an individual basis and may vary greatly based on the practice setting.

In our study we determined that a significant number of patients (47%) never used their PEG or used it for less than 2 wk. However, those patients who used it for more than 2 wk uniformly reported that PEG tube had critical impact on their nutritional status and “they would not have survived without it”. Prophylactic PEG placement may be unwarranted in some patients but the selection of patients needs to be better defined to prevent unnecessary

risk exposure. In our study there were no clear disease or treatment parameters predictive of PEG use *vs* non-use. The high rate of non-use or limited use and the inherent risk of complications related to PEG call this practice into question and require careful consideration by the referring physician. It also prompts the need for a large prospective study to better define the patients group most likely to require use of enteral feeds during their therapy.

In summary, our study suggests prophylactic PEG placement prior to HNC therapy is associated with a high rate of non use or limited use. Further prospective studies evaluating specific selection criteria for prophylactic PEG in this setting are needed. Similarly, additional studies are needed to assess the impact of prophylactic PEG tube placement on the cost-effectiveness of cancer care, quality of life, hospital admission rate, and, most importantly, survival.

COMMENTS

Background

Impairment of oral intake occurs in the majority of patients with head and neck cancer (HNC) receiving chemoradiotherapy. Placement of prophylactic percutaneous endoscopic gastrostomy (PEG) tube in asymptomatic newly diagnosed HNC before chemoradiation is a common practice in some centers. In some studies PEG has been associated with a decrease in treatment related weight loss in patients with HNC, but no studies have examined the utilization rate. PEG placement is an invasive procedure, with possible complications. The authors anecdotally noticed a finite rate of non use of prophylactic PEG tubes among those patients.

Research frontiers

This study aimed to determine the prevalence of non use or limited use of prophylactically placed PEG tubes in HNC patients and to evaluate any possible factors that might predict the non use or limited use of prophylactic PEGs.

Innovations and breakthroughs

This is the first study that addressed the issue of use of prophylactic PEG in HNC patients. The result of this study showed that a significant number of patients (47%) with prophylactic PEG tubes never used their PEG or used it for less than 2 wk. No association with PEG use *vs* non-use was observed for cancer diagnosis, stage, or specific cancer treatment.

Applications

Prophylactic PEG placement may be unwarranted in some patients but the selection of patients needs to be better defined to prevent unnecessary risk exposure.

Peer review

This is a well-written retrospective study, and it is important to realize that prophylactic PEG placement has its side effects.

Abstract

AIM: To investigate associations between ethnicity, age and sex and the risk, colon distribution and density scores of diverticular disease (DD).

METHODS: Barium enemas were examined in 1000 patients: 410 male, 590 female; 760 whites, 62 Asians, 44 black africans (BAs), and 134 other blacks (OBs). Risks and diverticula density of left-sided DD (LSDD) and right-sided-component DD (RSCDD = right-sided DD + right and left DD + Pan-DD) were compared using logistic regression.

RESULTS: Four hundred and forty-seven patients had DD (322 LSDD and 125 RSCDD). Adjusted risks: (1) LSDD: each year increase in age increased the odds by 6% (95% CI: 5-8, SE: 0.8%, $P < 0.001$); Asians: odds ratio (OR): 0.23 (95% CI: 0.10-0.53, SE: 0.1, $P \leq 0.001$) and OBs: OR: 0.25 (95% CI: 0.14-0.43, SE: 0.07, $P \leq 0.001$) appeared protected vs Whites; (2) RSCDD: each year increase in age increased the odds by 4% (95% CI: 2-6, SE: 1%, $P < 0.001$); females were 0.60 times (95% CI: 0.40-0.90, SE: 0.12, $P = 0.01$) less likely than males to have RSCDD; BAs were 3.51 times (95% CI: 1.70-7.24, SE: 1.30, $P < 0.001$) more likely than Whites to have RSCDD; and (3) DD density scores: each year increase in age increased the odds of high-density scores by 4% (95% CI: 1-6, SE: 1%, $P < 0.001$); RSCDD was 2.77 times (95% CI: 1.39-3.32, SE: 0.67, $P < 0.001$) more likely to be of high density than LSDD. No further significant differences were found in the adjusted models.

CONCLUSION: Right colonic DD might be more common and has higher diverticula density in the west than previously reported. BAs appear predisposed to DD, whereas other ethnic differences appear conserved following migration.

INTRODUCTION

Diverticular disease (DD) is a common disease in western societies^[1]. It causes considerable acute and chronic suffering and is a financial burden to health care systems^[2]. However, primary and secondary preventative treatment of DD is not possible because its cause and many aspects of its pathogenesis remain unknown. In particular, it is not known whether differences exist in the risk, colon distribution and density scores of DD between ethnic groups living in the west. Such information could aid diagnosis and point to areas of potential research into the etiology of the disease.

Such differences exist between ethnic groups living in their native countries. In Whites in the west, DD has an overall barium enema frequency of 15%-35%, affects only the left colon in 90%-99% of cases, has no sex predilection, and increases in incidence with age^[3-5]. In Southeast Asia, DD has a barium enema frequency of 8%-22%^[6,7], affects the right side of the colon in 70%-98% of cases^[6,8], has a slight female predilection, and a peak incidence in patients aged 50-60 years^[8,9]. In Sub-Saharan Africa, DD is thought to be uncommon, affects the right colon in 62%-94% of cases, affects males more often than females, and is found in patients aged 45-60 years^[10-12].

Patients with left-sided DD typically present with left-sided abdominal manifestations of acute or chronic inflammation or bleeding, and the diagnosis is usually made simply on history alone, or is confirmed by the combination of endoscopic and/or radiological investigations. In contrast, complications of right colon DD may be difficult to diagnose, because of overlap between associated symptoms and signs and those of other right-sided abdominal conditions, particularly in hospitals where the disease is considered uncommon^[7]. This can lead to misdiagnoses, to inappropriate operations, or to repeated and unnecessary investigations^[7,13], and to an increase in suffering for the patient and cost to the hospital.

This study aimed to investigate whether associations exist between ethnicity, age and sex and the risk, colon distribution and density scores of DD, in patients undergoing barium enema examination for non-emergency gastrointestinal symptoms in London, UK.

MATERIALS AND METHODS

Data collection

The Ethics Committee of University Hospital Lewisham approved the study. One thousand consecutive double contrast barium enema radiographs were analyzed from 1000 patients (410 male, 590 female, mean age: 58.73 years), who presented with non-emergency gastrointestinal symptoms, over 18 mo between 2004 and 2006, at the University Hospital Lewisham, London, UK. Non-emergency cases included those with changes in bowel habits, abdominal pain, and non-massive per-rectal bleeding. Emergency cases were excluded and included those with bowel obstruction, massive colon bleeding, colon perforation, inflammatory mass, or known colon or rectal cancer. These were investigated instead by a combination

Figure 1 Classification of the pattern of distribution of diverticula throughout the colon. A: Left-sided diverticular disease; B: Right-sided diverticular disease; C: Right and left diverticular disease; D: Pan-diverticular disease.

of computed tomography and colonoscopy.

The London Borough of Lewisham has a population of approximately 258 000, comprising whites (65%), Black Africans (BAs) (10%), Black Caribbean and other blacks (OBs) (15%), Asians (7.5%) and other ethnic groups (2.5%). The proportions of BAs and OBs in the Lewisham population are twice the London average.

Patients were divided into four groups according to self-reported ethnicity: (1) whites ($n = 760$) included White British ($n = 732$) and other white ethnic groups ($n = 29$); (2) Asians ($n = 62$) included Indian ($n = 10$), Chinese ($n = 4$), Bangladeshi ($n = 3$), Pakistani ($n = 4$) and other Asian background ($n = 41$); (3) BA ($n = 44$); and (4) OB ($n = 134$) included Black Caribbean ($n = 80$) and other black ethnicities ($n = 54$). An additional 20 patients of other ethnic background were excluded from the study, because this group did not have epidemiological relevance.

Double contrast barium enema is the most accurate method for the detection of diverticula^[14], therefore, the period of investigation was chosen to coincide with that of a previous temporary reconfiguration of endoscopy services at the hospital, during which time the combination of barium enema and flexible sigmoidoscopy, rather than colonoscopy, was the chosen investigation for non-emergency cases. Three consultant radiologists, AF, MB and AS, assessed the density of diverticula in the sigmoid, descending, transverse, ascending and cecum segments of the colon, according to the following ranking system: no diverticula = 0; 1-5 diverticula = 1; 6-10 = 2; 11-15 = 3; 16-20 = 4; 21-25 = 5; 25+ = 6. The highest score across these segments for each patient was then ranked to either lower density (scores 1-3) or higher density (scores 4-6) for the purpose of statistical analysis.

The pattern of colon distribution of diverticula was first assigned to one of four conventional categories of the disease: left-sided DD (LSDD), right-sided DD (RSDD), right and left DD (R&LDD) and Pan-DD (Figure 1). RSDD, R&LDD and Pan-DD were then grouped together

Table 1 Study sample partition by disease type, ethnicity and sex

as right-sided component DD (RSCDD), which included all those patients in whom DD affected the right side of the colon.

Statistical analysis

STATA 10.1 statistical package (Stata Corporation, College Station, TX, USA) was used for descriptive statistics, statistical inference and graphs. Groups, defined by sex, ethnicity and disease were compared using ANOVA or non-parametric tests. Logistic regression analysis was used to assess crude and adjusted associations between the odds of DD, DD subtypes (LSDD or RSCDD) and diverticula density, ethnicity, age and sex. Models of the risk of the disease/disease subtype/diverticula density were produced, and the Hosmer-Lemeshow test^[15] was used to assess goodness of fit. Post-estimation analysis was performed to detect possible differences between non-white ethnic groups. The predefined level of type 1 error was adjusted using Bonferroni correction. For the “DD overall” analyses, this was reduced to 0.0083 (0.05 divided by 6, representing the number of all possible comparisons between the four ethnic groups), and for the disease subtype analyses to 0.004 (0.05 divided by 2×6). This was the first investigation of its kind, therefore, no data existed prior to the study, regarding standard deviations for the above parameters. It was therefore not possible to make sample size calculations before the study began. Budgetary constraints limited our sample size to 1000 patients.

RESULTS

Data summary

Data related to diagnosis, ethnicity and sex are summarized in Table 1. Of 1000 patients, 447 (44.7%) had DD, 322 (72%) had LSDD, and 125 (28%) had RSCDD. One hundred and ninety-one (42.7%) were male and 256 (57.3%) were female. The mean age of patients with DD was 62.28 years, which was higher than that of those without DD (55.87 years); difference 6.41 (95% CI: 5.07-7.76, $P < 0.001$). The mean age of patients with LSDD was

2.74 years (95% CI: 0.52-4.95) greater than that of patients with RSCDD, $P = 0.016$ (Bonferroni correction, $P = 0.05/3 = 0.017$). The age distribution in the diseased population did not exhibit normality (Figure 2). The mean ages of BAs (57.6 years) and Asians (56.8 years) were lower than that for whites (62.9 years) and OBs (61.2 years) with the disease. Nevertheless, in BA there was a bimodal age distribution, centered in younger patients (12 less than 60 years old) with a mean age of 47.83 years, and older patients (11 more than 60 years old) with a mean age of 68.18 years.

Diverticular disease (overall)

Age and ethnicity, but not sex, were associated with the risk of DD (Table 2). A 1-year increase in the age of an individual increased the odds of having the disease by 6% (4%-7%), ($P < 0.001$), irrespective of ethnicity. Univariate analysis showed that Asians were 0.43 times (95% CI: 0.25-0.76, $P = 0.004$), and OBs were 0.40 times (95% CI: 0.27-0.61 $P < 0.001$) less likely than whites to have DD. BAs were 2.87-fold (95% CI: 1.42-5.77, $P = 0.003$) more likely to acquire the disease compared with OBs. There was a trend towards BA being more likely than Asians to develop the disease [odds ratio (OR): 2.68, 95% CI: 1.2-5.99, $P = 0.017$], but this was not significant when the pre-defined level dropped to 0.004. No significant differences were found between BAs and whites or between OBs and Asians at the studied sample size. In the adjusted models, sex was dropped because it had no confounding effect. Statistical significance was preserved for OR between OBs and whites ($P < 0.001$) and between BAs and OBs ($P = 0.002$), but the odds in Asians increased to 0.49 of that in whites ($P = 0.018$).

LSDD

Age, but not sex, was a predictor for LSDD, with the percentage increase in odds per year the same as for DD overall (Table 2). Asians and OBs appeared protected against left-sided disease compared with whites, even after adjusting for age, with the odds of LSDD being 23%

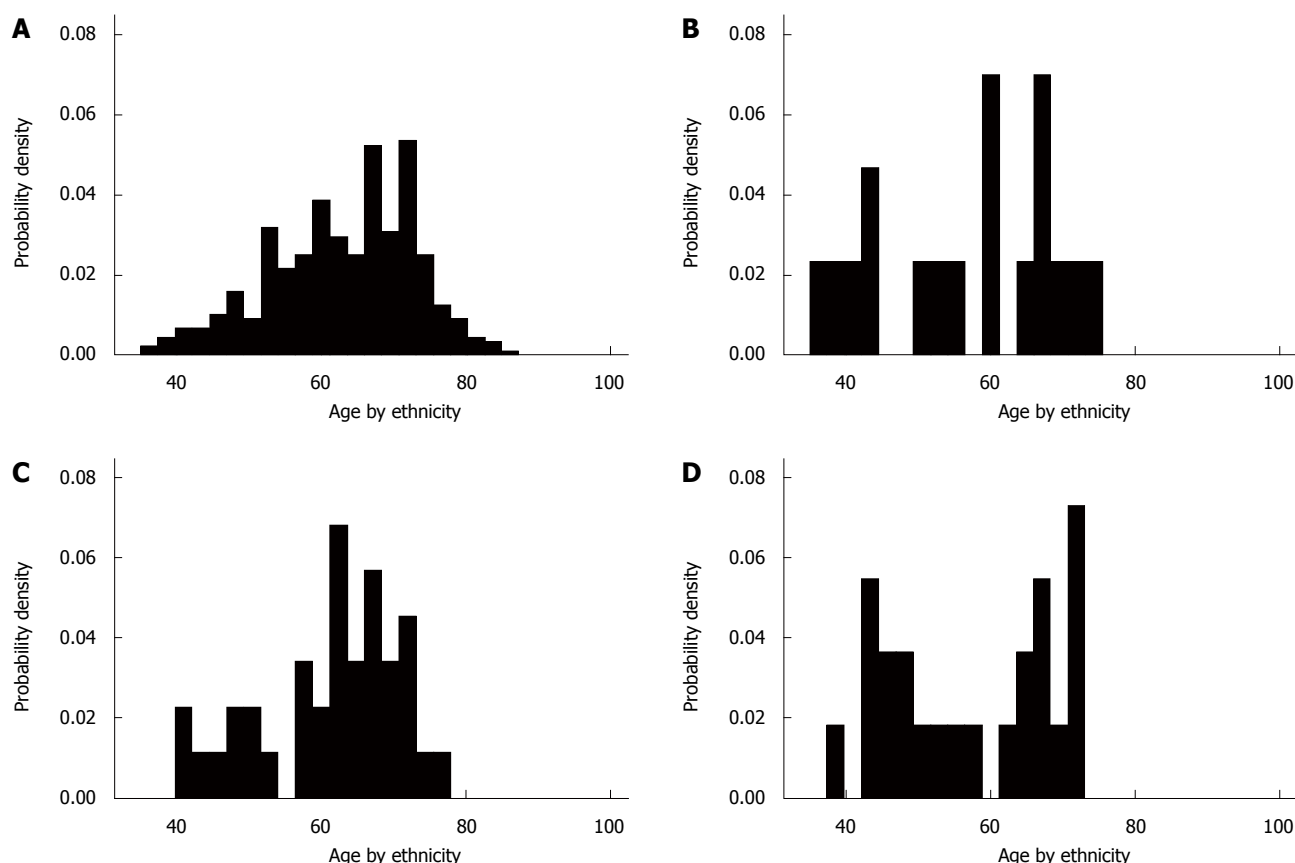

Figure 2 Age and probability density by ethnicity in patients diagnosed with diverticular disease. A: White; B: Asian; C: Other black; D: Black African.

(95% CI: 10-53) and 25% (95% CI: 14-43, $P \leq 0.001$) of that in whites, respectively, (Table 2). The differences between other groups were not statistically significant, at the studied sample size.

RSCDD

Sex was a predictor of RSCDD (Table 2). The odds of women having RSCDD was about 40% less than that in men; an effect that was conserved after adjusting for age and ethnicity (OR: 0.60, 95% CI: 0.40-0.90, $P = 0.01$). Age was a strong predictor, with the adjusted analysis (unchanged from the crude estimate) finding a 4% (95% CI: 2-6, $P < 0.001$) increase in the odds of RSCDD, per year of age. Univariate analysis showed that BAs were 3.54 times (95% CI: 1.75-7.16, $P < 0.001$) more likely than whites to have RSCDD (Table 2); a ratio that was relatively unchanged after adjusting for age and sex (OR: 3.51, 95% CI: 1.70-7.24, $P = 0.001$). BAs were 3.46-fold (95% CI: 1.53-7.86, $P < 0.003$) more likely to be diagnosed with RSCDD than OBs in the crude analysis, but the difference became non-significant following adjustments for age and sex. BAs were more likely to develop RSCDD than Asians, but this trend was not significant at the studied sample size.

Diverticula density

In the analysis of colon segments, Pan-DD had comparatively higher density scores [median (range)]: Pan-DD (sigmoid) 5 (0-6), (descending) 3 (0-6), (transverse) 3 (0-6), (ascending) 2 (0-6), (cecum) 0 (0-6); RSDD (transverse)

0 (0-2), (ascending) 1 (0-2), (cecum) 1 (0-3); R+LDD (sigmoid) 2 (0-6), (descending) 1 (0-3), (ascending) 2 (0-4), (cecum) 1 (0-2); LSDD (sigmoid) 3 (0-6), (descending) 0 (0-6), (transverse) 0 (0-4).

Disease subtype (LSDD and RSCDD) and age were strong predictors of density. The odds of a higher score in RSCDD was 1.91 times that found in LSDD (95% CI: 1.25-2.91 $P = 0.003$), and after adjustment for age, this increased to 2.77 (95% CI: 1.39-3.32, $P < 0.001$) (Table 3). In the final model, each year increase in age yielded a 4% (95% CI: 1-6, $P < 0.001$) increase in the odds of having a higher density score. There was not enough evidence to support an association between diverticula density and sex or ethnicity, in either the crude or final models, at the sample size studied.

Predictions

The tests for Hosmer-Lemeshow statistics were consistent with a good fit of the models to the data; with $P = 0.66$ for DD overall, and $P = 0.65$, $P = 0.71$ and $P = 0.55$ for LSDD, RSCDD and for diverticula density, respectively. Using the adjusted estimates from Tables 2 and 3, the predicted risks for disease overall, disease subtype and higher density (HD), ($R_{DD}/R_{LSDD}/R_{RSCDD}/R_{HD}$, respectively) were computed by:

$$\log [R_{DD}/(1-R_{DD})] = -0.10 - 0.71 \times I_{AS} - 0.84 \times I_{OB} + 0.33 \times I_{BA} + 0.05 \times (\text{age} - 58.73)$$

$$\log [R_{LSDD}/(1-R_{LSDD})] = -0.36 - 1.48 \times I_{AS} - 1.39 \times I_{OB} - 0.48 \times I_{BA} + 0.06 \times (\text{age} - 58.73)$$

OR: Odds ratio; OB: Other black; BA: Black african; RSCDD: Right-sided component diverticular disease; LSDD: Left-sided diverticular disease.

$$\log [R_{RSCDD}/(1-R_{RSCDD})] = -0.31 + 0.21 \times I_{AS} - 0.06 \times I_{OB} + 1.26 \times I_{BA} + 0.04 \times (\text{age} - 58.73) - 0.51 \times I_{FEMALE}$$

$$\log [R_{HD}/(1-R_{HD})] = -0.70 - 0.75 \times I_{AS} - 0.89 \times I_{OB} + 1.20 \times I_{BA} + 0.034 \times (\text{age} - 62.27) + 1.02 \times I_{RSCDD}$$

The symbols $I_{AS}/I_{OB}/I_{BA}/I_{FEMALE}$ were indicators that took the value 1 if an individual belonged to the AS/OB/BA ethnic group or was female, and 0 if otherwise. The linear combination on the right side of each expres-

sion was the linear predictor.

The free terms for disease risk R_{DD} (e.g. -0.10) represented the log odds of having that condition, where age was set to the average of 58.73 years of the population in the study and the ethnic group was set to white. For R_{RSCDD} , the free term had a similar connotation but was in addition set to males. The free term for higher density R_{HD} (e.g. -0.70) represented the log odds of acquiring a

Figure 3 Predictive risk of being diagnosed with diverticular disease by age, ethnicity and sex using the corresponding final models in Table 2. A: Diverticular disease (DD) overall; B: Left-sided DD (LSDD); C: Right-sided component DD (RSCDD)-female; D: RSCDD-male.

Figure 4 Predictive risks of having a higher diverticula density form, by age and ethnicity. A: Left-sided diverticular disease; B: Right-sided component diverticular disease.

higher density amongst white individuals of 62.27 years of age (mean age in *LSDD*/*RSCDD* patients), with the *LSDD* disease type. The generic risks of disease and higher density were calculated by: $R = [\exp(\text{linear predictor}) / 1 + (\text{linear predictor})]$.

The predicted curves for risk of DD overall, DD subtypes and higher density scores are given in Figures 3 and 4.

DISCUSSION

We investigated demographic factors associated with the

risk, colon distribution and density scores of DD in patients who underwent a barium enema examination for non-emergency gastrointestinal symptoms in London, UK. There were significant differences in the risk and colon distribution of DD between certain ethnic groups, and diverticula density was predicted by colon distribution and age. The results suggest that RSCDD, which comprises Pan-DD (54%), RSDD (21%) and R&LDD (25%), is significantly more common than previous studies in the west, and is most frequent in BAs. The prevalence of DD overall (47%) was high compared with previous studies in

the west (15%-35%)^[3-5] and supports previous reports that the prevalence of DD may be increasing with time^[16,17]. Age, but not sex, was found to be a strong predictor of DD, with the mean age of patients with the disease comparable to that found in previous studies^[5,18], and the chance of having the disease increased by 6% per year, irrespective of sex or ethnicity. Whites and BAs had a similar high predisposition to DD, while Asians and OBs appeared relatively protected.

These results suggest the risk of DD in BAs in London is higher than that of their indigenous counterparts, even if one accounts for an increase in prevalence of DD following urbanization in Africa^[10,12,19]. Our results appear to contradict two previous studies of African migrants in Europe, which found significantly lower rates of admissions with complications of the disease, compared with native whites^[16,20]. They reported that the rate was highest in younger migrants^[16], and that it increased with time following settlement, possibly due to acculturation to a western diet^[20]. However, the low rates of admission in those studies could have been related to low rates of acute complications that required admission amongst Africans with DD, compared with other ethnic groups, and not to an actual low prevalence of the disease. Furthermore, the reported relative high number of admissions in younger blacks could have been due to a higher proportion of blacks in the younger, compared with the older local populations. Such an explanation is supported by the current study, which found that, although there was a peak frequency of DD in young BAs, the predictive risk of the disease increased in a uniform manner with age.

It is possible that our study also suffered bias towards symptomatic patients, because it was an observational study, rather than a population study. It is therefore not possible to draw definitive conclusions from our results on actual population incidence of the disease. However, our study did have an advantage over previous studies, in that it determined with accuracy the proportion of the cases that had the disease. Furthermore, our study design did allow comparisons to be made with previous studies of DD, which all studied patients with symptomatic gastrointestinal disease, and which all included patients with symptomatic and asymptomatic DD. It also had the advantage of providing information on a cohort of patients that was typical of that seen in a standard gastrointestinal outpatient clinic. Any study that includes only asymptomatic patients or those with specific symptoms would appear artificial and could introduce bias towards certain ethnic groups and/or subtypes of the disease.

Our results suggest that the comparatively low risk of DD in Asians^[6,7] is conserved in those who live outside Asia, even though more recent reports have suggested that DD is increasing in frequency in Asia with time^[8,9]. Our results support those of a previous study that showed the admission rate in migrant Asians to be half that of native Europeans^[20]. There have been no previous reports on the prevalence of DD in OB groups, and it remains unclear why they should be protected against the disease.

LSDD was more frequent than RSCDD, but it ac-

counted for a lower proportion of cases compared with previous studies in the west^[3,5]. Age, but not sex, was a strong predictor, with the odds of LSDD increasing by 6% per annum. Whites appeared predisposed, with Asians and OBs significantly protected. The finding that Asians are relatively protected against LSDD suggests that the typical colon distribution of the disease in Asians is conserved following population migration. There were no significant differences in predisposition between BAs and other ethnic groups, at the studied sample size.

RSCDD accounted for 28% of all cases of DD, a far higher proportion than reported previously in the west (10%-17%)^[3,5], even though the sex and age mixes were comparable. This trend was probably due to predominance of Pan-DD in the largest ethnic group, whites. BA ethnicity was a strong predictor of RSCDD. BAs were significantly more likely than whites and OBs to develop RSCDD, and appeared equally predisposed to each of the three subtypes of RSCDD. There was a trend towards BAs being more likely than Asians to develop RSCDD, but this was not statistically significant, at the sample size studied.

Our findings suggest that the BA predisposition to right colon involvement^[10-12] is conserved following population migration. This, together with the fact that this distribution of DD in Africa is conserved even in those regions where the incidence of the disease has increased to western levels^[19] suggests that there could be specific genetic and/or environmental factors involved in the pathogenesis of DD in BAs, and that such environmental factors could be conserved following population migration. Important information on possible genetic and environmental causes of the disease may come from follow-up investigations into whether the patterns of DD found in this study are exhibited by specific generations of migrants.

Evidence suggests that dietary fiber may be protective against DD^[21] but exposure to red meat^[4,22] and other unidentified toxins^[10,12], inflammation^[23], as well as genetic factors^[24] may also be involved. It is probable that an imbalance between protective and promoting factors leads to abnormalities in colonic nerve innervation and connective tissue turnover found in DD^[25] and to the abnormalities in colon motility^[26] and subsequent diverticula formation^[27].

RSCDD and age were found to be strong independent predictors of the higher density form of the disease in the final models, whereas sex and ethnic background were not. It may be argued that because patients with RSCDD were on average twice as likely to have a higher density score compared with those with LSDD, this contradicts previous anecdotal reports that the density of RSDD is less than that of LSDD. However, our results suggest that the relative contribution made by Pan-DD, which accounted for 54% of the total RSCDD, and which had significantly higher median density scores compared with the other disease subtypes, was the reason for this apparent discrepancy.

However, it is not known whether differences in the distribution or density of diverticula affect the risk of acute or chronic complications of the disease. One study

has estimated that acute complications occur in 15%-20% for predominantly LSDD in the west^[28] and another cited 1.0%-4.5% for predominantly RSDD in Southeast Asia, and that patients with only one or two diverticula are least likely to experience acute symptoms^[8]. The proportion of patients diagnosed with DD on barium enema, who then go on to experience a chronic bleed or symptoms of irritable colon, is also unknown, although one uncontrolled study has suggested the latter may be as high as 55%^[29]. Nevertheless, our results suggest that one should maintain a high index of suspicion of RSCDD as a potential diagnosis, both in outpatient and emergency settings.

However, such a diagnosis and its management may not be straight forward. There is considerable overlap between symptoms and signs of RSDD and those of other abdominal conditions including acute appendicitis^[30], irritable bowel syndrome^[26] and colon cancer^[30]. Bleeding from RSDD can also be difficult to manage, because it may mimic upper gastrointestinal bleeding due to the presence of melena, and is less likely to respond to non-surgical treatment, compared with left-sided disease^[31].

Overall, our results suggest that right-colonic DD is more common and has higher density scores in the west than previously reported. BAs appear predisposed to DD, while other ethnic differences appear conserved following migration. Within clinical practice, such knowledge is likely to aid diagnosis and management, and within research, to point to areas of potential future investigation.

COMMENTS

Background

Diverticular disease (DD) is common in western societies, causes considerable suffering and is a financial burden to hospitals. Differences exist in the incidence and colon distribution of DD between indigenous populations worldwide, but it is unknown if these are conserved following ethnic migration.

Research frontiers

Indigenous Asians and Africans appear protected against DD compared with whites in the west. Right-colonic DD is more frequent in Asia and Africa than in the west. The etiology of DD and the reasons for variations in its colon distribution and severity remain unknown.

Innovations and breakthroughs

Right-colonic DD is more common in the west than previously reported and is most frequent in black africans (BAs). BAs appear predisposed to DD, while other ethnic differences appear conserved following migration. The severity of DD is determined by its colon distribution and patient age.

Applications

Within clinical practice, our findings are likely to aid diagnosis and management, and within research, to point to areas of potential future investigation.

Terminology

The density scores were used as an indication of the numbers of diverticula present within the respective segments of the colon, and were calculated by diverticula counts on barium enema examinations.

Peer review

This manuscript presents data on the incidence of diverticulosis in 1000 consecutive barium enema evaluations performed in London, UK. The development of diverticulosis as a result of immigration to the west is an interesting topic and one that has been reported little in contemporary literature.

Published online: February 28, 2011

RESULTS: Two hundred and fifty examinations representing 207 different patients were evaluated. Both modalities assessed similar bowel wall changes in 65% of the examinations, with more US findings in 11% and more MRE findings in 15%. When the reports were analyzed with regard to "bowel wall inflammation", US reported more findings in 2%, while MRE reported more findings in 53%. Stenoses were assessed to be identical in 8%, while US found more in 3% and MRE in 29% ($P < 0.01$). For abscess detection, US showed more findings in 2% ($n = 4$) while MRE detected more in 6% ($n = 16$). US detected more fistulas in 1% ($n = 2$), while MRE detected more in 13% ($n = 32$) ($P < 0.001$). The most common reason for no detected pathology by US was a difficult to assess anatomical region (lesser pelvis, $n = 72$).

CONCLUSION: US can miss clinically relevant pathological changes in patients with IBD mostly due to difficulty in assessing certain anatomical regions.

Abstract

AIM: To compare the results of high-resolution ultrasound (HR-US) and magnetic resonance enterography (MRE) examinations in patients with inflammatory bowel disease (IBD).

METHODS: The reports of 250 consecutive cases with known IBD, who had an MRE and HR-US examination, were retrospectively analyzed. Using a patient-based approach we evaluated morphological disease features such as affected bowel wall, stenosis, abscess and fistula. The comparison between the two modalities was based on the hypothesis, that any pathological change described in any imaging modality was a true finding, as no further standard of reference was available for complete assessment.

Key words: Crohn's disease; Diagnosis; Inflammatory bowel disease; Magnetic resonance imaging; Ultrasound

INTRODUCTION

Patients suffering from inflammatory bowel disease (IBD) need a complete bowel assessment for their primary diagnosis. In addition, follow-up examinations are necessary during deterioration of clinical symptoms or for therapy monitoring.

According to most recent national or international guidelines, high-resolution ultrasound (HR-US) should be the first-line diagnostic modality for disease assessment or follow up examinations^[1,2]. If an IBD is assumed, several guidelines recommend a complete sectional imaging of the small bowel. Because of the lack of any ionizing radiation, a dedicated magnetic resonance imaging (MRI) examination of the small bowel is therefore recommended. Currently magnetic resonance (MR) enteroclysis with contrast application *via* a naso-jejunal tube as well as MR enterography (MRE), where the contrast is applied orally, are the methods of choice. Because of the expensive radiological equipment and the need for intravenously applied contrast media, MRE is an examination which is less available and more cost intensive compared to HR-US. On the other hand, US is more subjective and highly dependent on the experience of the examiner, but requires less expensive equipment.

The current literature shows excellent sensitivity of between 78% and 96% with specificity between 67% and 100% for HR-US in IBD^[3]. On the other hand, MRE shows sensitivity of between 82% and 100% with specificity between 71% and 100%. Most studies were performed in an academic environment by specialists in their field. In our experience a total small bowel assessment by HR-US during daily routine is difficult to perform. Several segments of the bowel cannot be visualized by US because of residual air in the bowel, anatomical obstacles in the pelvic region or superposition of other bowel loops.

To assess the diagnostic and therapeutic impact of HR-US and MRE in patients with IBD in a day-to-day clinical setting, we decided to perform a retrospective study. By analyzing and comparing the written reports retrospectively, we intended to avoid the study bias sometimes caused by extremely motivated study examiners, and depict the report quality for both modalities under everyday circumstances.

In this study we compared and evaluated the results of HR-US and MRE examinations in patients suffering from IBD, with regard to clinically relevant disease features such as bowel wall affection, stenosis, fistula, abscess and indirect inflammation indicators such as local lymphadenopathy, mesenteric fat injection or enlarged local vessels.

MATERIALS AND METHODS

Patient selection

Using our radiological information system, we retrospec-

tively searched for patients who underwent an MRE examination between October 1999 and January 2007 in our tertiary care medical center. After identifying 1582 MRE examinations during this period, we selected all patients in this group with histologically and clinically proven IBD, resulting in 801 MRE examinations. Based on these 801 cases we evaluated all patients who had a HR-US examination within a 14-d period before or after MRE. Based on this selection we chose 250 consecutive cases for further analysis.

MRE examination

MRE was performed using a 1.5-Tesla MRI unit (Magnetom Symphony and Magnetom Sonata, Siemens Healthcare, Erlangen, Germany) using a circular polarized 6-channel phased array body coil supplemented with a spine array coil. The dark lumen technique with an oral contrast of 1.5-2 L of water mixed with methylcellulose was applied. A coronal True-fast imaging with steady state precession sequence and an axial T2-weighted half-Fourier acquired single-shot turbo spin echo sequence were acquired. Subsequently, 0.1 mmol/kg body weight of Gd-DTPA (different vendors during the examination period) was injected intravenously. A fat-suppressed 3D gradient echo sequence and a fat-suppressed T1-weighted 2D gradient echo sequence with axial and coronal orientation were acquired with a delay of 70 s after the start of the contrast injection.

If the clinical examination or anamnesis suggested fistulas, additional sequences with 4 mm slice thickness (axial and coronal T2 short tau inversion recovery and T1-weighted sequences before and after Gd-DTPA iv) were acquired. The MRE examinations were evaluated by a board certified radiologist and an experienced resident, resulting in a written and electronically documented report based on a consensus decision.

HR-US

HR-US of the bowel was performed in our interdisciplinary ultrasound department by a resident in internal medicine, surgery or radiology or by a consultant in internal medicine. To evaluate the influence of the individual experience of the examiner on the examination results in ultrasound, we subdivided the examiners into groups with moderate and high experience. Examiners with high experience were board certified with more than 2000 documented ultrasound examinations per year.

For a clinical routine ultrasound examination of the bowel, a 3.5 MHz convex transducer was applied first. A high-resolution 5 to 10 MHz transducer was then used for bowel imaging. During the evaluation period we used several ultrasound devices: SonolineElegra (Siemens, Erlangen, Germany), Logiq 9 (General Electric, Solingen, Germany) or EUB-8500 (Hitachi, Tokyo, Japan). Ultrasound images were documented in soft prints as part of the patient record. An electronically documented report of the examination was available for all patients.

Data analysis

We retrospectively evaluated the electronically documented reports of MRE and US examinations without reviewing the original imaging data. The 250 cases were evaluated in a patient-based analysis with regard to the following categories: affected bowel wall, bowel stenosis, abscess, fistula, local lymphadenopathy and local fat injection or comb sign. The evaluation of these categories was based on the written report of each modality.

For MRE, the bowel wall was deemed affected when having a diameter of at least 3 mm and/or showing increased contrast uptake. For ultrasound examinations a bowel wall diameter larger than 3 mm was also considered as “thickened bowel”. A thickened bowel wall larger than 3 mm without any data on contrast enhancement of vascularization is a very unspecific finding. For routine HR-US examinations of the bowel, an intravenous contrast application is currently not an established standard. Vascularization information based on Power Doppler imaging was integrated into the ultrasound findings. The mention of an “accentuated” or “slightly thickened” bowel wall in a written ultrasound report is not very specific. For our comparison we separately evaluated the assessment of the bowel wall of each modality regarding the terms “affected” or “inflamed”, which represents a clear clinical statement, and “accentuated” and “slightly thickened”, which is an unspecific statement without immediate clinical consequences.

For bowel stenosis in MRE and US the term “stenosis” as well as “narrowed bowel lumen” was considered as a positive finding. For the diagnosis of an abscess or a fistula the term had to be mentioned in the report. Local lymphadenopathy was not restricted to a certain size or amount of lymph nodes. In this study, the descriptive term “lymphadenopathy” as well as “enlarged” or “multiple” lymph nodes represented the diagnosis of local lymphadenopathy. The diagnosis of a local fat injection was made when terms such as “injected mesenteric fat” were used. The comb sign as an indirect inflammation criterion caused by enlarged vasa recta surrounding the affected bowel was diagnosed with the mention of “comb sign” or the finding of enlarged or accentuated local vessels^[4].

In the patient-based analysis we focused on all cases with identified pathological findings in only one modality, which were not noted in the other modality report. Possible reasons for discrepant findings were analyzed and noted.

Statistical significance was calculated using the Chi-test by McNemar. P -values ≤ 0.05 were considered statistically significant while P values ≤ 0.01 were considered highly significant. Descriptive statistics were calculated using Excel (Office: Mac 2008, Version 12.2.5; Microsoft, Redmond, WA, USA). Significance levels were calculated using SPSS for Windows 16 (SPSS, Chicago, IL, USA).

RESULTS

We evaluated a total of 250 consecutive cases of patients

Table 1 Contingency table of all evaluated 250 cases (patient based) n (%)

Any bowel wall changes (including unspecific changes such as “accentuated wall”, etc.)	Ultrasound	
	Negative	Positive
Magnetic resonance enterography		
Negative	21 (8.4)	28 (11.2)
Positive	38 (15.2)	163 (65.2)

Negative findings means no bowel wall change found in the modality (magnetic resonance enterography or ultrasound) report.

with known IBD, where a MRE and a HR-US examination of the bowel were performed within 14 d. The 250 cases were based on 207 patients. The 207 patients had a mean age of 35.6 years (range 14–77 years; 55% female, 45% male). The evaluated patients suffered from Crohn’s disease (CD; 84.5%, $n = 175$) or ulcerative colitis (UC; 15.5 %, $n = 32$).

In 69% of all evaluated cases ultrasound was performed before MRE, in 16% MRE and ultrasound were performed on the same day, while in 15% MRE was performed before ultrasound. On average, HR-US was performed 1.9 d before MRE. In 90% of all cases the time period between MRE and ultrasound was less than 7 d, in 72% both examinations were performed within 3 d.

During the evaluation period we found a total of 100 different examiners for high-resolution bowel ultrasound. Of these examiners, 13 were considered highly experienced (13%) while 87% had moderate experience in ultrasound. The highly experienced examiners performed 48% ($n = 119$) of all bowel examinations.

Affected bowel wall

In the 250 cases evaluated both modalities described no bowel wall pathology in 21 cases. In the remaining 229 cases, a total of 673 changes of the bowel wall were described with 439 changes described by MRE and 405 changes described by US. The described changes included subtle and unspecific findings such as “accentuated bowel wall” without any specific diagnostic statement. With regard to all bowel wall changes, there was no statistically significant difference between MRE and US (Table 1). MRE and ultrasound had similar results in 163 cases, while MRE detected more lesions in 38 cases and US found more affected bowel wall segments in 28 cases. When analyzing the 28 cases with more lesions found on US, we had no explanation for the negative MRE findings in 10 of the 28 cases. For 12 cases, possible explanations were subtle US findings describing a wall thickness of 3 mm as an accentuated bowel wall. In 6 patients the MRE report stated inferior image quality due to breathing and motion artifacts.

When analyzing the subgroup of 28 cases with more US findings with regard to the examiner’s experience, 43% ($n = 12$) of the cases were examined by moderately experienced examiners (9 cases with possible explanations and 3 cases with no explanation), while 57% ($n = 16$) where

Table 2 Influence of the experience of the ultrasound examiner on diagnosis

Pathological changes	Ultrasound examiner with moderate experience (%)	Ultrasound examiner with high experience (%)
MRI found more lesions than ultrasound		
Stenosis (<i>n</i> = 72)	62	38
Abscess (<i>n</i> = 16)	46	46
Fistula (<i>n</i> = 32)	59	41
Ultrasound found more lesions than MRI		
Stenosis (<i>n</i> = 8)	0	100
Abscess (<i>n</i> = 4)	50	50
Fistula (<i>n</i> = 2)	0	100

The percentage indicates the ratio of moderate or experienced ultrasound examiners in this scenario. MRI: Magnetic resonance imaging.

Table 3 Contingency table of all evaluated 250 cases (patient based) *n* (%)

Statement “inflammation” or “bowel wall affection” in the report	Ultrasound	
	Negative	Positive
Magnetic resonance enterography		
Negative	83 (33.2)	6 (2.4)
Positive	132 (52.8)	29 (11.6)

Negative findings means no bowel wall affection or inflammation assessed based on the report (magnetic resonance enterography or ultrasound).

examined by the highly experienced group (9 cases with possible explanations and 7 cases with no explanation). Based on these data, there was no relevant tendency or statistical relevance regarding the examiner's experience (Table 2).

For the 38 cases with a superior MRE examination we had no explanation for the inferior US in 18 cases. For the remaining cases, restricted image quality was stated in 14 cases. Additionally, in 12 cases (in some cases more than one explanation for the same case was reported) the pathological changes were in anatomical areas with a difficult access by US (lesser pelvis, rectum). The 38 cases were performed by 13 highly experienced examiners and 25 moderately experienced examiners.

Different results emerged when analyzing diagnostic statements such as “inflammation” and “affected bowel wall” only (Table 3). Restricted to these terms, which represent a definite diagnostic statement with therapeutic consequences, we found only 29 cases with similar results. There were six cases, where US detected more lesions than MRE and 132 cases (53%) where MRE described inflamed and affected bowel wall without US findings.

Stenosis

In 170 of 250 cases (68%) there was a consensus between US and MRE, while in 80 cases (32%) the findings regarding a stenosis were different (Table 4). In 72 cases (29%) the MRE examination described a stenosis, while

the US was negative. For 18 of 72 cases there was no explanation for the negative ultrasound findings. In 54 cases we found possible explanations. In 23 patients the stenosis was localized in an area which was difficult to assess by US. In 20 patients, the US image quality deteriorated due to residual bowel air. In 19 cases an explanation can be assumed because of a subtle finding in the MRE. The MRE findings were just reported as a “narrowing of the lumen” without mentioning the word “stenosis” or describing indirect signs such as “pre-stenotic dilatation”.

The moderately experienced examiners performed 44 of the 72 cases with a superior MRE result, while the highly experienced examiners performed 28 of these examinations (Table 2). In 8 cases (3%) a stenosis was described in the US report having a negative MRE. The 8 cases with more US findings were examined only by highly experienced examiners.

Abscess

In the majority of all cases (221 cases, 88%) we did not find any abscesses (Table 4). In 16 cases (6%) MRE detected an abscess which was not described by US and in 4 cases (2%) US described an abscess not mentioned in the MRE report. These 4 cases were assessed by 2 moderately and 2 highly experienced examiners.

For the 16 cases with an abscess described by MRE and not by US there was no explanation in 1 case, where several abscesses with a diameter of 1 cm in the region of the cecum and terminal ileum were described in the MRE report. For 13 cases, a possible explanation was assumed to be difficult access mostly in the lesser pelvis, and for another 2 cases reduced image quality. Highly experienced examiners (*n* = 9) and moderately experienced examiners (*n* = 7) were equally distributed in these 16 cases.

Fistula

Two hundred and eleven of 250 cases (84%) showed no fistulas in either of the modalities (Table 4). In 5 cases (2%) both modalities detected a fistula in the same patient while US identified 2 fistulas (1%), which were not described in the MRE report. We identified 32 cases (13%) where MRE identified fistulas not described by US. The 2 cases with more US findings were performed by a highly experienced examiner.

Thirty two cases of fistula were detected by MRE which were not identified by US. In 24 cases a possible explanation was difficult access for US, while in 9 cases reduced image quality was stated in the US report. Nineteen moderately experienced and 13 highly experienced examiners performed these 32 examinations. There was no statistical significance in the examiners experience.

Local lymphadenopathy

Because the exact measured diameter was mentioned in just 4 cases for US and MRE we were unable to compare these data quantitatively. Based on both modalities, local lymphadenopathy was reported in 63 of 250 cases (25%). In 4 cases, MRE as well as US described enlarged or mul-

Table 4 Diagnostic performance of ultrasound and magnetic resonance enterography regarding bowel wall changes, diagnosis of bowel inflammation, stenosis, abscess, fistula and indirect inflammation signs such as local lymphadenopathy and fat injection or comb sign *n* (%)

	Bowel wall changes	Diagnosis "bowel wall inflammation"	Stenosis	Abscess	Fistula	Local lymph-adenopathy	Mesenteric fat injection/comb sign
US = MRE (no pathological change)	21 (8)	83 (33)	150 (60)	221 (84)	211 (88)	187 (75)	182 (73)
US = MRE (pathological change)	163 (65)	29 (12)	20 (8)	9 (4)	5 (2)	4 (2)	4 (2)
US > MRE	28 (11)	6 (2)	8 (3)	4 (2)	2 (1)	15 (6)	4 (2)
MRE > US	38 (15)	132 (53)	72 (29)	16 (6)	32 (13)	44 (18)	60 (24)

US: Ultrasound; MRE: Magnetic resonance enterography. In "US = MRE" the number (and percentage) of cases, when both modalities found the same amount of pathological features (patient based) are identical. For "US > MRE" the reports based on ultrasound described more pathological changes compared to the MRE, while for "MRE > US" more findings in the MRE reports were detected (because of truncation the percentage values in a column can exceed 100%).

Table 5 Possible explanations for misdiagnosis of all evaluated features (wall affection, stenosis, abscess, fistula, lymph nodes and indirect inflammation signs) for ultrasound and magnetic resonance enterography for all 250 evaluated cases

	HR-US	MRE
Reduced imaging quality (obesity, breathing artifacts, residual bowel gas, etc.)	25	7
Region difficult to access (lesser pelvis)	72	N/A
Subtle findings	15	31

Magnetic resonance enterography (MRE) missed most of the diagnoses made by ultrasound (US) because of subtle US findings (*n* = 31), while the most common reason for a misdiagnosis based on the US report was an anatomical region difficult to assess (*n* = 72). N/A: Not available.

multiple local lymph nodes, while lymphadenopathy was reported in 15 cases solely by US (6%) and in 44 cases solely by MRE (18%).

Local fat injection and comb sign

A total of 68 cases (27%) with signs of indirect inflammation such as local fat injection or comb sign were detected based on both modalities. In 4 cases, US and MRE identified these signs, while US described 4 additional cases (2%), which were not described by MRE. In the MRE reports, 60 cases (24%) with positive findings of indirect inflammatory signs were found, which were not described in the US report.

Reasons for discrepant findings

When analyzing all these results, when one modality described a pathological finding, which was not described by the other modality, we detected several circumstances and possible reasons for this misdiagnosis (Table 5). In most cases (*n* = 72) a possible reason for misdiagnosis was the anatomical region, which was difficult to access by US such as the lesser pelvis and peri-rectal tissue. In particular, the localization of fistulas in the pelvis is frequently an obstacle for abdominal US diagnosis. Other reasons were reduced image quality on US due to obesity or residual bowel air in 25 patients and inadequate bowel distension or breathing artifacts in 7 patients on MRE examination.

In most evaluations, a higher ratio of detected lesions by US was found for examiners with a higher level of experience, however, this influence was not demonstrated with any statistical significance (Table 2).

DISCUSSION

Our study retrospectively evaluated the results of reports based on MRE and HR-US examinations in 250 consecutive patients with known IBD.

By analyzing the bowel wall changes on a patient basis we obtained different results when evaluating different key words in the reports. When we evaluated all the terms regarding bowel wall changes including unspecific terms such as "accentuated bowel wall" or "wall thickening" we did not show statistically relevant differences between HR-US and MRE. In this scenario, the HR-US misses totaled 38 cases (15%) and the MRE misses totaled 28 cases (11%), which were described in the opposite modality, respectively. Assuming that MRE depicts the whole abdomen including the bowel wall quite objectively, one of the main reasons for these differences could be, that HR-US sometimes subjectively overestimates bowel wall thickening without giving exact measurements. In this study, we found this in at least 12 of the 28 cases, when US described a thickening without a correlation in MRE. A possible reason for this was a very subtle finding mentioning a wall thickness between 2 mm and 3 mm. In the MRE findings, there were no signs of inflammation such as increased contrast uptake or indirect inflammation features. Therefore, HR-US could theoretically sometimes show "false positive" results, especially when describing subtle findings such as "accentuated bowel walls". For diagnostic features such as "inflamed" or "affected" bowel wall there were statistically significant differences between HR-US and MRE. In this scenario, the US misses consisted of 132 cases (53%), while MRE misses consisted of just 6 cases (2%). Obviously MRE has some methodological advantages for decision making such as contrast media and better bowel distension because of the oral contrast application before the examination.

Comparing our results with other studies we found the same tendencies in a study by Potthast *et al.*^[5] carried out in 2002. This group retrospectively compared 46

patients undergoing MR enteroclysis with US and conventional enteroclysis, surgery or colonoscopy as a gold standard. For bowel wall changes they calculated 22% false negative results for US and 2.4% false negative results for MRE. Martínez *et al*^[6] in their prospective study of 30 patients with CD published different results. They compared US and MRI with regard to the extension and transmural complications in CD. For localization of affected bowel wall, US was not statistically significantly superior to MRI having a sensitivity of 91%, while MRI detected changes with a sensitivity of 83%. There are several major limitations of this study. In addition to the small number of patients, the authors accepted a time period of up to 3 mo between the examinations and the standard of reference. Also their choice of the standard of reference is very questionable. In addition to surgery they accepted conventional barium studies and small bowel follow-through examinations as a standard of reference. In several studies these examinations showed a poorer sensitivity and accuracy than MRE^[7].

A meta-analysis from 2008 on the diagnostic accuracy of studies based on US, MRI, scintigraphy, CT and PET imaging in IBD, did not reveal any statistically significant differences between the modalities^[3]. The authors calculated that on a patient basis, US had a sensitivity of 90% (range 78%-96%) and MRE had a sensitivity of 93% (range 82%-100%).

It is not possible to compare our results directly using sensitivity values, because we did not have any standard of reference in our study and just compared the positive results from the two modalities performed in the same patient. Based on our data, MRE (11% missed cases) detected slightly more lesions than HR-US (15% missed cases). A certain problem in this study was the vagueness of the diagnostic statements with regard to the affection and inflammation of bowel wall segments. Because of the lack of bowel distension and intravenous contrast application in standard HR-US examinations it seems inherent to the system that US examinations were frequently describes as an unspecific bowel wall thickening without calling a finding an inflammation or affection. In our study, US reports missed 53% of the cases when evaluating for terms such as “inflammation” or “affection”, while MRE just missed 2% in this scenario.

With regard to terms such as “lumen narrowing” and “stenosis” we found a highly significant difference between HR-US, which missed 29% of the described stenoses, and MRE, which missed just 3%. There was certainly a problem with the exact definition of stenosis for HR-US and MRE. US has the advantage of dynamic real-time imaging, which allows an assessment of peristalsis with consecutive appreciation of a functional stenosis *vs* lumen narrowing. In MRE reports, a lumen narrowing of more than 50% can be called a stenosis. MRE is not a real-time imaging modality using a standard MR protocol. The only way to identify a functional stenosis is to evaluate all MRI sequences along the time line, which are

performed over 25 min. Theoretically, MRI could lead to an overstaging of lumen narrowing calling it a “stenosis” because of the lack of functional real-time image data. In 17 of the 72 cases with a stenosis diagnosed by MRE and not by US, the stenosis was not called functionally relevant in the MRE report, while US described a wall thickening in the same bowel segments. The localization of misdiagnosed stenoses by US was responsible for 23 of the 72 discrepant cases. These stenoses were especially located in the lesser pelvis, which is difficult to assess by transabdominal US. Our results are in contrast to the prospective results of 48 patients published by Schmidt *et al*^[8] in 2003. In this study, conventional enteroclysis was considered the standard of reference with data acquisition between 1999 and 2000. They calculated a sensitivity of 56% for detecting stenosis when using US with a specificity of 97%, while MRI had a sensitivity of 44% with a specificity of 100%. On the other hand, the retrospectively performed comparison by Potthast *et al*^[5] had a sensitivity of 58% for US with a false negative rate of 16%, while MRI had a sensitivity of 100% with a false negative rate of 2%. In our study, 6 (75%) of the 8 examinations with a superior US result were performed by a highly experienced examiner, while in the group of superior MRI results just 28 (39%) of the 72 examinations were performed by the highly experienced group.

For abscess diagnosis the differences between HR-US (16 missed abscesses) and MRE (4 missed abscesses) were statistically significant ($P < 0.05$). Considering the fact that all 4 abscesses diagnosed by US and not by MRE were most likely not present at the time of MRE examination ($n = 3$) due to treatment or a false positive US result ($n = 1$; probably hemorrhagic ovarian cyst), MRE seems to be the superior modality for detecting abscesses in the abdomen.

For 13 (81%) of the 16 cases with a missed abscess by HR-US, the localization of the abscess in the lesser pelvis and peri-rectal region, which is difficult to assess by US, was the most plausible reason. Our results were mirrored in the study by Potthast *et al*^[5], which showed a sensitivity of 100% for MRI and 89% for US. Another study from the same hospital attributed MRI with a sensitivity of 83%, and US with a sensitivity of 67%^[9].

For fistula detection, the differences between MRI, which missed 2 cases (1%), and HR-US, which missed 32 cases (13%), were highly significant. The localization of the fistula in the lesser pelvis and peri-rectal region was a possible explanation in 24 of the 32 cases. The experience of the examiners did not have any influence on the results. It should be noted that HR-US examinations were restricted to transabdominal US examinations. A HR-US examination performed transperineal or trans-rectally would most probably improve the results of US dramatically. When comparing dedicated US examinations such as endoscopic endorectal US to MRI, both modalities were found to have similar sensitivities and specificities^[10-12]. The study by Potthast *et al*^[5] supports our data,

showing a false negative rate of 26% for transabdominal US and 5% for MRI.

The mention of a local lymphadenopathy is an indirect unspecific sign of an inflammatory process. Maconi *et al.*^[13] found an unspecific lymphadenopathy in 25% of their patients ($n = 240$) with CD using US. They detected more enlarged lymph nodes in young patients and in patients with fistulas and abscesses. In our study, MRE missed 15 cases (6%) with lymphadenopathy while US missed 44 cases (18%). There was an identical tendency in the evaluation of local mesenteric fat injection and comb sign with a missed rate of 2% in MRI and 24% in HR-US.

One of the major restrictions of our study is the retrospective approach used as well as the long data acquisition period of 7 years using different equipment and different examination protocols. In addition there was no standard of reference for the evaluated parameters. The retrospective evaluation of consecutive patients was deliberately chosen to assess the actual quality of MRE and US without influencing the examiners using both modalities. The quality improvements in HR-US over time were accompanied by improvements in MR imaging and protocols. However, basically identical protocols (fast T2 weighted sequences as well as gradient echo sequences after contrast application) were used during the evaluation time period. Having a standard of reference for all features evaluated in this study was extremely difficult. For small bowel assessment, MRI together with multidetector CT is already considered an accepted standard of reference with superior sensitivity and specificity compared to conventional enteroclysis and follow-through examinations^[2,3]. When considering surgery as the standard of reference this would reduce the number of patients included in the study dramatically. Therefore, we considered a pathological finding mentioned in one report as a real finding, which was also to be described in the other modality. The analysis of 32 of 250 examinations, which were performed in patients with UC makes the patients evaluated more inhomogeneous, but does not influence our results significantly. On the other hand, we intended to analyze a realistic scenario in patients suffering from IBD.

In the recent literature, there are no major studies evaluating the diagnostic quality of HR-US and MRI with regard to bowel wall affections as well as transmural complications such as abscesses or fistulas. In our study, MR imaging was superior to US for all evaluated features. The difference was statistically significant for the diagnosis and detection of an abscess and highly significant for stenosis and fistula evaluation.

In conclusion, transabdominal HR-US can miss a certain number of pathological changes in patients with IBD. The localization of the pathological lesions in anatomical regions, which are difficult to assess by US, such as the lesser pelvis or the peri-rectal region, is one of the most frequent reasons for a missing a diagnosis. When

the clinical suspicion of bowel affection or complications is mentioned, an MRI examination should be performed after an US examination without relevant findings.

COMMENTS

Background

Patients suffering from inflammatory bowel disease (IBD) require a complete bowel assessment for primary diagnosis or follow-up, when their symptoms are increasing. Guidelines recommend high-resolution ultrasound (HR-US) or magnetic resonance imaging (MRI) as imaging modalities.

Research frontiers

Ultrasound and MRI are diagnostic modalities without ionizing radiation. In this study, the authors compared the findings of MRI as well as ultrasound examinations in the same patients. They evaluated the limitations of ultrasound imaging for whole bowel assessment in patients with IBD.

Innovations and breakthroughs

Currently there are no major studies comparing state of the art MRI with ultrasound in bowel imaging for IBD. Our study shows, that relevant complications such as fistulas, stenoses or abscesses are often missed when using ultrasound imaging only.

Applications

By understanding the limitations of ultrasound imaging due to difficult to assess anatomical areas, algorithms for IBD imaging can be improved.

Peer review

This is an interesting retrospective manuscript on the comparison of HR-US and magnetic resonance enterography in a high number of patients with IBD. The comparison of competing imaging methods is of high clinical relevance therefore the topic of the manuscript is of clinical importance.

Abstract

AIM: To study the cell-type specific subcellular distribution of the three isoforms of nitric oxide synthase (NOS) in the rat duodenum.

METHODS: Postembedding immunoelectronmicroscopy was performed, in which primary antibodies for neuronal NOS (nNOS), endothelial NOS (eNOS), and inducible NOS (iNOS), were visualized with protein A-gold-conjugated secondary antibodies. Stained ultrathin sections were examined and photographed with a Philips CM10 electron microscope equipped with a MEGAVIEW II camera. The specificity of the immunoreaction in all cases was assessed by omitting the primary antibodies in the labeling protocol and incubating the sections only in the protein A-gold conjugated secondary antibodies.

RESULTS: Postembedding immunoelectronmicroscopy revealed the presence of nNOS, eNOS, and iNOS immunoreactivity in the myenteric neurons, the enteric smooth muscle cells, and the endothelium of capillaries

running in the vicinity of the myenteric plexus of the rat duodenum. The cell type-specific distributions of the immunogold particles labeling the three different NOS isozymes were revealed. In the control experiments, in which the primary antiserum was omitted, virtually no postembedding gold particles were observed.

CONCLUSION: This postembedding immunoelectron-microscopic study provided the first evidence of cell-type-specific differences in the subcellular distributions of NOS isoforms.

INTRODUCTION

In the enteric nervous system, endogenous nitric oxide (NO) has an important role in mediating non-adrenergic, non-cholinergic (NANC) relaxation of the intestinal smooth muscle^[1]. There are three genetically different isoforms of NO synthase (NOS) that account for NO production: neuronal NOS (nNOS), endothelial NOS (eNOS), and inducible NOS (iNOS)^[2]. Of the three NOS

isoforms, nNOS constitutes the predominant source of NO in neurons, while eNOS is the predominant source in the endothelium^[3,4]. It has been demonstrated, however, that the myenteric neurons in the mouse colon express all three NOS isoforms^[5], and NO synthesized by nNOS, eNOS, and iNOS regulates motility by acting as an inhibitory neurotransmitter^[6,7]. NO cannot be stored in the cells; therefore, it depends on new synthesis to exert its functional properties. The subcellular compartmentalization of NOS is therefore determinative in NO production^[8]. However, the tissue specificity and subcellular distribution of NOS isoforms continue to be subject to debate^[9]. Accordingly, the aim of the present study was to establish the presence and subcellular distribution of NOS isoforms in the duodenum of adult rats.

MATERIALS AND METHODS

All the experiments were approved by the Local Ethics Committee for Animal Research Studies at the University of Szeged. Healthy adult male Wistar rats weighing 350-400 g were used throughout the experiments. The animals were killed by cervical dislocation and segments of the duodenum were dissected, rinsed in 0.05 mol/L phosphate buffer (PB, pH 7.4), and processed for postembedding immunohistochemistry.

The gut segments were cut along the mesentery, pinched flat, and fixed overnight at 4°C in 2% paraformaldehyde and 2% glutaraldehyde solution, buffered with 0.1 mol/L PB. The samples were then washed and further fixed for 1 h in 1% OsO₄. After fixation, the gut segments were rinsed in 0.1 mol/L PB, dehydrated in increasing alcohol concentrations (50, 70, 96% and absolute ethanol) and acetone, and embedded in Epon epoxy resin. The Epon blocks were used to prepare ultrathin (70 nm) sections, which were mounted on Formvar-coated nickel grids and processed for immunogold labeling. All steps were performed at room temperature. Sections were preincubated in 1% bovine serum albumin solution for 30 min, incubated overnight in the primary antibodies (Table 1), followed by protein A-gold-conjugated anti-mouse (18 nm gold particles, Jackson ImmunoResearch, USA) or anti-rabbit (10 nm gold particles, Sigma-Aldrich, USA) secondary antibodies for 3 h. Sections were counterstained with uranyl acetate and lead citrate, and then examined and photographed with a Philips CM10 electron microscope equipped with a MEGAVIEW II camera. The specificity of the immunoreaction was assessed in all cases by omitting the primary antibodies from the labeling protocol and incubating the sections only in the protein A-gold-conjugated secondary antibodies. The distributions of the gold particles coding for nNOS, iNOS, and eNOS were determined in 12 ultrathin sections of the duodenum from three different animals.

RESULTS

Postembedding immunoelectronmicroscopy revealed the presence of nNOS (Figures 1-3), eNOS (Figures 4-6)

Table 1 Primary antibodies and working dilutions applied in the experiments

Primary antibody	Clone	Host	Company	Working dilution
nNOS	Monoclonal IgG1, NOS-B1	Mouse	Sigma-Aldrich (USA)	0.18055556
eNOS	Monoclonal IgG1 clone 3	Mouse	Transduction Laboratories (Canada)	0.21527778
iNOS	Polyclonal IgG	Rabbit	Santa Cruz Biotechnology (USA)	0.38888889

nNOS: Neuronal nitric oxide synthase; eNOS: Endothelial nitric oxide synthase; iNOS: Inducible nitric oxide synthase.

the myenteric plexus of the rat duodenum. The cell type-specific distributions of the immunogold particles labeling the three different NOS isozymes were revealed. Gold particles labeling nNOS (Figure 3), eNOS (Figure 6), or iNOS (Figure 8) in the local endothelium were localized almost exclusively to vesicle membranes or the interior of vesicles. The majority of the gold particles labeling nNOS in enteric muscle cells (Figure 2), or eNOS in nerve terminals (Figure 4), accumulated in the mitochondria. The gold particles labeling nNOS in myenteric neurons (Figure 1) or eNOS in enteric smooth muscle cells (Figure 5) were dispersed above the structureless cytoplasm. iNOS was evenly distributed in enteric muscle cells and also in myenteric neurons (Figure 7). In the control experiments in which the primary antiserum was omitted, virtually no postembedding gold particles were observed (not shown).

Figure 7 Postembedding immunogold labeling for inducible nitric oxide synthase. Gold particles (encircled) are randomly distributed in the enteric muscle cells (SM) and also in the myenteric neurons (N). M: Mitochondria.

Figure 8 Postembedding immunogold labeling for inducible nitric oxide synthase in the endothelial cell of a capillary in the vicinity of the myenteric plexus of the rat duodenum. The majority of the gold particles were bound to the vesicular membranes or are situated inside vesicles (arrows).

DISCUSSION

The present postembedding immunoelectronmicroscopic study has provided the first evidence of cell-type-specific differences in the subcellular distributions of NOS isoforms in myenteric neurons, enteric muscle cells, and the endothelium of local capillaries in the rat duodenum. We confirmed previous results^[5] that all three NOS isoforms are present in myenteric neurons. However, the subcellular locations that we verified here for the NOS isoforms in the different cellular elements of the duodenal wall of rat contrasted with results of previous localization studies, where nNOS and iNOS were considered to be cytosolic^[3] and to be eNOS membrane-associated^[4]. To date, there has been no explanation as to why the three different NOS isoforms are expressed in myenteric neurons, enteric muscle cells, and the capillary endothelium. It appears, conceivable, however, that, in consequence of the differences in compartmentalization, the different NOS isoforms are not simultaneously active in NO synthesis in these cells. Hence, the presence of three NOS isoforms with similar functions in the same cells might reflect a functional plasticity, in which one NOS isoform can replace another under different pathophysiological conditions. The rearrangement of the subcellular NOS compartments under pathological conditions will therefore be the subject of our further investigations.

COMMENTS

Background

Despite being a simple molecule, nitric oxide (NO) has fundamental roles in the fields of neuroscience, physiology and immunology. In the intestine, NO has an important role in the gastrointestinal motility.

Research frontiers

The presence of the three nitric oxide synthase (NOS) isoforms in the same cells might reflect a functional plasticity.

Innovations and breakthroughs

The present study provided the first direct evidence of cell-type-specific differences in the subcellular distributions of NOS isoforms in the rat duodenum.

Applications

The presence of three NOS isoforms with similar functions in the same cells might reflect a functional plasticity, in which one NOS isoform can replace another under different pathophysiological conditions. Further research will focus on the potential rearrangement of the subcellular NOS compartments under pathological conditions. The regulatory elements of this rearrangement might offer attractive targets for therapeutic approaches.

Terminology

There are three genetically different isoforms of NOS, which account for NO production: neuronal, endothelial, and inducible NOS.

Peer review

NO is a highly active molecule; therefore, the subcellular compartmentalization of the three NOS is determinative in NO production. Using postembedding immunoelectronmicroscopy it has been demonstrated that neurons, smooth muscle cells, and also endothelial cells in the gut wall express all three NOS isoforms.

and demographic data were taken, as well as the history of non-steroidal anti-inflammatory drug (NSAID) consumption. After reading each VCE recording, a capsule endoscopy scoring index for small bowel mucosal inflammatory change (Lewis score) was calculated. Statistical analysis of the data was performed.

RESULTS: The Lewis score for the whole cohort was 397.73. It was higher in the NSAID consumption subgroup ($P = 0.036$). The difference in Lewis score between NSAID users and non-users was reproduced for the first and second proximal tertiles of the small bowel, but not for its distal third (P values of 0.036, 0.001 and 0.18, respectively). There was no statistical significant difference between the groups with regard to age or sex of the patients.

CONCLUSION: The intestinal inflammatory involvement of SpA patients is more prominent in NSAID users for the proximal/mid small bowel, but not for its distal part.

NSAID-induced deleterious effects on the proximal and mid small bowel in seronegative spondyloarthropathy patients. *World J Gastroenterol* 2011; 17(8): 1030-1035 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i8/1030.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i8.1030>

INTRODUCTION

Spondyloarthropathies (SpAs) are a group of related disorders with common clinical and genetic characteristics and a global prevalence between 0.5% and 1%^[1]. Entities included in the group of SpAs are ankylosing spondylitis, reactive arthritis, psoriatic arthritis, undifferentiated SpA, juvenile onset SpA and SpA in patients with inflammatory bowel disease (IBD). Some researchers also include within this concept Behçet's disease-associated SpA^[2].

Over 20 years ago, Mielants *et al*^[3] showed that a substantial number of these patients have subclinical ileal inflammation. They reported finding macroscopic ileal abnormalities in up to 30% of SpA patients, including erythema, edema, ulceration, granulation, and a cobblestone appearance of the ileal mucosa. Moreover, inflammatory lesions macroscopically resembling those found in SpAs are induced by non-steroidal anti-inflammatory drug (NSAID) consumption, and about two thirds of NSAID users demonstrate intestinal abnormalities^[4]; this is important, since many of the SpA patients use NSAIDs in the treatment of their disease.

Video capsule endoscopy (VCE) is a diagnostic tool that has recently made non-invasive imaging of the entire small bowel possible. This technique has been demonstrated as the first-line diagnostic tool for detecting small bowel pathologies^[5], and we have considered it to be suited for the evaluation of small bowel mucosal lesions.

The aim of this study was to evaluate the pattern, frequency, and severity of small bowel mucosal injury in patients with SpAs as assessed by VCE, and to clarify the role of NSAIDs in the occurrence of the lesions, given the inflammatory involvement of the small bowel that already exists in the SpA control group^[6].

MATERIALS AND METHODS

This is a single-center observational study in a tertiary referral teaching hospital in Bucharest, Romania, conducted from January 2008 to June 2010. All consecutive adult patients evaluated by the study team with a form of seronegative SpA (as defined by an Amor score ≥ 6 ^[1]) in whom no intestinal stenosis or obstruction was suspected were included, if they agreed to take part in the experiment. Exclusion criteria were also: pregnancy, swallowing disorders or the presence of cardiac pace-makers, and history of IBD. The study was conducted according to the Declaration of Helsinki, Good Clinical Practice (GCP) and local regulations. The protocol was approved by the institutional ethics committee and all the patients agreed to participate in the study and signed the informed consent before enrolling.

The patients were investigated using VCE examination. The preparation for the procedure included a fasting period of 12 h and a routine PEG-based bowel preparation (Endofalk, Dr. Falk Pharma GmbH, Freiburg, Germany) with 2 L administered in the evening before and 1 L on the morning of the procedure. Simethicone 80 mg was given orally 15 to 20 min prior to the initia-

NSAID: Non-steroidal anti-inflammatory drug.

tion of VCE examination (Espumisan L, Berlin Chemie AG, Berlin, Germany). Video capsule examination was performed with PillCam SB2 capsules (Given Imaging, Yokneam, Israel). The RAPID™ versions that were used for reading the VCE recordings were 5.0, and, starting with December 2009 recordings, 6.0.

Patients were allowed to drink clear liquids 2 h after VCE ingestion and were free to engage in their normal daily activities. They were allowed to eat a light lunch 4 h after capsule ingestion and returned for removal of the recorder 8-9 h after ingestion. No adverse effects were reported and all the capsules were excreted.

Two endoscopists (MR and MM) with experience in VCE examination reviewed the findings of VCE. Capsule endoscopy results were interpreted, and the Lewis score was calculated for every patient by one endoscopist (MR) in each tertile of the small bowel (stenosis score included), and then for the whole bowel.

Data regarding patient demographics and treatment taken were also retrieved, with emphasis on concurrent NSAID consumption. Collected data were recorded on a preformed questionnaire and introduced afterwards in the SPSS database. Results are expressed as frequencies for categorical variables (further analyzed by Fisher's exact test), mean and standard deviation for normal continuous variables (analyzed by Student's *t* test), and median and extremes for non-normal continuous variables (analyzed by Mann-Whitney *U* test). Hypothesis testing was 2-tailed, with *P* < 0.05 considered statistically significant.

The statistical software package SPSS for Windows Version 16.0 (SPSS Inc., Chicago, IL) was used to analyze the data.

RESULTS

Fifty-four patients (27 males and 27 females) were enrolled. The rheumatologic disease was ankylosing spondylitis in 36 patients (66%), psoriatic SpA in 3 (6%), undifferentiated SpA in 9 (17%) and 6 patients concurrently satisfied the criteria for Behçet's disease and SpA (11%) (Table 1).

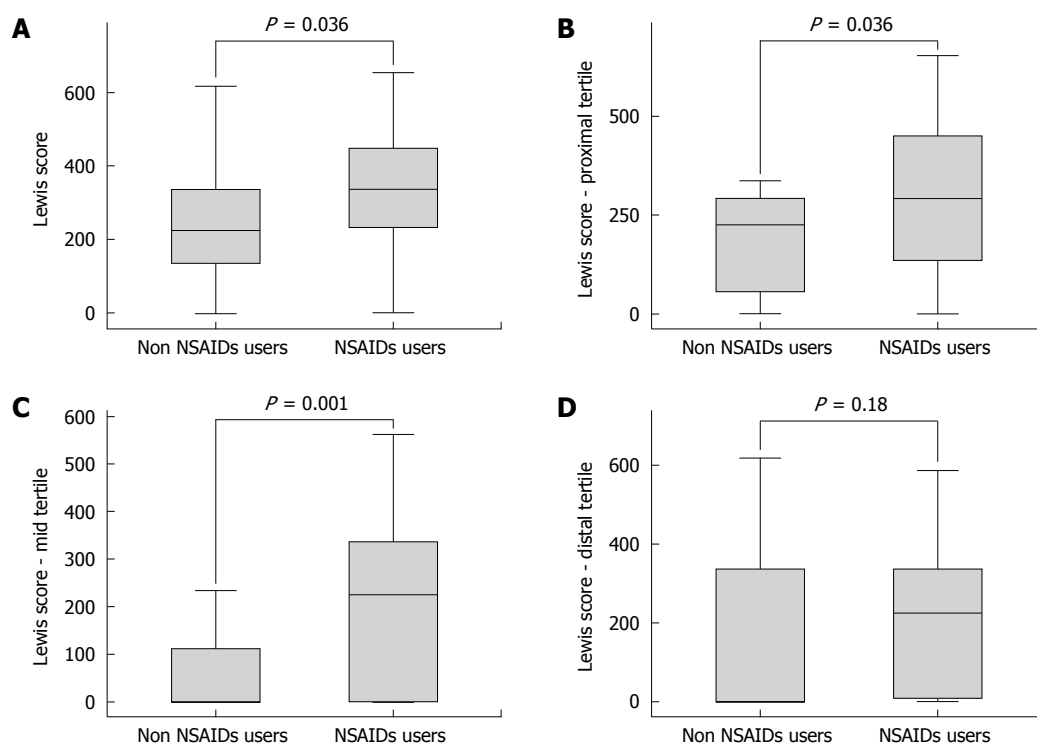

Figure 1 Comparison between the Lewis scores for the entire small bowel (A), proximal tertile of the small bowel (B), mid tertile of the small bowel (C) and distal tertile of the small bowel (D) in the groups of non-steroidal anti-inflammatory drug users and non-users (the median of values and quartiles represented). NSAID: Non-steroidal anti-inflammatory drug.

Table 2 Lewis score characteristics for the study patients. [mean; median (min, max)]

	Non NSAID users	NSAID users	P value
Whole small bowel (n = 51)	344; 225 (0, 1630)	438; 337 (0, 1462)	0.036 ^a
Proximal tertile (n = 53)	226; 225 (0, 1462)	428; 292 (0, 1690)	0.036 ^a
Mid tertile (n = 51)	63; 0 (0, 562)	196; 225 (0, 562)	0.001 ^a
Distal tertile (n = 51)	217; 0 (0, 1630)	215; 225 (0, 586)	0.186

^aStatistically significant. NSAID: Non-steroidal anti-inflammatory drug.

Thirty-one patients (57%) were concomitantly treated with at least one NSAID. The mean age was 38.65 ± 11.58 years for controls *vs* 37.87 ± 10.63 years for NSAID users ($P = 0.79$, *T*-Test, independent samples test). There were more males in the NSAID user (54.8%) *vs* non-NSAID user subgroup (43.5%) ($P = 0.41$, *T*-Test, paired samples correlations).

There was a large heterogeneity regarding the type of drug [either cyclooxygenase-2 (COX-2) selective or non-selective, or a combination of them], the doses taken (some patients were only taking acetylsalicylic acid in antiaggregant doses) and the duration of NSAID use (weeks to years).

The Lewis score for the whole small bowel could be calculated in 52 patients (96%). In one of these patients,

although the score could not be calculated for the distal tertile, the extremely high value in the mid tertile was extrapolated for the whole bowel; regardless, due to the fact that this subject had a very high discordant value of the Lewis score (4846), he was not considered for the descriptive and statistical analysis of the data. Approximating the capsule final position in the remaining 2 patients, the Lewis score could be estimated only for the proximal third of the small bowel because of the late passage of the video capsule through the pyloric ring into the small bowel.

The intraobserver reproducibility^[7] for the Lewis score was assessed in 20 patients, and was considered to be high-coefficient of variation reached 3.52%.

The mean value of the Lewis score for the whole cohort was 397.73 (range 0-1630, standard deviation 401.46), with mean values of 340.64, 138.92 and 215.63 for the proximal, mid and distal tertiles of the small bowel, respectively.

There was a significant difference in the Lewis scores for the whole small bowel between the subgroups with and without NSAID consumption ($P = 0.036$) (Table 2 and Figure 1A). The difference was reproduced for the proximal and mid small bowel tertiles, but not for the distal tertile (P values of 0.036, 0.001 and 0.18, respectively) (Table 2 and Figure 1B-D).

DISCUSSION

The term SpA indicates a group of related diseases, all

sharing common clinical features which are HLA-B27 positivity, sacroiliitis, inflammatory low back pain and oligoarticular asymmetric synovitis. The need for a standardized approach led to the development of the classification criteria proposed by Amor *et al*^[1] which consider clinical and historical symptoms, radiologic findings, genetic background and response to treatment. Given the high diagnostic sensitivity (85%) and specificity (95%), we used these criteria for our study; a patient was considered to have SpA if the sum of the criteria scores was at least 6.

SpAs are associated with several extra-articular manifestations including inflammatory gut lesions, the latter being reported in 25%-75% of patients, depending on the subtype of SpA^[8]. Although some of these patients may evolve to overt IBD, the immunological link between SpA and IBD is still poorly understood^[9], the genetic or environmental factors determining the progression within this cascade being largely unknown^[10].

A number of studies using different methodologies have evaluated the potential deleterious effects of NSAIDs on the small bowel. Considered together, they suggest that mild NSAID-related intestinal injury is common^[11]-up to two-thirds of NSAID users demonstrate intestinal inflammation on VCE examination^[12-14].

Having the above background, our aim was to investigate, using VCE examination, the possibility that NSAIDs could determine supplementary small bowel injury in SpA patients, these subjects being already predisposed to having mild inflammatory involvement of the bowel^[15].

The design of the study included calculation of the Lewis score, facilitated by latest versions of the RAPID™ software. The Lewis score represents a capsule endoscopy scoring index developed for quantification of small intestinal mucosal disease activity^[16]. It evaluates the aspect of the mucosal villi and the presence of ulcerative lesions and stenoses of the bowel lumen. A score is calculated for each tertile of the small bowel (proximal, mid, distal-resulting from dividing into three the time the capsule spent in the small bowel), and the total score equals the highest of these values plus the stenosis score. The Lewis score can range from 0 to 7840, and values below 136 are considered within normal.

A problem of the present study is represented by the large heterogeneity in the type of NSAID drug, the doses taken and the duration of NSAID use, therefore we had to group the subjects only according to NSAID concurrent use. This meant that we included in the same group of NSAID consumption patients those who ingested COX-2 selective and non-selective drugs. This might have been not so very wrong, because recent studies demonstrate that COX-2 inhibitors may not be more protective than some non-selective NSAIDs^[17]. The NSAID doses also varied widely in our study, as well as the amount of time over which the drugs were taken. Therefore, we could not evaluate the effects of different doses and durations of treatment on the small bowel. Another limitation of the present study is represented by the fact that many

Figure 2 Video capsule endoscopy image from the mid jejunum of a 39-year-old male spondyloarthropathy patient, non-steroidal anti-inflammatory drug user, showing a group of small aphthoid ulcerations in a circumscribed area of erythema (blue circle).

of the patients also received as part of their treatment immunosuppressive drugs, disease-modifying anti-rheumatic drugs, anti-tumor necrosis factor α therapy, or a combination of these.

In the present study, mild inflammatory involvement of the small bowel has been found in the whole cohort of SpA patients, given that the mean value of the Lewis score was 397.73. Subjects with NSAID consumption had more significant inflammatory lesions when the evaluation was performed for the whole small bowel. This result was expected because of the NSAID potential to induce small bowel inflammatory lesions. The above difference was reproduced for the proximal and mid small bowel tertiles but, surprisingly, not for the distal tertile, where there was no difference in bowel involvement between the NSAID concomitant users and non-users.

As it has already been established that NSAID intake predisposes to lesions in the distal small bowel^[11], partly because of the use of enteric-coated, sustained-release, or slow-release NSAIDs^[18], and because of the potential of NSAIDs to exacerbate the intestinal inflammation in Crohn's disease-an entity related to the concept of SpA and considered to be located mainly in the distal small bowel-we were expecting to find more lesions in the NSAID consumption group in the distal tertile of the small bowel.

Other studies have already been performed to detect small bowel mucosal abnormalities in patients with SpAs using endoscopy techniques. Significant small bowel findings (erythema, mucosal breaks, aphthous or linear ulcers, and erosions) were detected by capsule endoscopy in one third of patients in a small SpA recent series^[19], but in this study patients who were on NSAIDs in the 2 mo prior to enrollment were strictly excluded and the Lewis score was not calculated.

Up till now, the participation of the NSAIDs in the generation of bowel lesions in SpAs could only be postulated^[20]. At the mucosal level, predicted mechanisms of NSAID injury are inhibition of protective prostaglandins, alterations in blood flow, and increased small intestinal

permeability with subsequent invasion by luminal factors. The mucosal damage may lead to inflammation and ulceration^[11], but there is nothing endoscopically specific about NSAID-induced gut lesions^[12] (Figure 2); in the differential diagnosis could be included infectious etiologies, IBD, ischemia, radiation enteritis, vasculitides, and other drugs^[11].

The present study is not intended to delineate which of the bowel lesions are due to NSAID intake and which to the rheumatologic disease. It only aims to identify the pattern of involvement of the small bowel when the two conditions superimpose. It is worth mentioning that the statistically significant differences between the NSAID users and non-users regarding bowel lesions found in our study were actually small (differences in the mean values of the Lewis scores of 93.92, 201.69 and 133.43 for the whole small bowel, and proximal and mid tertiles, respectively). It is not clear why the distal part of the small bowel is not influenced by NSAID consumption in this subset of patients.

In our view, there remains a great deal of uncertainty regarding the place of invasive methods, such as push- or double-balloon enteroscopy, in providing histological assessment of the abnormalities found on VCE. Another unresolved issue is represented by the persistence of these lesions, when stopping or continuing NSAID intake. Further studies are needed in the era of biological therapy to elucidate the clinical relevance of the lesions that we have detected and their possible influences on prognosis and further management of SpA patients.

COMMENTS

Background

The term spondyloarthropathy (SpA) indicates a group of related diseases, all sharing common clinical features such as the presence of HLA-B27 antigen and particular rheumatologic involvement (sacroiliitis, inflammatory low back pain and oligoarticular asymmetric synovitis). Entities included in the group of SpAs are ankylosing spondylitis, reactive arthritis, psoriatic arthritis, undifferentiated SpA, juvenile onset SpA and SpA in patients with inflammatory bowel disease. SpAs are associated with several extra-articular manifestations, including inflammatory gut lesions. However, non-steroidal anti-inflammatory drugs (NSAIDs), frequently used to treat these patients, have the potential of inducing intestinal injury.

Research frontiers

Having the above background, our aim was to investigate, using videocapsule examination, the possibility that NSAIDs could determine supplementary small bowel injury in the subgroup of patients with a form of SpA, these subjects being already predisposed to having mild inflammatory involvement of the bowel.

Innovations and breakthroughs

We found a mild inflammatory involvement of the small bowel in all SpA patients. Subjects with NSAID consumption had more significant inflammatory lesions in the whole small bowel. The above difference was reproduced for the proximal and mid small bowel tertiles but, surprisingly, not for the distal tertile, where there was no difference in bowel involvement between the NSAID concomitant users and non-users.

Applications

In our view, there remains a great deal of uncertainty regarding the place of invasive methods, such as push- or double-balloon enteroscopy, in providing histological confirmation of the abnormalities found on capsule endoscopy. Another unanswered question is how stable these lesions are, when stopping or continuing NSAID intake. Further studies will be needed in this era of biological therapy to elucidate the clinical relevance of the lesions that we detected

and their possible influence on prognosis and further management of the SpA patients.

Peer review

Based on the background that NSAID intake has potential deleterious effects on the small bowel, and SpAs are associated with inflammatory gut lesions, the authors designed this statistical study, trying to provide more evidence for the participation of NSAIDs in generation of bowel lesions in SpA patients. The results confirmed the inflammatory involvement of small bowel, especially in the proximal and mid tertiles, in SpA patients that have been treated with NSAIDs. The conclusion is of interest.

Abstract

AIM: To investigate miR-200 family expression in Barrett's epithelium, gastric and duodenal epithelia, and esophageal adenocarcinoma.

METHODS: Real-time reverse transcriptase-polymerase chain reaction was used to measure miR-200, *ZEB1* and *ZEB2* expression. Ingenuity Pathway Analysis of miR-200 targets was used to predict biological outcomes.

RESULTS: Barrett's epithelium expressed lower levels of miR-141 and miR-200c than did gastric and duodenal epithelia ($P < 0.001$). *In silico* analysis indicated roles for the miR-200 family in molecular pathways that distinguish Barrett's epithelium from gastric and duodenal

epithelia, and which control apoptosis and proliferation. All miR-200 members were downregulated in adenocarcinoma ($P < 0.02$), and miR-200c expression was also downregulated in non-invasive epithelium adjacent to adenocarcinoma ($P < 0.02$). The expression of all miR-200 members was lower in Barrett's epithelium derived high-grade dysplastic cell lines than in a cell line derived from benign Barrett's epithelium. We observed significant inverse correlations between miR-200 family expression and *ZEB1* and *ZEB2* expression in Barrett's epithelium and esophageal adenocarcinoma ($P < 0.05$).

CONCLUSION: miR-200 expression might contribute to the anti-apoptotic and proliferative phenotype of Barrett's epithelium and regulate key neoplastic processes in this epithelium.

INTRODUCTION

Barrett's esophagus is characterized by the replacement of the normal stratified squamous esophageal epithelium

with metaplastic columnar epithelium. Metaplasia to Barrett's esophagus is probably an adaptive response to the insult from reflux of gastric acid and duodenal bile salts into the esophagus, which occurs in chronic gastroesophageal reflux^[1]. Barrett's esophagus epithelium possesses secretory and absorptive cell types, and these closely resemble those found in normal gastric and intestinal epithelia^[2,3]. mRNA expression profiling studies confirm its similarity to gastric and duodenal epithelia^[4-6]. However, Barrett's esophagus epithelium also expresses a specific cluster of genes, including those associated with alterations in cell cycle/proliferation, apoptosis, stress response, and cellular migration pathways, and these distinguish it from all related gastrointestinal mucosae^[4]. Other studies have confirmed unique phenotypic characteristics of Barrett's epithelium that correspond with this specific gene expression cluster. For example, unlike gastric and duodenal epithelia, cellular proliferation in Barrett's esophagus continues along the upper crypt and at the luminal surface, possibly due to abnormal cell cycle entry or exit^[7]. Furthermore, Barrett's esophagus epithelium expresses unusually high levels of anti-apoptotic proteins^[8] and can mount a unique anti-apoptotic and proliferative response to reflux^[9-12].

Barrett's esophagus is clinically important because it is the only visibly identifiable precursor to esophageal adenocarcinoma^[13]. Progression to dysplastic stages involves increased abnormalities in the cell cycle and overall proliferation^[13]. Neoplastic progression commonly occurs without obvious symptoms, and at the time of diagnosis, most patients with esophageal adenocarcinoma have local invasion or metastases^[14]. Several lines of evidence suggest that epithelial to mesenchymal transition is required for local invasion and metastasis^[15]. Epithelial to mesenchymal transition involves inhibition of E-cadherin expression and transition from epithelial to fibroblastic cell type, with associated alterations in cellular adhesion and migration^[15]. Other studies have presented immunohistochemical, gene expression and cell line data that suggest a role for epithelial to mesenchymal transition in esophageal adenocarcinoma^[16,17].

miRNAs downregulate target gene expression at the post-transcriptional level through the binding of their "seed" sequences with complementary sites in the 3'-untranslated region of target mRNAs^[18]. The miR-200 family of miRNAs (miR-141, 200a, 200b, 200c and 429) are key regulators/inhibitors of epithelial to mesenchymal transition, and act to maintain the epithelial phenotype by targeting the expression of the E-cadherin transcriptional repressors ZEB1 and ZEB2^[19-21]. Accordingly, the number of studies reporting downregulation of miR-200 family expression in cancer is increasing^[19-25]. In addition, members of the miR-200 family have recently been shown to affect other cell behaviors including proliferation, cell cycle and apoptosis^[26-28].

Given the unique gene expression profile and cellular behavior in Barrett's esophagus epithelium, the phenotypic features that characterize its neoplastic progression, and the potential relevance of epithelial to mesenchymal transition to esophageal adenocarcinoma, we sought to determine the expression of miR-200 family members in gastric, duodenal and Barrett's esophagus epithelium, and

to assess their expression with neoplastic progression of Barrett's esophagus. We hypothesized that Barrett's esophagus epithelium may possess a miR-200 expression profile different to gastric and duodenal epithelia, and that downregulation of miR-200 family expression may occur upon progression to esophageal adenocarcinoma.

MATERIALS AND METHODS

Tissue collection and processing

Tissues from patients diagnosed with either Barrett's esophagus ($n = 17$) or esophageal adenocarcinoma ($n = 20$) were collected at endoscopy or after surgical resection. The clinical research ethics committees of Flinders University and Erasmus Medical Centre approved the protocol for this study. Details of the collection process, information about the clinical characteristics of the patients, and RNA isolation from tissues have been published in full elsewhere^[29]. In brief, endoscopic biopsy samples were obtained from the second part of the duodenum, proximal stomach, and distal esophagus. All biopsies were immediately stored in RNAlater (Ambion, Austin, TX, USA) and frozen at -20°C until required. All biopsy samples used in this study were collected from the most distal level of endoscopically visualized Barrett's esophagus epithelium, which was confirmed by concurrent histopathology to be from columnar mucosa with intestinal metaplasia. In individuals with esophageal adenocarcinoma, a similar biopsy collection protocol was used for endoscopic biopsy. Samples were obtained from the second part of the duodenum, proximal stomach and the adenocarcinoma. Samples from surgical resection specimens were obtained from the normal upper stomach, and the tumor site, and immediately stored in RNAlater (Ambion) and frozen at -20°C until required. If any Barrett's esophagus epithelium was present proximal to an esophageal adenocarcinoma, this was also sampled using the same protocols. Samples from patients with adenocarcinoma of the esophagus were always obtained before any neoadjuvant chemotherapy or radiotherapy was commenced, if clinically indicated.

The stored endoscopic biopsies and resection tissues were thawed in RNAlater as required. Thirty percent of each endoscopic biopsy sample, or a small portion of the resection samples, was dissected from the thawed tissue sample, fixed in formalin, embedded in paraffin, and processed for conventional histopathology. This was done to confirm that the biopsy contained only the appropriate tissue type. The remaining tissue had any remaining RNAlater removed, and was then processed in Trizol (Invitrogen, Carlsbad, CA, USA) for RNA extraction. RNA was also extracted from cell lines derived from benign Barrett's esophagus (Qh) and high grade dysplastic (Ch and Gi) epithelium^[30].

Quantitative reverse transcriptase-polymerase chain reaction analysis of miR-200 family, ZEB1 and ZEB2 expression

miR-200 expression was determined using commercially available TaqMan[®] miRNA assays specific for each member of the miR-200 family (Applied Biosystems, Foster City, CA,

Table 1 Relative miRNA expression in Barrett's esophagus, gastric and duodenal mucosal tissues

MiRNA	Duodenal (n = 10)	Barrett's esophagus (n = 17)	Gastric (n = 15)	P value (Kruskal-Wallis test)
miR-141	0.076 (0.039, 0.167)	0.026 (0.023, 0.036)	0.051 (0.042, 0.092)	0.0002 ^{1,2}
miR-200a	0.148 (0.067, 0.340)	0.148 (0.126, 0.177)	0.247 (0.154, 0.509)	0.0314 ²
miR-200b	0.796 (0.606, 1.276)	0.833 (0.750, 0.993)	1.233 (1.089, 1.963)	0.0011 ²
miR-200c	2.700 (1.890, 3.511)	1.049 (0.929, 1.170)	2.335 (1.792, 2.773)	< 0.0001 ^{1,2}
miR-429	0.095 (0.042, 0.070)	0.070 (0.061, 0.087)	0.078 (0.072, 0.153)	0.259

Relative expression for each epithelial tissue type. Relative expression values are median (95% CI). The group *P* value was the result of a Kruskal-Wallis test across the three tissue groups. Significant differences were identified by post hoc testing by the Holm-Bonferroni method for: ¹Duodenal versus Barrett's esophagus mucosa - miR-141 (*P* = 0.0008) and miR-200c (*P* < 0.0001); ²Gastric versus Barrett's esophagus mucosa - miR-141 (*P* = 0.0004) miR-200a (*P* = 0.0078), miR-200b (*P* = 0.0001), and miR-200c (*P* < 0.0001).

USA). *ZEB1* and *ZEB2* mRNA expression was assessed using the Quantiscript® RT kit for reverse transcription and the Quantitect® SYBRGreen mastermix for polymerase chain reaction (PCR). Primer details are available upon request. miRNA expression was normalized using RNU44, and mRNA expression was normalized using 18S rRNA. Data were analyzed quantitatively using Q-Gene software^[31]. Apparent differences in gene expression between the tissues were assessed for statistical significance using the Kruskal-Wallis test (significance cut-off *P* < 0.05). If significance was reached for this analysis, then the *post hoc* Holm-Bonferroni test was used for pairwise comparisons. Statistical testing was performed using Microsoft Excel. Spearman rank order correlation tests between miRNA and mRNA expression were conducted on-line (<http://www.wessa.net/rankcorr.wasp>). In addition to miR-200 expression, we also tested miR-215 because we have previously demonstrated down-regulation of this miRNA in esophageal adenocarcinoma^[29], and it was recently shown to target *ZEB2* directly^[32].

miRNA target prediction and pathway analysis

Target prediction using miRecords (<http://mirecords.biolead.org/>)^[33] and a core analysis using Ingenuity Pathway Analysis (www.ingenuity.com) were combined to elucidate possible implications of reduced miRNA expression. Predicted targets used in this analysis were required to be predicted by at least five databases in the miRecords search engine. Ingenuity Pathway Analysis parameters were set to assess a knowledge base derived from direct and indirect associations between genes in human experiments, and also in epithelial cell lines. In the Ingenuity Pathway Analysis, genes are grouped according to function and are allocated to top associated networks and cellular functions. Ingenuity Pathway Analysis uses a right-tailed Fisher's exact test to assign *P* values to each grouping, testing each result against a result from random groups of input predicted genes. Networks and cellular functions are ranked according to their score with the highest scoring networks representing the greatest statistical significance.

RESULTS

miR-200 family expression analysis in Barrett's esophagus, gastric and duodenal epithelia

Taqman Quantitative reverse transcriptase-PCR (qRT-

PCR) revealed that expression levels of miR-141 and 200c were significantly lower in Barrett's esophagus epithelium compared with gastric and duodenal epithelia (Table 1). miR-200a and miR-200b expression was significantly lower in Barrett's esophagus epithelium than in gastric epithelium, but did not differ in expression between Barrett's esophagus and duodenal epithelia. The expression level of miR-429 was not significantly different across these three epithelial types.

Predicted implications of reduced miR-200 family expression in Barrett's esophagus

Core Ingenuity Pathway Analysis on predicted targets of miR-141 and miR-200c were performed to determine the probable biological effects of their reduced expression. The collection of target predictions from multiple algorithms, presented in miRecords, listed 272 gene targets for miR-141 and 429 targets for miR-200c. The top associated biological networks for these targets are illustrated in Figure 1, and the biological functions associated with these targets are listed in Table 2.

miR-200, ZEB1 and ZEB2 expression in Barrett's esophagus and esophageal adenocarcinoma

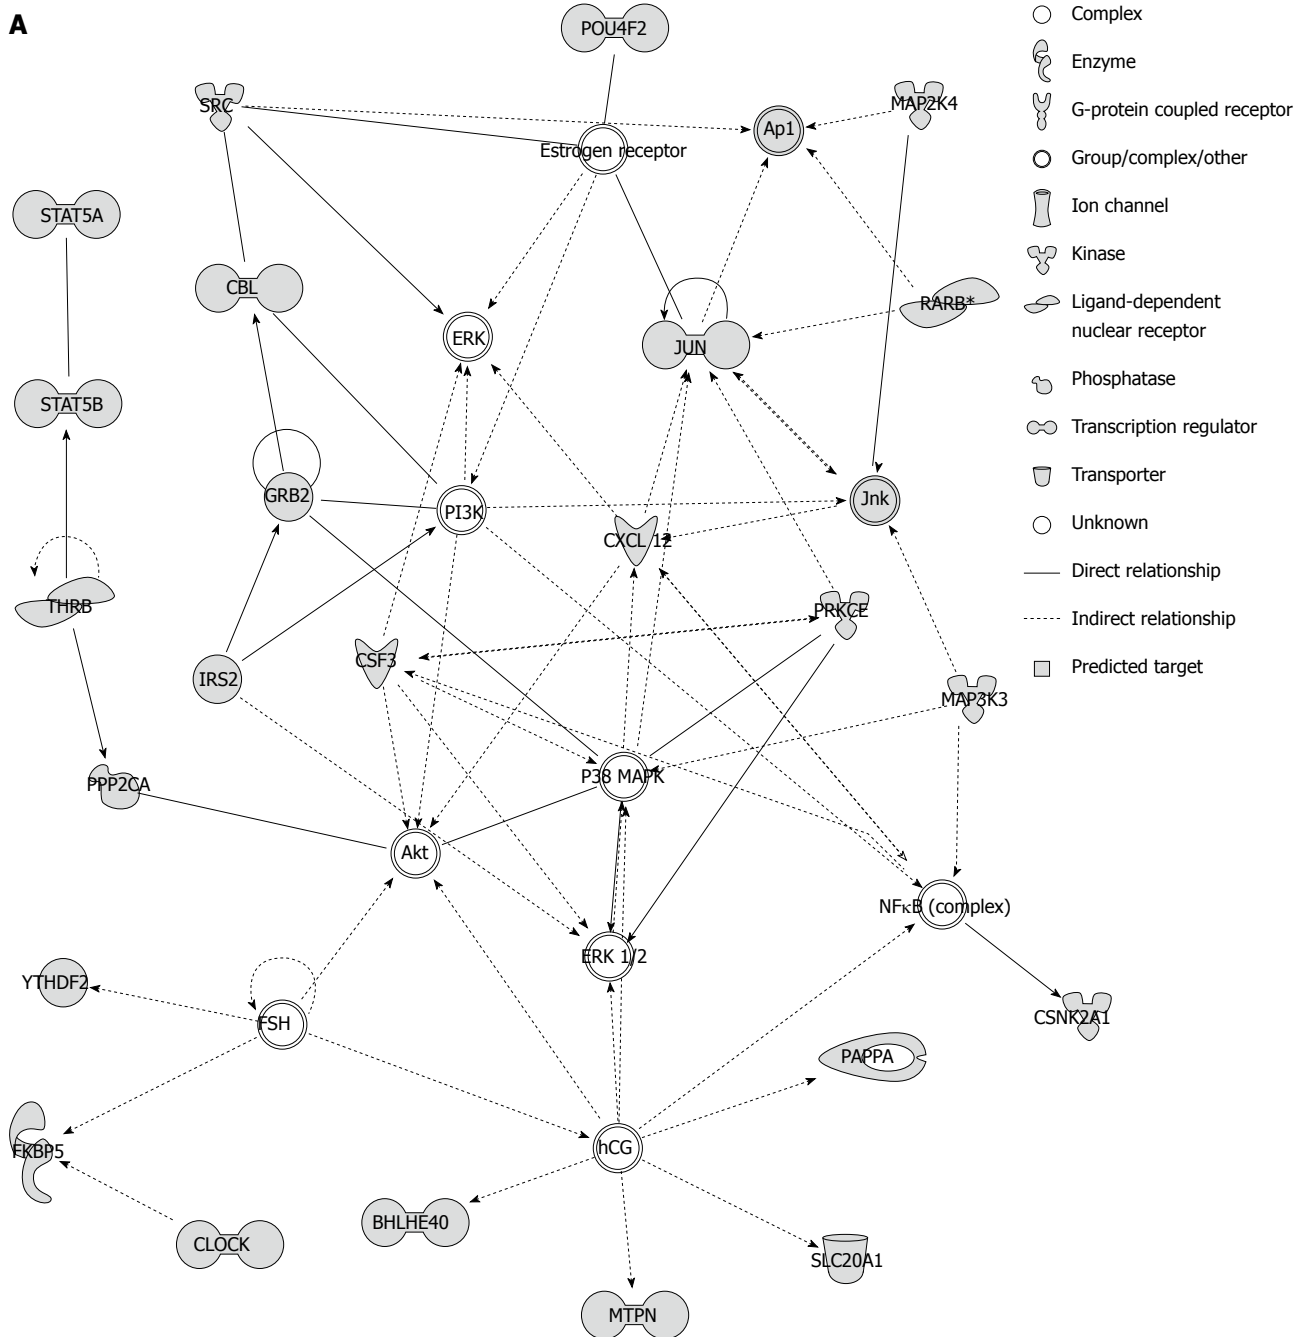

Expression of all members of the miR-200 family was significantly lower in esophageal adenocarcinoma compared with Barrett's esophagus epithelium (Table 3). The median expression of all miR-200 family members was lower in Barrett's esophagus epithelium proximal to esophageal adenocarcinoma than in Barrett's epithelium from patients without cancer or dysplasia. However, after *post hoc* analysis, only the difference in miR-200c expression was statistically significant. To determine whether this could indicate downregulation of miR-200 expression in dysplasia, prior to the development of adenocarcinoma, miR-200 family expression was further assessed in a non-dysplastic Barrett's esophagus derived cell line (Qh), and two cell lines derived from Barrett's esophagus with high-grade dysplasia (Ch, Gi). Figure 2 shows that the expression of all miR-200 members was markedly reduced in both dysplastic cell lines compared to expression in the benign cell line.

To determine whether the miRNA switch for epithelial to mesenchymal transition might be active in esophageal adenocarcinoma development, we also assessed the mRNA expression of miR-200 targets *ZEB1* and *ZEB2*.

Table 2 Top molecular and cellular functions of miR-200 gene targets

miRNA	Molecular and cellular functions	Molecules involved	P value
miR-141	Cell cycle	41	1.90E-07-2.82E-02
	Gene expression	53	4.94E-07-2.82E-02
	Cellular movement	39	2.45E-05-2.82E-02
	Cellular assembly and organization	61	2.88E-04-2.82E-02
	Cellular growth and proliferation	68	2.88E-04-2.28E-02
miR-200c	Gene expression	84	1.37E-09-2.32E-02
	Cellular growth and proliferation	108	5.65E-05-2.32E-02
	Cell cycle	53	9.17E-05-2.32E-02
	Cell death	95	9.62E-05-2.32E-02
	Cellular assembly and organization	55	1.19E-04-2.32E-02

The top five functions associated with the predicted targets of miR-141 and miR-200c, as determined by Ingenuity Pathway Analysis, are shown in this table. This analysis used a right-tailed Fisher's exact test to calculate the probability (P value above) that each cellular function ascribed to the predicted target gene list was due to chance alone. For each miRNA, the molecular and cellular functions are ranked according to their P value.

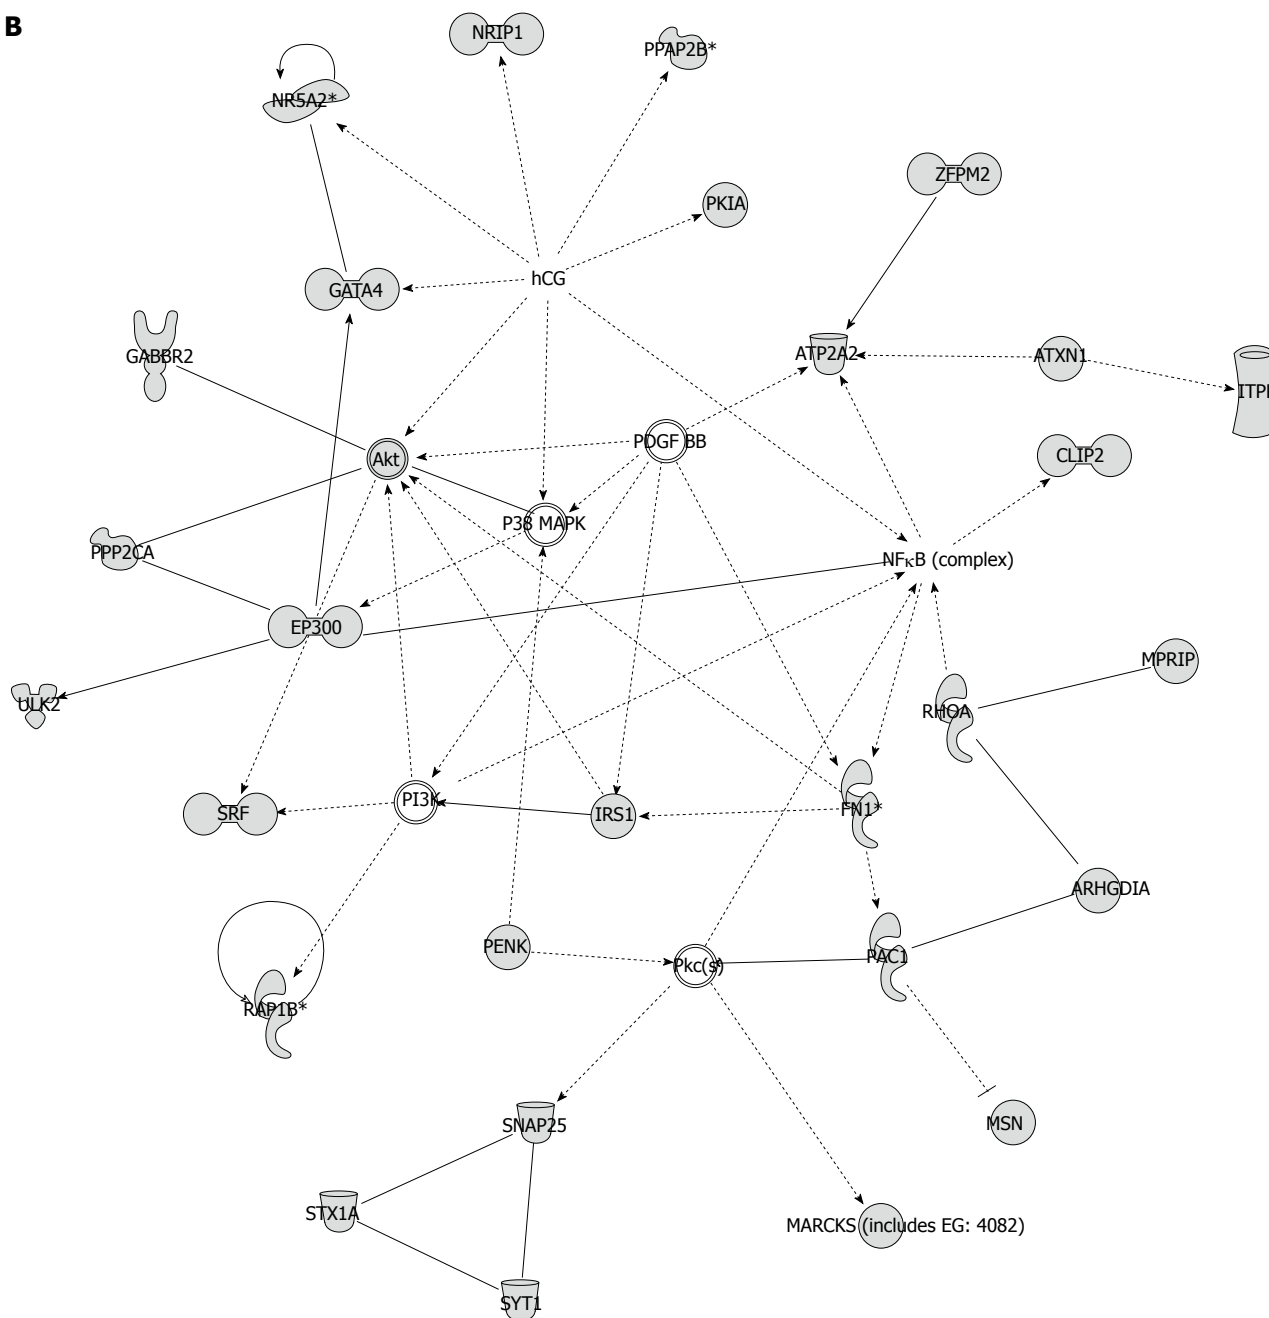

B

Figure 1 Top associated network functions for miR-141 and miR-200c. A: Ingenuity Pathway Analysis predicted that the top associated network functions for miR-141 were gene expression, cell death and cell cycle ($P = 1 \times 10^{-35}$). B: The top associated network functions for miR-200c were cell morphology, cellular assembly and organization, cellular function and maintenance ($P = 1 \times 10^{-38}$). Predicted targets of miR-141 or miR-200c are highlighted in grey. Uncolored entries represent molecules that are associated with the pathway but are not predicted miR-141 or miR-200c targets. The P values were derived from a right-tailed Fisher's exact test to calculate the probability that each predicted miRNA target matches the ascribed network function due to chance alone.

ZEB1 and *ZEB2* expression was significantly higher in esophageal adenocarcinoma compared to Barrett's esophagus epithelium from patients without cancer or dysplasia (Table 4). There were significant inverse correlations between the expression of *ZEB1/ZEB2* and the expression of some miR-200 members. miR-215 and *ZEB2* expression were inversely correlated (Table 4).

DISCUSSION

We found that miR-141 and miR-200c were expressed at

lower levels in Barrett's esophagus epithelium, compared to normal gastric and duodenal epithelia. Bioinformatics analysis indicated that this might contribute to the cell cycle, stress response (proliferation, apoptosis), and cellular migration behavior, which are known to make Barrett's esophagus epithelium different to gastric and duodenal epithelia^[4,7-12,34]. The reduced miR-200 levels that we observed in Barrett's esophagus epithelium adjacent to adenocarcinoma, and Barrett's esophagus with high-grade dysplasia derived cell lines suggested an association between down-regulation of miR-200 expression and neoplastic progres-

Table 3 miRNA expression in Barrett's esophagus and esophageal adenocarcinoma

	$P < 0.0001$	$P = 0.341$	$P = 0.046$	$P = 0.009$	$P = 0.006$	$P = 0.159$	$P = 0.152$
ZEB2	1.5	R = -0.3	R = -0.3	R = -0.5	R = -0.5	R = -0.4	R = -0.4
	$P = 0.029$	$P = 0.101$	$P = 0.085$	$P = 0.008$	$P = 0.015$	$P = 0.067$	$P = 0.044$

The fold increase (↑) in median ZEB1 and ZEB2 expression in esophageal adenocarcinoma versus Barrett's esophagus mucosa from individuals without cancer, and the P value derived using the Mann-Whitney test are given. Spearman correlations (R = Spearman's rho) between ZEB1/2 expression and each miR-200 member, with associated P values are also shown.

Figure 2 miR-200 family expression in benign Barrett's and dysplastic cell lines. Relative expression of all miR-141, miR-200a, miR-200b and miR-429, normalized to U44 expression is shown on the left hand y axis. Relative expression of miR-200c is shown on the right hand y axis. The pattern of relative expression of miR-200 members in the Qh (benign Barrett's) cell line closely resembled that in benign Barrett's esophagus mucosa (see relative expression values in Table 1).

sion in Barrett's esophagus. The increased expressions of ZEB1 and ZEB2 in esophageal adenocarcinoma, and their inverse correlations with miR-200 expression, are consistent with induction of epithelial to mesenchymal transition mediated by loss of miR-200 expression. Taken together with the known biological functions of the miR-200 family^[26-28], our study provides evidence for their influence in patterning the known unique gene expression^[4] and phenotypic characteristics^[4,7-12,34] of benign Barrett's esophagus epithelium, as well as features that characterize its neoplastic progression^[13]. Furthermore, our data indicate that the

miRNA switch for turning on epithelial to mesenchymal transition^[20] might be activated during the development of esophageal adenocarcinoma.

Although the miR-200 family has some redundancy in seed sequence, and therefore the genes they target, they act co-operatively to control the expression of their targets, and a change in expression of just one member is sufficient to alter target transcript levels^[20]. miR-141 and miR-200c are known to modulate apoptosis, cell cycle and proliferation, and cellular migration through regulation of their target genes^[26-28]. Several *in vivo* and *in vitro* studies have elucidated the molecules/complexes that are upregulated/activated in Barrett's epithelium and are responsible for its unique anti-apoptotic and proliferative responses to reflux-induced stress. These include three mitogen-activated protein kinases (MAPKs), extracellular signal-regulated kinase, p38 and C-Jun N-terminal kinase^[35]; protein kinase C^[11]; phosphatidylinositol 3-kinases (PI3K) and downstream Akt^[36]; and transcription factors nuclear factor (NF)- κ B^[37] and activator protein-1^[36]. Our combined target prediction and Ingenuity Pathway Analysis predicted indirect (or direct in the case of Akt) targeting of all of the aforementioned molecules/complexes in the top associated network functions of miR-141 and/or miR-200c. Overall, this suggests that reduced miR-141 and miR-200c expression in Barrett's esophagus epithelium (*vs* gastric and duodenal epithelia) might activate molecular pathways that are known to promote the specific response of Barrett's esophagus epithelium to the insult of gastroesophageal reflux.

Our analysis predicted direct targeting and downregulation of fibronectin by miR-200c, and this was evident in the top associated network. A recent study has shown that fibronectin expression is reduced in cell lines in direct

response to miR-200c expression^[38]. Therefore, it is reasonable to expect that fibronectin expression should be higher in Barrett's esophagus epithelium than in gastric and duodenal epithelia; due at least partly to reduced miR-200c expression in Barrett's esophagus. In agreement with this, fibronectin is in the gene expression cluster that separates Barrett's esophagus epithelium from gastric and duodenal epithelium^[4]. Fibronectin has key roles in cellular adhesion and migration^[39]. In the development of Barrett's esophagus, its expression is proposed to help facilitate expansion of epithelial cell populations in order to replace areas of denuded squamous epithelium with metaplastic cells^[4]. Furthermore, fibronectin expression contributes to increased proliferative and anti-apoptotic behavior through NF- κ B and PI3K signaling^[40]. Taken together, these observations lend support to the biological validity of our bioinformatics-based approach, and further promote a likely role for reduced miR-200c expression in Barrett's esophagus.

The development of high-grade dysplasia significantly increases the risk of progression to esophageal adenocarcinoma^[41,42]. Features of dysplastic epithelium that make it distinct from benign Barrett's esophagus epithelium include increased proliferative and anti-apoptotic behavior^[13]. We found that miR-200c expression is downregulated in Barrett's esophagus sampled from patients with a concurrent esophageal cancer, and the entire miR-200 family was downregulated in cell lines derived from patients with high-grade dysplasia. Our pathway analysis indicates that this could result in the molecular events known to contribute to the features of dysplastic Barrett's esophagus, including increased signaling through MAPK pathways^[43], increased activation and expression of NF- κ B^[44,45], and increased activation of Akt^[43,46]. Activation of Akt is stimulated by interaction of the obesity-related hormone leptin and its receptor, and this results in increased proliferation and resistance to apoptosis in Barrett's esophagus derived cancer cell lines^[46]. The leptin receptor is downregulated *in vitro* in response to miR-200c expression^[38], and our miRecords searches predicted direct targeting of the leptin receptor by miR-200c. We speculate that reduced miR-200 family expression in dysplasia could be an important mechanism for leptin receptor mediated activation of Akt, and this could contribute to the established link between obesity and an increased risk of esophageal adenocarcinoma development^[47]. In further support of the direct relevance of decreased miR-200 expression to the molecular features of neoplastic progression of Barrett's esophagus, we found that three gene transcripts (*EGR3*, *HS3ST1* and *RPS6KB1*), listed in miRecords to be targets of miR-200c, were present in a panel of 18 transcripts that are upregulated in Barrett's epithelium, from which cancer has arisen *versus* benign Barrett's esophagus epithelium^[48].

Downregulation of E-cadherin expression *via* transcriptional repression is a central mechanism for epithelial to mesenchymal transition^[15]. ZEB1 and ZEB2 are amongst a group of transcription factors that repress transcription of E-cadherin^[15]. ZEB1 and ZEB2 are targets of the miR-200 family, and an increase in ZEB1 and ZEB2 activity caused by downregulation of miR-200 expression is sufficient to

induce epithelial to mesenchymal transition^[20]. Epithelial to mesenchymal transition that is promoted by downregulation of the miR-200 family has now been implicated as an important mechanism for invasion and metastasis in several cancers^[20,22-25]. Previous epithelial and mesenchymal cell marker studies have provided evidence for the involvement of epithelial mesenchymal transition in the development of esophageal adenocarcinoma^[16,17], but to the best of our knowledge, no studies have investigated loss of miR-200 mediated control of ZEB1 and ZEB2 expression as a possible mechanism for epithelial to mesenchymal transition in this disease. We found downregulation of the entire miR-200 family and upregulation of ZEB1 and ZEB2 transcription levels upon progression of Barrett's esophagus to adenocarcinoma. We observed significant inverse correlations between expression of miR-200 members and ZEB1/ZEB2 transcripts. miR-215 expression, which we have previously reported as downregulated in neoplastic progression of Barrett's esophagus^[29], was also inversely correlated with ZEB2 expression. miR-215 has recently been shown to target ZEB2 expression directly in kidney cells^[32], and our results suggest the same in Barrett's esophagus. Together, these results suggest that the miR-200 family contributes to control of ZEB1 and ZEB2 expression in Barrett's esophagus, and this might be important for maintaining the epithelial phenotype. They add to the current evidence for the involvement of epithelial to mesenchymal transition in esophageal adenocarcinoma, and indicate downregulation of miR-200 expression as a potential mechanism for this.

With regard to the potential clinical relevance of our findings, we hypothesize that the miR-200 family might be useful biomarkers for identifying patients with Barrett's esophagus who are at increased risk of adenocarcinoma. They may also be helpful for assessing the potential antineoplastic effects of medical and surgical treatment of Barrett's esophagus. Further studies are required to evaluate this hypothesis. Recent advances in delivery of small RNAs in a clinical setting^[49], and the demonstrated *in vitro* antineoplastic effects of endogenous miR-200 expression^[38,50], suggest a possible future role for the therapeutic use of this family of miRNAs in treating early cancer in Barrett's epithelium.

Our study had some limitations. First, we used Barrett's esophagus epithelium proximal to cancer, and cell lines derived from dysplastic epithelium, to determine evidence for reduced miR-200 expression in dysplasia. We did not demonstrate miR-200 downregulation in dysplastic epithelium from patients who did not have invasive cancer, and this is an important area for investigation in future studies. Second, although our study provides evidence for effects of miR-200 expression on known gene-expression and phenotypic features of benign and dysplastic Barrett's esophagus, we did not expand this evidence using functional studies.

In summary, we showed that the miR-200 expression profile in Barrett's esophagus distinguished it from gastric and duodenal epithelia, and that downregulation of miR-200 expression was associated with dysplasia and adenocarcinoma. Further investigation is warranted to evaluate whether changes in the expression of these miRNAs can

be used to identify patients with Barrett's esophagus who are at risk of progression to esophageal adenocarcinoma.

ACKNOWLEDGMENTS

We thank Dr. Peter Rabinovitch for kindly providing the Barrett's esophagus and dysplastic cell lines Qh, Ch and Gi. We thank Associate Professor Greg Goodall and Dr. Tina Bianco-Miotto for helpful discussions. This study was funded by a grant from the National Health and Medical Research Council of Australia. Cameron Smith was supported by a scholarship from the New South Wales Cancer Council.

COMMENTS

Background

Barrett's esophagus is a precursor to esophageal adenocarcinoma and develops in response to chronic gastroesophageal reflux. Barrett's esophagus epithelium closely resembles that of the stomach and small intestine. However, some genes are expressed uniquely in Barrett's esophagus, and this is associated with pronounced anti-apoptotic and proliferative behavior in response to reflux. Esophageal adenocarcinoma development may involve an epithelial to mesenchymal transition-mediated acquisition of invasive phenotype. The miR-200 family of miRNAs can regulate cell death and proliferation, and control epithelial to mesenchymal transition through targeting of *ZEB1* and *ZEB2* gene expression.

Research frontiers

miRNAs have been implicated in almost every cellular process investigated. Recent evidence highlights a role for the miR-200 family members in numerous cellular processes including cell proliferation, cell death and epithelial to mesenchymal transition. All of these processes have been implicated in Barrett's esophagus and esophageal adenocarcinoma. We identified aberrant expression of the miR-200 family in Barrett's esophagus and esophageal adenocarcinoma and hypothesize that this differential expression contributes to aspects of neoplastic progression.

Innovations and breakthroughs

This study is the first to identify differential expression of the miR-200 family in Barrett's esophagus and esophageal adenocarcinoma. The miR-200 family expression data in Barrett's esophagus paired with functional studies in other cell types provides evidence that aberrant miR-200 family member expression may contribute to the increased proliferation and decreased cell death associated with Barrett's esophagus. The complete downregulation of the miR-200 family and subsequent upregulation of mRNA targets *ZEB1* and *ZEB2* in esophageal adenocarcinoma mimics what is seen in epithelial to mesenchymal transition and other invasive solid tumors, which suggests that the miR-200 family is involved in invasive esophageal adenocarcinoma development.

Applications

The authors hypothesize that the miR-200 family might be useful biomarkers for identifying patients with Barrett's esophagus who are at increased risk of adenocarcinoma. They may also be helpful for assessing the potential antineoplastic effects of medical and surgical treatment of Barrett's esophagus.

Terminology

Barrett's esophagus is a precursor to esophageal adenocarcinoma and develops in response to chronic gastroesophageal reflux. The miR-200 family of miRNAs can regulate cell death and proliferation, and control epithelial to mesenchymal transition through targeting of *ZEB1* and *ZEB2* gene expression.

Peer review

This is a well-written manuscript that describes miRNAs in Barrett's epithelium. The authors' conclusions are supported by the data.

Abstract

AIM: To verify whether arterial-phase contrast-enhanced ultrasonography (CEUS) of tumor parenchymal tissue is useful for evaluation of anti-angiogenesis agents.

METHODS: Rabbits with liver tumor were subjected to CEUS, and images of the nodular maximal diameter in vascular phase were recorded. Image analysis was performed to plot the time intensity curve (TIC) at the tumor parenchyma, which set the diameter of the region of interest of intensity measurement. The TIC was calculated to obtain the time to peak intensity (TPI) and the magnitude of PI. Rabbits were randomly assigned to a treatment group with sorafenib and a control group. Two weeks later, the same ultrasound examination was repeated followed by pathological testing to assess the effect of sorafenib on the liver tumor.

RESULTS: In four rabbits in the treatment group, the rate of change of tumor size was decreased compared

with that of the control (the rate 2.3 vs 7.9, $P = 0.02$). The TPI of the treatment group elongated significantly (the rate 3.1 vs 1.1, $P = 0.07$ for SonoVue, 2.0 vs 0.88, $P = 0.09$ for Sonazoid). The magnitude of PI showed no significant changes. In pathological examination, capillary diameters in the treatment group were significantly smaller than those in the control group (26.4 vs 42.8 μm , $P = 0.013$).

CONCLUSION: Analysis of the TIC in the arterial phase of tumor tissue could evaluate the efficacy of anti-angiogenesis drug treatment in liver tumor.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the sixth largest cause of neoplasms worldwide^[1]. Although effective treatment for early-stage HCC exists in the form of surgery and locally destructive techniques such as radiofrequency ablation, there are few treatments for advanced HCC. Recent randomized control trials of the anti-angiogenesis drug sorafenib have shown effectiveness for the first time. Time to radiological progression and overall survival were

prolonged in patients with advanced HCC who received sorafenib. However, some problems remain for anti-angiogenesis treatment. One of them is how to assess clinically whether the drugs are effective, because some tumors develop tolerance. Oncologists have to change the therapy as soon as they find that the liver tumor has become refractory to anti-angiogenesis therapy^[2].

Enhanced computed tomography (CT) and magnetic resonance imaging (MRI) are generally used for this screening. They are convenient to assess the response of anti-angiogenesis therapy, because tumor size, necrotic lesions, vascularity and perfusion are evaluated at the same time. However, these modalities sometimes make incorrect assessments, because tumor perfusion is difficult to evaluate. Perfusion is more important than the size for anti-angiogenesis drug therapy^[3].

Ultrasound examination can evaluate tumor size and necrotic lesions. Moreover, contrast-enhanced ultrasonography (CEUS) can evaluate tumor blood flow and perfusion more easily at the bedside than can CT and MRI with contrast agents^[4]. Recently, CEUS has been used for differential diagnosis of liver tumor and to determine the degree of differentiation of HCC^[5].

Previously, the usefulness of CEUS for the evaluation has been reported. However, a long time is needed for the ultrasound examination^[6]. In response to this, we tried to simplify the evaluation method with CEUS. The purpose of this study was to probe whether the perfusion information from tumors at the arterial phase of CEUS is useful for monitoring the early-phase response of anti-angiogenesis treatment.

MATERIALS AND METHODS

In situ tumor model

Twenty male Japanese white rabbits (body weight 2.5–5.0 kg, aged 12–16 wk) were used in this study. After habituation, implantation of Vx-2 tumor into the liver was performed. The Vx-2 tumor is a product of a virus-induced papilloma of rabbits, and the implanted nodules in liver are often used as an HCC model^[7,8]. Rabbits were anesthetized by intravenous injection of 8 mg/kg pentobarbital. Each rabbit received a single percutaneous injection of about 1 mm × 1 mm × 2 mm of Vx-2 tumor directly into the liver parenchyma from a donor rabbit, with a fine 14 G needle guided by ultrasound. Every 2 wk after implantation, ultrasound examination was repeated until the tumor grew to 7–10 mm and was available for ultrasound evaluation. Tumors were successfully grown in 10 animals. Six rabbits were assigned randomly to receive sorafenib and the others were assigned to a control group. The study was approved by the animal ethical committee of Tokyo Medical University.

Administration of sorafenib

Sorafenib was used as an anti-angiogenesis drug. It inhibits multiple kinases and signaling pathways of angiogenesis including vascular endothelial growth factor (VEGF), and induces apoptosis of tumor cells^[2]. Sorafenib was

suspended into a carboxymethyl cellulose sodium salt solution and orally administered to six rabbits at a dose of 30 mg/kg once daily (30 mg/kg per day) for 14 d. The other four rabbits received no medication.

Conventional ultrasound and CEUS examination

Ultrasonography was performed after placement of an intravenous catheter, and monitoring of respiration and heartbeat under anesthesia. Before injection of contrast agents, the livers were scanned in fundamental imaging mode. Ultrasound settings were as follows: diagnostic ultrasound system, SSA-770A (Toshiba Medical Systems, Japan) with PLT-1204AT (12 MHz) or PLT-704AT (7.5 MHz) probe, 2D mode for the abdomen, gain 80, dynamic range 65, rate 50 frames/s.

CEUS examination was performed by manually stabilizing the probe at the plane including its maximum diameter. Contrast agents were injected intravenously: SonoVue and Sonazoid. SonoVue is commercially available in Europe and China, and Sonazoid in Japan. A bolus of 0.05 mL/body of SonoVue was administered intravenously. After recording of images with SonoVue, 0.03 mL/body Sonazoid was given in the same way. For each agent, contrast-enhanced imaging of the tumor and surrounding parenchyma was performed for 3 min from just after injection, from the arterial to the portal phase, and for 7–8 min at the late phase.

Ultrasound settings were as follows: diagnostic ultrasound system, SSA-770A with PLT-1204AT (12 MHz) or PLT-704AT (7.5 MHz) probe, harmonic mode for CEUS, gain 70, dynamic range 50, rate 15 frames/s, mechanical index 0.23 for SonoVue and 0.32 for Sonazoid in harmonic imaging.

In the sorafenib group, the ultrasound examinations were performed on d 1 and 14 after sorafenib administration. In the control group, the same examinations were performed at 14 d after implantation and were repeated at 14 d after the first examination.

Images were recorded digitally on an optical disc and analyzed offline. Average video intensity (VI) of the region of interest (ROI) on every frame was measured automatically by the software Image Lab (Toshiba Corporation, Japan), after the ROI that included the most markedly enhanced area of a whole tumor region was identified. Necrotic regions, vessels, and liver parenchyma surrounding the tumor were excluded from the ROI. The corresponding time intensity curve (TIC) was plotted. The following parameters of blood flow were measured from the TIC: baseline intensity of ROI (VI₀), maximal signal of the ROI (VI_{max}), peak intensity (PI) that shows the difference between VI_{max} and VI₀ (VI_{max}–VI₀), and time to peak intensity (TPI) – time required from the onset of tumor contrast enhancement to VI_{max} (Figure 1)^[6]. Variation of TPI was the ratio of the post-treatment TPI to the pre-treatment TPI.

Pathological examination

Animals were euthanized by injection of a lethal dose of pentobarbital just after the second ultrasound examina-

Figure 1 Time intensity curve. V0 is the baseline intensity of ROI; VImax is the maximal signal of the ROI; PI is the difference between VImax and VIO (VImax-VIO); time to peak intensity (TPI) is the time required from the onset of tumor contrast enhancement to reach VImax.

tion. Their livers were excised and examined pathologically to assess the response to sorafenib and its effects. After the examination of gross features, hematoxylin-eosin staining and immunological staining by anti-VEGF antibody were performed. Specimens were fixed in 10% formalin. Paraffin-embedded 5- μ m-thick tissue sections were de-waxed, dehydrated, washed in distilled water, and rinsed in PBS, and then incubated with VEGF antibody (clone JH121; Thermo Fisher Scientific, CA, USA), which has species reactivity for humans and rabbits. Positive staining was identified when brown staining was found in the cytoplasm of the vascular endothelial cells.

Measurement of vascular diameter

Cross-sectional images of the tumors were recorded in their maximum diameter as TIFF files at 40 \times magnification using a BX50 microscope (Olympus, Tokyo, Japan) and Micropublisher 5.0 imaging system (Q Imaging, Canada). Blood vessels were identified in the image, and the diameters of the five largest vessels were measured macroscopically with Q Capture pro. 5.0 software (Q Imaging). The mean blood vessel diameters were compared. Vessels in the surrounding parenchyma and necrotic lesions and vessels that connected to the capsules were excluded because they were thought to correlate poorly with enhancement of the tumor.

Statistical analysis

SPSS version 16 software (SPSS Inc, Chicago, IL, USA) was used for all statistical analysis. The differences between the anti-angiogenesis treatment and control groups were compared using the Mann-Whitney test for tumor size and *t* test for other parameters. $P < 0.10$ was considered statistically significant.

RESULTS

Two rabbits in the treatment group died of systemic metastasis of the implanted tumor. The other four rabbits were used for evaluation.

Tumor size was calculated by multiplying the longest diameter by the shortest. In the sorafenib group, the tumor grew more slowly than in the control group. Pre-treatment tumor size was a mean 107.5 mm² (range: 58.6-192.9 mm²),

Figure 2 Tumor size variation. Solid lines show the size variation of the sorafenib-treated group. Interrupted lines show the size variation of the control group. The control group showed greater tumor enlargement than the sorafenib group did.

Table 1 Tumor size

	Pre-treatment	Post-treatment	Ratio
Sorafenib 1	69.4	159.0	2.3
Sorafenib 2	58.6	165.3	2.8
Sorafenib 3	109.0	150.9	1.4
Sorafenib 4	192.9	547.2	2.8
Control 1	49.0	210.3	4.3
Control 2	24.5	240.0	9.8
Control 3	78.8	246.1	3.1
Control 4	30.6	436.6	14.0

and post-treatment size was a mean 255.6 mm² (150.9-547.2 mm²) in the sorafenib group. In the control group, tumor size increased more rapidly. Baseline tumor size was a mean 45.7 mm² (range: 24.5-78.8 mm²) and that at 14 days was a mean 283.2 mm² (range: 210.3-436.6 mm²). Ratio (post-/pre-treatment) of the tumor size was a mean 2.3 (1.4-2.8) in the sorafenib group and 7.9 (3.1-14.2) in the control group ($P = 0.02$) (Figure 2, Table 1).

There were no significant differences in variation of PI in the tumor. In SonoVue imaging, variation in PI in the sorafenib group was a mean 2.1 (range: 0.5-5.5) and that of the control group was a mean 1.3 (range: 0.9-1.7) ($P = 0.84$). In Sonazoid imaging, variation in PI in the sorafenib group was a mean 1.6 (range: 1.2-2.5) and that in the control group was a mean 1.2 (range: 1.0-1.4) ($P = 0.28$, Table 2).

Variation in TPI in the tumor was prolonged in the sorafenib group. In contrast, variation in TPI in the tumor did not change or was shortened in the control group. In SonoVue imaging, variation in TPI in the sorafenib group was a mean 3.1 (range: 1.1-4.8) and that in the control group was a mean 1.1 (range: 0.56-1.4) ($P = 0.07$). In Sonazoid imaging, variation in TPI in the sorafenib group was a mean 2.0 (range: 1.0-3.2) and that in the control group was a mean 0.88 (range: 0.42-1.33) ($P = 0.09$, Figures 3 and 4, Table 2).

Pathological examination showed peritoneal dissemination and multiple metastases outside the liver. Some of the rabbits also showed ascites. Tumors appeared round, yellow/white, and separate from the surrounding parenchyma, with large necrotic lesions inside.

In vascular measurement, tumors in the sorafenib group had smaller vessels than in the control group. In

Figure 3 Contrast-enhanced ultrasonography examination showed that time to peak intensity was delayed in the sorafenib-treated group.

TPI: Time to peak intensity.

the sorafenib group, the diameter of the tumor vessels was a mean 26.4 μm (range: 23.9-26.7 μm) and that in the control group was a mean 42.8 μm (range: 34.2-50.1 μm) ($P = 0.013$, Figure 5).

Figure 4 Time to peak intensity in the tumor was significantly prolonged in the sorafenib group with both SonoVue and Sonazoid imaging. Time to peak intensity (TPI) in the tumor did not change or was shortened in the control group.

VEGF immunostaining examination presented no significant difference between both groups.

DISCUSSION

In the present study, prolonged TPI in arterial phase CEUS was shown during treatment with anti-angiogenesis agent.

Lavisse *et al*^[6] have reported that TPI of tumor was elongated and PI was decreased in an anti-angiogenesis treatment group compared with a control group. Tumors induce new vessels to obtain oxygen and nutrition for their growth, and total blood flow of tumors increases, so-called angiogenesis. According to the study of Wilhelm *et al*^[9], the anti-angiogenesis agent sorafenib inhibits angiogenesis and reduces microvessel density. This should be the reason why PI is reduced and TPI is prolonged in the sorafenib group.

In our study, TPI of tumors in the sorafenib group was similarly prolonged significantly, but no significant

Figure 5 Pathological examination (HE stain, × 40). A: Sorafenib group: vessels were relatively small and not obvious; B: Control group: dilated vessels were shown in the parenchyma of the tumor.

difference was detected in PI. In a previous study, entire tumors were estimated as the ROI, but in the present study, part of the viable region of the tumor was estimated as the ROI to simplify the measurement procedure. The analysis software that we used could not cover the entire tumor for the ROI. That was why no significant difference was detected in PI in our study.

The fact that we used rabbits in this study, unlike many previous studies that used mice and rats, is considered to have influenced the difference. First, rabbit liver is sufficiently large to be scanned by ultrasonography and more appropriate than that of mice and rats. The liver of mice is so small that we have to perform ultrasonography under different conditions. We implanted Vx-2 tumor in rabbit liver to satisfy conditions, because intrahepatic tumor and ectopic tumor behave differently in terms of proliferation. The blood supply and the biochemical environment are different in the skin and liver. Furthermore, there are enzymes that metabolize drugs in the liver. As a result, tumor responses to drugs differ depending on its location^[10]. Second, we wanted to examine our simplified method, so nodules were implanted in the left lobe of the rabbits, where fixing the scan plane is difficult because of the movement of the heart and lungs. If a significant difference is shown under difficult conditions by a given method, then that method can be performed under most conditions and considered to be useful. As mentioned above, the TPI was significantly prolonged with both ultrasound contrast agents.

Ultrasound examination has less reproducibility and integrity than CT and MRI, because it needs more expertise and stable scanning fields. Our simplified method needs less examination time and no fixing probe or expensive location system. If the tumor has a rich parenchymal vascular network due to increased angiogenic activity, dilation of arterioles in the parenchyma can occur, and increased blood perfusion per unit volume should accelerate onset of tumor enhancement from ultrasound contrast agent. However, accurate blood flow, speed, and flux are difficult to evaluate, and TPI can show them better than other modalities can. When the administrated anti-angiogenesis drug induces a reaction in tumor vessels, the arterioles are not dilated, which results in a different enhancement pattern in CEUS in the arterial phase. TPI is considered to represent flux per unit volume of a scanning lesion. In spite of a lack of samples, the results of this study probably support this hypothesis.

In this study, we compared the dynamics of enhanced signals by a single dose of contrast agent. We did not use more accurate methods, such as the replenish curve or attenuation curve methods, because of complications^[11].

In pathological examination, we detected a reduction of tumor vessel density in some parts of the tumors. Sorafenib is an anti-angiogenesis agent that prevents formation of new vessels and affects pre-existing capillaries to cause morphological alterations. As a result, the number of tumor vessels and their area and volume are reduced^[12]. This is one of the explanations for prolongation of TPI in the sorafenib group. We could not evaluate endothelial cells because there is no appropriate antibody for CD34 immunostaining in rabbits. No significant difference was observed in VEGF immunostaining between the sorafenib and control groups, which is consistent with inhibition of VEGF signaling by sorafenib at the level of VEGF receptors.

Most HCC occurs in Eastern and Southeastern Asia, Africa and Melanesia. About 70% of patients are not eligible for curative treatment and prognosis is poor^[1]. Treatment with anti-angiogenesis drugs such as sorafenib will become widespread and effective assessment of treatment will be needed. Although efficacy of antitumor drugs has previously been evaluated mainly by variation in tumor size, it is complex and demanding to evaluate the size of tumors with necrotic lesions. Tumor markers do not correspond with efficacy of anti-angiogenesis drugs.

It is undeniable that a greater number of samples were required than we used. However, an adequate number of animals were used to allow for proper statistical analysis.

In conclusion, Analyzing the TIC of arterial phase CEUS in tumor parenchyma could be helpful for evaluation of the efficacy of anti-angiogenesis drug treatment of liver tumor.

ACKNOWLEDGMENTS

We would like to thank Dr. Longzhong Liu for his special contribution to planning and conducting the experi-

ments in this project, as well as Dr. Munire Rexiati for her management of the animals and tumor cells.

COMMENTS

Background

Although most patients with hepatocellular carcinoma are candidates for systemic therapy, conventional cytotoxic drugs yield poor therapeutic results. Recently, randomized control trials of the anti-angiogenesis drug sorafenib have shown effectiveness for the first time.

Research frontiers

Therapeutic efficacy has been assessed by time to radiological progression and overall survival in previous studies. Anti-angiogenesis treatment might produce necrosis and no tumor shrinkage, so that new imaging techniques are needed to assess antitumor effects. In this study, we verified that arterial phase contrast-enhanced ultrasonography (CEUS) of tumor parenchymal tissue is useful for evaluation for anti-angiogenesis treatment.

Innovations and breakthroughs

Enhanced computed tomography (CT) and magnetic resonance imaging (MRI) are generally used to assess treatment, but tumor perfusion is difficult to evaluate by these methods. CEUS with our simplified method can evaluate the blood flow and perfusion of tumor more easily than CT and MRI at the bedside.

Applications

This was a pilot study with an animal model. A clinical study with a large number of patients and application of sorafenib to clinical practice are awaited.

Terminology

Ultrasound contrast agents consist of microbubbles that visualize the blood flow. The time intensity curve is a graph that shows the variation in echo signal intensity with time. Peak intensity is the difference between maximal signal and baseline intensity, and correlates with blood flow volume. Time to peak intensity is the time to reach maximal intensity and correlates with blood flow volume per unit time. We can establish tumor perfusion by these parameters.

Peer review

This is an interesting paper that looks at the role of CEUS in assessing sorafenib response and the value of using only arterial phase as compared to triphasic CEUS for evaluation. The use of the rabbit model was good and the comparisons between Sonovue and SonoVue are useful. The initial tumor sizes for the treatment and control group however are too distinct, a mean 107.5 for the treatment group and 45.7 for the control group, which could have affected the validity of the observations at 14 d. Despite this, the study did demonstrate a significant reduction in vascular diameter in the sorafenib-treated group at 14 d compared to the controls.

RESULTS: The respective sensitivities and specificities [reviewer 1: blinded, 20% (22/110) and 98% (215/220); unblinded, 27% (30/110) and 100% (219/220)/reviewer 2: blinded, 19% (21/110) and 98% (216/220); unblinded, 25% (27/110) and 98% (215/220)] were not significantly different. Although intraobserver agreements were good (weighted $\kappa = 0.677$ and 0.666), interobserver agreements were fair (blinded, 0.371) or moderate (unblinded, 0.558). For both univariate and multivariate analyses, the tumor size and invasion depth were statistically significant factors affecting visibility.

CONCLUSION: The diagnostic performance of hydro-stomach CT to detect an EGC was not significantly different between blinded and unblinded analysis. The tumor size and invasion depth were independent factors for visibility.

Abstract

AIM: To evaluate the difference in diagnostic performance of hydro-stomach computed tomography (CT) to detect early gastric cancer (EGC) between blinded and unblinded analysis and to assess independent factors affecting visibility of cancer foci.

METHODS: Two radiologists initially blinded and then unblinded to gastroscopic and surgical-histological findings independently reviewed hydro-stomach CT images of 110 patients with single EGC. They graded the visibility of cancer foci for each of three gastric segments (upper, middle and lower thirds) using a 4-point scale (1: definitely absent, 2: probably absent, 3: probably present, and 4: definitely present). The sensitivity and specificity for detecting an EGC were calculated. Intraobserver and interobserver agreements were analyzed. The visibility of an EGC was evaluated with regard to tumor size, invasion depth, gastric segments, histological type and gross morphology using univariate and multivariate analysis.

Detection of early gastric cancer using hydro-stomach CT: Blinded vs unblinded analysis. *World J Gastroenterol* 2011; 17(8): 1051-1057 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i8/1051.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i8.1051>

INTRODUCTION

With the introduction of a screening test for stomach cancer, the incidence of early gastric cancer (EGC) has increased more than 40% in South Korea^[1,2]. Since the

prognosis of EGC after curative resection is highly favorable (5-year survival rate > 90%), early detection of stomach cancer is essential to improve prognosis^[3-5].

Due to the limited role of computed tomography (CT) for the detection of EGC, preoperative stomach CT imaging has been principally used for N and M staging^[6-8]. However, considering that an EGC lesion sometimes lacks a tactile sensation on the operative field, especially for laparoscopic surgery, the exact detection and localization of a cancer focus on preoperative stomach CT imaging is of great help to omit preoperative gastroscopic clipping for localization of a cancer focus, as well as for surgical planning. Therefore, preoperative CT imaging is important for not only N and M staging, but also for detection and localization of EGC.

Traditionally, both air and tap water have been used as oral contrast agents to achieve adequate gastric distension. As compared to the use of CT gastrography with air-distension, stomach CT with water-distension (hydro-stomach CT) is less hindered by artifacts caused by air in the lumen. Thus, detailed mucosal enhancement of cancer foci is well demonstrated on hydro-stomach CT^[9,10]. However, despite the use of multiplanar reconstruction (MPR) images, the detection rate of EGC on hydro-stomach CT is still low, ranging from 36% to 48%^[9,11,12]. Therefore, we have postulated that hydro-stomach CT is intrinsically limited for the detection of EGC. If this assumption is correct, the detection rate of EGC on an unblinded analysis will not improve as compared to that of a blinded analysis.

The purpose of this study was to (1) evaluate the difference in diagnostic performance of hydro-stomach CT to detect EGC between a blinded analysis and unblinded analysis with reference to gastroscopic and surgical-histological findings and to (2) assess factors affecting visibility of cancer foci on hydro-stomach CT imaging.

MATERIALS AND METHODS

Patients and enrollment criteria

The institutional review board approved this retrospective study and informed consent of patients was waived. Between July 2008 and August 2008, 159 consecutive patients with a pathologically proven single EGC in our institution, a tertiary care hospital, were enrolled in the study. Surgical or endoscopic submucosal dissection was performed within 1 mo after CT image acquisition. Of the 159 patients, 49 patients were excluded from the analysis for one of the following reasons: (1) CT scanning obtained at other hospital ($n = 31$); (2) post-endoscopic clipping state ($n = 10$); (3) post-endoscopic submucosal dissection state ($n = 1$); (4) no available MPR images ($n = 2$); (5) the presence of a synchronous advanced gastric cancer at another site ($n = 1$); (6) the presence of a synchronous gastric polyp at another site ($n = 1$); and (7) improper gastric distension ($n = 3$). Ultimately, 110 patients comprised the study population. The patients consisted

of 74 men and 36 women (age range, 22-86 years; mean age, 57 years).

CT acquisition

Hydro-stomach CT was performed with a 64-detector row CT scanner (LightSpeed VCT; GE Healthcare, Milwaukee, WI, USA) with the patient in the prone position on the CT table. With this protocol, non-dependent side of the stomach (i.e. the fundus for a patient in the prone position) was frequently distended by air rather than by water. In order to avoid air distension, if the cancer was located in the gastric fundus, a CT scan was performed with the patient in the supine position. Before CT scanning, each patient had fasted for over 6 h. A total of 500-1000 mL tap water was administered orally to obtain gastric distension just prior to scanning. A CT scan was obtained 70 s after the injection of a dose of 2 mg/kg of nonionic contrast material iopromide (Ultravist 300; Schering, Berlin, Germany) at a rate of 4 mL/s using an automated power injector. The scanning ranged from the diaphragm to the lower end of the symphysis pubis. The CT parameters used were as follows: 40 mm beam collimation (0.625 mm \times 64); pitch, 0.984; kVp/mA, 120/300 with automatic exposure control using both Auto mA and Smart mA; gantry rotation time, 0.6 s. Axial images (slice thickness/interval, 5 mm/5 mm) and sagittal and coronal MPR images (slice thickness/interval, 3 mm/3 mm) were obtained with the use of isotropic raw data (slice thickness/interval, 0.625 mm/0.625 mm).

Image analysis

Two gastrointestinal radiologists (D.C., 11 years experience; M.W.L., 6 years experience) evaluated the visibility of EGC by interpretation of both axial and MPR images on a 2K \times 2K picture archiving and communication system (PACS, GE Medical Systems Integrated Imaging Solutions, Mt Prospect, IL, USA) monitor (MDL9DLB020; Totoku, Tokyo, Japan), independently. At the first interpretation session, although the radiologists were aware that each patient was confirmed to have an EGC, the radiologists were blinded to the gastroscopic and surgical-histological findings. The stomach was divided into three segments along the longitudinal axis (from gastroesophageal junction to pyloric canal): upper, middle and lower thirds. For 330 gastric segments, both reviewers graded the likelihood of the presence of an EGC focus for each segment based on the use of a 4-point scale as follows: (1) definitely absent; (2) probably absent; (3) probably present; and (4) definitely present. The presence of an EGC was defined as focal plaque-like wall thickening compared to adjacent gastric wall with or without prominent enhancement of the gastric inner layer^[12]. In addition, the radiologists marked the lesion with an arrow during image analysis. A study coordinator (Park KJ) captured and stored the marked images into a JPEG file whenever one reviewer finished the interpretation of the CT images. Then the study coordinator erased the mark on the CT

images before the initiation of the next interpretation session.

Two weeks after the first blinded interpretation session, a second interpretation was performed. For the second session, the reviewers were not blinded to the clinical information of patients and were provided with all data including the gastroscopic, surgical and pathological findings.

Evaluation and statistical analysis

The two reviewers and a study coordinator assessed whether the indicated lesions on CT images were in accord or not in consensus based on the gastroscopic, surgical, and pathological findings. If at least one of the two reviewers correctly indicated an EGC lesion, it was regarded as a visible EGC. If both reviewers missed an EGC lesion, it was regarded as an invisible EGC.

The scores 1 and 2 for the likelihood of the presence of an EGC focus for each segment were regarded as an absence of an EGC focus. The scores 3 and 4 were regarded as a presence of an EGC focus. The sensitivity and specificity for the detection of an EGC focus on CT images were calculated and compared between the blinded analysis and unblinded analysis. Intraobserver and interobserver agreements were analyzed with the use of weighted κ statistics.

Reasons of visibility for the subjective assessment by the radiologists were analyzed. Visible EGCs were compared with invisible EGCs for tumor size, depth of invasion, involved gastric segments, type of histology and type of gross morphology by use of univariate analysis and multivariate analysis. The size of an EGC was based on the maximal diameter as measured on a gross specimen. The univariate association between individual

variables for visibility was tested using the χ^2 test for categorical variables (depth of invasion, involved gastric segments, type of histology and type of gross morphology). The size of a tumor between visible and invisible EGC was compared using the unpaired *t* test. In order to assess independent factors that affected the visibility of an EGC on hydro-stomach CT images, multiple logistic regression analysis was used to test the significance of adjusted factors. Variables with *P* < 0.05 determined by univariate analysis were chosen as variables for multiple logistic regression analysis. For both univariate analysis and multiple logistic regression analysis, *P* < 0.05 was considered to indicate a statistically significant difference.

RESULTS

Hydro-stomach CT

No significant technical failure, such as a severe artifact that interfered with image interpretation of hydro-stomach CT, was noted for all patients. Thus, 330 segments (110 segments with EGC and 220 segments without EGC) were included and were analyzed.

Pathological findings

The pathological findings of 110 EGCs are summarized in Table 1. Seventy-one EGCs were confined to the mucosa and the other 39 EGCs invaded the submucosal layer. There were 18 elevated (type I and IIa), 24 flat (type II b) and 68 depressed (type II c and III) EGCs.

Diagnostic performance for EGC

The sensitivity and specificity of the blinded analysis and unblinded analysis are summarized in Table 2. Based on a consensus review, 39 EGCs were indicated by at least one

Table 2 Diagnostic performance of early gastric cancer on hydro-stomach computed tomography *n* (%)

	Reviewer 1			Reviewer 2		
	Blinded	Unblinded	<i>P</i> value	Blinded	Unblinded	<i>P</i> value
Sensitivity	22/110 (20)	30/110 (27)	> 0.05	21/110 (19)	27/110 (25)	> 0.05
Specificity	215/220 (98)	219/220 (100)	> 0.05	216/220 (98)	215/220 (98)	> 0.05

Data in parenthesis are numbers of lesions. McNemar test was used for statistical analysis.

Figure 1 Early gastric cancer in a 45-year-old man. The size of tumor was 3.8 cm at the longest diameter and the tumor extended to submucosal layer. The transverse (A) and coronal multiplanar (B) images show an ulcerative, thickened wall with enhancement in posterior wall of gastric antrum (arrows). It was graded as 4 at lower 1/3 segment of stomach on both blinded and unblinded analysis by both reviewers.

Figure 2 Early gastric cancer in a 45-year-old woman. The size of tumor was 9.5 cm at the longest diameter and the tumor extended to submucosal layer. A: The gastroscopy shows a large ill-defined lesion with abnormal convergence of gastric folds in posterior wall of gastric mid body (arrowheads); B: The transverse computed tomography scan shows equivocal enhancement and thickening (arrowheads) in posterior wall of gastric mid body. Although one reviewer indicated this lesion on both blinded and unblinded analysis, the other did not find this lesion even on unblinded analysis.

reviewer and were regarded as visible EGCs. The other 71 EGCs were regarded as invisible. There were frequent false positives at blinded analysis for both reviewers (five for reviewer 1 and four for reviewer 2). The sensitivity and specificity of both reviewers were not significantly different between the blinded analysis and unblinded analysis (Figures 1-3). Despite an unblinded analysis, the detection rates were not improved for both reviewers. For mucosal cancer ($n = 71$), the sensitivity and specificity for reviewer 1 blinded to the findings were 17% (12/71) and 98% (139/142), respectively, and were 21% (15/71) and 100% (142/142), respectively, for reviewer 1 unblinded to the findings. The sensitivity and specificity for reviewer 2 blinded to the findings were 10% (7/71) and 98%

(139/142), respectively, and were 14% (10/71) and 100% (142/142), respectively, for reviewer 2 unblinded to the findings. For both reviewers, differences were not significant (McNemar test, each $P > 0.05$). The intraobserver agreements were good for both reviewers (weighted $\kappa = 0.677$ for reviewer 1 and 0.666 for reviewer 2). However, interobserver agreements were fair (blinded, 0.371) or moderate (unblinded, 0.558).

Comparison of cancer characteristics between visible and invisible EGCs

The baseline characteristics of 110 EGCs are summarized in Table 1. For both univariate analysis and multivariate analysis, the size and depth of invasion of the tu-

Figure 3 Early gastric cancer in a 62-year-old man. The size of tumor was 2.2 cm at the longest diameter and the tumor extended to submucosal layer. A: The transverse computed tomography scan shows thickened wall with enhancement in greater curvature of gastric antrum (arrow), which was true lesion based on gastroscopy and pathologic examination; B: Reviewer 1 indicated a lesion (arrow) as a cancer focus because thickened wall was suspicious on blinded analysis. However, on unblinded analysis, focal lesion (arrow) in greater curvature of gastric antrum in lower gastric 1/3 segment was indicated correctly.

mor were statistically significant factors affecting visibility (Table 1).

DISCUSSION

Our study demonstrated that EGCs are poorly visible on hydro-stomach CT images even though both axial and MPR (sagittal and coronal) images were evaluated. The detection rate was not significantly different between blinded and unblinded analysis for both reviewers, which indicated that EGC detection on hydro-stomach CT imaging is intrinsically limited due to poor detection performance. These findings correspond well with results of an earlier study by Yu *et al*^[13]. In that study, almost all primary gastric cancers (43/44, 98%) not visualized on preoperative hydro-stomach CT images were identified as EGCs.

In comparison, CT gastrography with air-distension has enabled the ability to obtain various three-dimensional (3D) rendering images such as virtual gastroscopy, surface shaded display, volume rendering and transparent rendering images^[8,14-17]. On CT gastrography, combined interpretation of axial and various 3D reconstructed images have shown an improved detection rate of EGC in many previous studies^[8,15-17]. The detection rate of EGC by the use of CT gastrography has been reported to range from 73% to 96%^[8,15-17], which seems to be superior to that of hydro-stomach CT (36% to 48%)^[9,11,12]. Using both two-dimensional (2D) and various 3D rendering images of CT gastrography, mucosal nodularity, a malignant fold change and the presence of a depressed or elevated lesion could be demonstrated^[15,16]. Furthermore, virtual gastroscopy can be used as a complimentary study to conventional gastroscopy, as the modality provides endoluminal images with a wider field of view, resulting in no blind spots unlike those which occur with the use of conventional gastroscopy^[16]. However, as compared to conventional gastroscopy, virtual gastroscopy is limited in the detection of superficial flat lesions, as the method cannot provide discoloration of a flat EGC lesion.

Although hydro-stomach CT has been known to provide improved visualization of the gastric wall and gastric tumors without image degradation by artifacts derived from intraluminal air^[6,18], only 2D-based images (axial and MPR images) are used for the interpretation of preoperative evaluation of stomach cancer with the use of hydro-stomach CT. Although the addition of MPR images to conventional axial images has offered improved detection and localization of EGC^[11], detection of EGC in the absence of thickened wall and enhancement is still difficult with the use of 2D images only. In addition, partial volume averaging artifacts can be problematic for the evaluation of the gastric wall, especially in a case located on the antrum or angle where the gastric wall is tangent to an axial scan^[11]. Nevertheless, hydro-stomach CT has been widely utilized for the preoperative staging work-up of stomach cancer due to increased workload of radiologists and time-consuming postprocessing of CT gastrography.

In our study, the detection of EGC was highly related to the depth of invasion. Mucosal cancer is less visible as compared to submucosal cancer, a finding similar to the results of previous studies^[11,12]. As compared to the EGC detection rate (48%, 34/71) determined by Kim *et al*^[9], although the exact proportion of mucosal and submucosal cancer in that study was not known, the detection rate of EGC based on the blinded analysis (20%, 22/110, reviewer 1; 19%, 21/110, reviewer 2) in our study was inferior. This finding could be explained by the fact that the proportion of mucosal cancer that is known as difficult to detect on hydro-stomach CT was as high as 65% (71/110) in our study. The sensitivity for mucosal cancer as determined by the two reviewers was only 17% and 10% in our study. These results are in close agreement with sensitivity values of 17% (3/18) reported by Shimizu *et al*^[11] and 16% (11/69) reported by Woo *et al*^[12].

In addition to the depth of invasion, the size of a tumor was another cause of invisibility in our study (Table 1). The size (3.59 ± 1.91 cm) of a visible EGC was larger as compared to an invisible EGC (2.20 ± 1.37 cm). Howev-

er, this result is in disagreement with that (2.80 ± 1.35 cm *vs* 2.18 ± 1.85 cm) reported in a study by Woo *et al*^[12] in which the size was not significantly different between invisible and visible EGCs. This discrepancy between two studies could have been influenced by differences in the study population.

Gross morphology was not a factor that affected EGC visibility in our study. If lesions were grouped into two categories (depressed *vs* non-depressed lesions), visibility was not significantly different between the two categories (Table 1), which coincides well with a previous study^[12]. We believe that the perception of a shallow depressed lesion on 2D images is more difficult as compared to various 3D reconstructed images provided by CT gastrography, as the 3D images intuitively show malignant fold changes, mucosal nodularity and elevated or depressed lesions^[15,16].

This study has some limitations. Firstly, this study was a retrospective, single institution study over a defined period. The ability to detect an EGC lesion on a CT scan may be different, depending on factors such as the experience of the radiologists, CT protocol, patient population and tumor characteristics. In addition, we did not perform CT gastrography with air-distension. Therefore, although we compared our results with findings of previous investigations that used CT gastrography, a direct comparison is limited due to the different patient populations, type of CT equipment and experience of the radiologists. Thus, a further comparison study may be warranted between hydro-stomach CT and CT gastrography to detect EGC lesions. Secondly, we did not evaluate the visibility of EGC according to gastric distension. As a collapsed stomach could obscure a gastric lesion or simulate the pathology, detection of EGC could be influenced by gastric distension^[14]. In addition, as with the transverse colon as visualized on CT colonography^[19], the lower one-third segment of the stomach is more likely to be compressed than the upper one-third segment for a patient in the prone position. However, as oral administration of more than 500 mL of water has been widely used for optimal gastric distension on hydro-stomach CT^[9,12,13], gastric distension was not taken into consideration at the time of analysis. Thirdly, some of the EGC lesions marked by the reviewers were discordant between each other. In addition, there were frequent false positives at blinded analysis by both reviewers. Therefore, visible EGC lesions in our study have a possibility of false positives. However, this problem seems to be intrinsically inevitable for this style of study, since a fully reliable method was not available to confirm the location of EGC on CT images. Fourthly, since patient position at CT acquisition partially gives the information about the location of an EGC focus, this might have influenced the blinded image analysis of reviewers.

In conclusion, hydro-stomach CT imaging was not a reliable tool for the detection of EGC. The poor diagnostic performance of hydro-stomach CT to detect EGC was not significantly different between blinded and

unblinded analysis. The size and depth of invasion of an EGC were two independent factors for visibility.

COMMENTS

Background

The incidence of early gastric cancer (EGC) is currently rising faster than previously, correlating with the introduction of a screening test for stomach cancer. Considering the poor tactile sensation of an EGC lesion on the operative field, especially for laparoscopic surgery, the exact localization of a cancer focus on preoperative stomach CT imaging is important to omit preoperative gastroscopic clipping for localization of a cancer focus as well as for surgical planning.

Research frontiers

Despite introduction of multi-detector row CT techniques and the use of multiplanar reconstruction (MPR) images, the detection rate of EGC on hydro-stomach CT has still been unsatisfactory. In order to see whether the detection rate of EGC on unblinded analysis can be improved as compared to that of blinded analysis with reference to gastroscopic and surgical-histological findings, diagnostic performance of hydro-stomach CT to detect EGC was compared between blinded analysis and unblinded analysis. In this study, the authors demonstrate that the diagnostic performance of hydro-stomach CT to detect EGC was poor and was not significantly different between blinded and unblinded analysis.

Innovations and breakthroughs

Traditionally, both air and tap water have been used as oral contrast agents to achieve adequate gastric distension for preoperative CT imaging in patients with EGC. This study demonstrates that diagnostic performance of hydro-stomach CT for the detection of EGC is poor and unenhanced even when unblinded analysis is performed. The tumor size and invasion depth were independent factors for visibility of EGC on hydro-stomach CT.

Applications

Hydro-stomach CT imaging seems not to be a reliable tool for the detection of EGC. In this context, for the preoperative evaluation of patients with EGCs, it is time to consider CT gastrography which can offer not only 2D images but also various 3D reconstructed images showing malignant fold changes, mucosal nodularities and elevated or depressed lesions.

Terminology

Hydro-stomach CT refers to stomach CT with water-distension. Compared with CT gastrography with air-distension, hydro-stomach CT has been believed to be less affected by artifacts caused by intraluminal air and is likely to demonstrate detailed mucosal enhancement of cancer foci.

Peer review

This study was designed to evaluate the difference of diagnostic performance of hydro-stomach CT to detect EGC between blinded and unblinded analysis. The English is written well.

Abstract

AIM: To evaluate the relationship between peptic ulcer disease (PUD) and acute pancreatitis.

METHODS: A cohort of 78 patients with acute pancreatitis were included in this study. The presence of PUD and the *Helicobacter pylori* (*H. pylori*) status were assessed by an endoscopic method. The severity of acute pancreatitis was assessed using Ranson's score, the Acute Physiology and Chronic Health Evaluation (APACHE) II score, computed tomography severity index and the clinical data during hospitalization, all of which were compared between the patients with and without PUD. The risk factors for PUD were also evaluated.

RESULTS: Among 78 patients, 41 patients (52.6%) with acute pancreatitis suffered from PUD, but only 13 (31.7%) patients with PUD were infected by *H. pylori*. On univariate analysis, male gender, an etiology of alcohol-induced pancreatitis, a history of smoking or alcohol consumption, elevated triglyceride and C-reactive protein levels, and high APACHE II score were significantly associated with PUD. However, on multivariate logistic regression

analysis, the APACHE II score (odds ratio: 7.69; 95% confidence interval: 1.78-33.33; $P < 0.01$) was found to be the only independent risk factor for PUD.

CONCLUSION: Patients with acute pancreatitis are liable to suffer from PUD. PUD is associated with severe acute pancreatitis according to the APACHE II score, and treatment for PUD should be considered for patients with severe acute pancreatitis.

INTRODUCTION

Acute pancreatitis is a common disease that has shown an increased incidence in the past two decades^[1-3]. Acute pancreatitis is caused by an acute inflammatory response resulting from unregulated activation of pancreatic enzymes, which can lead to extrapancreatic complications due to the persistence of hypovolemia, a decreased intravascular volume and multiorgan dysfunction. In fact, patients with acute pancreatitis may complain of various abdominal symptoms such as nausea, vomiting and pain, and these symptoms are sometimes confused with dyspeptic symptoms^[4,5]. In a recent study, 65% of patients with acute

pancreatitis were found to have acute gastrointestinal mucosal lesions^[6]. We hypothesized that the decrease in intravascular volume, and the stress response that diminishes the blood flow could result in upper gastrointestinal ischemia or inflammation, and cause peptic ulcer disease (PUD). The aims of this study were to evaluate the prevalence of PUD among patients with acute pancreatitis, and to compare the clinical characteristics and severity of acute pancreatitis according to the presence of PUD.

MATERIALS AND METHODS

The study was conducted at St. Vincent's Hospital, a teaching hospital of the Catholic University of Korea. The medical records, charts and the digitalized picture archived images of consecutive patients who were admitted with acute pancreatitis between February 2008 and August 2009 were collected. The study was approved by the Institutional Review Board of the Catholic University of Korea. The patients included in this study were all older than 17 years of age, had visited our clinic within 2 d of the occurrence of abdominal symptoms, and underwent endoscopic gastroduodenoscopy during hospitalization. The patients with acute pancreatitis due to endoscopic retrograde cholangiopancreatography were excluded. The diagnosis of acute pancreatitis was based on the presence of two of the following three features^[7]: (1) acute onset of typical abdominal pain; (2) serum amylase and/or lipase level ≥ 3 times the upper limit of normal; and (3) characteristic findings of acute pancreatitis on an abdominal computed tomography (CT) scan or on ultrasonography. Gallstone pancreatitis was diagnosed by CT or ultrasonography in the absence of another etiology such as excessive alcohol consumption^[6,9]. Hyperlipidemia was diagnosed in cases with a serum triglyceride level above 500 mg/mL^[6]. The exclusion criteria were previous abdominal surgery, a previous history of acute or chronic pancreatitis, a diagnosis of PUD in the previous 3 mo, a history of taking drugs such as non-steroidal antiinflammatory drugs, aspirin, anticoagulants and/or antiplatelet drugs in the previous month, and incomplete medical records. Our institute routinely recommended endoscopy to confirm and treat acute mucosal lesions in the stomach or duodenum in patients with acute pancreatitis before the patient was permitted any oral intake, and determination of the severity score of acute pancreatitis for evaluating and managing the patients. An ulcer was defined as a lesion with loss of mucosal integrity (a whitish exudate was observed) and the lesion was > 5 mm in size with apparent depth determined by endoscopy^[10]. The status of *Helicobacter pylori* (*H. pylori*) was evaluated in patients with PUD, who underwent antral or body biopsy for histopathology or a rapid urease test (CLO test). The prevalence of PUD and *H. pylori* in the patients with acute pancreatitis were evaluated. The severity of acute pancreatitis were evaluated by laboratory data and scores such as Ranson's score, the Acute Physiology and Chronic Health Evaluation (APACHE) II score and the CT severity index (CTSI) during hospitalization. The clinical characteristics including demographic, labora-

tory, or radiologic data and the severity of acute pancreatitis in the patients with and without PUD were compared.

Statistical analysis

The primary end points of the study were the prevalence of PUD associated with acute pancreatitis. The secondary end points were the risk factors for PUD in the patients with acute pancreatitis. The continuous data were expressed as mean \pm SE (standard error of the mean) determined using the independent sample Student *t*-test, while categorical variables were expressed as quantities and were analyzed using the χ^2 test. Multiple stepwise logistic regression analysis was used to identify the risk factors for PUD. The analyses were performed with a statistical software package (SPSS, version 15.0; SPSS Inc). A *P*-value < 0.05 was considered significant for all tests. This research adhered to the principles of the Declaration of Helsinki.

RESULTS

During the study period, a total of 123 consecutive patients with acute pancreatitis and who were not related were enrolled. Patients who did not undergo endoscopic gastroduodenoscopy during hospitalization were excluded ($n = 30$). Of the remaining 93 patients, 15 were excluded due to a history of acute or chronic pancreatitis ($n = 10$), a diagnosis of PUD in the previous 3 mo ($n = 1$), a history of taking drugs such as aspirin in the previous month ($n = 3$), and incomplete medical records ($n = 1$).

A total of 78 patients were finally enrolled and included in the analysis. The mean age of the patients was 53.4 ± 1.8 years (range, 18-86 years) and 52 patients (66.7%) were male. The mean time to the endoscopic procedure after admission was 3.3 ± 0.3 d (range, 1-16 days). Forty one patients (52.6%) were found to have PUD. The characteristics of the patients with or without PUD are shown in Table 1. On univariate analysis, male gender ($P = 0.03$), an etiology of pancreatitis due to alcohol ($P = 0.03$), a history of smoking ($P = 0.05$), a history of excessive alcohol consumption ($P = 0.01$), an elevated triglyceride level ($P = 0.05$), an elevated C-reactive protein level ($P < 0.001$) and an elevated APACHE II score ($P = 0.001$), in particular an APACHE II score ≥ 6 ($P < 0.001$), were found to be significantly associated with PUD in patients with acute pancreatitis (Table 1). The receiver-operating characteristic (ROC) curve with a cutoff of an APACHE II score of 6 was selected as the highest sensitivity and specificity values for evaluating the factors for PUD [area under the curve (AUC), 0.75; 95% confidence interval (95% CI): 0.67-0.86] (Figure 1). On multivariate logistic regression analysis, only an APACHE II score ≥ 6 was found to be a significant risk factor (Table 2).

Among the 41 patients with PUD and acute pancreatitis, *H. pylori* was detected in 13 patients (31.7%). Any demographic differences were not found between the *H. pylori*-positive and -negative groups, except for the location of the ulcer. Among the 13 patients in the *H. pylori*-positive ulcer group, 10 (76.9%) patients revealed only a gastric ulcer, and a duodenal ulcer was not found. Howev-

er, for the 28 patients in the *H. pylori*-negative ulcer group, gastric ulcers were found in 12 patients (42.9%), duodenal ulcers in 12 patients (42.9%), and both gastric and duodenal ulcers in 4 patients (14.3%). The location of the ulcers was different according to the status of *H. pylori* (Table 3).

DISCUSSION

The current study showed that the prevalence of PUD in patients with acute pancreatitis was relatively high (52.6%), and the cause of may be related to the stressful condition of the underlying pancreatitis.

Although the previous literature has reported that the use of histamine 2 (H₂) receptor antagonists or proton pump inhibitors (PPI) could prevent stress ulcers in cases of severe pancreatitis^[7,11], the published clinical evidence is still scanty and controversial. Only one clinical study

reported that acute gastrointestinal lesions occurred in 65% of patients with acute pancreatitis^[6], and this rate was higher than that of our study (52.6%). Our strict selection of enrolled patients with only PUD, as demonstrated by endoscopy with definitive criteria, was the reason

why a relatively low rate was demonstrated in our study. Because the prevalence of PUD in the general population is known to be about 5% according to recent data^[12], the 52.6% prevalence of our data was high, and so PUD seems to be associated with acute pancreatitis.

The pathogenesis of PUD associated with acute pancreatitis is still not understood. However, gastric mucosal ischemia under the stressful condition of acute pancreatitis might be a major factor for peptic ulcer occurring together with acute pancreatitis^[6]. Acute pancreatitis may be complicated by the hypovolemic status of the pancreas or extrapancreatic ischemia due to the diminished effective blood volume or hypoperfusion^[4,7,11,13], which have been reported to be causative factors for stress ulcers^[14]. Another suggestion is that acidic conditions in the intestine develop because of reduced bicarbonate secretion by the pancreas, resulting in patients with pancreatitis becoming susceptible to a duodenal ulcer^[7]. Furthermore, intestinal ischemia increases intestinal permeability to bacteria, bacterial products and/or endotoxins, permitting a secondary pancreatic infection, and also stimulates cytokine release, and increases the level of nitric oxide, which serially contributes to ongoing pancreatic injury as well as organ failure^[15-17]. In our study, an association between PUD and acute pancreatitis was observed, and the use of antiulcer medication may have an impact on the treatment or prognosis of patients with acute pancreatitis.

PUD disease is a multifactorial disease that has been largely attributed to the presence of *H. pylori* infection^[18-20], and the presence of *H. pylori* infection in patients with PUD has been reported to range between 61% and 94%^[21-23]. However, in our data the prevalence of *H. pylori* infection was only 31.7%. The distinct difference in location of ulcers between *H. pylori*-positive and -negative groups was interesting. Why a low prevalence of *H. pylori* infection was revealed in patients with a duodenal ulcer was unclear. The suggested hypothesis is that inflammation of the pancreas affects sites nearer to the duodenum than the stomach. Because our study excluded patients with a recent drug history that could cause PUD, our study at least demonstrated that the main cause of PUD might be associated with acute pancreatitis.

An ulcer was clearly defined and selected to exclude other mucosal lesions such as erythema, erosion and edema that were seen on endoscopy. The reason is that by excluding subjective ambiguous mucosal lesions and including the clinically significant meaningful lesion, the prevalence or characteristics of the ulcer could be evaluated. Another reason is that in our country, patients who have PUD revealed on endoscopy can receive the medical benefits of health insurance for treatment with drugs such as PPI. The patients were not placed on ulcer prophylaxis at admission with acute pancreatitis because prescription of anti-ulcer medications such as PPI or H₂ blockers under health insurance need documentation of an ulcer by endoscopy.

The APACHE II score was the only independent risk factor associated with PUD in our study. Many prognostic factors for acute pancreatitis have been previously sug-

gested, such as laboratory markers, radiologic views and scoring systems. A previous study reported that the occurrence of an acute gastric mucosal lesion was not related to the severity of acute pancreatitis^[6]. However, that study lacked a proven method, such as the APACHE scoring system, for evaluating the severity of acute pancreatitis. The APACHE II score reflects the systemic or physiologic response to inflammation-driven stress during the course of acute pancreatitis^[24], and it was reported to be superior to the Balthazar CTSI for predicting organ failure^[25-27]. On the basis of the highest sensitivity and specificity values that were generated from the ROC curves, the cutoff of an APACHE II score of 6 was selected for evaluating the factors for PUD (AUC, 0.75; 95% CI: 0.64-0.86). The score of 6 was somewhat low to reflect the severity in patients with acute pancreatitis^[10,15], and may be due to the exclusion of critically ill patients.

The potential limitations of our study were the small number of patients ultimately enrolled, and the retrospective design. However, the subjects of this study were limited to patients with acute pancreatitis and who underwent endoscopy under strict criteria that considered the patient's history of medication or surgery. Our clinic has routinely recommended that hospitalized patients are evaluated, and the severity of acute pancreatitis predicted, by using scoring systems for acute pancreatitis such as Ranson's score, the APACHE II score and the CTSI. Another limitation of this study was the exclusion of critically ill patients who did not undergo endoscopy, which affected the exact prevalence of PUD, but this would cause underestimation of the prevalence of PUD because some of these patients had a possibility of having PUD combined with severe acute pancreatitis.

In conclusion, patients with acute pancreatitis have a strong possibility of suffering from PUD. In particular, if patients are diagnosed with severe acute pancreatitis, based on the APACHE II scoring system, then treatment for PUD is strongly recommended.

The authors thank Mrs Yu-Jung Kim for help with the literature and statistical research.

COMMENTS

Background

Acute pancreatitis is caused by an acute inflammatory response due to unregulated activation of pancreatic enzymes, which can lead to extrapancreatic complications because of the persistence of hypovolemia, a decreased intravascular volume and multiorgan dysfunction. The possibility of inflammation due to ischemia in the upper gastrointestinal tract may exist. In fact, patients with acute pancreatitis may complain of various abdominal symptoms such as nausea, vomiting and pain, and these symptoms can sometimes be confused with dyspeptic symptoms; these patients may have complications of acute gastrointestinal mucosal lesions.

Research frontiers

The authors hypothesized that the reduction in intravascular volume and the stress response that diminishes the blood flow will affect the upper gastrointestinal lesion and cause peptic ulcer diseases (PUD). In analysis of PUD, we also tried to identify the status of *Helicobacter pylori* (*H. pylori*) infection through endoscopy.

Innovations and breakthroughs

Patients with acute pancreatitis are liable to suffer from PUD, and PUD is related to severe acute pancreatitis according to the Acute Physiology and Chronic Health Evaluation (APACHE) II score with a cutoff value of 6. Among patients with acute pancreatitis, a low prevalence of *H. pylori* infection was revealed in patients with PUD, especially in patients with a duodenal ulcer.

Applications

In the authors' study, an association between PUD and acute pancreatitis was observed and the use of antiulcer medication may be recommended for patients with acute pancreatitis to relieve symptoms of the suspected ulcer, especially in severe acute pancreatitis. By identifying a definite relationship between acute pancreatitis and PUD, this study provides a challenge to clarify the basic mechanisms of these two diseases. In addition, a large prospective study to confirm these observations is required.

Peer review

This study retrospectively reviewed the clinical records of the patients of acute pancreatitis (AP) focusing on the relationship between AP and gastroduodenal PUD and found a positive relationship between APACHE II score and PUD.

served as the control group in this study. Venous blood (10 mL) of each subject was drawn into EDTA-containing tubes after 8 h overnight fasting.

RESULTS: Compared to the control group, patients with ALD showed significantly lower erythrocytic catalase (11.1 ± 0.7 U/mg Hb vs 8.0 ± 0.7 U/mg Hb, $P < 0.05$) and superoxide dismutase (9.5 ± 1.6 U/mg Hb vs 3.0 ± 0.2 U/mg Hb, $P < 0.05$) activities. Furthermore, the erythrocytic reduced glutathione/oxidized glutathione ratio was significantly lower in ALD patients than that in the control group (38.1 ± 5.4 vs 15.7 ± 1.9 , $P < 0.05$). The results revealed that patients with ALD experienced more oxidative stress than those in the control group. The non-aboriginal, but not the aboriginal, ALD group had higher erythrocytic glutathione peroxidase (GPX) activity than that in the control group (46.1 ± 7.8 U/g Hb vs 27.9 ± 2.2 U/g Hb, $P < 0.05$). Hepatitis, but not cirrhosis, ALD patients had higher erythrocytic GPX activity than that in the control group (44.3 ± 8.6 U/g Hb vs 27.9 ± 2.2 U/g Hb, $P < 0.05$).

CONCLUSION: Our results indicate that both ethnicity and the severity of ALD may cause different erythrocytic antioxidative enzyme activities especially GPX activity.

Abstract

AIM: To investigate the antioxidative status of patients with alcoholic liver disease (ALD) in southeastern Taiwan.

METHODS: Our study comprised 27 patients with ALD recruited from Taitung Mackay Memorial Hospital, located in southeastern Taiwan. Patients with ALD included 12 non-aborigines (12 men) and 15 aborigines (11 men and 4 women). According to the severity of ALD, patients with ALD included 10 with hepatitis (9 men and 1 woman) and 17 with cirrhosis (14 men and 3 women). Twenty-two age- and gender-matched healthy adults

INTRODUCTION

Alcohol is one of the major causes of liver disease worldwide. In Taiwan, the prevalence of alcohol dependence has increased 80-fold compared to three decades ago^[1,2]. Except for alcoholic liver disease (ALD), most liver diseases and cirrhosis are due to chronic infection with hepatitis viruses in Taiwan^[3]. Rates of chronic hepatitis B virus and hepatitis C viral infections can reach as high as 15%-20% and 1%-5% respectively^[4]. Evidence shows that chronic hepatitis C viral hepatitis can increase liver damage in alcoholic patients with liver disease^[3], which indicates that a chronic hepatitis virus infection may aggravate the severity of ALD.

It was found that Taiwanese aborigines, who are belong to the Malayo-Polynesia group, are more susceptible to alcohol abuse than ethnic Han Chinese^[5]. In the 1990s a higher prevalence of alcoholism in aborigines was reported (44.2%-55.2%)^[6]. Viral infections and alcohol consumption play important roles in the development of chronic liver diseases in Taiwanese aborigines^[7]. Therefore, ALD is an important issue for aborigines in Taiwan.

Alcohol is mainly metabolized in the liver. Hepatocytes metabolize alcohol in three ways: (1) alcohol dehydrogenase (ADH) which produces acetaldehyde from alcohol in the cytosol; (2) the microsomal ethanol-oxidizing system (MEOS) which catalyzes alcohol to acetaldehyde in the endoplasmic reticulum is highly induced by chronic alcohol consumption; and (3) aldehyde dehydrogenase which catalyzes acetaldehyde to acetate in mitochondria. The ADH pathway reduces nicotinamide adenine dinucleotide (NAD) to its reduced form (NADH) and an imbalance in the NAD/NADH ratio causes a number of metabolic disorders, including inhibition of the Krebs cycle and fatty acid oxidation in ALD^[8-10].

It is well-established that oxidative stress is one of the pathogenic mechanisms of ALD, and oxidative stress is mainly caused by the generation of reactive oxygen species (ROS). ROS associated with alcohol toxicity are generated by the mitochondrial respiratory chain, by ethanol-metabolizing cytochrome P4502E1 (CYP2E1) which is involved in the MEOS of hepatocytes and by NADPH oxidase of Kupffer's cells and liver-infiltrating granulocytes^[11]. Besides hydroxyethyl radicals produced during ethanol oxidation by CYP2E1, nitric oxide (NO) produced by Kupffer's cell NO synthetase and alterations in hepatic iron homeostasis may further result in oxidative damage^[12,13]. Oxidative stress in ALD leads to lipid peroxidation and protein oxidation^[14]. To protect the body from oxidative stress, there are several antioxidant defense mechanisms. The most important antioxidant enzymes involved in these mechanisms are glutathione peroxidase (GPX), glutathione reductase (GRD), superoxide dismutase (SOD) and catalase (CAT)^[15].

The pathological process of ALD can be characterized by different stages of liver damage. The first stage of ALD is hepatic steatosis which is obviously caused by abnormal lipid metabolism^[16-18]. In this stage, steatosis is reversible after alcohol abstinence^[19,20]. The progressive

stage after steatosis is hepatitis. In this stage, steatosis is accompanied by inflammation and cytokine production. The presence of hepatitis indicates initiation of liver cirrhosis, the terminal stage of alcoholic liver disease^[20,21].

Although a few studies discussed ALD in Western countries, the clinical data of patients with ALD in Taiwan, especially data on Taiwanese aborigines, are not well-established. In addition, there are different genetic types of alcohol metabolic enzymes between Western and Asian people^[22]. Therefore it is necessary to establish clinical data on aboriginal patients with ALD in Taiwan. Taitung, situated in southeastern Taiwan, contains the highest proportion of aboriginal residents. There are approximately 240 000 people in Taitung, one-third of whom are aborigines, and the rest are ethnic Han Chinese^[5]. The aim of this study was to compare the antioxidative status between aboriginal and non-aboriginal patients with ALD in the Taitung area. Furthermore, the effect of different severities of ALD, i.e. hepatitis and cirrhosis, on the antioxidative status is also discussed in this study.

MATERIALS AND METHODS

Subjects

This study examined 27 patients with ALD recruited from Taitung Mackay Memorial Hospital. Patients with ALD included 12 non-aboriginal patients (the non-aboriginal ALD group) (12 men) and 15 aboriginal patients (the aboriginal ALD group) (11 men and 4 women). According to the severity of ALD, patients with ALD consisted of 10 patients with alcoholic hepatitis (the hepatitis ALD group) (9 men and 1 woman) and 17 patients with alcoholic cirrhosis (the cirrhosis ALD group) (14 men and 3 women). Twenty-two age- and gender-matched healthy adults served as the control group in this study. The Institutional Review Board for Human studies approved this study. Patient consent was obtained prior to blood collection. Venous blood (10 mL) of each subject was drawn into an EDTA-containing tube after an overnight fasting period of 8 h. Plasma samples were obtained by centrifugation at $1200 \times g$ for 15 min at 4°C. After removing the plasma, erythrocytes were obtained by washing twice with ice-cold physiological saline. Plasma and erythrocyte samples were stored at -80°C until being analyzed.

Biochemical analysis

Plasma aspartate aminotransferase (AST) activity, alanine aminotransferase (ALT) activity, γ glutamyltransferase (γ -GT) activity, total cholesterol (TC) concentration, triglyceride (TG) concentration, high-density lipoprotein-cholesterol (HDL-C) concentration, low-density lipoprotein-cholesterol (LDL-C) concentration, albumin concentration, uric acid concentration, and total bilirubin concentration were measured in each patient and control group using standard procedures on an autoanalyzer (SYNCHRON CX System, Hitachi 7170, Tokyo, Japan).

Deionized water (300 μ L) was added to 100 μ L of the erythrocyte sample and mixed well. The mixture was centrifuged at 4°C, and $8000 \times g$ for 10 min. Then the supernatant fractions were used to determine antioxidant enzymes and the reduced glutathione (GSH)/oxidized glutathione (GSSG) ratio.

GPX activity

The GPX activity of erythrocytes was determined with a commercial kit (RS 504; Randox Laboratories, Antrim, UK). First, 20 μ L of the diluted sample was added to 1 mL of a mixed substrate (4 mmol/L GSH, 0.5 U/L GRD, and 0.34 mmol/L NADPH dissolved in 50 mmol/L phosphate buffer, at pH 7.2, 4.3 mmol/L EDTA). Then, 40 μ L of cumene hydroperoxide (diluted in deionized water) was added to the mixture. The reaction mixture was incubated at 37°C, and the absorbance at 340 nm was determined every minute for 3 min using a microplate reader (Molecular Devices, Sunnyvale, CA, USA).

GRD activity

The GRD activity of erythrocytes was measured with a commercial kit (GR 2368; Randox Laboratories, Antrim, UK). First, 200 μ L of the diluted sample and 400 μ L of 2.4 mmol/L GSSG buffer (dissolved in 125 mmol/L potassium phosphate buffer, at pH 7.5, with 2.5 mmol/L EDTA) were added to 400 μ L of 0.55 mmol/L NADPH (dissolved in deionized water). The absorbance was measured at 340 nm every minute for 5 min using a microplate reader (Molecular Devices).

SOD activity

The SOD activity of erythrocytes was measured with a commercial kit (SD 125; Randox Laboratories, Antrim, UK). First, 50 μ L of the diluted sample and 1.7 mL of the mixed substrate (50 μ mol/L xanthine and 25 μ mol/L 2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyl tetrazolium chloride, INT) were added to 250 μ L of xanthine oxidase. The reaction mixture was incubated at 37°C, and the absorbance was measured at 340 nm every minute for 3 min using a microplate reader (Molecular Devices).

CAT activity

The CAT activity of erythrocytes was determined according to the method reported by Beers and Sizer^[23]. First, 100 μ L of the diluted sample and 1 mL of 59 mmol/L H₂O₂ (dissolved in 50 mmol/L potassium phosphate buffer, at pH 7.0) were added to 1.9 mL of deionized water. The absorbance was measured at 240 nm every minute for 3 min using a Hitachi U-2000 ultraviolet-visible (UV-VIS) spectrophotometer. One unit of CAT activity was defined as mmol of H₂O₂ degraded/min.

Determination of the GSH/GSSG ratio in erythrocytes and liver tissue

GSH concentration: The concentration of GSH in erythrocytes was determined according to the method of Tietze^[24], using GSH (0-100 μ mol/L) as the standard. The

diluted sample solution or standard (10 μ L) was mixed with 95 μ L of the reagent (2 U/mL glutathione reductase, 200 μ mol/L NADPH, and 2 mmol/L EDTA in 50 mmol/L phosphate buffer, at pH 7.2), followed by the addition of 100 μ L of the reagent (10 mmol/L DTNB in 50 mmol/L phosphate buffer, at pH 7.2). The reaction mixture was then incubated at room temperature, and the absorbance at 405 nm was determined every minute for 5 min using an enzyme-linked immunosorbent assay (ELISA) reader (Molecular Devices). The concentration was expressed as GSH (μ mol/L) in erythrocytes.

GSSG concentration: The concentration of GSSG in erythrocytes was measured according to the method of Tietze^[24], using GSSG (0-100 μ mol/L) as the standard. The diluted sample solution or standard (70 μ L) was mixed with 4 μ L of 1-methyl-2-vinylpyridinium trifluoromethanesulfonate (M2VP). The mixture was allowed to stand at room temperature for 1 h. The reaction mixture (10 μ L) was mixed with 95 μ L of the reagent (2 U/mL glutathione reductase, 200 μ mol/L NADPH, and 2 mmol/L EDTA in 50 mmol/L phosphate buffer, at pH 7.2), followed by the addition of 100 μ L of the reagent (10 mmol/L DTNB in 50 mmol/L phosphate buffer, at pH 7.2). The reaction mixture was then incubated at room temperature, and the absorbance at 405 nm was determined every minute for 5 min using an ELISA reader (Molecular Devices). The concentration was expressed as GSSG (μ mol/L) in erythrocytes.

The GSH/GSSG ratio: The GSH/GSSG ratio was then calculated by dividing the difference between the total GSH and GSSG concentrations (reduced GSH) by the concentration of GSSG. $\text{GSH/GSSG} = (\text{total GSH} - 2\text{GSSG})/\text{GSSG}$.

Measurement of lipid peroxidation in plasma

Lipid peroxidation was quantitatively measured by measuring the concentration of thiobarbituric acid reactive substances (TBARS) in plasma using the method of Ohkawa *et al.*^[25] with minor modifications. 20 μ L plasma or various levels of TMP (1,1,3,3-tetramethoxypropane; as a standard) were shaken with 800 μ L of 0.22% H₂SO₄ in a 2 mL centrifuge tube. Phosphotungstic acid (100 μ L; 10%) and 200 μ L of 0.67% TBA (in H₂O: glacial acetic acid = 1:1, v/v) were added to the mixture, shaken, and warmed for 60 min in a boiling water bath followed by rapid cooling. Then 600 μ L of an *n*-butyl-alcohol layer was shaken in a separation tube, and the MDA content in the plasma or liver homogenates was determined fluorometrically (with respective excitation and emission wavelengths of 531 and 590 nm) using a Wallace Victor-2 1420 Multilabel Counter (Perkin-Elmer, Waltham, MA, USA).

Statistical analysis

All data are expressed as the means \pm SE. Student's *t* test was used to compare differences of means between the control group and ALD group using EXCEL software

(Redmond, WA, USA). Statistical significance was assigned at the *P* < 0.05 level. To evaluate differences among the three groups in this study, one-way analysis of variance with Fisher's post hoc test was used. The SAS software (vers. 8.2, SAS Institute., Cary, NC, USA) was used to analyze all data. Differences were considered statistically significant at *P* < 0.05.

RESULTS

The biochemical parameters of the control and ALD group are shown in Table 1. No significant difference was observed with regard to age, weight, body-mass index (BMI), or plasma uric acid concentration between the control and ALD group. The plasma AST activity, ALT activity, AST/ALT ratio, γ -GT activity and total bilirubin

Values in the same row with different letters (a, b, c) significantly different at *P* < 0.05 (by one-way analysis of variance). ALD: Alcoholic liver disease; BMI: Body-mass index; AST: Aspartate aminotransferase; ALT: Alanine transaminase; γ -GT: γ -glutamyltransferase; TC: Total cholesterol; TG: Triglycerides; HDL-C: High-density lipoprotein-cholesterol; LDL-C: Low-density lipoprotein-cholesterol.

concentrations were significantly higher in the ALD group than those in the control group (*P* < 0.05). The plasma TC, HDL-C, and LDL-C concentrations were significantly lower in the ALD group than those in the control group (*P* < 0.05). Furthermore, patients with ALD had significantly lower plasma albumin concentrations than that in the control subjects (*P* < 0.05). As shown in Table 2, no significant difference in erythrocytic GPX or GRD activities was observed between the control and ALD groups. Patients with ALD showed significantly lower erythrocytic CAT and SOD activities when compared to those in the control group (*P* < 0.05). Furthermore, the erythrocytic GSH/GSSG ratio was significantly lower in patients with ALD than that in the control group (*P* < 0.05). But no significant difference was observed with regard to the plasma TBARS concentration between the control and ALD group.

In order to understand the antioxidant status in aboriginal patients with ALD (aboriginal ALD group) in the Taitung area, patients were divided into an aboriginal ALD, and a non-aboriginal ALD (non-aboriginal ALD group). Biochemical parameters of the control, non-aboriginal ALD, and aboriginal ALD group are given in Table 3. No significant difference was observed in the weight, BMI, AST/ALT, plasma TC, TG or uric acid concentrations among the three groups. Both the non-aboriginal and aboriginal ALD groups had significantly higher plasma AST activity than the control group (*P* < 0.05). The non-aboriginal, but not the aboriginal, ALD group had significantly higher plasma ALT and γ -GT activities than that in the control group (*P* < 0.05). Both the non-aboriginal and aboriginal ALD groups had significantly lower plasma

GSH/GSSG	38.0 \pm 5.4 ^a	16.5 \pm 3.8 ^b	15.0 \pm 1.6 ^b
TBARS (μ mol/L)	3.5 \pm 0.2 ^a	3.4 \pm 0.5 ^a	4.6 \pm 1.0 ^a

Values in the same row with different letters (a, b) significantly different at $P < 0.05$. (by one-way analysis of variance). ALD: Alcoholic liver disease; GPX: Glutathione peroxidase; GRD: Glutathione reductase; CAT: Catalase; SOD: Superoxide dismutase; GSH: Reduced glutathione; GSSG: Oxidized glutathione; TBARS: Thiobarbituric acid reactive substances.

HDL-C, LDL-C and albumin concentrations than those in the control group ($P < 0.05$). In addition, the aboriginal ALD group had lower plasma LDL-C and albumin concentrations than those in the non-aborigine ALD group ($P < 0.05$). The aboriginal, but not non-aboriginal, ALD had significantly higher plasma total bilirubin than that in the control group ($P < 0.05$).

As shown in Table 4, the non-aboriginal, but not the aboriginal ALD group had significantly higher erythrocytic GPX activity than the control group ($P < 0.05$). In addition, no significant difference was observed in the erythrocytic GRD activities and plasma TBARS concentration among the three groups. Both the non-aboriginal and aboriginal ALD group had significantly lower erythrocytic CAT activity, erythrocytic SOD activity and erythrocytic GSH/GSSG ratio than those in the control group ($P < 0.05$).

The antioxidant status with different severities of alcoholic liver disease was investigated. Patients with ALD were divided into those with hepatitis ALD (hepatitis ALD) and those with cirrhosis (cirrhosis ALD). In Table 5, no significant difference was observed in the weight, BMI or uric acid concentration among the control, hepatitis ALD, and cirrhosis ALD groups. Both the hepatitis ALD and cirrhosis ALD groups had significantly higher plasma AST activity compared to the control group ($P < 0.05$). The hepatitis, but not the cirrhosis, ALD group had significantly higher plasma ALT activity and AST/ALT ratio than those in the control group ($P < 0.05$). The cirrhosis, but not the hepatitis, ALD group had significantly higher plasma γ -GT activity compared to the control group ($P < 0.05$). The cirrhosis, but not the hepatitis, ALD group had lower plasma HDL-C concentrations than the control group ($P < 0.05$). Both the hepatitis and cirrhosis ALD groups had significantly lower plasma LDL-C concentrations when compared to the control group ($P < 0.05$). In addition, the cirrhosis ALD group had significantly lower plasma albumin concentrations than the hepatitis ALD group ($P < 0.05$). The cirrhosis, but not the hepatitis, ALD group had significantly higher plasma total bilirubin concentrations than the control group ($P < 0.05$).

As shown in Table 6, the hepatitis ALD, but not the cirrhosis ALD group, had significantly higher erythrocytic

GPX activity than the control group ($P < 0.05$). There was no significant difference in erythrocytic GRD activity and plasma TBARS concentration among the three groups. The cirrhosis, but not the hepatitis, ALD group had significantly lower erythrocytic CAT activity than the control group ($P < 0.05$). Both the hepatitis and cirrhosis ALD groups had significantly lower erythrocytic SOD activities and GSH/GSSG ratio than those in the control group ($P < 0.05$).

DISCUSSION

In most patients with liver injury, the ratio of AST to ALT is 1 or less, whereas in alcoholic hepatitis it is generally

about 2^[26]. An AST to ALT ratio > 1 was reported in patients with alcoholic cirrhosis^[27]. Our observation agreed with the previous study, the AST to ALT ratio was 2.86 in patients with ALD (Table 1) and the AST to ALT ratio in hepatitis ALD was higher than that in cirrhosis ALD (Table 5).

Erythrocytes can easily suffer oxidative damage due to the presence of polyunsaturated fatty acid, heme, iron, and oxygen. The antioxidant enzymes, GPX, GRD, CAT and SOD, located in erythrocytes protect the body from oxidative stress^[28]. In an animal study, decreased activity of Cu, Zn SOD was demonstrated in the liver of rodents after chronic ethanol exposure^[29]. However, both increased and decreased SOD activities in the blood of alcoholics were reported^[30-33], and this may have been due to different durations of alcohol dependence. Free radical scavenging enzymes such as SOD, CAT, and GPX are known to be the first line cellular defense against oxidative damage, disposing of superoxide anion and H₂O₂ before their interaction to form the more harmful hydroxyl radical. In the present study, both CAT and SOD activities decreased significantly in the ALD groups compared with the control group, and it is assumed that excessive superoxide anions might elicit lipoperoxide formation and induce cell damage before being converted to H₂O₂ by SOD^[34]. In the absence of adequate SOD activity, superoxide anion is not converted into H₂O₂, which is the substrate for the H₂O₂ scavenging enzyme CAT^[35]. As a result, there is an inactivation of the H₂O₂ scavenging enzyme CAT, leading to a decrease in its activity^[36].

GPX produces GSSG from GSH, while GRD maintains the cellular level of GSH by reducing oxidized glutathione to its reduced form. Change in activities of these two antioxidant enzymes are not consistent in ALD^[37]. In the present study, erythrocytic GPX and GRD activities showed no difference between patients with ALD and the control group (Table 2). The limited size of the study populations may have contributed to this anomaly.

Glutathione, a tripeptide (γ -glutamylcysteinylglycine), plays an important role in coordinating the body's antioxidant defense processes^[38]. Lower hepatic GSH levels were reported in alcoholic cirrhosis^[38,39]. GSH is also present in erythrocytes^[40]. GSH can be exported from hepatocytes to the sinusoidal blood, where it is rapidly broken down to dipeptides and amino acid by γ -GT and dipeptidases^[40,41]. Erythrocytes can resynthesize GSH after taking up the precursor amino acid^[30]. In agreement with a previous study^[42], the erythrocytic GSH/GSSG ratio, an indicator of the antioxidant status, was significantly lower in the ALD group than the control group in this study (Table 2). The lower erythrocytic GSH concentrations may be due to impaired biosynthesis or decreased release from damaged liver cells^[42]. The TBARS concentration reflects the level of malondialdehyde (MDA) which is the end product of lipid peroxidation. As shown by Peng *et al.*^[15], the MDA concentration not only significantly increased in the ALD group than in the control group, but was also significantly correlated with the duration of alcohol dependence.

However, our present study is not in accordance with a previous study. The plasma TBARS concentration showed a slight increase over that of the control, but it did not reach significance. We believe that the dietary lipid composition may play an important role in lipid peroxidation. Evidence showed that the effect of saturated fatty acids may reduce endotoxemia and lipid peroxidation^[43]. In addition, rats fed diets high in polyunsaturated fatty acids and ethanol could increase the susceptibility of peroxidation^[44]. Therefore, the dietary lipid composition of control subjects and patients with ALD in southeastern Taiwan should be investigated in the future.

Poor health knowledge, a relatively low socioeconomic status, high rates of alcohol abuse, and poor control of chronic diseases are the characteristics of Taiwanese aborigines^[45]. It is believed that both poor health knowledge and relatively low socioeconomic status may lead to malnutrition in Taiwanese aborigines. As shown in this study, the significantly lower albumin concentration, which is an index of malnutrition, was found in the aboriginal ALD group (Table 3). On the other hand, the non-aboriginal, but not the aboriginal, ALD group had higher erythrocytic GPX activities than the control group (Table 4). The higher erythrocytic GPX activity can be explained as an adaption to the oxidative stress of ALD. However, the aboriginal ALD group did not show an adaptive capacity.

As shown in table 5, the cirrhosis ALD group had significantly lower plasma TC, HDL-C, and LDL-C concentrations than those in the hepatitis ALD and control groups. A previous study indicated that patients with alcoholic cirrhosis with Child-Pugh score C showed lower plasma TC concentrations than patients with alcohol abuse without cirrhosis^[46]. This confirms that the severity of liver impairment may affect plasma TC concentrations. In addition, lower plasma HDL-C and LDL-C concentrations with alcoholic cirrhosis were also reported in previous studies^[47,48]. The lower lipoprotein results from impairment lipoprotein synthesis can be explained by decreased protein secretion and increased protein retention in the liver under ethanol exposure^[49].

Changes in erythrocytic antioxidant enzymes differed between the hepatitis and cirrhosis ALD groups compared to the control group (Table 6). The hepatitis, but not cirrhosis, ALD group had higher erythrocytic GPX activity than the control group. The higher GPX activity in hepatitis ALD patients can be explained by adaptation to oxidative stress. In addition, the hepatitis ALD group showed significantly higher erythrocytic CAT activity than the cirrhosis ALD group. The lower erythrocytic CAT activity of cirrhosis ALD patients is consistent with a previous study^[50]. This result reveals that cirrhosis ALD patients had lower erythrocytic enzyme activities than hepatitis ALD patients. Although there were different changes in erythrocytic antioxidant enzymes between the two ALD groups, both the hepatitis and cirrhosis ALD groups showed a lower erythrocytic GSH/GSSG ratio than the control group.

In conclusion, this study indicated that both ethnicity and the severity of alcoholic liver disease can cause different erythrocytic antioxidative enzyme activities especially GPX activity. This finding can not only establish the clinical data of patients in Taiwan but also provide a few clues for the treatment of alcoholic liver disease. Our research also showed no significant difference in plasma TBARS level between control subjects and ALD patients. This different result from studies in Western countries might be attributed to the dietary lipid composition in the Taitung area of southeastern Taiwan.

COMMENTS

Background

Alcohol abuse is one of the major causes of liver disease worldwide. The prevalence of alcohol dependence is increasing in Taiwan. Besides the hepatic viral infection, another high rate prevalence liver disease in Taiwan may increase liver damage in alcoholic liver disease. Thus, more research should be done on establishing the clinical data of alcoholic liver disease in Taiwan area.

Research frontiers

A higher prevalence of alcoholism in aborigines was reported in Taiwan. Besides, both viral infection and alcohol consumption play important roles in the development of chronic liver diseases in Taiwanese aborigines. Therefore, alcoholic liver disease is an important issue for aborigines in Taiwan.

Innovations and breakthroughs

In this study, we indicated that both ethnicity and the severity of alcoholic liver disease may cause different erythrocytic antioxidative enzyme activities, especially erythrocytic glutathione peroxidase (GPX) activity.

Applications

By understanding the different changes of antioxidative enzyme activities between either different ethnicity or severity of alcoholic liver disease, we can not only establish the clinical data of patients in Taiwan but also provide a few clues for treatment of alcoholic liver disease.

Peer review

The manuscript describes the antioxidative condition of 27 alcoholic liver disease (ALD) patients in southeastern Taiwan by biochemical analysis, such as erythrocytic catalase, superoxide dismutase, reduced glutathione/oxidized glutathione ratio and GPX, and plasma low-density lipoprotein-cholesterol concentration. The authors concluded that both ethnicity and the severity of ALD may cause different erythrocytic antioxidative enzyme activities especially GPX activity and the findings are of interest.

Abstract

AIM: To investigate the current status of peritoneal carcinomatosis (PC) management, as well as the usage of cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) in mainland China.

METHODS: A potentially curative therapeutic strategy for selecting patients with PC, known as "Techniques", consists of CRS in combination with HIPEC. A systemic search of published works and clinical trials was performed. Additional papers were retrieved by cross-checking references and obtaining information from Chinese oncologists and relevant conferences. One hundred and one papers and one registered clinical trial on HIPEC were included.

RESULTS: A literature review identified 86 hospitals in 25 out of all 31 areas of mainland China that perform HIPEC. The earliest report included in our survey was published in 1993. Different approaches to HIPEC have been utilized, i.e. palliative, prophylactic, and possibly

curative treatment. Only one center has consistently performed HIPEC according to the "Sugarbaker Protocol", which involves evaluating the extent of PC with peritoneal cancer index and the results of CRS with the completeness of cytoreduction. Positive preliminary results were reported: 7 of 21 patients with PC survived, free of tumors, during an 8-43-mo follow-up period. Hyperthermic strategies that include HIPEC have been practiced for a long time in mainland China, whereas the "Sugarbaker Protocol/Techniques" has been only rarely implemented in China. The Peritoneal Surface Oncology Group International hosts a biannual workshop with the intent to train more specialists in this field and provide support for the construction of quality treatment centers, especially in developing countries like China, whose population is huge and has a dramatically increased incidence of cancer.

CONCLUSION: To popularize Sugarbaker Protocol/Techniques in mainland China in PC management arising from gastric cancer or colorectal cancer will be the responsibility of the upcoming Chinese Peritoneal Surface Oncology Group.

INTRODUCTION

China has a population of more than 1.3 billion, which makes it the largest developing country in the world with a consequently huge medical burden. The incidence of gastrointestinal cancer in China has been rapidly increasing in recent years^[1]. In 2004-2005 alone, there were 428 380 newly reported cases of gastric cancer (GC) and 339 308 GC-related deaths. Furthermore, in the same period of time, there were 197 873 newly reported cases of colorectal cancer (CRC), including cancers of anal canal, and 101 684 CRC-related deaths^[2]. Although the incidence of GC has decreased for both men and women in some areas of China, the incidence of CRC has annually increased by 4.2% in Shanghai, which is higher than the observed global rate of increase. Notably, a report of 1075 cases of CRC in China has revealed that advanced stage III and VI cases account for 46.8% of all reported cases^[3].

The peritoneum is one of the most commonly affected sites in patients with recurrent GC or CRC. One study performed on a Chinese population found that even early GC has a 1.63% (4/308) rate of peritoneal recurrence^[4]. The natural course of peritoneal carcinomatosis (PC), including those arising from GC and CRC, is only 6-8 mo^[5,6]. In regard to the traditional treatment and follow-up, PC is considered to be a terminal event of systemic metastasis. Over the past two decades, "Sugarbaker Protocol/Techniques", i.e. surgical removal of all macroscopic PC in combination with hyperthermic intraperitoneal chemotherapy (HIPEC), has emerged as a potential curative treatment option for some patients. It becomes increasingly acceptable as a standard method of treatment for certain local peritoneal surface diseases. In recent years, many institutions all over the world have applied this combined modality treatment and have achieved exciting results^[7-14].

The purpose of this survey was to investigate the current status of PC treatment, as well as the frequency of cytoreductive surgery (CRS) and HIPEC utilization in China, as determined by a review of the English and Chinese literature. We sought to identify the number of specialized centers that use this approach in the treatment of GC and CRC. We examined the logic behind the decision to pursue HIPEC and/or CRS and the location of the hospitals that reported the use of the technique. We sought to evaluate the popularity of these strategies and quantified the patients who were involved therein in order to determine the frequency with which this approach was utilized. The design, methodology, and results of those clinical trials are not analyzed and discussed in this report.

MATERIALS AND METHODS

An electronic search was conducted using English and/or Chinese language restrictions and Medline databases (from 1949 to January 2010) on PubMed^[15], Cochrane databases^[16], and other databases for registered clinical trials^[17-19]. We used the following search strategy: (China or Chinese) and (cancer or tumor or carcinoma or malign*)

and (mesothel* or periton*) and (heat* or hyper*) and chemotherapy.

The Chinese National Knowledge Infrastructure (CNKI) database^[20] and the Chongqing Weipu Information Company (CQVIP) database^[21] encompass 95.96% and 83.86% of all significant Chinese journals, respectively. The following search strategy was used for our investigation of the Chinese literature: (associated with abdomen) and (associated with cancer) and (associated with heat or hyperthermia) and (chemotherapy) and (associated with surgery and operation).

In order to supplement the electronic search, additional studies about registered clinical trials in China and intra-peritoneal chemotherapy were retrieved by cross-checking references. Chinese oncologists and relevant conferences provided the information as well.

The reference lists of the obtained articles were also examined so as to identify further relevant citations. The first author performed electronic searches in January 2010. All of the abstracts of citations identified by the search were then scrutinized by the first author to determine their eligibility for this study.

Selection criteria

All reported cases with < 10 subjects, cases that lacked a description of the detailed process, cases without follow-up, and cases with brief reports that lacked abstracts and reviews were excluded. If a series of trials at the same center had been documented, we focused on the most recent results. Papers on the same trial published in different languages were considered to be one publication. As mentioned in the introduction, the quality of these clinical trials and their HIPEC technologies are not evaluated or discussed in this paper.

The included papers and clinical trials were categorized into three groups according to the purpose of treatment (Table 1) as follows.

Perioperative prophylactic strategy: intraoperative and early postoperative HIPEC for patients without visible peritoneal metastasis at the time of primary tumor surgery.

Palliative strategy: HIPEC after palliative operation without an attempt to eliminate visible peritoneal tumors or without surgery.

CRS and HIPEC: use "Sugarbaker Protocol", with an attempt to eliminate PC as a potentially curative strategy, following the HIPEC to control residual diseases. An evaluation of the PC and peritoneal cancer index (PCI), in addition to the extent of the CRS and the completeness of cytoreduction (CCR), was included in this category^[9].

RESULTS

Initially, we obtained 629 records from the CQVIP database, 439 records from the CNKI database, 86 records from Medline, and 11 records from the clinical trial registration database. All 715 abstracts about GC and CRC were skimmed. Ultimately, 101 papers and one registered

GC: Gastric cancer; CRC: Colorectal cancer; PC: Peritoneal carcinomatosis; HIPEC: Hyperthermic intraperitoneal chemotherapy; iHIPEC: Intraoperative HIPEC; pHIPEC: Postoperative HIPEC. ¹A trial including both prophylactic and palliative strategies was counted twice according different purposes of HIPEC.

clinical trial on HIPEC in China were identified. Among these, nine papers were obtained from Medline with English abstracts and five were published in English^[9,22-29].

Based on the aforementioned criteria, we included 86 hospitals in mainland China whose doctors have extensive experience with HIPEC. The hospitals were located in 25 of the 31 areas of mainland China. In total, these institutions reported 101 clinical trials, and the earliest report was published in 1993. Among the included trials, 68 investigated GC, 14 studied CRC, and 19 examined both. In these trials, as a prophylactic strategy, intraoperative and postoperative HIPEC were used, and some centers used HIPEC for patients who were considered to have no chance of surviving surgery. Forty-two trials involved the use of intraoperative HIPEC, 51 utilized postoperative HIPEC, and eight studies adopted both strategies. Ninety-one trials were performed with prophylactic goals and 17 with palliative goals. Only one trial utilized CRS and HIPEC as two parts of a potentially curative strategy. The doctors in these studies adhered to the "Sugarbaker Protocol" in 21 cases that included 12 patients with GC and 5 patients with CRC (registered trial NCT00454519)^[9]. The authors reported positive preliminary results: 7 of the 21

patients with PC survived and were tumor-free during an 8-43-mo follow-up.

Mitomycin C (MMC), Cisplatin (DDP) and 5-Fu are commonly used alone or in combination with HIPEC to treat GC and CRC. The dosage ranges of these treatments extensively vary across trials. The usage of some other drugs, such as Mitomycin C adsorbed on activated carbon particles (MMC-CH) and Tegafur, has been reported in some trials that examined GC. One trial reported on the combination of IL-2 with HIPEC.

The HIPEC centers located in different areas of mainland China and their respective reports are presented in Table 1.

DISCUSSION

Intraoperative intraperitoneal chemotherapy with heat is regarded as a typical prophylactic strategy for advanced GC in China. Among the 101 trials included in this survey, 91 utilized HIPEC for prophylactic purposes. Two other registered trials sponsored by two university hospitals in Shanghai are currently recruiting participants. Chinese authors have also performed a Cochrane review in order

to assess the efficacy and safety of intraperitoneal chemotherapy for GC. Fewer trials have been performed to examine HIPEC for CRC. Some centers have reported their results after performing HIPEC on patients who were not suited for surgical treatment. This survey reveals that hyperthermic treatment, intraperitoneal chemotherapy and HIPEC are popularly accepted in China as therapies for GC and CRC. The “Sugarbaker Protocol” has been implemented in China, although its application has been limited. In the only trial that examined CRS and HIPEC (21 reported cases), the extent of PC with PCI and the result of CRS with CCR were evaluated. The preliminary results are positive, and these authors have concluded that CRS and HIPEC are relatively safe treatment options for selecting patients with PC originating from the gastrointestinal tract and gynecological malignancies, and result in improved outcomes. On the basis of these results, their registered phase II randomized clinical trial is still recruiting participants.

PC is usually regarded as a disseminated, lethal stage of disease and a situation that necessitates palliative care. Based on the studies that are examined in this survey, we found that most authors still consider PC to be an incurable disease. If doctors do not implement the recent advanced treatment for loco-regional disease, their patients can not benefit from this. CRS followed by HIPEC changes the situation and provides selected patients with a chance for possible long-term survival. This novel approach would represent not only a technological advancement but also a paradigm shift in the conception of treatment. The efforts of the Peritoneal Surface Oncology Group International (PSOGI) and their biannual workshop support such progress. This group has cooperated with numerous individuals from the United States, Europe, Korea and Japan, who all have a common interest in the prevention and treatment of peritoneal surface malignancy. The latest reports from their 2008 meeting provide additional supporting evidence of the efficacy of “Sugarbaker Protocol”^[11-13,30-39].

On one hand, the international community insists that CRS followed by HIPEC is effective for selected patients and will continue to improve with additional research. On the other hand, the “Sugarbaker Protocol” is not widely accepted in China, wherein the general population carries a heavy cancer-related medical burden. For example, only one researcher from China registered for the 7th Uppsala Workshop (2010-03-03 in Sweden). Notably, the most effective strategy will be beneficial for the patients and will be supported by academic researches. By sharing their experiences, these professionals from all over the world can work together to improve the treatment methods available for PC and prolong the patient survival. Another important issue is the dissemination of useful information by PSOGI and the biannual workshop. More specialists need to be trained and funding will be necessary in order to build high-quality centers. The necessary skills should be improved and constructed for specialized institutes^[40], and collaborations with well-established centers that perform

the techniques will be essential for the implementation of this strategy in the developing countries. As expected, 20% of the world's population would benefit from this technique if this approach was established in China.

This report is based on a comprehensive literature review and may also provide some advice to doctors and clinical researchers in China. The professionals that are involved in GC and CRC treatment and research must assimilate new concepts that are supported by strong evidence and rapidly apply the related techniques to patients in need. These doctors must publish the results they obtained from clinical practice in English as well as in Chinese, and furthermore, the results should be presented at conferences and in the medical literature. This hard work and collaboration will facilitate the fight against cancer.

As we mentioned in the introduction, this report did not include all of the clinical trials that relate to HIPEC and have been published in Chinese. The authors selected certain hospitals that met established criteria. These hospitals should be dedicated as HIPEC and CRS centers and potential collaborators with PSOGI in the near future.

Hyperthermic strategies have been practised for a long time in mainland China, whereas the “Sugarbaker Protocol” is only rarely implemented. The PSOGI hosts a biannual workshop with the intent to train more specialists in this field and provide support for the construction of quality treatment centers, especially in the developing countries like China.

COMMENTS

Background

According to the traditional treatment and follow-up, peritoneal carcinomatosis (PC) is considered to be a terminal event of systemic metastasis. Over the past two decades, “Sugarbaker Protocol/Techniques”, i.e. surgical removal of all macroscopic PC in combination with hyperthermic intraperitoneal chemotherapy (HIPEC), has emerged as a potential curative treatment option for some patients. It becomes increasingly acceptable as a standard method of treatment for certain local peritoneal surface diseases by many institutions all over the world, and has achieved exciting results. Hyperthermic strategies have been practiced for a long time in mainland China, whereas the “Sugarbaker Protocol” is only rarely implemented.

Research frontiers

Over the past two decades, “Sugarbaker Protocol/Techniques” has emerged as a potential curative treatment option for some patients. It becomes increasingly acceptable as a standard method of treatment for certain local peritoneal surface diseases. In recent years, many institutions all over the world have applied this combined modality treatment and have achieved exciting results.

Innovations and breakthroughs

This study investigated the current status of PC treatment, as well as the frequency of cytoreductive surgery (CRS) and HIPEC utilization in China, as determined by a review of the English and Chinese literature.

Applications

The Peritoneal Surface Oncology Group International hosts a biannual workshop with the intent to train more specialists in this field and provide support for the construction of quality treatment centers, especially in the developing countries like China. As expected, 20% of the world's population would benefit from this technique if this approach was established in China.

Terminology

PC: most PCs come from gastric, colorectal, appendiceal and ovarian cancers. Peritoneal Surface Malignancy/Oncology: include not only PC, but malignancies other than epithelial cancer, such as sarcomatosis and malignant peritoneal

mesothelioma. Sugarbaker Protocol: surgical removal of all macroscopic PC in combination with HIPEC, has emerged as a potential curative treatment option for some patients.

Peer review

The authors present a very important work on HIPEC procedures in mainland China. Standard operating procedures by the Peritoneal Surface Oncology Group are stated to be necessary. However, it is not quite correct, that HIPEC with or without CRS could ever be done in a curative intention, since the patients treated are all in a metastasized situation and any treatment will be palliative. It would be very interesting if the authors can present an analysis of the many prophylactic HIPEC procedures that seem to have taken place in China. Overall, the presented manuscript gives interesting and so far unknown information.

Abstract

AIM: To investigate the differences in cultivable gut bacteria and peroxisome proliferator-activated receptor $\gamma 2$ (*PPAR- $\gamma 2$*) gene Pro12Ala variation in obese and normal-weight Chinese people.

METHODS: Using culture methods, the amounts of *Escherichia coli*, *Enterococci*, *Bacteroides*, *Lactobacilli*, *Bifidobacteria* and *Clostridium perfringens* (*C. perfringens*) in the feces of 52 obese participants [body mass index (BMI): ≥ 28 kg/m²] and 52 participants of normal-weight (BMI: 18.5-24 kg/m²) were obtained. Study participants completed comprehensive questionnaires and underwent clinical laboratory tests. The polymerase chain reaction-restriction fragment length polymorphism (PCR-PFLP) assay was used to analyze *PPAR- $\gamma 2$* gene Pro12Ala variation.

RESULTS: The obese group exhibited a lower amount of *C. perfringens* (6.54 ± 0.65 vs 6.94 ± 0.57 , $P = 0.001$)

and *Bacteroides* (9.81 ± 0.58 vs 10.06 ± 0.39 , $P = 0.012$) than their normal-weight counterparts. No major differences were observed in Pro12Ala genotype distribution between the two groups; however, obese individuals with a Pro/Ala genotype had a significantly lower level of *Bacteroides* (9.45 ± 0.62 vs 9.93 ± 0.51 , $P = 0.027$) than those with a Pro/Pro genotype. In addition, the obese group demonstrated a higher stool frequency ($U = 975$, $P < 0.001$) and a looser stool ($U = 1062$, $P = 0.015$) than the normal-weight group.

CONCLUSION: Our results indicated interactions among cultivable gut flora, host genetic factors and obese phenotype and this might be helpful for obesity prevention.

Gut bacteria alteration in obese people and its relationship with gene polymorphism. *World J Gastroenterol* 2011; 17(8): 1076-1081 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i8/1076.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i8.1076>

INTRODUCTION

Obesity and its concomitant consequences are a major cause of metabolic disease in both developed and developing countries^[1]. Its occurrence is attributed to a variety of factors. Recent studies have revealed that gut flora, as an environmental factor, might play an important role in

the development of obesity^[2-6]. However, the majority of these results are based on animal experiments or on studies that involved a small number of human samples. Although molecular methods can detect the majority of uncultivable gut flora, microorganisms present in low numbers but with critical functions are usually omitted; thus, molecular methods provide only a rough profile of gut microbial ecology^[7]. This prompted us to consider using culture methods to reveal differences in cultivable gut bacteria. Moreover, culture methods can demonstrate differences in predominantly cultivable bacteria and provide isolates for further characterization and potential application in animal models, which is important for uncovering the relationship between obesity and gut flora.

Along with gut flora, genetic factors are thought to be important in initiating obesity^[8]. Previous studies have suggested that the nuclear hormone receptor peroxisome proliferator-activated receptor γ 2 (PPAR- γ 2) modulates cellular differentiation and lipid accumulation during adipogenesis^[9-12], which is essential for the development of obesity. Although it is widely accepted that obesity is caused by various environmental and genetic factors, as well as the complex interactions between them, how environmental and genetic factors interact with each other in obesity remains to be elucidated.

Thus, the aim of this study was to analyze the composition of cultivable bacteria in obese individuals and their normal-weight counterparts to obtain cultivable, obesity-related gut bacteria for further study, and to investigate the potential relationship between the PPAR- γ 2 gene Pro12Ala polymorphism and cultivable gut bacteria.

MATERIALS AND METHODS

Participant recruitment and clinical laboratory tests

Participants were randomly recruited from Chengdu, a city located in southwest China. All subjects were Chengdu residents. Participants who were taking antibiotics or microecological modulators, and those who had had a gastrointestinal disease during the preceding month, were excluded from the study. Pregnant or lactating women and individuals with major systemic disorders or a history of malignant tumors were also excluded from the study.

The body height and weight of study participants were measured to determine their body mass index (BMI; kg/m²). According to the definition of obesity and normal-weight recommended by the Chinese guidelines for prevention and management of overweight and obesity in Chinese adults, subjects were divided into obese (BMI ≥ 28 kg/m²) and normal-weight (BMI 18.5-24 kg/m²) groups^[13]. Routine blood, hepatic and renal function tests and electrocardiogram and B-mode ultrasonic abdominal examinations were performed to assess the health status of each participant. Ultimately, 104 volunteers were included in the study: 52 obese and 52 normal-weight subjects. The study was approved by the Ethics Committee of Sichuan University and informed consent was obtained from all participants before data collection.

Table 1 Culture media and incubation conditions

Medium	Time (d)	Culture conditions	Bacterial group
EMB agar ¹	1	Aerobic	<i>Escherichia coli</i>
BEA agar ²	1	Aerobic	<i>Enterococci</i>
LBS agar ²	2	Aerobic with 5% CO ₂	<i>Lactobacilli</i>
BBL agar ¹	2	Anaerobic	<i>Bifidobacteria</i>
SPS agar ¹	2	Anaerobic	<i>Clostridium perfringens</i>
GAM agar ²	2	Anaerobic	<i>Bacteroides</i>

¹Purchased from Beijing Land Bridge Technology Co. Ltd., China;

²Prepared in the laboratory according to methods defined by the Chinese Ministry of Health^[16]. EMB: Eosin methylene blue; BEA: Bile esculin azide; LBS: Lactobacillus selection; BBL: Bifidobacterium culture; SPS: Sulfite-polymyxin-sulfadiazine; GAM: Gifu anaerobic medium.

Questionnaire survey

A comprehensive questionnaire was used to gather basic information as well as information on dietary intake, physical activity and defecation conditions for each participant. In the questionnaire, a 72-h diet recall for each participant was recorded, which was used to assess macronutrient intake from food composition tables for Chinese diets^[14]. For each food, participants selected their serving size, which was represented by standard cups and spoons. Questions about stool form scales and bowel frequency were also included. According to the Bristol stool scale^[15], stool forms are classified into three categories: type 1, emerging stools exhibiting fluffy pieces with ragged edges or soft blobs (transit fast, defecate easily); type 2, emerging stools exhibiting a smooth snake or sausage shape with cracks in the surface (transit normally, defecate normally); and type 3, stools that appear as separate, hard or even nut-like lumps (transit slowly, defecate with difficulty).

Fecal sample preparation, bacterial cultivation and counting

Fecal samples were obtained in the morning and quantitatively cultured for aerobic, facultative and anaerobic bacteria using the methods defined by the Chinese Ministry of Health^[16]. Briefly, freshly voided feces were collected in a sterile box. Fecal samples (10 g) were homogenized and serially diluted in sterile anaerobic solution. Appropriate dilutions were incubated aerobically or anaerobically at 37°C in duplicate using selective media within 2 h after collection. The culture times and conditions are shown in Table 1. The target bacterial colonies on each medium at the corresponding dilution were counted, and the bacteria were subsequently characterized by Gram staining and analytical profile index (API) fermentation tests (bioMérieux, France). Colony counts were expressed as the log of colony forming units per gram of wet feces.

DNA extraction and PPAR- γ 2 genotyping

The Pro12Ala polymorphism of the PPAR- γ 2 gene was characterized using the polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) assay according to the previously published methods with minor modifications^[17]. Briefly, peripheral blood was collected into

EDTA-coated tubes. Genomic DNA was isolated using a genomic DNA purification kit (SBS Genetech, China). PCR was performed in a total volume of 50 μ L, containing 30 ng of DNA, 0.4 μ mol/L of each primer (forward: 5'-GCCAATTCAAGCCAGTC-3'; reverse: 5'-GATATGTTTGCAGACAGTGTATCAGTGAAGGAA-3'), 1 \times PCR buffer, 2 mmol/L of $MgCl_2$, 0.2 mmol/L of dNTP, and 4 U of *Taq* DNA polymerase (SBS Genetech, China). The PCR cycle conditions consisted of an initial denaturation at 94°C for 2 min followed by 35 cycles of denaturation at 95°C for 15 s, annealing at 58°C for 30 s and extension at 72°C for 30 s, with a final extension at 72°C for 10 min. Then, the PCR product (267 bp) was incubated with 1 U of *Hpa* II (Fermentas Life Sciences, Canada) for 4 h and digested fragments were separated by electrophoresis in a 3.5% agarose gel and visualized by staining with GoldView I (Solarbio, China). To improve the genotyping quality and validation, all samples were re-genotyped and the results were reproduced with no discrepancies.

Statistical analysis

The populations of six different types of bacteria were log-transformed for further analysis. Quantitative data were expressed as the mean \pm SD. The Student's *t* test was used to compare the amounts of cultivable bacteria in obese and normal-weight groups. Chi-squared tests were performed to analyze differences in qualitative data between the two groups. Abnormal distribution data were analyzed using nonparametric tests. The Hardy-Weinberg equilibrium was tested using the χ^2 test with one degree of freedom. Two-tailed *P* values less than 0.05 were considered statistically significant. The Statistical Program for Social Sciences 13.0 software (SPSS Inc., Chicago, IL) was used for all statistical analyses.

RESULTS

Clinical laboratory tests

A total of 104 participants were recruited for the study: 52 obese (18 females) and 52 normal-weight (26 females) individuals. A homogeneity test indicated that the two groups were comparable with respect to age and sex (Table 2). With regard to the results of the clinical laboratory examination, total cholesterol, triglycerides and fasting glucose in the obese group were considerably higher than those in the normal-weight group ($P < 0.01$). Leukocyte counts, granulocytes and intermediate cell counts in the obese group were significantly lower than those of normal-weight subjects ($P < 0.05$). No obvious differences between the obese and normal-weight groups were detected in other parameters (data not shown).

Questionnaire analysis

Physical activity and dietary intake of energy and macronutrients demonstrated no statistical differences between the two groups (data not shown). The results obtained for stool frequency and stool form scales are shown in Figures 1 and 2, respectively. For most people in the obese (44 of 52) and normal-weight (40 of 52) groups,

Table 2 Descriptive characteristics of the study groups (mean \pm SD)

	Obese (<i>n</i> = 52)	Normal-weight (<i>n</i> = 52)
Age (yr)	34.65 \pm 11.91	33.02 \pm 10.37
Sex		
Male	34	26
Female	18	26
Body mass index (kg/m ²)	30.79 \pm 2.80 ^b	20.26 \pm 1.50
Total cholesterol (mmol/L)	4.91 \pm 0.80 ^b	4.26 \pm 0.75
Triglycerides (mmol/L)	2.33 \pm 1.22 ^b	0.95 \pm 0.37
Fasting glucose (mmol/L)	5.42 \pm 0.88 ^b	4.90 \pm 0.45
Leukocyte counts ($\times 10^9$ /L)	6.96 \pm 1.71 ^b	5.85 \pm 1.49
Intermediate cells ($\times 10^9$ /L)	0.48 \pm 0.12 ^a	0.43 \pm 0.10
Granulocytes ($\times 10^9$ /L)	4.44 \pm 1.24 ^b	3.59 \pm 1.14

^a $P < 0.05$, ^b $P \leq 0.01$ vs the normal-weight group.

Figure 1 Stool frequency in obese and normal-weight groups. The obese group demonstrated a higher stool frequency ($U = 975$, $P < 0.001$).

stool frequency was once a day. However, stool frequency was higher in the obese group than in the normal-weight group (Figure 1; $U = 975$, $P < 0.001$). Furthermore, a notable difference in stool form scales was observed between the two groups (Figure 2; $U = 1062$, $P = 0.015$). In general, obese participants produced looser stools and defecated more easily than normal-weight controls.

Bacterial cultivation and counting

Quantitative bacterial studies (Table 3) demonstrated that the amount of *Bacteroides* and *Clostridium perfringens* (*C. perfringens*) in feces was significantly lower (*Bacteroides*, 9.81 ± 0.58 vs 10.06 ± 0.39 , $P = 0.012$; *C. perfringens*, 6.54 ± 0.65 vs 6.94 ± 0.57 , $P = 0.001$) in the obese group than in the normal-weight participants. No differences in the concentrations of *Escherichia coli*, *Enterococci*, *Lactobacilli* or *Bifidobacteria* were observed. However, there was a tendency for the amount of *Enterococci* to be higher in the obese group, despite the five other target bacteria demonstrating the reverse trend (Table 3).

Pro12Ala polymorphism in PPAR- γ 2 gene

The *PPAR- γ 2* gene polymorphism was analyzed in 88 subjects. The genotype frequencies were in Hardy-Weinberg

Figure 2 Stool form scale in obese and normal-weight groups. A substantial difference was observed in the stool form scale between the obese and normal-weight groups ($U = 1062$, $P < 0.05$). A greater number of participants in the normal-weight group demonstrated a type 2 (stools exhibiting a smooth snake or sausage shape with cracks in the surface) and type 3 (stools appearing in separate, hard lumps or even in a nut-like form) stool form compared with their obese counterparts (42 vs 34, 3 vs 1).

Table 3 Viable counts of the six gut bacteria in obese and normal-weight groups (mean \pm SD)

Bacterial groups	Obese ($n = 52$)	Normal-weight ($n = 52$)
<i>Bacteroides</i> ^a	9.81 \pm 0.58	10.06 \pm 0.39
<i>Escherichia coli</i>	7.76 \pm 0.92	8.09 \pm 0.81
<i>Enterococci</i>	7.53 \pm 1.05	7.27 \pm 2.07

Table 4 Genotype distribution and allele frequency of peroxisome proliferator-activated receptor $\gamma 2$ Pro12Ala n (%)

Group	Genotype			Allele	
	Pro/Pro	Pro/Ala	Ala/Ala	Pro	Ala
Obese group ($n = 41$)	33 (80.5)	8 (19.5)	0 (0)	74 (90.2)	8 (9.8)
Normal-weight group ($n = 47$)	40 (85.1)	7 (14.9)	0 (0)	87 (92.6)	7 (7.4)

equilibrium ($\chi^2 = 0.764$, $P = 0.382$). Pro/Pro and Pro/Ala were found in both obese and normal-weight groups; however, Ala/Ala was not detected in either group. No differences were observed in the distribution of Pro12Ala genotypes ($\chi^2 = 0.107$, $P = 0.743$) or allele frequencies ($\chi^2 = 0.300$, $P = 0.584$) between the groups (Table 4). A typical electrophoresis of the PPAR- $\gamma 2$ Pro12Ala polymorphism PCR product digested by *Hpa* II is presented in Figure 3.

Relationship between PPAR- $\gamma 2$ gene polymorphism and cultivable gut bacteria

The genetic effects of the Pro12Ala variant on the six gut bacteria were analyzed in the obese and normal-weight groups. No significant differences between the genotype groups, with respect to the six types of gut bacteria, were observed (data not shown) except in the obese group. Obese individuals with a Pro/Ala genotype had a lower amount of *Bacteroides* than those with a Pro/Pro genotype

Figure 3 Genotyping analysis of peroxisome proliferator-activated receptor $\gamma 2$ Pro12Ala polymorphism by polymerase chain reaction-restriction fragment length polymorphism. M: Molecular marker; PA: Pro/Ala heterozygote; PP: Pro/Pro homozygote.

(9.45 \pm 0.62 vs 9.93 \pm 0.51, $P = 0.027$). Moreover, in our study, obese Ala allele carriers had a slightly higher BMI value than obese participants without the Ala allele (31.88 \pm 3.26 vs 31.01 \pm 2.37, $P = 0.393$); however, the difference was not statistically significant.

DISCUSSION

Since the first publication on obesity and gut bacteria in 2004^[3], molecular analysis assays have been used to reveal differences in gut bacteria between obese and non-obese individuals as well as in animal models. Although 6 years have passed, data from large-scale human studies using culture methods are lacking, possibly because it is a time-consuming and labor-intensive process. However, culture methods are indispensable for studying the relationship between obesity and gut bacteria.

Our study is the first to use culture methods to analyze differences in fecal bacteria in more than 100 participants (52 obese and 52 normal-weight individuals). Our results demonstrated that the obese people had fewer cultivable *Bacteroides* than normal-weight individuals, which is consistent with previous studies that detected fewer *Bacteroides* in obese rodent models and humans using different molecular detection methods^[4,6,18,19]. Other studies indicated that the abundance of *Bacteroides* could promote the generation of propionate, which limits lipid synthesis from acetate and may contribute to a lean phenotype^[20,21]. Our study supports this by showing that a larger amount of cultivable *Bacteroides* occurs in normal-weight people; thus, altering the amount of this cultivable bacterium in obese individuals may help them lose weight.

Bacteroides are the most dominant group of bacteria in the gut and comprise at least four key species (*B. thetaiotaomicron*, *B. vulgatus*, *B. distasonis* and *B. fragilis*)^[22,23]. *B. thetaiotaomicron* salvages energy by breaking down numerous types of otherwise indigestible polysaccharides and helps shape the metabolic milieu of the intestinal ecosystem^[24-26]; however, symbiotic roles for other members of *Bacteroides* remain unclear. *In vitro* and *in vivo* culture methods, such as

the inoculation of target species of *Bacteroides* into animal models, could facilitate further studies on the role of the different *Bacteroides*. Culture methods can also help isolate and characterize specific cultivable *Bacteroides*, and strains with desirable traits may be applied in animal models to elucidate how their mechanisms of action may be associated with obesity.

In our study, the obese group also demonstrated a lower amount of *C. perfringens* than the normal-weight group. This ubiquitous bacterium is a normal inhabitant of the mammalian colon^[27]. A previous study demonstrated that *Clostridia* produces medium-length fatty acids that increase water absorption, dry up feces, weaken stool mobility and eventually result in constipation^[28]. Another study found that lower numbers of *C. perfringens* might enhance fecal moisture content^[29]. These results may help interpret our findings that the obese group had looser feces and higher stool frequencies (Figures 1 and 2), along with lower levels of *C. perfringens*. However, no study has previously shown that *C. perfringens* interferes with host energy balance, and the role of this bacteria in the development of obesity requires further studies.

Our study also found that the amount of *Enterococci* in the obese group was higher than that in the normal-weight group. *Enterococci* are the most controversial group of gut bacteria because of their beneficial and virulent characteristics^[30], and their role in the development of obesity remains unknown. The abundance of *Enterococci* in the obese group in our study indicates that they may play a role in the development of obesity; however, this has yet to be conclusively demonstrated.

Genetic variations and gut flora could both affect obesity status. Recent evidence^[31] suggests that factors related to host genotype have an important effect on determining the bacterial composition of the gastrointestinal tract. Our study evaluated the possible relationship between polymorphism of the *PPAR-γ2* gene and gut bacteria, and found that the obese Ala allele carriers had a lower amount of *Bacteroides* than their obese counterparts without the Ala allele. This may indicate an association between reduced *Bacteroides* in the gut and the obese Ala allele carriers (Pro/Ala, BMI ≥ 28 kg/m²).

Of the potential thrifty genes, *PPAR-γ2* plays a key role in modulating adipogenic differentiation^[11,12]. During the past decade, the relationship between Pro12Ala variants of the *PPAR-γ2* gene and the obese phenotype has been investigated. However, conclusions from the different studies have been inconsistent. To resolve the apparent discrepancies, a meta-analysis was carried out to evaluate data from 19 136 subjects in 30 independent studies. This analysis demonstrated that Ala allele carriers in a recessive model with a BMI above 27 kg/m² had a significantly higher BMI than noncarriers^[32]. As described above, a lower level of *Bacteroides* might be associated with obesity. Thus, the Pro12Ala variant of the *PPAR-γ2* gene may only have an effect on individuals with a higher BMI because of the collective actions of decreased *Bacteroides* levels in the gut, the Pro12Ala polymorphism and their complex interactions on obesity status.

In this study, we tested a relatively larger sample (52 participants for each group) and decreased numbers of *Bacteroides* and *C. perfringens* were found in the obese group. However, further studies are needed to make a clear conclusion on the relationship between gut bacteria and obesity. Our study also found that obese individuals with a Pro/Ala genotype had a statistically lower level of *Bacteroides* than obese participants with a Pro/Pro genotype. However, the relationship between genotype and gut bacteria requires further elucidation. Furthermore, as this study was only confined to a Chinese population, caution should be taken when extrapolating these results to other races.

In conclusion, this study provides for the first time the data on the differences between six types of gut bacteria in obese and normal-weight Chinese individuals in a large sample (104 participants) using culture methods. We found that the obese group exhibited a lower amount of *Bacteroides* and *C. perfringens*, and a slightly higher amount of *Enterococci* than the normal-weight group. This suggests that obesity may be combated through alteration of specific cultivable gut bacteria. Moreover, our results found that gut bacteria (*Bacteroides*) might be affected by variations in human genetic factors. These results indicate that interactions between gut flora, host genetic factors and the obese phenotype might lead to development of new measures for the prevention, intervention and treatment of obesity.

COMMENTS

Background

The development of obesity is associated with various factors, but the exact etiological mechanisms still remain unclear. Previous studies demonstrated that gut bacteria along with genetic factors might be important in obesity development.

Research frontiers

The relationship between gut bacteria and obesity has been addressed in several journals like Nature and Science in recent years. But the majority of the results are based on animal experiments or on studies that involved a small number of human samples using molecular analysis. Few reports have focused on the relationship between obesity-related genes and gut flora variation. In this study, the authors demonstrated the gut bacteria alteration in obese people using culture methods and its relationship with peroxisome proliferator-activated receptor $\gamma 2$ (*PPAR-γ2*) gene polymorphism.

Innovations and breakthroughs

Recent reports demonstrated less *Bacteroidetes* in obese rodent models and humans using different molecular detection methods, and it was also confirmed in this research by culture method. This study first noticed that the obese individuals with a Pro/Ala genotype had a lower level of *Bacteroides* than obese participants with a Pro/Pro genotype. These results indicate that there may be a relationship between gut bacteria, the *PPAR-γ2* gene and obesity.

Applications

The results of this study indicate that interactions between gut flora, host genetic factors and the obese phenotype might lead to development of new measures for the prevention, intervention and treatment of obesity.

Terminology

The *PPAR-γ2* gene is one of the potential thrifty genes, which encodes the nuclear hormone receptor *PPAR-γ2*. This hormone receptor is selectively expressed in adipose tissue and is strongly up-regulated during adipogenesis, suggesting that it has a specific role in fat-cell differentiation. Thus, the *PPAR-γ2* gene might be related to the development of obesity.

Peer review

The work was well carried out and the manuscript is well written and includes potentially interesting findings.

Abstract

AIM: To compare the efficacy and safety of paclitaxel combined with fluorouracil plus cisplatin (PCF), and oxaliplatin combined with fluorouracil plus leucovorin (FOLFOX-4) regimens for advanced gastric cancer (AGC).

METHODS: Ninety-four patients with AGC were randomly assigned to receive paclitaxel (50 mg/m² iv) on days 1, 8 and 15, cisplatin (20 mg/m² iv) and fluorouracil (750 mg/m² iv) on days 1-5, or oxaliplatin (85 mg/m² iv) and leucovorin (200 mg/m² iv) on day 1, followed by bolus fluorouracil (400 mg/m² iv) and fluorouracil (600 mg/m² iv) on days 1 and 2. The primary end point was the 1-year survival time.

RESULTS: The overall response rate (ORR) of the pa-

tients was 48.0% and 45.5% to PCF and FOLFOX-4, respectively. The disease control rate (DCR) of PCF and FOLFOX-4 was 82.0% and 81.8%, respectively. The median survival times (MSTs) of the patients were 10.8 and 9.9 mo, respectively, after treatment with PCF and FOLFOX-4. The 1-year survival rate of the patients was 36.0% and 34.1%, respectively, after treatment with PCF and FOLFOX-4. No significant difference was observed in ORR, DCR, MST or 1-year survival rate between the two groups. The most common adverse events were anemia, nausea and vomiting, and grade 3/4 alopecia in PCF treatment group, and anemia, grade 1/2 neurotoxic effect and grade 3/4 neutropenia in FOLFOX-4 treatment group.

CONCLUSION: Patients with AGC have a similar response rate to PCF and FOLFOX-4 regimens with a similar survival rate. The PCF and FOLFOX-4 regimens are efficacious and tolerable as a promising therapy for AGC.

Li XD, Shen H, Jiang JT, Zhang HZ, Zheng X, Shu YQ, Wu CP. Paclitaxel based vs oxaliplatin based regimens for advanced gastric cancer. *World J Gastroenterol* 2011; 17(8): 1082-1087 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v17/i8/1082.htm> DOI: <http://dx.doi.org/10.3748/wjg.v17.i8.1082>

INTRODUCTION

Gastric cancer is the second leading cause of cancer-relat-

ed death worldwide, with the highest incidence in Eastern Asian and European countries^[1]. The incidence of gastric cancer in Jiangsu Province of China is particularly high, and the death rate is much higher than the national average^[2]. Unfortunately, most patients with advanced gastric cancer (AGC) have a miserable outcome. Even after curative gastrectomy, 60% of AGC patients develop local recurrences or distant metastasis^[3-5].

Although the efficacy of palliative chemotherapy is now widely accepted^[6-8], no chemotherapeutic regimen has been established as the consensus standard treatment for AGC. Among various chemotherapy regimens, paclitaxel combined with fluorouracil plus cisplatin (PCF) and oxaliplatin combined with fluorouracil plus leucovorin (FOLFOX-4) regimens are the two commonly used modalities.

It has been demonstrated that paclitaxel, an anticancer agent which binds to microtubules and induces hyperstabilization leading to cell cycle arrest and apoptosis^[9,10], has a promising efficacy against gastric cancer. The response rate of gastric cancer patients to it is about 20%-25%, and the median response time of gastric cancer patients is about 7 mo after treatment with paclitaxel^[11-13]. It was reported that the response rate of patients with gastric cancer to PCF regimen is 33%^[14-17].

Oxaliplatin, a third-generation diaminocyclohexane platinum compound that has a wide range of antitumor activities, appears to have a better safety profile than cisplatin in terms of nausea, vomiting, nephrotoxicity, and ototoxicity^[18,19]. The response rate of AGC patients to FOLFOX-4 regimen is 38%-43% and FOLFOX-4 regimen shows a manageable toxicity profile as the first-line treatment modality for AGC^[20-24].

As is commonly known, there is only one best regimen at one time. No study is available comparing the efficacy and safety of PCF and FOLFOX-4 regimens. Therefore, we designed the present study to observe the therapeutic indexes of the two regimens for AGC.

MATERIALS AND METHODS

Patients

The inclusion criteria for AGC patients were (1) pathologically proved locally advanced (non-resectable) or metastatic gastric cancer; (2) age between 20 and 75 years; (3) measurable or assessable lesions by imaging studies according to the RECIST guidelines^[25]; (4) no prior chemotherapy except for postoperative adjuvant chemotherapy for more than 12 mo before entry into the study; (5) Eastern Cooperative Oncology Group (ECOG) performance status 0-2; (6) adequate bone marrow functions (hemoglobin level ≥ 90 g/L, white blood cell count of $4-10 \times 10^9$ /L, neutrophil count $\geq 2 \times 10^9$ /L, and platelet count $\geq 100 \times 10^9$ /L), hepatic function (total bilirubin $\leq 1.5 \times$ the institutional upper limit of normal value, aspartate aminotransferase/alanine aminotransferase $\leq 2.5 \times$ the institutional upper limit of normal value, and

alkaline phosphatase $\leq 2.5 \times$ the institutional upper limit of normal value), renal function (serum creatinine level ≤ 1.5 mg/dL and creatinine clearance ≥ 50 mL/min); and (7) estimated life expectancy of at least 3 mo and no other malignancies.

The exclusion criteria for patients included (1) pre-existing peripheral toxicity \geq grade 2 of the National Cancer Institute Common Toxicity Criteria (NCI-CTC, Version 3.0); (2) pregnant, and breastfeeding women or women of child-bearing potential without adequate contraception; (3) concurrent or prior malignancy; (4) central nervous system metastases; (5) active infection; (6) other uncontrolled underlying medical conditions that would impair the ability of the patients to receive the planned treatment; (7) inadequate calorie and fluid intake; and (8) concurrent treatment that interfered with the study evaluation.

The study, approved by the ethics committees of all participating medical institutions, was conducted according to the principles of the Declaration of Helsinki and Good Clinical Practice Guidelines. All patients gave their written informed consent before enrollment.

Treatment methods

The patients were divided into PCF group and FOLFOX-4 group. Patients in the PCF group received paclitaxel (50 mg/m^2 iv) for 3 h on days 1, 8 and 15, cisplatin (20 mg/m^2 iv) for 2 h on days 1-5, fluorouracil (750 mg/m^2 iv) for 24 h for 5 d. The treatment was repeated every 28 d for 6 cycles. Patients in the FOLFOX-4 group received oxaliplatin (85 mg/m^2 iv) and leucovorin (200 mg/m^2 iv) for 2 h on day 1, bolus fluorouracil (400 mg/m^2 iv) and fluorouracil (600 mg/m^2 iv) for 22 h on days 1 and 2. The treatment was repeated every 14 d for 12 cycles.

The dose was modified based on the hematologic parameters and the degree of non-hematologic toxicities. Physical examination, chest X-ray, complete blood test and biochemical tests were performed before each chemotherapy cycle. The toxicity was graded based on the NCI-CTC (Version 3.0).

Dose modification

The dose was modified for the PCF group as follows: (1) If the hepatotoxicity was grade 2, the dose of paclitaxel for the following treatment was reduced to 40 mg/m^2 on days 1, 8 and 15. If the hepatotoxicity was grade 3/4, the study was discontinued; (2) If the bone marrow suppression was grade 4, the dose of paclitaxel for the following treatment was reduced to 40 mg/m^2 on days 1, 8 and 15. If the bone marrow suppression was grade 4, the study was discontinued; (3) If the mucositis was grade 3/4, fluorouracil was administered from the next cycle for 3 d; and (4) If the creatinine clearance rate was 30-50 mL/min due to the nephrotoxicity, the dose of cisplatin was reduced by 50%. If the creatinine clearance rate was lower than 30 mL/min, the study was discontinued.

The dose was modified for the FOLFOX-4 group as

follows: (1) If the neurotoxic effect was grade 1/2, the dose of oxaliplatin was reduced by 25%. If the neurotoxic effect was grade 3/4 or persistent, the oxaliplatin was omitted from the regimen until the neurotoxic effect was resolved to grade 1 or better; (2) If the mucositis was grade 3/4, fluorouracil was administered from the next cycle for 3 d; and (3) If grade 3/4 diarrhea, stomatitis or dermatitis occurred, the dose of fluorouracil was reduced by 25%.

Evaluation

The parameters of 12-lead electrocardiogram, computed tomography (CT) scan, and levels of tumor markers (CA19-9, CA72-4, CA24-2 and carcinoembryonic antigen) were obtained from the patients within 7 d after enrollment. Hematology tests, biochemistry tests, and assessment of symptoms and signs were carried out for the patients within 3 d before enrollment and every week during the study period. CT scans were carried out and levels of tumor markers were measured before each cycle. According to the RECIST guidelines^[17], responses concluded complete response (CR), partial response (PR), stable disease (SD), and progressive disease (PD). To confirm the PR or CR, the levels of tumor markers were measured no less than 4 wk after the objective response was obtained. Responses were assessed by the independent review committee. The overall response rate (ORR) was defined as the sum of CR and PR rates. The disease control rate (DCR) was defined as the sum of CR, PR and SD rates. Toxic effects were evaluated according to the NCI-CTC (Version 3.0). The overall survival time (OST) was defined as the period from the date of treatment to the death of patients. The median survival time (MST) was defined as the half of OST.

Statistical analysis

Statistical analysis was performed with the SPSS software (Version 17.0, SPSS). Chi-square test was used to compare the categorical data. KaplanMeier method was used to calculate the OST. Logrank test was used to compare the OST. $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of patients

From January 2003 to December 2007, 94 patients were enrolled in this study. The baseline clinical characteristics of the patients were compared between the two groups (Table 1). No significant difference was observed in any clinical characteristics between the two groups.

Objective response

All the patients were evaluated for their response to PCF and FOLFOX-4 regimens and no patient was excluded from the efficacy analysis because of severe side effects.

Of the patients in PCF group, 1 achieved a CR and 23 a PR, 17 had SD, and 9 PD, with an ORR of 48%. The re-

PCF: Paclitaxel combined with fluorouracil plus cisplatin; FOLFOX-4: Oxaliplatin combined with fluorouracil plus leucovorin.

sponse rate of patients who received prior chemotherapy to PCF was 52.6% (20/38) and 33.3% (4/12), respectively, with a DCR of 82.0%.

Of the patients in FOLFOX-4 group, 1 achieved a CR and 19 a PR, and 16 had SD and 8 PD, with an ORR of 45.5%. The response rate of patients who received prior chemotherapy to FOLFOX-4 was 54.8% (17/31) and 23.1% (3/13), respectively, with a DCR of 81.8%. No significance was observed in ORR and DCR between the two groups.

Survival analysis

The MST and the 1-year survival rate of patients in the PCF group was 10.8 mo (95% CI: 8.9-12.7 mo) and 36.0%, respectively.

The MST and the 1-year survival rate of patients in the FOLFOX-4 group was 9.9 mo (95% CI: 8.3-11.4 mo) and 34.1%, respectively.

No significant difference was found in MST and survival rate between the two groups (Figure 1).

Profile of safety and adverse events

No patient was excluded from the efficacy analysis because of severe side effects. Grade 3/4 neutropenia occurred in 8% and 10% of patients in the PCF and FOLFOX-4 groups, respectively. Anemia occurred in 60% and 57% of patients in the PCF and FOLFOX-4 groups, respectively. Nausea and vomiting occurred in 12.0% and 9% of patients in the PCF and FOLFOX-4 groups, respectively.

Figure 1 Overall survival curves for patients in PCF and FOLFOX-4 groups. PCF: Paclitaxel combined with fluorouracil plus cisplatin; FOLFOX-4: Oxaliplatin combined with fluorouracil plus leucovorin.

Grade 3/4 alopecia occurred in 10.0% and 0% of patients in the PCF group and FOLFOX-4 group, respectively ($P < 0.05$). Grade 1/2 neurotoxic effect was observed in 6% and 17% of patients in the PCF group and FOLFOX-4 group, respectively ($P < 0.05$).

Diarrhea, hepatic or renal toxicities and oral mucosa ulcer were relatively infrequent and slight.

DISCUSSION

In China, gastric cancer patients are usually diagnosed at a relative advanced stage with metastasis to other organs^[26]. Although a number of treatment modalities for gastric cancer such as surgical resection combined with chemotherapy are available^[27,28], no current regimen can be considered a standard therapy for AGC, thus new therapeutic strategies are required to achieve a better clinical efficacy with an acceptable toxicity profile. PCF and FOLFOX-4 regimens are commonly used as the first-line therapy for AGC. The efficacies of the two regimens against AGC are similar with different adverse events.

Taxane is one of the three milestones of anti-cancer drugs, used in the 1990s. It was reported that the ORR of AGC patients to PCF is 34%-52%^[13]. The survival time of most AGC patients does not exceed 12 mo after PCF therapy with taxane or 5-FU plus cisplatin^[11,12]. Kim *et al*^[14] reported that the MST of AGC patients is 13.2 mo. The results of this study are consistent with the reported findings^[11,12]. Overall, the efficacy of PCF against AGC is stable.

Oxaliplatin has been used in treatment of advanced colorectal carcinoma. It has been shown that the response rate of patients with advanced colorectal carcinoma to oxaliplatin in combination with fluorouracil is 36%-58%^[29-31]. Vita *et al*^[32] revealed that the ORR of patients with advanced colorectal carcinoma to oxaliplatin is 38% with a TTP of 7.1 mo and an OST of 11.2 mo. The results of the current study indicate that a biweekly FOLFOX-4 regimen can significantly improve the symptoms of AGC patients. The decreased ORR observed in our study might be related to the selected gastric cancer patients at IIIb

or IV stage. Considering the smaller sample size and the modified doses in the present study, further study is warranted to confirm the results.

It was reported that the toxic rate of FOLFOX-4 regimen for grade 3/4 neutropenia, and nausea and vomiting is 7.6%-34% and 4%-18.1%, respectively^[13], which is consistent with our results. In the present study, the neurotoxic rate of FOLFOX-4 regimen for diarrhea and oral mucosa ulcer was low, which might be due to the low PS score. The reported neurotoxic rate of PCF regimen for grade 3/4 neutropenia is 22%-86%^[12,33], which is also consistent with our results. Alopecia occurred more frequently in PCF group than in FOLFOX-4 group, and vice versa. Overall, these regimens may not only prolong the survival time but also for improve the life quality of gastric cancer patients.

In summary, both PCF and FOLFOX-4 regimens can be used in treatment of AGC. Further study is warranted to confirm the results of this study.

COMMENTS

Background

Gastric cancer is the second most common cause of cancer-related death globally. Its incidence is the highest in Eastern Asian and European countries. Unfortunately, most gastric cancer patients are at the advanced stage when they are diagnosed. The outcome of patients with advanced gastric cancer (AGC) is poor. Chemotherapy is often used for AGC and its efficacy is now widely accepted. However, no standard combination of chemical drugs has been established. Among the different combinations, paclitaxel combined with fluorouracil plus cisplatin (PCF) and oxaliplatin combined with fluorouracil plus leucovorin (FOLFOX-4) regimens are the two commonly used modalities. There is only one best regimen at one time. No study comparing the efficacy and safety of PCF and FOLFOX-4 regimens is available at present. Therefore, we designed the present phase-2 study to observe the therapeutic indexes of the two regimens for AGC.

Research frontiers

No current regimen can be considered as a standard therapy for AGC. PCF and FOLFOX-4 regimens are the commonly used first-line therapy for AGC. The overall survival rate (ORR) of AGC patients is 34%-52% after PCF therapy. The survival time of most AGC patients after PCF therapy with taxane, or 5-FU plus cisplatin does not exceed 12 mo. It was reported that the response rate of AGC patients to FOLFOX-4 regimen is 36%-58%. Both PCF and FOLFOX-4 regimens can be used in treatment of AGC.

Innovations and breakthroughs

No study comparing the efficacy and safety of PCF and FOLFOX-4 regimens. Therefore, we designed the present phase II study to observe the therapeutic indexes of the two regimens for AGC. The results of this study show that the two regimens are benefit not only for survival but also for quality of life patients after resection of colorectal cancer.

Applications

PCF regimen can be used for those who need to do fine jobs, and FOLFOX-4 regimen can be used for those who care more about their appearance. The current study may help patients to take more consideration about various demands in daily life.

Peer review

The present study provides important data about PCF and FOLFOX-4 regimens for gastric cancer and the article is well written.

INTRODUCTION

Colonoscopy is considered a safe procedure, although complications can occur. The most dreaded of these is iatrogenic perforation. The literature reports perforation rates of 0.03%-0.8% for diagnostic procedures, and a rate of 0.15%-3% for therapeutic procedures^[1]. Mechanisms of perforation are the result of either mechanical disruption of the colonic wall (e.g. thermal injury, forced push into a diverticulum, or stretching of the bowel with loops or the slide-by technique) or excessive air insufflation^[1]. After perforation, prompt abdominal surgery is usually recommended, particularly in the last few years, following the introduction of laparoscopic approaches in clinical practice^[2,3]. Nevertheless, conservative treatment is a feasible and effective option for patients who are clinically stable and without peritonism or life threatening signs. We describe a case of a sigmoid perforation repaired with endoclips and endoloops, and sealed with fibrin glue. The effectiveness of this approach was confirmed on laparoscopic examination.

CASE REPORT

A 63-year-old male with a history of polypectomy for a large polyp of the caecum was admitted to our department for a scheduled colonoscopy. Physical examination, blood chemistry and coagulation tests were normal. After obtaining informed consent, the colonoscopy was per-

Abstract

We report a case of a 63-year-old male who experienced an iatrogenic sigmoid perforation repaired combining three endoscopic techniques. The lesion was large and irregular with three discrete perforations, therefore, we decided to close it by placing one clip per perforation, and then connecting all the clips with two endoloops. Finally we chose to use a fibrin glue injection to obtain a complete sealing. Four days after the colonoscopy the patient underwent a laparoscopic right hemicolectomy due to evidence of a large polyp of the caecum with high grade dysplasia and focal carcinoma *in situ*. Inspection of the sigma showed complete repair of the perforation. This report underlines how a conservative approach, together with a combination of various endoscopic techniques, can resolve complicated iatrogenic perforations of the colon.

Key words: Colonic perforation; Endoscopic treatment; Fibrin glue injection; Tulip bundle technique

Figure 1 Figure shows the colonic perforation (A), two borders of the perforation did not fit well (arrow) after clips and endoloops placement (B) and completely sealing after fibrin glue injection (C, D).

formed under conscious sedation (propofol). The colon was quite clean, and the colonoscopy proceeded without difficulty, lasting 15 min. Caecum examination, at the same site of the previous polypectomy, showed a large sessile polyp (4 cm in diameter), which was biopsied. No other polyps were detected, although in the sigma, in an environment of diverticula and hyperaemic mucosa, a large and irregular lesion (2.5 cm with 3 discrete perforations) was observed (Figure 1A). The patient's blood pressure, heart rate and O₂ saturation were normal. Due to the form of the lesion, we believed that repair with endoclips alone would have been ineffective, so we decided to close it by placing through-the-scope endoclips over each perforation of the lesion (one clip per perforation), and then connecting all the clips with two endoloops (Figure 1B). Each endoloop was tightened slightly and the endoclips were anchored together securely. However, at the base, two borders of the perforation did not fit well (Figure 1B, arrow), so we chose to use a fibrin glue (Beriplast P®), injected into the submucosa, and obtained complete sealing (Figure 1C and D). Four days after the colonoscopy, the patient underwent a laparoscopic right hemicolectomy due to evidence of high grade dysplasia with focal carcinoma *in situ*, revealed by biopsies of the polyp. Inspection of the sigma showed complete repair of the perforation (Figure 2, arrow). The patient was able to resume oral diet 4 d later and was discharged 7 d later.

Figure 2 Complete repair of the perforation at laparoscopy (arrow).

a diagnostic, therapeutic, and screening tool^[4]. It is safe, with a low rate of perforation (a post-procedure incidence of 0.082% at 7 d in a population-based study of 277 434 colonoscopies^[5]). Risk factors are increasing age, significant comorbidities, obstruction as an indication for colonoscopy, diverticulosis, and invasive interventions during colonoscopy^[3]. Despite the fact that laparoscopic resection is effective in resolving colonic perforation caused by colonoscopy^[2], recent improvements in endoscopic techniques have made it possible to close iatrogenic colonic perforations using mini-invasive procedures. Repair with endoclips has been well described in the literature since 1997^[6-8]. Furthermore, large or difficult intestinal perforations can be treated with a combined placement of endoclips and endoloops, as recently reported by Nakagawa *et al*^[9]. There is little documentation of the use

DISCUSSION

Colonoscopy has played an increasingly important role as

of fibrin sealant for repairing perforations^[10], however, some reports suggest that endoclip placement with fibrin glue sealing is effective in repairing benign lesions, such as fistulas^[11]. In our patient, conservative treatment of the colonic perforation was quite difficult because of both the size and shape of the lesion. An approach using only endoclips may have proved to be ineffective, but endoloop placement made it possible to anchor the clips together. Unfortunately, when closed with the endoloops, the star-like points of the lesion did not fully close the perforation, so we decided to seal the base of the perforation with a submucosal injection of fibrin glue. This conservative approach resulted in full closure of the lesion, as subsequently confirmed by laparoscopic examination.

This report underlines how a conservative approach, together with a combination of various endoscopic techniques, can resolve complicated perforations without the need for surgical intervention.

Meetings

Events Calendar 2011

January 14-15, 2011
AGA Clinical Congress of
Gastroenterology and Hepatology:
Best Practices in 2011 Miami, FL
33101, United States

January 20-22, 2011
Gastrointestinal Cancers Symposium
2011, San Francisco, CA 94143,
United States

January 27-28, 2011
Falk Workshop, Liver and
Immunology, Medical University,
Franz-Josef-Strauss-Allee 11, 93053
Regensburg, Germany

January 28-29, 2011
9. Gastro Forum München, Munich,
Germany

February 4-5, 2011
13th Duesseldorf International
Endoscopy Symposium,
Duesseldorf, Germany

February 13-27, 2011
Gastroenterology: New Zealand
CME Cruise Conference, Sydney,
NSW, Australia

February 17-20, 2011
APASL 2011-The 21st Conference of
the Asian Pacific Association for the
Study of the Liver
Bangkok, Thailand

February 22, 2011-March 04, 2011
Canadian Digestive Diseases Week
2011, Vancouver, BC, Canada

February 24-26, 2011
Inflammatory Bowel Diseases
2011-6th Congress of the European
Crohn's and Colitis Organisation,
Dublin, Ireland

February 24-26, 2011
2nd International Congress on
Abdominal Obesity, Buenos Aires,
Brazil

February 24-26, 2011
International Colorectal Disease
Symposium 2011, Hong Kong, China

February 26-March 1, 2011
Canadian Digestive Diseases Week,

Westin Bayshore, Vancouver, British
Columbia, Canada

February 28-March 1, 2011
Childhood & Adolescent Obesity:
A whole-system strategic approach,
Abu Dhabi, United Arab Emirates

March 3-5, 2011
42nd Annual Topics in Internal
Medicine, Gainesville, FL 32614,
United States

March 7-11, 2011
Infectious Diseases: Adult Issues
in the Outpatient and Inpatient
Settings, Sarasota, FL 34234,
United States

March 14-17, 2011
British Society of Gastroenterology
Annual Meeting 2011, Birmingham,
England, United Kingdom

March 17-19, 2011
41. Kongress der Deutschen
Gesellschaft für Endoskopie und
Bildgebende Verfahren e.V., Munich,
Germany

March 17-20, 2011
Mayo Clinic Gastroenterology &
Hepatology 2011, Jacksonville, FL
34234, United States

March 18, 2011
UC Davis Health Informatics:
Change Management and Health
Informatics, The Keys to Health
Reform, Sacramento, CA 94143,
United States

March 25-27, 2011

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organizations]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit on-

line. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review.

Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use

Instructions to authors

uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of P values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date,

volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Instructions to authors

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make com-

ments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.
