Elevated intestinal permeability is implicated in the pathogenesis of a wide variety of diseases, including those of liver[126,127]. While the translocation of whole bacteria across the intact intestinal wall is unusual, the inflamed gut is permissive to bacterial-derived products, including endotoxin, which acts as TLR4 ligand and is considered a 2nd hit in the pathogenesis of several liver diseases, including non-alcoholic fatty liver disease and ALD[12,13,126,127]. In this context, it has been hypothesized that gut colonization plays a key role in the pathogenesis of liver diseases. Campylobacter species represent a risk factor for the development of inflammation in the GI tract via largely unknown mechanisms. Kalischuk et al[128] reported that Campylobacter jejuni (C. jejuni) induced translocation of commensal intestinal bacteria to the liver of infected mice. In vitro Campylobacter-induced internalization and translocation of Escherichia coli (E. coli) occurred via a transcellular pathway without increasing epithelial permeability; this process was blocked by cholesterol depletion and thus LR impairment[128]. Invasion-defective mutants and Campylobacter-conditioned cell culture medium also favored E. coli translocation, indicating that C. jejuni does not directly "shuttle" other bacteria into enterocytes. In C. jejuni-treated epithelial monolayers, translocating E. coli was associated with LRs and this phenomenon was blocked by cholesterol depletion[128]. However, translocation of commensals does not require the presence of active infection with pathogens at the intestinal epithelial border. Clark et al[129] reported that interferon (IFN)-γ influences the epithelium to mediate transcellular translocation of E. coli C25; this process required intact LRs. These data suggest that intestinal LRs are key to establishing leaky gut, which in turn plays a role in the pathogenesis of liver diseases; it remains to be identified whether liver infection with translocated commensal intestinal bacteria is mediated by the LRs in hepatocytes.

Role of LRs in viral infections of liver: (1) Hepatitis C virus (HCV). The lifecycle of HCV is dependent on the integrity of LRs. Using a subgenomic HCV replicon system, Aizaki et al[130] showed that HCV RNA synthesis occurs in LRs. HCV replication complex is highly dependent on the abundance of cholesterol and it is protected within LRs; only LRs that contain both non-structural proteins and viral RNA were capable of performing HCV RNA synthesis using the endogenous HCV RNA template, while depletion of cellular cholesterol selectively reduced HCV RNA replication[130]. However, the virus has preferences for specific types of LRs. Core protein, for example, does not colocalize with classical PM LR markers, such as

caveolin-1 and the B subunit of cholera toxin, suggesting that core protein is bound to cytoplasmic raft microdomains distinct from caveolin-based LRs[131]. Furthermore, while both the structural core and NS5A protein associate with membranes, they do not always colocalize in the LR. Finally, the ability of core protein to localize to the LRs does not require other elements of the HCV polyprotein[131]. These results suggest that the LR implications in HCV lifecycle are complex and require further investigation. Nevertheless, HCV takes over LR control in the host cells and leads to modification of host LR-resident proteome upon its replication[131]. Roughly 10% of proteins residing in LRs of HUH7 cells are modified by HCV presence[132]. Interestingly, the majority of the host proteins involved in HCV recognition/internalization/sensing[133] including CD81, claudins, TLR2, LDL-R, Scavenger Receptor type B, and DC-SIGN/L-SIGN reside in LRs[134-140]. It is thus plausible to foresee that LR modulation may have a place in anti-HCV therapy; the proof of this hypothesis is awaited; (2) Hepatitis B virus (HBV). Funk et al[141] identified that duck hepatitis B virus (DHBV) attaches predominantly to detergent-soluble LR domains on the PM, but that cholesterol depletion from host membranes and thus disruption of LRs does not affect DHBV infection. In contrast, depletion of cholesterol from the envelope of both DHBV and human HBV strongly reduces virus infectivity[141]. Cholesterol depletion increases the density of viral particles and leads to changes in the ultrastructural appearance of the virus envelope; the infectivity and density of viral particles were partially restored upon cholesterol replenishment. Binding and entry of cholesterol-deficient DHBV into hepatocytes were not significantly impaired, in contrast to their release from endosomes. The authors therefore concluded that viral, but not host cholesterol is required for endosomal escape of DHBV[141]. Bremer et al[142] did not confirm a role of LRs in viral binding, but identified that LRs are indispensable for the entry process of HBV and might be important for a later step in viral uptake, such as fusion in a yet-unknown compartment.

Cholesterol accumulation/storage diseases

Niemann-Pick type C disease (NPCD) is a lysosomal storage disorder that affects the neural system and viscera, including liver[143,144]. Defective trafficking of cholesterol, sphingolipids and fatty acids leading to endosomal cholesterol sequestration coupled to impaired cholesterol transport to PM and ER were identified as key in the pathogenesis of NPCD[145]. Sequestration of cholesterol/sphingolipid-rich LRs in the late endosomal compartment was also reported in NPCD[146,147]. Vainio et al[76] reported a significant perturbation of LR composition and LR-dependent signaling in NPCD livers. They also showed that the membrane of NPCD hepatocytes is stabilized with cholesterol, exhibits higher anisotropy and resides in a more ordered phase; i.e. it is less fluid and thus has higher ratio of raft/non-raft content, compared to normal hepatocytes. More importantly, these rigid LRs lead to

increased expression and enrichment of IR in the membrane of NPCD hepatocytes. Further, IR redistribution was associated with its defective function, thus aggravating the metabolic syndrome in NPCD[76].

Alcohol-induced liver disease

Alcohol exposure is associated with a significant amount of ROS production, which leads to oxidative stress[148-156]. While the generation of alcohol-induced oxidative stress is well documented, the understanding of the effects of oxidative stress on different molecular systems is poor. Marquês et al[46] employed in situ AFM to show that low ethanol concentrations lead to a marked thinning of the fluid but not of the gel domains of the model membranes, due to water/bilayer interfacial tension variation and freezing point depression, induction of acyl chain disordering (including opening and looping), tilting, and interdigitation. These results suggested that ethanol influences the bilayer properties by altering the lateral organization of the membrane. Several groups have confirmed the pivotal role of membrane fluidity in ethanol-induced oxidative stress using both in vitro and in vivo models of alcohol exposure[150-156]; however, the role of LRs per se in this process is still under evaluated.

In primary rat hepatocytes, short-term alcohol exposure increases membrane fluidity and leads to ethanol-induced ROS generation, which interferes with mitochondria, ER, cytochrome P450, cytosolic free iron, and cytosolic enzymes such as xanthine oxidase or aldehyde oxidases[153,154,157]. More recently, it was appreciated that LRs play a pivotal role in ethanol-induced oxidative stress in hepatocytes[152]. Alcohol exposure modulates the LR composition of hepatocytes, causes spontaneous clustering of LRs due to elevation in membrane fluidity, and promotes the increase of low-molecular-weight iron intracellular content via the activation of a PI-PLC-dependent mechanism. Further, ethanol oxidizes the LR proteins, as indicated by the increased LR content of malondialdehyde-acetaldehyde (MDA) adduct, which is a secondary end product of the degradation of oxidized PUFAs that can diffuse from its production site to react with free amino groups in proteins and lipids. From the therapeutic point of view, thiourea and vitamin E pretreatment inhibited the alcohol-induced MDA adduct formation in LRs[152]. The effects of chronic alcohol exposure on LR function in hepatocytes are largely unknown.

Alcohol exposure affects the Shh signaling in an in vivo model of fetal alcohol syndrome in zebrafish[90]. Various cell function alterations due to changes in cell membrane composition in alcohol-induced fetal damage have also been described[15]. Mao et al[90] identified that alcohol does not significantly interrupt translation of Shh mRNA in ER or the trafficking of Shh from the ER to the Golgi apparatus in the SC line HSC8B. However, alcohol does prevent the entry of Shh into transport vesicles from Golgi to PM and specifically decreases the amount of caveolin-1/Shh complex found in LRs, causing cytoplasmic accumulation of Shh and leading to a deficiency of Shh

ligand secretion into the extracellular matrix[90]. These data indicate that SC-mediated tissue remodeling upon alcohol exposure involves LRs.

In macrophages, and presumably KCs, acute alcohol exposure dampens the inflammatory response to pathogens *via* TLRs in a LR-dependent manner and involves downregulation of MAPK activity, low nuclear factor κB activity and impaired TNF-α production[81,82,158]. Such profound inhibitory effects could be envisioned as a protective measure; the effects of chronic alcohol exposure on LR function in Mf are largely unknown.

RAFTS AS THERAPEUTIC TARGETS

Development of new treatment strategies using low-toxicity high-efficiency chemotherapeutic agents is a forefront priority in research. Several novel approaches to therapeutic agents are based on LRs. In drug discovery, a viable strategy to block viral entry and its replication may incorporate the use of natural dietary and plant-derived compounds that target LRs; this strategy is based on the affinity of these products to cholesterol, as proposed in a recent review by Verma regarding HIV[159]. The nanoparticle-based drug-delivery approach for delivery of lipophilic substances to the target cell PM acts *via* lipid mixing and subsequent intracellular trafficking through LR-dependent processes[160]; the advantage of the latter strategy is in its ability to deliver therapeutics specifically to selected cell types, thus limiting general toxicity.

Regulation of cell death is yet another area influenced by LR modulation. Cell death occurs at low rate in normal tissue and stimulates tissue regeneration as part of normal organ lifecycle; when the tissue is malignant the cell death is deliberately desired. LRs ensure the connection between extrinsic and intrinsic apoptotic pathways[161,162], thus become an attractive therapeutic target. The Fas death receptor (CD95 or APO-1) delivers apoptotic signals through binding to its cognate ligand, FasL (CD95L). However, because of severe liver toxicity due to the high presence of Fas in hepatocytes, the putative clinical antitumor action of FasL cannot be accomplished for extra-hepatic tumors; the utility of this approach for liver tumors is yet to be defined. Recent evidence for FasL-independent activation of Fas suggests that the death receptor can also be activated intracellularly, in the absence of its ligand. According to Mollinedo *et al*[161], Fas-mediated apoptosis involves translocation of Fas - and downstream signaling molecules - into LRs, a process that can be pharmacologically modulated. FasL-independent clustering of Fas in membrane LRs generates high local concentrations of death receptor, providing scaffolds for coupling adaptor and effector proteins involved in Fas-mediated apoptosis. Thus, LRs act as the linchpin from which a potent death signal is launched and have become a new promising anticancer target[161-164]. The utility of this therapeutic approach has been explored in B cell malignancy[120,121,163] and seems plausible for other diseases.

Sakamoto *et al*[165] reported that a secondary fungal metabolite, NA255, which targets LRs, also inhibits HCV replication and suggested that the inhibition of sphingolipid metabolism and thus LR modulation may provide a new therapeutic strategy for treatment of HCV infection. Hirata showed that serine palmitoyltransferase (SerPT) inhibitor had the ability to favor the transport of HCV RNA-dependent RNA polymerase NS5B to LRs, thus facilitating binding of sphingomyelin to NS5B[166]. Further, the authors identified that the anti-HCV effect of SerPT inhibitor could be translated to *in vivo* systems using humanized chimeric mice: SerPT inhibitor led to a rapid decline in serum HCV-RNA of about 1-2 log within 8 d. Furthermore, combination therapy of SerPT inhibitor and PEG-IFN achieved about 3 log reduction in serum HCV-RNA[166]. Several research groups have reported that lipid metabolism could be a target in anti-HCV therapy[165-167]. Amemiya *et al*[167] used combination treatment with myriocin, a sphingomyelin synthesis inhibitor, and IFN, a pleiotropic cytokine, or myriocin and simvastatin, an inhibitor of cholesterol biosynthesis with pleiotropic effects owed to inhibition of prenylation, to show synergistically attenuated HCV replication. They also identified impaired replication of HCV-1b replicon and of JFH-1 strain of genotype 2a infectious HCV RNA in Huh7/Rep-Feo cells, upon treatment with either myriocin-based combination[167]. While encouraging, these data do not fully translate into human systems: O'Leary *et al*[168] recently reported that statins alone do not exhibit antiviral activity against HCV at conventional doses.

CONCLUSION

In conclusion, we have compiled the published evidence that LRs are present in all liver cells; more importantly, data suggest that LRs play a role in liver health and diseases. The LR area of liver physiology and pathology is understudied. In order to facilitate exploration of this area future improvements are needed, the foremost of which are listed below: (1) Better markers and better methodologies for LR research; (2) New drugs for LR modulation; and (3) Experimental data-supported evidence of the feasibility and outcomes of LR modulation in liver health and disease.

Abstract

microRNAs (miRs) are small non-coding RNAs that regulate both mRNA and protein expression of target genes, which results in alterations in mRNA stability or translation inhibition. miRs influence at least one third of all human transcripts and are known regulators of various important cellular growth and differentiation factors. miRs have recently emerged as key regulatory molecules in chronic liver disease. This review details recent contributions to the field of miRs that influence liver development and the broad spectrum of disease, from non-alcoholic fatty liver disease to fibrosis/cirrhosis, with particular emphasis on hepatic stellate cells and potential use of miRs as therapeutic tools.

INTRODUCTION

Post-transcriptional regulation of gene expression involves numerous modifications to the mRNA, including alterations at both 5' and 3' ends in addition to splicing of the transcripts. The 3' untranslated regions (UTRs) of mRNAs contain key stability elements that are subject to various regulatory proteins, as well as microRNA (miR) binding sites. miRs are small non-coding RNAs that alter gene expression through perfect complementarity of the miR to the target sequence, which results in mRNA instability and subsequent endonucleolytic cleavage or alternate 5' modifications[1]. Imperfect base pairing with the 3' UTR of target mRNA results in gene translation inhibition[2]. Research focusing on miR modes of action has primarily examined interactions with the 3' UTR of target genes; however, recent studies have expanded our knowledge and have demonstrated that miRs can interact with the 5' UTR as well as interact with DNA methylation machinery and affect chromatin status[3]. Since their discovery in 1993, miRs have been described in all multicellular organisms

and are associated with a vast breadth of biological functions including proliferation, cellular differentiation and immunity, as well as tissue remodeling and various human disease states, notably cancer[4]. Although much remains to be learned, miRs have already been shown to influence the expression of many mRNAs and proteins that are important in liver homeostasis in health and disease (Table 1). Emerging roles for miRs in liver development and disease are discussed in this review, as well as their potential for clinical application.

miRs IN LIVER DEVELOPMENT AND DISEASE

Liver development

miRs, while currently being exploited to understand disease pathologies, have been less appreciated in the role of functional gene repression during cellular growth and liver development. miRs, specifically let 7 and lin4, control larval development transition in *Caenorhabditis elegans*, as well as apoptotic pathways and growth in *Drosophila*[5]. Recent studies have elegantly demonstrated that miRs regulate differentiation of human cells and development of whole organ systems, which shows tissue-specific expression. miR 122 accounts for approximately 70% of the total liver miR population; however, specific roles for this miR outside of disease-associated functions [e.g. hepatitis C virus (HCV) and hepatocellular carcinoma (HCC)] are less clear, especially with regard to normal liver development. Xu *et al*[6] have shown that miR 122 is strongly upregulated during liver embryonic development with expression correlative to liver enriched transcription factors (LETFs) C/EBPα, HNF1α and HNF3 isoforms, which are all necessary for proper hepatocyte development and function. Additionally, the transcriptional repressor CUTL1, which is known to promote proliferation and suppress differentiation, is gradually repressed by miR 122 during development. *In vitro* miR 122 knockdown experiments have shown restoration of CUTL1 expression and of downstream target genes, which emphasizes that, during development, miR 122, as an effector molecule of LETFs, regulates a delicate balance between differentiation and proliferation[6]. Quantitative analysis of miRs in fetal *vs* adult livers has demonstrated that miR expression levels are higher in the fetal period and expression levels during this time are dynamic[5]. Additionally, recent studies have demonstrated that 162 miRs exhibit tissue-specific distribution in mice[7]. Endoderm-derived liver, jejunum and pancreas display differential miR enrichment, with miRs 122, 21, 101b, 107, 192 and 221 among those with the highest reads per million concentrations. Additionally, mapping of transcriptional start sites has demonstrated that divergent sites are used by miRs in endoderm-derived liver tissue as opposed to stem cells. Maternal influences on miR expression have also been identified and may be affected by diet. For example, studies by Zhang *et al*[8] have shown that, as a result of maternal high-fat diet, expression of miR let 7c is decreased in offspring, along with 23 other miRs including 122 and 194. let 7c was

identified by Tzur *et al*[9] as being highly expressed in adult compared to embryonic liver, and that profibrotic transforming growth factor-β receptor 1 is a target of this miR. The miR 30 family has recently been shown to be crucial for liver development, because it is upregulated during later stages that influence known regulators of hepatic function, including epidermal growth factor receptor. GW182, a crucial component in miR-mediated gene repression, is also a target of this miR family, which indicates a more global role for miRs in earlier stages of epigenetic silencing *via* the RNA-induced silencing complex[10]. Functional analyses in zebrafish larvae have demonstrated that biliary morphogenesis is under the regulation of miR 30a, as knockdown studies have resulted in defective bile duct excretion[11]. The liver, as a vital multifunctional organ, must maintain proper epigenetic programming to ensure xenobiotic and bile metabolism, and vitamin and glucose storage among a plethora of other tasks, which emphasizes the importance of proper cellular differentiation and development.

Nonalcoholic fatty liver disease/nonalcoholic steatohepatitis

Nonalcoholic fatty liver disease (NAFLD) is characterized by hepatic fat accumulation without significant alcohol consumption or other underlying etiology[12]. NAFLD incidence is rising as a result of the increased population of obese individuals worldwide, with severity of the disease ranging from steatosis/steatohepatitis (NASH) to cirrhosis. Although most patients with NAFLD are asymptomatic, clinical manifestations of the disease are well described and include hyperechoic appearance of the liver on ultrasound, dyslipidemia, systemic arterial hypertension, and insulin resistance. Although disease pathogenesis is not completely understood, recently, a role for miRs in NAFLD has been established[13]. Lipid droplet accumulation in hepatocytes as a marker of steatosis is associated with various liver diseases including NAFLD. Recent high-content screening studies have shown that 11 miRs are able to alter lipid droplet formation/retention[14]. Specifically, miR 181d decreased droplets by approximately 60%, which subsequently reduced cellular triglycerides and cholesterol. Peroxisome proliferator-activated receptor (PPAR)α, a major contributor to NAFLD pathogenesis, has recently been identified as a target of miR 10b, which has been shown to regulate steatosis level in L02 cells (steatotic hepatocyte model)[15]. Additionally, post-transcriptional regulation of PPARα by miR 10b is maintained by a single binding site, as demonstrated by mutation analyses. NASH can progress to end-stage cirrhosis in approximately 15% of patients, with the mechanism that underlies disease progression being undefined. Recent studies in humans have demonstrated that miR expression profiles are altered in NASH. Unsurprisingly, miR 122 is significantly underexpressed (63%) in NASH subjects compared to those without the metabolic syndrome[16]. Overexpression of miR 122 in HepG2 cells results in a significant decrease in sterol regulatory element binding proteins (SREBP1-c, SREBP2), FAS and 3-hydroxy-3-methyl-glutaryl-CoA reductase; all of which are key lipogenic genes in human NASH. Lesser known

miRs 34a and 146b are significantly overexpressed (99 and 80%, respectively) in NASH. In a smaller sample study (*n* = 12/group), seven miRs have been found to be differentially expressed, including 132, 150, 197 and 99; the latter two are significantly associated with pericellular fibrosis[17]. It is of particular importance to note that previous studies have shown that miR signatures change in accordance with disease stage and source of hepatic injury (ethanol or high fat diet)[18,19]. These studies emphasize the importance of avoiding generalization when examining miRs as potential biomarkers, because miR expression patterns of end-stage disease may be similar but expression profiles that lead to organ dysfunction appear to be divergent.

Viral infection

Along with NASH, HCV is one of the most common global causes of hepatic fibrosis and cirrhosis. According to the World Health Organization, over 180 million people are infected with the single-stranded RNA virus, with > 70% of that population at risk for developing cirrhosis[20]. Pegylated interferons in conjunction with ribavirin have improved treatment of chronic hepatitis C; however, a large percentage of the infected population remains unresponsive to available regimens, which emphasizes the need to better understand the mechanisms of cellular infection, for development of novel drug therapies. Numerous studies have emphasized a role for miR 122 in several aspects of hepatic function and disease, including HCV replication[21]. Plasma levels of miR 122 are elevated in hepatitis B virus (HBV)- and HCV-infected patients, as well as in models of alcohol and drug-induced liver damage reinforcing a role for miRs as biomarkers[22]. However, recent studies by Ura *et al*[23] have shown that miR expression patterns are divergent in HBV- and HCV-infected livers. Additionally, elegant studies by Hou *et al*[24] have demonstrated that miR 196 directly acts on the 3'UTR of Bach1, the transcriptional repressor of heme oxygenase 1, a critical cytoprotective enzyme. This miR also inhibits HCV expression (both genotype 1b and 2a) in human hepatocytes *in vitro*, which shows clinical promise. Accordingly, parallel miR and mRNA expression profiling studies in genotype-1b-expressing cells have shown numerous anti-correlated miR/mRNA pairs affected by the presence HCV[25]. Among the noted anti-correlated pairs that have been detected in a human cell line that expresses the HCV Con1 replicon, miR 130a/b is correlated with decreased PPARγ expression, which is a known regulator of

the quiescent hepatic stellate cell (HSC) profile. Additional miR/mRNA profiling in HCV-infected hepatoma cells has shown a total of 108 differentially expressed miRs, and among this pool, miRs 24, 149, 638 and 1182 are predicted to control HCV entry, replication and viral propagation[26]. Scagnolari *et al*[27] have examined miR expression in peripheral blood mononuclear cells from healthy and chronic-HCV-infected patients and have found that miRs 1, 30, 128, 196 and 296 are differentially expressed and that treatment with interferon (IFN)α induces all aforementioned miRs. Although limited by small sample size, baseline levels of miRs do not appear to differ significantly between responders and non-responders; however, expression of miRs 128 and 196 appears higher in the responsive population. Additionally, Pedersen *et al*[28] have demonstrated this same set of miRs, which possess sequence-predicted targets within HCV genomic RNA, and are induced by IFNβ stimulation. The tumor suppressor gene DLC-1 (deleted in liver cancer-1) is also a target of miR repression[29]. Levels of DLC-1 are decreased in HCV-infected cells, which are correlated with the increase in miR 141. Depletion of this miR inhibits viral replication, while addition of exogenous miR 141 increases replication rates, which indicates that miR regulation of tumor suppressor genes can influence HCV infection and play a role in HCC development (for a comprehensive review of miRs in HCC see[30,31]).

Alcoholic liver disease

Alcoholic liver disease (ALD) is a major healthcare burden worldwide and a leading cause of liver-related mortality. It is well known that ethanol consumption alters methylation status and other epigenetic factors, including histone tail signatures, signal transduction pathways and transcription factor expression. Ethanol metabolism affects chromatin condensation, which results from direct DNA methylation or histone protein alterations (acetylation, methylation or phosphorylation)[32]. Additionally, DNA methylation is connected to direct interference by small RNAs[33]. Therefore, it is plausible that, as a result of epigenetic remodeling, ethanol exposure can also alter miR expression. Ethanol has been shown to repress miRs 9, 21, 153 and 335 in neural stem cells and neural progenitor cells that alter cellular development and maturation[34]. Additionally, miR 21 influences PTEN/PI3K signaling, which ultimately contributes to the fibrotic response, and both miRs 9 and 335 are predicted (by TargetScan) to bind to targets

that influence the progression of ALD[35]. Previous studies have highlighted the importance of miRs in the gut-liver axis and have shown that ethanol exposure alters miR profiles in liver cells[36]. Specifically, endotoxemia and direct ethanol exposure modulate hepatic miRs 182, 183, 705, 1224 and 199a-3p[37]. Symptomatic of ALD, hepatic microcirculation is disrupted when increased portal pressure arises as a result of altered endothelin-1 (ET-1) expression, with subsequent increases in NADPH oxidase and hypoxia inducible factor-1α[38]. Recent studies have shown that miR 199 is involved in ET-1 expression in rat liver sinusoidal endothelial cells and human endothelial cells, by functioning as a negative regulator of ET-1 transcription and thus vascular tone in ALD[39]. For still unknown reasons, only 20%-30% of chronic heavy alcohol users develop hepatic fibrosis. Future studies of miRs involved in ALD may allow us to uncover additional factors that contribute to the disparity that exists in disease development.

Liver fibrosis

Commonalities of miR expression can also be seen among fibrotic disorders of different organ systems, including cardiac and renal fibrosis, with an overarching effect of the miR 29 family in regulation of effector cellular differentiation or in translation of extracellular matrix (ECM) components[35]. Additionally, miRs involved with translation of profibrotic transforming growth factor (TGF)β/SMAD signaling are shared amongst pathologies. Roderburg *et al*[40] have examined miR expression profiles in a CCl4 rodent model of hepatic fibrosis, and microarray analyses have revealed 31 differentially expressed miRs; 10 of which are overexpressed in fibrotic tissue, including miRs 125-p, 199b, 221 and 302c. Marked downregulation has been observed in a pool of 21 miRs; specifically, miR 29 family members were significantly reduced. Additional experiments in an alternate model of fibrosis (bile duct ligation; BDL) have confirmed that miRs 29b/c are significantly reduced compared to sham controls. Downregulation of miRs 29a/b/c could also be observed in explanted liver samples with patients denoted by a Desmet fibrosis score of 2-4. Low plasma levels of miR 29a correlate with advanced stage liver fibrosis in human patients. The idea that low miR levels in the tissue correlate with low miR in the circulating plasma is in opposition to recent hypotheses that an inverse correlation between tissue and plasma miR concentrations exists as a byproduct of vesicles that release miRs[41]. Hepatic fibrosis is influenced by several epigenetic factors that control the wound-healing response. Recent studies by Mann *et al*[42] have shown that miR 132 is significantly decreased in fibrotic livers as demonstrated in two different models (BDL, CCl4), and this downregulation influences HSC activation. Collectively, these studies have emphasized that, during development of fibrosis, there are important changes in miR expression that regulate wound-healing transcripts; however, effects exerted by miRs appear to act in concert with other epigenetic factors to direct disease progression.

miRs IN HSCs

HSCs are the main effector cell population in hepatic fi-

Figure 1 microRNAs involved in hepatic stellate cell transdifferentiation. Functional manipulation studies utilizing mimics and/or antagomirs have demonstrated that the miRs depicted in the above schematic regulate key genes/functions in hepatic stellate cells (HSCs). (Quiescent HSC: yellow circles represent cytoplasmic lipid droplets; activated HSC: purple lines indicate cytoskeletal protein smooth muscle alpha actin; green oval represents Bcl-2; red fibrils represent collagen). Additional profiling studies have shown upregulation of several microRNAs (miRs) in both phenotypes, some of which are already associated with hepatic disease (boxes contain a small fraction of published miRs). References[38-43,47] were used to generate the contents of this figure with design software BioDraw Ultra 12.0.

brosis as the primary source of type I collagen deposition following injury. Injury from several sources, including viral infection, obesity and alcohol consumption, causes activation of HSCs, in which quiescent lipid-rich cells transdifferentiate into fully activated myofibroblasts. The activated form of the HSC secretes profibrogenic mediators, including TGFβ, and generates ECM components including fibrillar collagens, fibronectin and laminin, which exacerbates the wound-healing process[38]. Recent studies have shown that miRs are involved in HSC transdifferentiation (Figure 1). Specifically, miRs 150, 187, 194 and 207 are significantly downregulated in HSCs isolated from BDL animals compared to sham controls, whereas let 7 family members are significantly upregulated[43]. Overexpression of miRs 150 and 194 in human HSCs (LX-2) results in proliferation inhibition as well as decreases in type I collagen and smooth muscle alpha actin (αSMA), which are hallmarks of HSC activation. Specific action of these two miRs includes inhibition of c-Myb and Ras-related C3 botulinum toxin substrate 1 (Rac-1), which both contribute to development and progression of fibrosis. Additional studies have examined differential expression in quiescent (day 2) and activated (day 14) rat HSCs, and have shown 12 upregulated and nine downregulated miRs, of which, 15b, 16, 122, 138, 140 and 143 have been validated[44,45]. Gene ontology has revealed specific linkages between the miR 15/16 family and anti-apoptotic pathways that are important in HSC activation. Administration of miR mimics induced Bcl-2 inhibition and subsequent apoptosis in the activated HSCs, an important aspect of potential therapeutic targeting. Additional studies by Guo *et al*[44] have further demonstrated that lentiviral delivery of miR 16 greatly reduces cyclin D1 levels in addition to inhibiting proliferation and increasing apoptosis in activated HSCs. More recent studies by Ogawa *et al*[46] have shown

that TGFβ1 or IFNα stimulation validate *in silico* analyses of miR-pro-collagen [Colα1 (Ⅰ)] mRNA binding sites. miRs 29b, 143 and 218 demonstrate the highest degree of homology to the Colα1 (Ⅰ) 3'UTR and have been further analyzed. miR 29b directly bound to the 3'UTR suppresses type Ⅰ collagen at the mRNA and protein levels. Potential antifibrotic benefit to miR 29b has also been validated *in vivo* using a murine CCl₄ model of injury (see Liver fibrosis section). *In vitro* studies conducted by Roderburg *et al*[40] have also shown that overexpression of miR-29b in murine HSCs results in decreased collagen expression and that lipopolysaccharide and nuclear factor (NF)κB are involved in downregulation of this miR. The process of HSC activation includes the methyl CpG binding protein MeCP2 and constituents of the polycomb repressive complex. More recently, miR 132 has been shown to activate this epigenetic pathway because its downregulation, observed in fibrotic livers, permits translation of MeCP2, which is subsequently recruited to the 5' end of PPARγ, and through altered methylation patterns, it confers suppression of the quiescent profile[42]. Previously studies by Ji *et al*[47] showed miRs 27a and b are upregulated during activation and directly repress RXRalpha. Inactivation of these miRs in vitro showed partial reversion of the cell to a quiescent phenotype with restoration of lipid droplet accumulation. Improved understanding of the regulation of HSC activation by miRs will undoubtedly advance our knowledge of many liver etiologies.

miRs IN LIVER REGENERATION

As a result of hepatic injury, hepatocytes are capable of undergoing multiple divisions, and in the case of partial (2/3) hepatectomy (PH), liver mass is restored within 7 d[48]. Liver regeneration is a complex process that involves intricate cytokine and growth factor signaling influencing cell cycle progression. Recent studies have begun to examine the role of miRs in this process, to uncover underlying mechanisms that may be manipulated to ensure rapid tissue repair. miR-deficient mice (DGCR8 inactivated) that have undergone PH are clearly delayed in cell cycle progression; specifically G1 to S phase transition[48]. Examination of differentially expressed miRs in wild-type mice has revealed marked induction of miR 21 at 18 h post-PH, and downregulation of miR 378. These studies also have shown that miR 21 targets cell cycle inhibitor B cell translocation gene 2 (*Btg2*), which prevents DNA synthesis in hepatocytes, whereas miR 378 inhibits ornithine decarboxylase (*Odc1*), a promoter of DNA synthesis. Studies by Castro *et al*[49] have confirmed that miR 21 expression is increased following PH, and can be modulated by ursodeoxycholic acid (UDCA), a pro-survival agent in hepatic regeneration. miR profiles from rats that have undergone 70% PH have shown that miR 21 levels are highest at 24, 36 and 72 h post-hepatectomy. Inhibition of this miR reduces hepatocyte proliferation and increases levels of lactate dehydrogenase. UDCA treatments increase miR 21 as well as several others, including 143 and 151, which points towards a mechanism of action of the compound. As previously noted, miR 21 has been shown to repress PTEN signaling,

the negative repressor of the AKT pathway that is necessary for hepatic regeneration. Additional experiments with miR 21 have shown that it is upregulated in early stages of regeneration and its overexpression inhibits NF-κB signaling[50]. Although the miR signature following 50% PH is slightly distinct from published data on 2/3 PH, miR 21 as well as miRs 22a, 26a, 30b and members of the let 7 family, which are already known to play a role in hepatic tissue development, are also differentially expressed[51]. Although key regulatory factors that govern organ regeneration are mostly unknown, recent studies in zebrafish have shown that suppression of miRs 133 and 203 is required for appendage regeneration; however, this process is mediated by stem cells in contrast to fully differentiated hepatocytes that are necessary to regenerate mammalian liver tissue. Enhanced knowledge of miRs that regulate hepatocyte proliferation following PH may also allow restoration of this function in diseased parenchymal cells[48].

CLINICAL APPLICATION OF miRs

Currently, there are no established FDA-approved treatments for hepatic fibrosis. Outside of surgical resection, full organ transplantation is an option for certain disease states; however, the current list of patients in need of transplant far exceeds the annual donor rate. As is always the case, the clinical applications of new discoveries, such as the existence and manifold roles of miRs in liver physiology and pathophysiology, lag behind the laboratory-based discoveries summarized above. Thus, currently, profiles of miRs and creation of miRs in various liver diseases, and the use of alterations in these as prognostic indicators or for categorization of liver diseases, have not been introduced into routine clinical practice. Nevertheless, it seems likely that, within the next 3-5 years, some centers and physicians will begin to use miR profiling to help categorize patients at higher or lower risk of adverse outcomes, especially from acute liver diseases, such as drug- or toxin-induced injury or fulminant liver failure of any cause. Another likely application will be the profiling of miR expression in hepatic tumors as an aid to prognosis, and perhaps, to help guide therapeutic decisions. However, it seems unlikely that such profiling will become generally available for widespread clinical application within the next 10 years, because many more studies with large numbers of subjects will be needed, with demonstration that such specialized profiling offers clear advantages in improving outcomes at reasonable and justifiable incremental costs.

What seems more likely is that therapy directed at influencing the hepatic levels of selected miRs such as miR 122, already shown to play an important role in affecting levels of serum cholesterol and levels of the HCV, both in cell culture[52,53] and chimpanzee models[54], will find a place in clinical therapeutics. Indeed, phase 2 clinical studies of locked nucleic acids that downregulate miR 122 expression are already in progress, and results of these are awaited with great interest. Similarly, therapeutic alteration of miR 196[24] and, in future, other miRs seems likely also to be pursued. However, we must also keep in mind

the high costs and lengthy duration usually needed for approvals of all new drugs. Also, the unwanted side effects of such treatments may limit their clinical application.

CONCLUSION

Thus, at this juncture, miRs are clearly more than just the latest fad. They are important and fundamental modulators of mRNA and protein expression. In future, purposeful modulation of these levels and effects will, more likely than not, become important in the therapeutic armamentarium of hepatic and other diseases. Although the clinicopathological and prognostic value of miRs remains highly anticipated, further exploration into systemic effects of miR modulation, both endogenously and exogenously, is needed, as well as a deeper understanding of miR biogenesis in both the development and progression of liver diseases.

Abstract

Constant alcohol consumption is a major cause of chronic liver disease, and there has been a growing concern regarding the increased mortality rates worldwide. Alcoholic liver diseases (ALDs) range from mild to more severe conditions, such as steatosis, steatohepatitis, fibrosis, cirrhosis, and hepatocellular carcinoma. The liver is enriched with innate immune cells (e.g. natural killer cells and Kupffer cells) and hepatic stellate cells (HSCs), and interestingly, emerging evidence suggests that innate immunity contributes to the development of ALDs (e.g. steatohepatitis and liver fibrosis). Indeed, HSCs play a crucial role in alcoholic steatosis *via* production of endocannabinoid and retinol metabolites. This review describes the roles of the innate immunity and HSCs in the pathogenesis of ALDs, and suggests therapeutic targets and strategies to assist in the reduction of ALD.

Key words: Alcoholic liver disease; Hepatic stellate cell; Natural killer cell; Kupffer cell; Endocannabinoid; Steatosis; Steatohepatitis; Fibrosis

INTRODUCTION

Alcoholic liver disease (ALD) caused by chronic alcohol consumption shows increased mortality rates worldwide[1,2]. As an adverse risk factor of alcohol abuse, ALD includes a broad spectrum of liver diseases, ranging from steatosis (fatty liver), steatohepatitis, fibrosis, and cirrhosis to hepatocellular carcinoma[3,4]. Generally, steatosis is considered to be a mild or reversible condition, whereas steatohepatitis is a pathogenic condition, which has the potential to progress into more severe diseases, such as liver fibrosis/cirrhosis, insulin resistance, and metabolic syndrome in rodents and humans[5-7]. For the past decade, evidence has suggested that the innate immune cells of liver and hepatic stellate cells (HSCs) play crucial roles in ALD. For example, previous studies demonstrated that alcoholic liver steatosis was induced by HSC-derived endocannabinoid and its hepatic CB1 receptor, and alcoholic liver fibrosis was accelerated due to abrogated antifibrotic effects of natural killer (NK) cells/interferon-γ (IFN-γ) against activated HSCs *via* the upregulation of transforming growth factor-β (TGF-β) and suppressor of cytokine

signaling 1 (SOCS1)[8,9]. However, the molecular and cellular mechanisms underlying ALD remain controversial[4,6,10]. Therefore, in the present review, we briefly describe the innate immunity of liver and HSCs, summarize the roles of these in ALD (with particular emphasis on alcoholic liver steatosis, steatohepatitis and liver fibrosis), and provide better strategies for the prevention and treatment of ALD.

INNATE IMMUNITY AND HSC IN LIVER

The innate immune system is the first line of defense against pathogenic microbes and other dangerous insults, such as tissue injury, stress, and foreign bodies[11]. It consists of three sub-barriers: physical (e.g. mucous membrane and skin), chemical (e.g. secreted enzymes for antimicrobial activity and stomach HCL), and cellular barriers (e.g. humoral factors, phagocytic cells, lymphocytic cells, *etc*), which immediately respond to the pathogens entering the body. Most body defense cells have pattern recognition receptors (PRRs) that recognize the overall molecular patterns of pathogens, known as pathogen associated molecular patterns. The examples of PRRs are toll-like receptors (TLR), nucleotide-binding oligomerization domain-like receptors, and the retinoic acid-induced gene I-like helicases[12].

When extraneous molecules enter the human body, they have to be processed by the liver, either by metabolism or detoxification. Therefore, the liver is considered as a barrier against pathogens, toxins, and nutrients absorbed from the gut *via* the portal circulation system. Consequently, the liver is enriched in innate immune system including humoral factors (e.g. complement and interferon), phagocytic cells (e.g. Kupffer cells and neutrophils), and lymphocytes [e.g. NK cells, natural killer T (NKT) cells and T cell receptor γδ T cells][11,13-15]. In a healthy liver, the principal phagocytic cells, the Kupffer cells, representing 20% of the non-parenchymal cells (NPC), assist in the clearance of wastes *via* phagocytosis in the body[15,16]. However, when the liver is injured, Kupffer cells elicit immune and inflammatory responses (e.g. hepatitis, fibrosis, and regeneration) by producing several mediators, including tumor necrosis factor-α (TNF-α), TGF-β, interleukin-6 (IL-6), and reactive oxygen species (ROS)[17-19]. Among these, TGF-β plays a crucial role in the transdifferentiation of quiescent HSCs into fibrogenic activated HSCs, *via* the suppression of their degradation and the stimulation of the production of extracellular matrix (ECM), especially in collagen fibers[19-21]. In a healthy liver, liver lymphocytes constitute about 25% of the NPC. Mouse liver lymphocytes contain 5%-10% NK cells and 30%-40% NKT cells, whereas rat and human liver lymphocytes consist of approximately 30%-50% NK cells and 5%-10% NKT cells[11,13,15,16]. These distributions of NK and NKT cells are quite abundant compared with those in peripheral blood, which contains 2% of NKT cells and 13% of NK cells[13]. Previously, NK/NKT cells were regarded to assume a crucial role in mediating the immune responses against tumor and microbial pathogens. However, recent studies have suggested that they contribute significantly to liver injury, regeneration, and fibrosis[22-25].

More interestingly, there are enigmatic cells in the liver that were previously called Ito cells or sinusoidal fat-storing cells, but are now standardized as HSCs[21]. HSCs comprise up to 30% of NPC in the liver and are located in specialized spaces called Disse, between hepatocytes and sinusoidal endothelial cells. In addition, quiescent HSCs store retinol (vitamin A) lipid droplets and regulate retinoid homeostasis in healthy livers. However, they become activated and transformed into myofibroblastic cells that have special features with retinol (vitamin A) loss and enhanced collagen expression when liver injuries occur[19,21,26]. For several decades, activated HSCs have been considered to be major cells that induce liver fibrosis *via* the production of ECM and inflammatory mediators (e.g. TGF-β) in humans and rodents[19-21]. However, recent studies have suggested that the novel roles of HSCs are closely associated with other diseases, such as alcoholic liver steatosis and immune responses, by producing endocannabinoids and presenting antigen molecules, respectively[8,27,28]. Moreover, HSCs can directly interact with immune cells, such as NK cells, NKT cells and T cells, *via* the expression of retinoic acid early inducible-1 (RAE1), CD1d, and major histocompatibility complex (MHC) I and II[22,28,29]. During HSC activation, they metabolize the retinols into retinaldehyde (retinal) *via* alcohol dehydrogenase (ADH), and the retinal is further metabolized into retinoic acid (RA) *via* retinaldehyde dehydrogenase (Raldh)[3,29]. Surprisingly, activated HSCs express an NK cell activating ligand known as RAE1; however, RAE1 expression is absent in quiescent HSCs. This suggests that the activation processes of HSCs are necessary for the expression of a NK cell activated ligand, RAE1. Furthermore, several TLRs have also been identified in HSCs[30]. Taken together, HSCs might be important not only in liver fibrosis, but also in other liver diseases related to immune responses.

ALCOHOLIC LIVER STEATOSIS BY INNATE IMMUNITY AND HSCS

Alcoholic liver steatosis has long been considered as a mild condition; however, increasing evidence suggests that it is a potentially pathologic state, which progresses into a more severe condition in the presence of other cofactors, such as the sustained consumption of alcohol, viral hepatitis, diabetes, and drug abuse[31,32]. It is believed that fat accumulation in the hepatocytes is a result of an imbalanced fat metabolism, such as decreased mitochondrial lipid oxidation and enhanced synthesis of triglycerides. Several underlying mechanisms of these processes indicate that it might be related to an increased NADH/NAD+ ratio[33,34], increased sterol regulatory element-binding protein-1 (SREBP-1) activity[35,36], decreased peroxisome proliferator-activated receptor-α activity[37,38], and decreased AMP-activated protein kinase (AMPK) activity[8,36].

Moreover, recent studies have suggested the involvement of innate immune cells, particularly Kupffer cells,

in alcoholic liver steatosis[39,40]. Generally, alcohol intake increases gut permeabilization, which allows an increased uptake of endotoxin/lipopolysaccharide (LPS) in portal circulation[18]. Kupffer cells are then activated in response to LPS *via* TLR4 signaling cascade, leading to the production of several types of pro-inflammatory mediators such as TNF-α, IL-1, IL-6, and ROS[3,4,39]. Of these mediators, the increased expression of TNF-α and enhanced activity of its receptor (TNF-α R1) have been observed in alcoholic liver steatosis in mice[39-42]. In addition, it has been reported that TNF-α has the potential to increase mRNA expression of SREBP-1c, a potent transcription factor of fat synthesis, in the liver of mice and to stimulate the maturation of SREBP-1 in human hepatocytes[43,44]. Furthermore, a recent report demonstrated that alcohol-mediated infiltration of macrophages decreased the amount of adiponectin (known as anti-steatosis peptide hormone) production of adipocytes, leading to alcoholic liver steatosis[45]. Therefore, Kupffer cells/macrophages might contribute to the development of alcoholic liver steatosis *via* the upregulation of the SREBP1 activity in hepatocytes and the downregulation of the production of adiponectin in adipocytes. In contrast, IL-6 produced by Kupffer cells/macrophages is a positive regulator in protecting against alcoholic liver steatosis *via* activation of signal transducer and activator of transcription (STAT)3, consequently inhibiting of SREBP1 gene expression in hepatocytes[46-48].

Endocannabinoids, endogenous cannabinoids, are lipid mediators that interact with cannabinoid receptors (CB1 and CB2) to produce effects similar to those of marijuana[49]. There are the two main endocannabinoids, arachidonoyl ethanolamide (anandamide) and 2-arachidonoylglycerol (2-AG). Recently, an intriguing report suggested that alcoholic liver steatosis is mediated mainly through HSC-derived endocannabinoid and its hepatocytic receptor[8]. The study suggested that chronic alcohol consumption stimulated HSC to produce 2-AG, and the interaction with the CB1 receptor upregulated the expression of lipogenic genes SREPB1c and fatty acid synthase but downregulated the activities of AMPK and carnitine palmitoyltransferase 1. Consequently fat is accumulated in the hepatocyte. More recently, a related study reported that the increased expression of CB1 receptors on hepatocytes because of alcohol consumption was mediated by RA acting *via* a RA receptor (RAR)-γ[27]. This study also showed that 2-AG treatment in mouse hepatocytes increased the production of RA by Raldh1, the catalytic enzyme of retinaldehyde into RA. RA then binds with RAR-γ, increasing the expression of CB1 receptor mRNA and protein, and consequently exacerbating the alcohol-mediated fat accumulation *via* enhanced endocannabinoid and lipogenic signaling pathways[27]. Reports stating that alcohol consumption simultaneously elevated the expression of RAR and the production of retinol metabolites, including RA, in mouse and rat liver, supported these findings[50-52]. Moreover, hepatocytes and HSCs are major sources of retinoids, including retinol and RA, in the body[26,53]. In contrast to the CB1 receptors, the association of CB2 receptors with the development of

Figure 1 Regulatory mechanisms of the hepatic lipogenesis and CB1 receptor expression *via* hepatic stellate cell-derived endocannabinoids/CB1 receptors and retinoic acid/retinoic acid receptor-γ in hepatocytes, respectively. hepatic steatosis has not yet been studied in depth. One study showed that the expression of CB2 receptors was increased in the livers of patients with non-alcoholic fatty liver disease[54]. In an animal model, however, feeding of high-fat diet for 15 wk induced severe fatty liver in wild-type mice, but not in hepatic CB2 knockout mice[55]. The involvement of endocannabinoid, RA, and their receptors has been integrated in Figure 1.

Interestingly, in contrast with previous reports that endocannabinoids activated HSCs to induce liver fibrosis and alcoholic liver steatosis[8,56], Siegmund *et al* reported that HSCs' sensitivity to anandamide (AEA)-induced cell death was because of low expression of fatty acid amide hydrolase and that 2-AG also induced apoptotic death of HSCs *via* ROS induction[57-59]. These data indicated that endocannabinoids might play negative roles in liver fibrosis. Therefore, the functions of endocannabinoids to HSCs are still unclear and need to be studied further.

ALCOHOLIC STEATOHEPATITIS BY INNATE IMMUNITY AND HSCS

Alcoholic steatohepatitis has a mixed status with fat accumulation and inflammation in the liver, which has the potential to progress into more severe pathologic states such as alcoholic liver fibrosis, cirrhosis, and hepatocellular carcinoma. In response to alcohol uptake, many hepatic cells participate in the pathogenesis of alcoholic steatohepatitis. However, as described above, mainly Kupffer cells and HSCs initiate and maintain hepatic inflammation and steatosis[4,8,60-63]. Considering their specific location at the interface between the portal and systemic circulation, Kupffer cells are the central players in orchestrating the immune response against endotoxin (LPS) *via* TLR4 signaling pathways[62,64]. TLR4 initiates two main pathways, and when TLR4 binds LPS, TIR domain-containing adaptor protein and myeloid differentiation factor 88 (MyD88) are recruited, resulting in the early-phase activation of nu-

clear factor-κB (NF-κB). The activation of NF-κB leads to the production of pro-inflammatory cytokines, including TNF-α, IL-6, and monocyte chemotactic protein-1 (MCP-1). Meanwhile, TIR-domain containing adaptor inducing IFN-β (TRIF) and TRIF-related adaptor molecule activate interferon regulatory factor 3 (IRF3), leading to the production of type I IFN and late activation of NF-κB[62,65]. Recent studies reported that alcohol-mediated liver injury and inflammation were primarily induced by in a TLR4-dependent, but MyD88-independent, manner in NPCs (Kupffer cells and macrophages), whereas IRF3 activation in parenchymal cells (hepatocytes) rendered protective effects to ALD[66,67]. In addition, the importance of gut-derived endotoxin/LPS in ALD was suggested by experiments where animals were treated with either antibiotics or lactobacilli to remove or reduce the gut microflora provided protection from the features of ALD[68]. Among pro-inflammatory cytokines, TNF-α primarily contributes to the development of ALD, and its levels are increased in patients with alcoholic steatohepatitis[39] and in the liver of alcohol-fed animals[40,69]. Moreover, Kupffer cells secrete other important cytokines, including IL-8, IL-12, and IFNs, which contribute to the intrahepatic recruitment and activation of granulocytes that are characteristically found in severe ALD, and influence immune system polarization[70]. Interestingly, TLR4 is expressed not only on innate immune cells, such as Kupffer cells and recruited macrophages, but also on hepatocytes, sinusoidal endothelial cells, and HSCs in the liver[30].

In addition to LPS, oxidative stress-mediated cellular responses also play an important role in activations of innate immune cells and HSCs. Furthermore, Kupffer cells represent a major source of ROS in response to chronic alcohol exposure[71,72]. One important ROS is the superoxide ion, which is mainly generated by the enzyme complex NADPH oxidase. Underlining the important role of ROS in mediating ethanol damage, treatment with antioxidants and deletion of the p47phox subunit of NADPH oxidase in ethanol-fed animals reduced oxidative stress, activation of NF-κB, and TNF-α release in Kupffer cells, thus preventing liver injury[71,73]. Moreover, NADPH oxidase induces TLR2 and TLR4 expression in human monocytic cells[74], and direct interaction of NADPH oxidase isozyme 4 with TLR4 is involved in LPS-mediated ROS generation and NF-κB activation in neutrophils[75].

Besides Kupffer cells, HSCs also contribute to alcoholic steatohepatitis by producing endocannabinoids and releasing proinflammatory cytokines and chemokines, such as TNF-α, IL-6, MCP-1, and macrophage inflammatory protein-2[63,76-78]. Moreover, Kupffer cells activated by alcohol stimulate the proliferation and activation of HSCs *via* IL-6 and ROS-dependent mechanisms in a co-culturing system[17,79]. Furthermore, retinol metabolites of HSCs activate latent TGF-β, leading to suppression of apoptosis of HSCs[80-82]. Recently, an intriguing review provided novel roles for HSCs in liver immunology, where HSCs, depending on their activation status, can produce several mediators, including TGF-β, IL-6, and RA, which are important components in naïve T cell differentiation

Figure 2 Mechanism of natural killer cell cytotoxicity against activated hepatic stellate cells. into regulatory T cells (Treg cells) or IL-17 producing T cells (Th-17 cells)[83]. Based on this review, it can be hypothesized that HSCs regulate hepatic inflammation *via* modulation of T cell differentiation into Treg or Th-17 cell under certain circumstances. However, this remains an unclear proposition; therefore, further studies on the role of HSCs in hepatic inflammatory diseases, including alcoholic steatohepatitis and viral hepatitis, are necessary.

ALCOHOLIC LIVER FIBROSIS BY INNATE IMMUNITY AND HSCS

Chronic alcohol drinking is one of major causes of liver fibrosis, which is characterized by the excessive accumulation of ECM components because an imbalanced ECM degradation and production[6]. However, only 10%-40% of heavy drinkers develop alcoholic liver fibrosis[1,3]. Although the underlying mechanisms of alcoholic liver fibrosis are not yet completely understood, several suggestions have been made in the literature. First, acetaldehyde and ROS generated by hepatic alcohol metabolism activate the production of collagen and TGF-β1 in HSCs through a paracrine mechanism[84,85]. Secondly, hepatocyte apoptotic bodies induced by alcohol are phagocytosed in Kupffer cells and HSCs, resulting in the production of TGF-β1 and subsequently activating HSCs[86,87]. Thirdly, alcohol-mediated activation of Kupffer cells, such as LPS/TLR4 signaling, also activates HSCs *via* release of cytokines, chemokines, and ROS[17,63,88]. Moreover, TLR4/MyD88 signaling in HSCs enhances TGF-β signaling, inducing liver fibrosis *via* down-regulation of a transmembrane TGF-β receptor inhibitor, Bambi[89]. Furthermore, it is reported that NADPH oxidase–mediated ROS production contributes to liver fibrosis[90]. However, recent studies have inferred another possibility - that chronic alcohol consumption predisposes NK/NKT cells to decrease in function, which accelerates the development of liver fibrosis[9,91].

Originally, as we depicted in Figure 2, NK cells have

Figure 3 A model for chronic alcohol acceleration of liver fibrosis *via* inhibition of natural killer cell killing against hepatic stellate cells and suppressor of cytokine signaling 1 suppression of interferon-γ signaling in hepatic stellate cells. SEC: Sinusoidal endothelial cell; ADH: Alcohol dehydrogenase; HSC: Hepatic stellate cell; RA: Retinoic acid; RAE1: Retinoic acid early inducible-1; IFN: Interferon; NK: Natural killer; TGF: Transforming growth factor; SOCS1: Suppressor of cytokine signaling 1.

anti-fibrotic effects *via* several mechanisms. First, NK cells can directly kill activated HSCs by NKG2D- and TNF-related apoptosis, dependent on the induction TRAIL ligand, whereas NK cells cannot induce apoptosis of quiescent HSCs[24,92]. This is because early activated HSCs express NK cell-activating ligand RAE-1, which is an activating ligand of NKG2D on NK cells, by RA and TRAIL receptors, but they express decreased MHC- I , an NK cell-inhibitory ligand[29,92]. Second, NK cells can suppress liver fibrosis *via* production of IFN-γ, which can induce HSC cell cycle arrest and apoptosis in a STAT1-dependant manner and induce autocrine activation of NK cells[93,94]. Similar to NK cells, NKT cells (invariant NKT cells) can also suppress HSC activation *via* direct killing and IFN-γ production; however, the anti-fibrotic effects of NKT cells are beneficial only at the onset stage of liver fibrosis because of iNKT depletion tolerance[22]. In contrast, strong activation of iNKT cells by a single injection of α-galactosylceramide adversely enhanced liver fibrosis *via* highly increased IFN-γ-mediated hepatocyte apoptosis[22]. However, in alcoholic liver fibrosis, it is now accepted that chronic alcohol consumption accelerates liver fibrosis because of the suppressed activity of NK cells (as shown in patients and mice)[9,91,95]. In patients with alcoholic liver cirrhosis, the number and cytolytic activity of peripheral blood NK cells were significantly decreased compared to those of patients without liver disease[95]. In parallel with this report, decreased numbers and cytotoxicity of liver NK cells against HSCs and tumor cells were observed in chronically alcohol-fed mice[9,91]. In addition, direct IFN-γ treatment failed to increase activities of NK cells and to suppress activated HSCs in chronically alcohol-fed mice, showing no beneficial effects of IFN-γ in alcoholic liver fibrosis[9]. These results are possibly due to increased expression and production of TGF-β and SOCS1 by monocytes and activated HSCs[9,96]. We have integrated these

findings in Figure 3, and in the case of NKT cells, they seem to contribute to alcoholic liver injury because the activation of NKT cells accelerate alcoholic liver injury while NKT deficiency delays the process[97,98]. Nevertheless, reports on the effects of alcohol on NK/NKT cell functions are still controversial. Therefore, further studies of the effect of alcohol on NK/NKT functions are necessary.

Although the underlying mechanisms of liver fibrosis are not clear, alcohol consumption in patients with hepatitis C virus (HCV) infection may accelerate the process. This is because HCV triggers dysfunction and apoptosis of lymphocytes, such as T cells, NK cells, and NKT cells, *via* NADPH oxidase-derived oxygen radicals, which might be enhanced by alcohol-mediated apoptosis of hepatocyte and ROS production, and subsequently accelerating liver fibrosis[99,100]. In addition, HCV core and nonstructural proteins either induce TLR4 expression in hepatocytes and B cells, leading to enhanced production of IFN-β and IL-6, or enhance the secretion of TGF-β1 and the expressions of procollagen α(I) or α-smooth muscle actin in human-activated HSCs and LX-2 cells[101,102]. Therefore, all these factors and findings may be promoting the effect of alcohol on liver fibrosis in patients with HCV infection.

TREATMENT STRATEGY FOR ALD

In alcoholic patients, the best therapeutic is to reduce ethanol intake significantly, subsequently avoiding further liver injury[1]. However, abstinence is very difficult to achieve. The alternative option is liver transplantation, but donors are relatively scarce[2]. For these reasons, many studies have been performed to determine targets or strategies for treating ALD. Regarding the critical role of TNF-α and ROS in animal models with ALD, several

drugs have been developed and are currently available for clinical trial. To suppress the inflammatory responses, phosphodiesterase inhibitor (Pentoxifylline) and corticosteroid therapies were also administered and resulted in reductions of TNF-α, IL-8, and soluble and membranous forms of intracellular adhesion molecule 1 in patients with ALD, *via* inhibition of activator protein 1 and NF-κB[103-106]. Even though treatments with antioxidants have shown inhibitory effects on alcohol-mediated oxidative stress in animal models, studies of treatment with antioxidants (S-adenosylmethionine, vitamin E, and silymarin, the active element in milk thistle) had no beneficial effects in either patients with alcoholic hepatitis or those with alcoholic cirrhosis[107,108]. In addition, other treatments, such as antifibrotics (colchicines) and nutritional therapies, have been tried, but the effects were minimal. Based on this discrepancy between animal studies and clinical trials, therapeutic strategies should be reconstituted to overcome ALD. For example, treatments for the amelioration of ALD should be targeted simultaneously to HSCs and innate immune cells (e.g. Kupffer cells and NK cells), because these cells can produce endocannabinoid (e.g. 2-AG), inflammatory mediators (e.g. TNF-α, ROS), pro-fibrotic cytokines (e.g. TGF-β), and negative regulators against NK cells (e.g. TGF-β, SOCS1) concurrently in response to chronic alcohol consumption. Thus, we need novel orchestrated strategies, which are capable of enhancing NK cell cytotoxicity while simultaneously suppressing the activation of HSCs and Kupffer cells.

CONCLUSION

The present review summarized the pathogenesis of ALD, in which NK cells, Kupffer cells and HSCs are highly involved. Alcohol-mediated activation of Kupffer cells appears to be required for the development of alcoholic steatohepatitis *via* LPS-TLR4 signaling pathways. In addition, alcohol-induced paracrine activation of HSC-derived endocannabinoid in hepatocytes might be a major factor in the induction of alcoholic steatosis. Furthermore, both Kupffer cells and HSCs play important roles in alcoholic liver fibrosis *via* the suppression of the antifibrotic effects of NK cells. Therefore, the interactions among them should be simultaneously considered when developing therapeutics for ALD. For example, even though Kupffer cells are appropriately suppressed by a certain drug, alcohol-activated HSCs still might enhance the accumulation of fat in the liver, leading to lipotoxicity, which in turn generates oxidative stress and inflammation, subsequently restoring steatohepatitis. Besides, functions of NK cells are abrogated or suppressed by alcohol-induced ROS and high levels of TGF-β in the liver. Thus, additional antioxidant and neutralizing TGF-β1 antibody treatment may have beneficial effects in slowing down ALD. Conclusively, further studies to elucidate the roles of innate immunity and HSCs might aid in the development of novel therapeutic targets for the treatment of ALD.

Abstract

Microsomal glutathione transferase (MGST1, EC 2.5.1.18) is a membrane bound glutathione transferase extensively studied for its ability to detoxify reactive intermediates, including metabolic electrophile intermediates and lipophilic hydroperoxides through its glutathione dependent transferase and peroxidase activities. It is expressed in high amounts in the liver, located both in the endoplasmic reticulum and the inner and outer mitochondrial membranes. This enzyme is activated by oxidative stress. Binding of GSH and modification of cysteine 49 (the oxidative stress sensor) has been shown to increase activation and induce conformational changes in the enzyme. These changes have either been shown to enhance the protective effect ascribed to this enzyme or have been shown to contribute to cell death through mitochondrial permeability transition pore formation. The purpose of this review is to elucidate how one enzyme found in two places in the cell subjected to the same conditions of oxidative stress could both help protect against and contribute to reactive oxygen species-induced liver injury.

INTRODUCTION

Tissue damage due to excessive production of reactive intermediates (reactive oxygen species (ROS), reactive nitrogen species (RNS), lipid peroxides, free radicals) has been shown to be a major part of various pathologies including atherosclerosis, diabetes, cancer, ischemia-reperfusion injury, aging, and liver injury from both alcoholic and non-alcoholic origins[1-3]. Organisms have evolved many defense mechanisms as protection from these reactive intermediates. These include, but aren't limited to, various enzymes such as superoxide dismutase, Se-dependent glutathione peroxidase, catalase, glutaredoxins, peroxiredoxins, and glutathione transferases (GSTs)[4]. GSTs bind and conjugate electrophiles to GSH to, in effect, neutralize them, and protect the cells. Some GSTs also have glutathione peroxidase activities. While many GSTs are cytosolic, other GSTs exist that are integral membrane proteins. They are members of the membrane associated proteins in eicosanoid and glutathione metabolism (MAPEG) family, which include enzymes that synthesize prostaglandins and leukotrienes. Microsomal glutathione transferase 1 (MGST1) is a member of this family and is the subject of the following review.

MGST1 STRUCTURE AND FUNCTION

MGST1 is an approximately 17 kDa membrane bound glutathione s-transferase[5]. It is found in the highest

quantity in the liver; however it is also present in other tissues in smaller amounts. It is found primarily in the microsomes (3% of microsomal protein) and the inner and outer mitochondrial membranes (5% of mitochondrial membrane protein) of cells, where the majority of reactive intermediates are produced[6]. It exists in membranes as a homotrimer which can bind three molecules of GSH. However, only one molecule is modified to a thiolate anion, and this molecule binding site has a much higher affinity than the other two sites[7-10].

MGST1 has two enzymatic activities; one as a GST, and the other as a glutathione dependent peroxidase (GPX)[11]. The function of MGST1 in both organelles is thought to be the neutralization of lipid peroxides and conjugation of other reactive intermediates to glutathione. Based on these two enzymatic activities, MGST1 has been shown to have three substrate binding sites[12]. One site binds GSH on the cytosolic face of each monomer. A second site binds electrophilic substances in a hydrophobic pocket, also on the cytosolic face. This site may partially overlap with the glutathione thiolate anion binding site. This site contains cys49 (the only cysteine per monomer) which acts as an oxidative and chemical stress sensor[13]. Because the binding pocket for electrophiles is hydrophobic, MGST1 is uniquely suited among the GSTs to detoxify more hydrophobic reactive intermediates, as often occurs during drug metabolism. The third site is the phospholipid/fatty acid binding site that may bind these hydrophobic lipid peroxides through an opening in the tertiary structure of the trimer, rather than binding them through the cytosolic face. This site also overlaps the GSH binding site, but is separate from the electrophilic site[12].

The majority of research has been performed on MGST1 purified from liver microsomes. These studies have identified that MGST1 exists as a trimeric complex where three monomers interact to give the active enzyme[10,14]. Modification of the thiol group of cys49 induces a conformational change and increased activation, and at increasing protein concentration, the trimers aggregate into higher molecular weight complexes that have even further increased activity as measured by GST assay[15]. Multiple studies have also shown that the MGST1 trimer is activated by various chemical treatments that appear to modify the cys49. These modifications include alkylation, formation of disulfide bonds (either mixed disulfides with glutathione, or protein dimer formation), or sulfenic acid modification[16-20]. An additional mechanism of activation is proteolysis at lys41[21]. In fact, a liver enzyme, hepsin, has been implicated in this mode of activation[22]. It is postulated that proteolysis and cysteine modification induce a conformational change that induces the GSH that is bound to be converted to the thiolate anion more readily than what occurs under basal levels.

PROTECTIVE EFFECTS OF MGST1

A variety of reactive intermediates can induce activation of MGST1 *in vitro* and *in vivo*[16-20,23,24], but the physiological function of MGST1 is still unclear. It as also been noted that transfection of cytochrome P450 2E1 (CYP2E1), a significant generator of ROS, in a hepatoma cell line (HepG2) induced increased expression and activation of catalase, GSTα (cytosolic GST) and MGST1[25]. Incubation of these cells with increasing concentrations of H_2O_2 showed that they had better viability and were better able to remove the H_2O_2, when compared with vector controls. The CYP2E1 transfected cells also showed higher viability compared to controls when incubated with 4-HNE (a lipid peroxidation product) or the free radical generators, menadione or antimycin A. Resistance to ROS-induced injury in this cell line was attributed to the increased expression of the previously mentioned antioxidant response proteins; although it is unclear if similar effects would be observed if only MGST1 were overexpressed.

To help specifically determine the role of MGST1 in protection against oxidative stress, a series of studies was performed using a breast cancer cell line, MCF7, stably transfected either with the sense strand of MGST1 or its anti-sense negative control. Transfection yielded a clone that expressed MGST1 at 0.2-0.5 μg/mg total cellular protein. This level is approximately a tenth of what is expressed in the liver, but is comparable to other extrahepatic tissue expression levels. This cell line was originally designed to determine the contribution of MGST1 to anticancer drug resistance[26], but was used in subsequent studies to test the ability of MGST1 to protect the cells from reactive intermediates[27,28]. Treatment of the MGST1 transfected cells with either lipophilic hydroperoxide (cumene hydroperoxide, CuOOH), or hydrophilic H_2O_2, revealed that they were more resistant to cell death (by MTT, LDH, and colony forming efficiency assays) than the cells transfected with the antisense vector. CuOOH is a substrate for MGST1 and is a target for its GPX activity, while H_2O_2 is not a direct substrate. So MGST1 in this system has both direct and indirect effects on hydroperoxide induced toxicity. Measurement of hydroperoxide levels in these cell lines revealed a significant drop only in the MGST1 containing cell line. These results are consistent with transient MGST1 transfection studies by Maeda *et al*[29].

Subsequent studies revealed that not only did MGST1 lower hydroperoxide levels, it lowered lipid peroxidation[27]. Treatment of MGST1 transfected cells with CuOOH and tert-Butyl hydroperoxide (BuOOH) resulted in fewer lipid peroxidation products than in antisense controls. Notably, in the absence of any treatments, the MGST1 transfected cells exhibited less lipid peroxidation than their control counterparts. Vitamin E added to the MGST1 transfected cells mediated protection against cytotoxicity induced by the hydroperoxides, but was ineffective in contributing to the MGST1 mediated suppression of the cytotoxic effects of 4-HNE (lipid peroxidation product) or cisplatin. This suggests that these cytotoxic agents may be neutralized by the GST activity of MGST1 rather than its GPX activity. This is consistent with the previous findings that MGST1 neutralizes 4-HNE through its GST activity[30]. The study by Johansson *et al*[27] also examined the effect of hydroperox-

ides on mitochondrial function in the control and MGST1 transfected cells. Excessive ROS has been shown to induce mitochondrial dysfunction, MPT and cell death[3,31] and MGST1 makes up a sizable amount of the mitochondrial outer membrane protein, possibly as a defense mechanism against lipid peroxidation and reactive oxygen species generated by normal mitochondrial function[27]. This study examined mitochondrial respiration in the control and MGST1 transfected cells after treatment with CuOOH[27]. They found that in control cells, treatment with CuOOH suppressed both phosphorylating respiration and uncoupled respiration, while overexpression of MGST1 protected against the CuOOH induced suppression. The effect of MGST1 on mitochondrial Ca++ loading and release was also examined after CuOOH treatment, since high levels of Ca++, especially under conditions of oxidative stress, can damage the mitochondria, inducing mitochondrial permeability transition (MPT). MPT is identified as a key event in some forms of apoptosis and in necrosis[31]. CuOOH treatment lowered the amount of Ca++ required to induce MPT in the control cells. However, MGST1 overexpression had a protective effect on the mitochondria, as an increased amount of Ca++ was required to induce MPT in these cells after CuOOH treatment. These authors attribute this to the mitochondrial population of MGST1 (hereafter, referred to as mtMGST1), but it cannot be ruled out that the microsomal population of MGST1 is also actively detoxifying the CuOOH, since these experiments were performed in plasma membrane permeabilized cells. Further studies need to be performed on mitochondria from these cells to discern the role of mtMGST1 concerning oxidative stress induced mitochondrial dysfunction. In addition, while overexpression of MGST1 has protective effects in this study, the levels in the MGST1 transfected cells are only one tenth of what occurs normally in the liver. Therefore this cell line may not be appropriate for studying the deleterious effects of mtMGST1 that contribute to oxidative stress induced liver injury as described below.

DELETERIOUS EFFECTS OF MGST1

Until recently, examination of MGST1 has focused on the microsomal population. From these studies, it has been suggested that MGST1 plays an essential role in the protection of cells from reactive intermediates[13,25,27,28]. Up to this point, virtually nothing was known about the mitochondrial population of MGST1 concerning its activation and function. Mitochondria are a significant producer of ROS, and oxidative stress has been shown to deplete mitochondrial glutathione and induce both MPT and the release of cytochrome C[3,32-34]. This mitochondrial dysfunction leads to apoptosis and necrosis. Since mtMGST1 is localized in the inner and outer mitochondrial membranes, it is most likely activated under these conditions of oxidative stress, similar to the microsomal population. In fact, early animal studies showed that administration of galactosamine, carbon tetrachloride, or a combination of galactosamine and lipopolysaccharide (GalN/LPS) induced

liver injury that was characterized by damaged mitochondria, depleted mitochondrial GSH, increased ROS and lipid peroxidation and apoptosis, and increased mtMGST1 activity[35-37]. Preliminary studies indicated that mtMGST1 was activated by ROS, so using the GalN/LPS animal model of liver injury, Lee *et al*[32] set out to examine specifically the activation and function of mtMGST1. GalN/LPS induced activation of mtMGST1, which was reduced by dithiothreitol. Immunoblotting of mitochondrial extracts showed the formation of S-S linked mtMGST1 dimers, as well as glutathionylated mtMGST1 (mixed S-S with GSH). In contrast, mitochondrial extracts from control rat livers showed no modified mtMGST1. This is consistent with previous studies which showed that modification of cys49 in purified MGST1 by disulfide and mixed disulfide formation induced activation[17,23]. In addition, mitochondria from the GalN/LPS treated rats exhibited cytochrome C release, indicative of MPT and mitochondrial dysfunction[32]. Incubation of mitochondria with anti-MGST1 antibodies inhibited the cytochrome C release, suggesting the involvement of activated mtMGST1 in ROS-induced mitochondrial dysfunction and MPT pore formation.

Complementary *in vitro* studies using mitochondria from control rats treated with diamide (a thiol oxidizing agent) or diamide with GSH showed that treatment induced dimerization or glutathionylation of mtMGST1 through cys49. These treatments increased mtMGST1 activity, and induced mitochondrial swelling and cytochrome C release similar to the GalN/LPS treatment mentioned above[32]. Addition of cyclosporin A (CsA) or bongkrekic acid (BKA) (two inhibitors of MPT pore formation) inhibited mtMGST1 activation, mitochondrial swelling and cytochrome C release. Based on the *in vivo* and *in vitro* studies, the authors concluded that activation of mtMGST1 through modification of cys49 contributed to MPT pore formation and mitochondrial dysfunction.

Subsequent studies delved further into the role of mtMGST1 activation and MPT pore formation. Hossain *et al*[38] investigated the effect of the ROS generator gallic acid (GA), MPT inhibitors and GST inhibitors on activation of mtMGST1 and MPT. Incubation of rat liver mitochondria with GA induced significant activation of mtMGST1, which was blocked by antioxidant enzymes and singlet oxygen quenchers. Activation of mtMGST1 was also inhibited by GST inhibitors and CsA. However, when mitochondrial swelling was examined, GST inhibitors inhibited the swelling induced by GA, whereas addition of MPT inhibitors was largely ineffective. This suggested that GA induced non-classical or unregulated MPT, and that mtMGST1 activation was involved. Previous studies have indicated that protein misfolding induces aggregation and pore formation in a Ca++ independent manner that is insensitive to CsA. In fact, there is evidence that triterpenoids like GA interact with mitochondrial proteins, resulting in oxidation of their thiol residues and leading to formation of higher molecular weight aggregates, which then form a CsA insensitive MPT pore[39-42]. It was noted that GA treatment induced thiol oxidation (sulfenic acid) of cys49 of

mtMGST1, instead of disulfide formation as observed previously with diamide and diamide + GSH[32]. In addition, treatment of mitochondria with GA induced formation of high molecular weight protein aggregates containing mtMGST1, consistent with previous studies showing protein aggregation is involved in the non-classical MPT[40,41,43]. It is also noteworthy that examination of the inner and outer membrane populations of mtMGST1 showed that only the outer membrane population was affected by GA. Based on these results, the authors concluded that oxidation of the outer membrane mtMGST1 population by GA leads to its activation, protein aggregation and induction of non-classical MPT, suggesting a novel function for mtMGST1 involving mitochondrial dysfunction and cell death.

Further studies examined the contributions of the inner and outer membrane populations of mtMGST1 to MPT[44]. Using rat liver mitochondria under basal conditions, this group examined the effect of both MPT inhibitors and GST inhibitors on mtMGST1 activation. They observed that in the absence of nonionic detergent, MPT inhibitors CsA, BKA, ADP and ATP were all effective in decreasing basal mtMGST1 activity. However, addition of detergent ameliorated this effect. Incubation of mitochondria with GST inhibitors decreased mtMGST1 activity regardless of addition of detergent. These results indicated that while the GST inhibitors directly affected the mtMGST1 activity, the MPT inhibitors affected mtMGST1 activity indirectly, possibly by affecting interaction of mtMGST1 with other proteins like cyclophilin D (CypD) and the adenine nucleotide translocator (ANT), which are known to be involved in MPT. Further studies using inner mitochondrial and outer mitochondrial membrane fractions showed that MPT inhibitors were effective in reducing mtMGST1 activity only in the inner membrane component, and this inhibition was lost after addition of detergent. Subsequent experiments with cytosolic GST and microsomal MGST1 showed that the MPT inhibitors had no effect on their activity, further suggesting that the contribution of inner membrane mtMGST1 to oxidative stress-induced MPT resides in its ability to interact with specific proteins involved in regulating MPT (CypD and ANT). This may be due to activation induced (cys49 modification) conformational changes in the protein, that allow interaction with other MPT regulating proteins. Collectively, the studies using mtMGST have shown that it is activated by oxidant-induced modification of cys49, which induces a conformational change. This path to activation is similar to what has been observed for the microsomal population of MGST1. However, activation of mtMGST1 by reactive intermediates induces protein aggregation, MPT and mitochondrial dysfunction, either through non-classical or classical pathways which results in apoptosis and necrosis. Interestingly, it is unclear if activated mtMGST1 is able to actually detoxify reactive intermediates while contributing to MPT. It is also unclear if ROS-induced depletion of mitochondrial GSH could induce or contribute to mtMGST1 participation in mitochondrial dysfunction.

ETHANOL-INDUCED CHANGES IN MGST1

It has been previously shown that chronic alcoholism induces liver oxidative stress that is in great part produced by the mitochondria[3]. Ethanol-induced production of ROS is detrimental to the mitochondria, leading to glutathione depletion and mitochondrial dysfunction, including MPT and cytochrome C release. Initial studies have found that MGST1 from the livers of ethanol-fed rats is modified by a product of ethanol metabolism, the malondialdehyde-acetaldehyde (MAA) adduct[45-47]. Examination of both the mitochondrial and microsomal fractions from ethanol-fed rat livers and their pair-fed controls show that while ethanol feeding induces activation of both microsomal MGST1 and mtMGST1, the mitochondrial population has a higher activity, and is more highly modified with MAA[45]. These results suggest that the mtMGST1 may be involved in ethanol-induced mitochondrial dysfunction. Studies are in progress to further characterize both the ethanol-induced modification and the contribution of modified MGST1 to ethanol-induced liver injury.

CONCLUSION

This review focuses on the function of MGST1 in situations of oxidative stress. Extensive studies on this protein have identified its monomeric and trimeric structures, its three substrate binding sites, its ability to be activated by oxidation or alkylation of the lone cysteine (cys49) in each subunit, and its ability to detoxify reactive intermediates by either its GST activity or its GPX activity. Additional studies have also indicated that activation of the enzyme alters its conformation. Therefore, this enzyme has been implicated as part of a complex method of defense by cells in response to reactive intermediates to protect them from cell death. However, these studies focused only on the microsomal population of this enzyme. Recent studies examining mtMGST1 indicate that this population is activated by oxidative stress in a manner similar to that reported for the microsomal enzyme. mtMGST1 also undergoes cys49 modification, leading to increased GST activity and activation-induced conformational changes. However, in the mitochondria, oxidant-induced mtMGST1 activation induces or increases its association with other mitochondrial proteins, resulting in MPT pore formation, cytochrome C release and induction of apoptotic and/or necrotic pathways. From these collective studies it is apparent, depending on the context and MGST1 population involved, that MGST1 activation can either exhibit a protective or toxic effect on the liver (and possibly other tissues). However, much more work is necessary to evaluate not only the individual contributions of these two populations to oxidative stress-induced liver injury, but also how the effects of the activation of these two populations combine to help determine cell survival.

Abstract

Oxidative stress, generated by chronic ethanol consumption, is a major cause of hepatotoxicity and liver injury. Increased production of oxygen-derived free radicals due to ethanol metabolism by CYP2E1 is principally located in the cytoplasm and in the mitochondria, which does not only injure liver cells, but also other vital organs, such as the heart and the brain. Therefore, there is a need for better treatment to enhance the antioxidant response elements. To date, there is no established treatment to attenuate high levels of oxidative stress in the liver of alcoholic patients. To block this oxidative stress, proteasome inhibitor treatment has been found to significantly enhance the antioxidant response elements of hepatocytes exposed to ethanol. Recent studies have shown in an experimental model of alcoholic liver disease that proteasome inhibitor treatment at low dose has cytoprotective effects against ethanol-induced oxidative stress and liver steatosis. The beneficial effects of proteasome inhibitor treatment against oxidative stress occurred because antioxidant response elements (glutathione peroxidase 2, superoxide dismutase 2, glutathione synthetase, glutathione reductase, and GCLC) were up-regulated when rats fed alcohol were treated with a low dose of PS-341 (Bortezomib, Velcade®). This is an important finding because proteasome inhibitor treatment up-regulated reactive oxygen species removal and glutathione recycling enzymes, while ethanol feeding alone down-regulated these antioxidant elements. For the first time, it was shown that proteasome inhibition by a highly specific and reversible inhibitor is different from the chronic ethanol feeding-induced proteasome inhibition. As previously shown by our group, chronic ethanol feeding causes a complex dysfunction in the ubiquitin proteasome pathway, which affects the proteasome system, as well as the ubiquitination system. The beneficial effects of proteasome inhibitor treatment in alcoholic liver disease are related to proteasome inhibitor reversibility and the rebound of proteasome activity 72 h post PS-341 administration.

INTRODUCTION

Excessive alcohol consumption is recognized worldwide as a leading cause of disease, disability, and death[1]. Alcoholic liver disease (ALD) is a collective term for the pathophysiological changes caused by chronic alcohol consumption. These changes include oxidative stress generation, liver steatosis and inflammatory response fibrosis, and cirrhosis.

The marked generation of oxidative stress associated with ethanol metabolism is one of the main liver injuries caused by chronic alcohol consumption. Oxidative stress causes dysfunctions in several cellular mechanisms, such as DNA repair and antioxidant systems. CYP2E1, which is up-regulated to metabolize ethanol[2], in mitochondria[3], and activated Kupffer cells[4], generates free radicals through the oxidation of NADPH to NADP+, which induces hepatocyte necrosis and apoptosis[5]. In addition, high levels of reactive oxygen species (ROS) promote lipid peroxidation and end-products formation, such as malondialdehyde and 4-hydroxynonenal. These aldehydes are highly interactive and form adducts by binding covalently to cellular proteins, thus forming antigenic adducts, which cause inflammation[6,7].

Oxidant stress can be counterbalanced by the hepatocyte antioxidant defense, which induces both enzymatic and non-enzymatic mechanisms. One of the major mechanisms by which cells protect themselves against oxidative stress is the up-regulation of a wide range of antioxidant genes. Among the intracellular antioxidant molecules, reduced glutathione (GSH) is the most abundant intracellular non-protein thiol in cells. Glutathione is the first level of cellular antioxidative response, and is important for a variety of biological functions, including protection of cells from oxidative damage by free radicals, detoxification of xenobiotics, and membrane transport. By keeping the cellular environment in a reduced state, GSH is responsible for the removal of potentially toxic electrophiles and metals, thereby protecting cells from toxic oxygen products[8]. Furthermore, GSH exhibits a large panel of actions in controlling gene expression, apoptosis mechanisms, and membrane transport[9]. Therefore, cells tightly regulate the synthesis, utilization, and export of GSH. L-S,R-buthionine sulfoximine (BSO), a potent specific inhibitor of γ-glutamylcysteine synthetase, the rate-limiting enzyme in GSH biosynthesis, has been used to deplete intracellular GSH and reverse drug resistance in tumor cells[10], showing that GSH is a chemoresistance factor in cancer cells. The second level of cellular antioxidative response is the gene expression up-regulation of antioxidative enzymes. Among the enzymatic antioxidant defenses are: (1) glutathione synthetase (GSS) and superoxide dismutases (SOD), which dismutates O_2 into H_2O_2 and O_2; (2) catalase, which removes H_2O_2, generating H_2O and O_2; and (3) glutathione peroxidase (GPX) and glutathione reductase (GSR), which, using the cofactor NADPH, decompose H_2O_2, while reducing glutathione[11]. Alcohol has been shown to deplete GSH levels, particularly in the mitochondria. Mitochondria are usually characterized by high levels of GSH needed to eliminate the ROS generated during respiratory chain activity[12], and can not synthesize GSH, but import it from the cytosol using a carrier protein embedded in the membrane surrounding the mitochondria. Alcohol has been reported to interfere with the function of this carrier protein, thereby leading to the depletion of mitochondrial GSH[13].

CURRENT TREATMENT FOR ALD

Several pharmaco-therapeutic studies have been undertaken to cure alcoholic hepatitis. The best known are the treatments that block tumor necrosis factor α and reduce inflammation (pentoxifylline, infliximab, etanercept)[14-16]. However, these treatments are associated with an increase of infections and death.

The antioxidant therapy included Vitamin E supplementation. However, the outcome of clinical trials did not show any improvement in patients with alcoholic hepatitis[17]. In addition, it has been shown that alcohol not only increases the production of ROS, but it also inhibits the antioxidants defense. It has also been shown that antioxidant therapy alone, or in combination with corticosteroids, did not improve 6-mo survival in severe alcoholic hepatitis[18]. The drug most widely used for alcoholism today is Disulfiram. Disulfiram, an inhibitor of aldehyde dehydrogenase, prevents acetaldehyde metabolism, and causes immediate and severe negative reactions to alcohol intake[19]. Recently, it has been used as an anti-tumor drug because it has the characteristic of a proteasome inhibitor[20,21]. New drugs and new treatments are thus needed since currently available treatments are not adequate. The latest studies using Disulfiram point to the potential of proteasome inhibitor treatment for ALD.

PROTEASOME INHIBITOR TREATMENT FOR ALD

Proteasome controls the degradation of cellular proteins and is closely implicated in signal transduction, development and cell cycle progression[22], antigen processing and immune response[23], and inflammation[24]. Proteasome inhibition has already proved to be a novel and promising strategy for the treatment of cancer[25-27]. Specifically, PS-341 (Bortezomib, Velcade®), a boronic acid dipeptide with selective activity as a proteasome inhibitor, has demonstrated clinical efficacy in patients with multiple myeloma[28], and has been approved by the U.S. Food and Drug Administration[29]. It is now under evaluation for its activity in a variety of other hematologic and solid malignancies[30-33]. Proteasome is considered an antioxidant defense in the cell due to its activity of removing damaged and oxidized proteins. Numerous reports have demonstrated that proteasome inhibitors cause an accumulation of oxidatively damaged proteins, indicating that a large majority of oxidatively damaged proteins, both in the cytosol and the nucleus of mammalian cells, are removed by the 20S proteasome[34,35]. However, it is also important to mention that proteasome inhibition is also an antioxidative defense, as it leads to an up-regulation in the gene expression of antioxidative enzymes. Although it is now well established that impairment of the ubiquitin proteasome pathway is implicated in the pathogenesis of ALD, a growing body of evidence shows that proteasome inhibitors provide protection against oxidative stress in the brain and in the heart[36-39].

Ethanol ingestion appears to have diverse effects on 26S proteasome activity, and no significant effects on the 20S proteasome[2]. The 26S proteasome activities are significantly decreased in the liver of rats fed ethanol[2,40-43]. This ethanol-induced proteasome pathway dysfunction is different from the proteasome inhibition obtained by using the proteasome inhibitor PS-341[44]. Microarray analysis studies have shown that the gene expression of antioxidative enzymes was not increased in the liver of rats fed ethanol chronically, when compared to that of rats given proteasome inhibitor PS-341[45].

Moreover, chronic ethanol exposure has been shown to deplete GSH levels, particularly in the mitochondria, which are usually characterized by high levels of GSH needed to eliminate the ROS generated during respiratory chain activity[13,46,47], while proteasome inhibition by PS-341 activates the gene expression of GSH recycling enzymes[48]. These authors showed a significant increase in the gene expression of antioxidative enzymes, such as glutathione reductase (GSR), glutathione synthetase (GSS), glutathione peroxidase 2 (GPX2), and superoxide dismutase 2 (SOD2), when rats were treated with the proteasome inhibitor PS-341. Exposure to a non-toxic low dose of proteasome inhibitor induced an increase in the antioxidative defense, thus suppressing ROS production, and therefore protecting against oxidative stress-induced hepatotoxicity due to chronic ethanol feeding. The beneficial effects of proteasome inhibition are not only related to the up-regulation of antioxidative enzyme gene expression[49], but also to the up-regulation of heat shock proteins[50], which is believed to prevent protein misfolding and the formation of protein aggregates. Thus, it is now postulated that these cytoprotective qualities obtained by the inhibition of proteasome at non-toxic doses might be beneficial in the treatment of hepatocyte injury associated with ALD. In addition, PS-341 is a highly specific and reversible proteasome inhibitor that produces a recovery and even a rebound of proteasome activity to higher levels 48 to 72 h post-treatment[48]. At the same time that proteasome inhibitor treatment up-regulated the antioxidant response elements, it down-regulated SREBP1-c[51] and the lipogenic enzymes gene expression, thus significantly decreasing steatosis in the liver of rats fed ethanol chronically[51]. It has also been found that IκB was significantly stabilized by proteasome inhibitor treatment in the liver of rats fed ethanol for 1 mo, which reflected a significant decrease in nNuclear factor (NF)-κB activation and a decrease in the expression of inflammatory genes regulated by NF-κB[52].

Chronic ethanol exposure increases the production of pro-inflammatory cytokines and disrupts immune defenses, increasing susceptibility to and the severity of infections. Proteasome inhibitor treatment can modulate the chronic ethanol-induced impairment of immune response and its consequences on host defense against microbial pathogens and tissue injury. These discoveries strongly indicate that proteasome inhibitor treatment has great potential in alcoholic liver disease therapy.

CONCLUSION

PS-341 is currently used in humans as an antitumor drug[26], and numerous studies have shown that it also represents a potential drug treatment for alcoholic liver disease. Proteasome inhibitors are a promising treatment to reduce ROS production, to reduce liver steatosis, and to reduce the production of pro-inflammatory cytokines caused by chronic ethanol feeding.

Abstract

AIM: To evaluate the effect of silencing *Livin* gene expression with siRNA to apoptosis and proliferation in a colon cancer cell line.

METHODS: To investigate the anticancer effect of silencing *Livin* gene expression, we established an siRNA transfected cell line using the HCT116 colon cancer cell line. After confirming the successful transfection, MTT assay, flow cytometry and annexin V staining were employed to evaluate the antiapoptotic effect. To confirm the *in vivo* effect of Livin-siRNA, different doses of Livin-siRNA were injected into xenografted tumors in BALB/c nude mice model.

RESULTS: Livin expression was dramatically decreased after siRNA transfection, especially at 25 μmol/L of siRNA, but this suppression was not dose-dependent. The cell count at 18 h after transfection was significantly reduced as compared with controls ($P < 0.01$), but tended not to decrease proportionally depending on transfected dose or time. MTT assay revealed that silencing the *Livin* gene suppressed cellular proliferation at 18 h after transfection ($P = 0.04$); however, the inhibitory effect disappeared thereafter. Also, there was no significant difference in cellular proliferation depending on siRNA dose. The rate of apoptosis also increased with silencing of the *Livin* gene. *In vivo*, the tumor size significantly decreased after Livin-siRNA injection at 20 μmol/L concentration ($P = 0.03$). There were no significant body weight changes of mice after siRNA injection. Histologic examination revealed no significant toxic reaction in kidney, liver and brain of mice.

CONCLUSION: siRNA-mediated downregulation of Livin expression can induce apoptosis in colon cancer in vitro and *in vivo*, which suggests the possibility of new cancer therapeutics using siRNA.

INTRODUCTION

Colon cancer is one of the most common malignancies worldwide and has shown increased incidence, especially in developing countries[1]. Until recently, a major treatment strategy has been surgical resection that shows good outcome over other treatments. With the activation of a screen-

ing program, early cancer, less than stage I, is curable with only surgical treatment. But the treatment results for metastatic disease are still unsatisfactory with surgery alone. In these cases, clinicians consider other treatment options such as chemotherapeutic agents and targeted agents. Recently, development of techniques in manipulation of nucleic acids makes gene therapy possible to adopt in cancer therapy.

RNA interference (RNAi) is a fundamental protective process in eukaryotic cells including invertebrates and vertebrates, which is able to block harmful signal by targeting complementary mRNA and cleaving thereof[2]. Small interfering RNA (siRNA) is fragments from double-stranded RNA by the enzyme Dicer[3-5]. The natural role of RNAi is supposed to be a defense mechanism against some viral infection or deleterious genomic instability. This special mechanism has been of great interest recently as siRNA targeting small genes are easily manufactured and applied to major clinical problems such as cancer, asthma, inflammatory disease and infection[6]. This methodology is becoming a powerful tool for new drug development in such areas and is replacing the techniques of using antisense oligonucleotide and ribozymes[7,8].

Livin, a 280 amino acid protein and a member of the mammalian type of inhibitor of apoptosis (IAP), are well-conserved proteins across the species. It has a single baculovirus IAP repeat (BIR) domain and a COOH-terminal RING domain and is localized predominantly in the nucleus and a filamentous pattern of cytoplasm[9]. The Livin gene spans 46 kb and is located on chromosome 20 at band q13[10]. The major function of Livin is an inhibition of apoptosis by binding to caspase 3, caspase 7 and caspase 9 and also in inhibition of proteolytic processes of caspase 9[9,11]. Its overexpression protects cells from various proapoptotic stimuli.

The expression of Livin, similar to expression of Survivin, is rarely detected in normal adult tissues but exists abundantly in cancerous tissues and transformed cells[9]. The overexpression of Livin protein has been reported in colorectal cancer, leukemia, hepatocellular carcinoma, and melanoma[12]. Recently, major attention has been focused on the IAP family, especially Survivin and Livin, as they are easy to handle in the genetic field due to their small size. Moreover, the lack of expression in normal adult tissues of Livin is a very attractive characteristic in cancer therapy[9].

In this study, we used siRNA targeting to Livin transfection into the HCT116 colon cancer cell line to confirm the antitumor effect and blockade of Livin gene and performed an additional *in vivo* study using BALB/c nude mice xenografts to determine the direct tumor regression effect of Livin silencing with siRNA. These results suggested that Livin is an effective target for colorectal cancer treatment using siRNA technique.

MATERIALS AND METHODS

Materials

Cell culture-The HCT116 colon cancer cell line, purchased from Korean cell line bank, was grown in RPMI1640 medium (Life Technologies, Inc., Grand Island, NY) sup-plemented with 10% fetal bovine serum (FBS, Life Technologies, Inc.), penicillin (100 U/mL) and streptomycin (100 g/mL). Cells were maintained at 37℃ in a humidified atmosphere of 50 mL/L CO_2.

RT-PCR procedure

Total RNA was extracted using the Trizol reagent (Invitrogen, Carlsbad, CA). The method for extracting total RNA was according to the manufacturer's protocol. RNA samples were quantified at 260 nm using spectrophotometry. One μg of total RNA was reacted for 15 min at 42℃ using the Promega's Reverse Transcription System (Promega Corp., Madison, WI), reacted for 5 min at 95℃, and cDNA was obtained. For polymerase chain reaction (PCR), cDNA (3 μL) was obtained by reverse transcription, 0.1 μmol primers, 1.25 μL GoTaq DNA polymerase, 0.2 mmol/L deoxynucleotide triphosphate (dNTP), 1 Go Taq reaction buffer and each primer was added, and DNA was amplified by performing PCR with primer of Livin; forward, 5-GTCAGTTCCT-GCTCCGGTCAA-3; reverse, 5-GGGCACTTTCAGACT-GGACCTC-3. Electrophoresis of PCR products was performed on 1.5% agarose gel and examined by staining with ethidium bromide. By measuring the brightness of bands using a densitometer, their amount was quantified using the value of β-actin as the standard value.

siRNA design and preparation

Synthetic 21-nt RNAs were purchased from Dharmacon Research (Lafayette, CO; in deprotected, desalted, and annealed form.). We used 4 primers for silencing the Livin gene to improve the blocking efficiency. The target sequences of Livin for production of siRNA were 5'-GGAGAGA-GGTCCAGTCTGA-3', 5'-GGAAGAACCGGAAGAC-GCA-3', 5'-GCTCTGAGGAGTTGCGTCT-3' and 5'-GCTCTGAGGAGTTGCGTCTTT-3'. The nonspecific control siRNA duplex was also purchased from Dharmacon Research.

Briefly, centrifuge tubes containing siRNA to ensure that the siRNA pellet was collected at the bottom of the tube. Resuspended siRNA to a convenient stock concentration with 1X siRNA buffer (Dharmacon, Inc., Lafayette, CO). After placing the solution on a shaker for 30 min at room temperature, the concentration of siRNA was verified using UV spectrophotometry at 260 nm.

HCT116 cells were diluted in fresh media without antibiotics and transferred to six-well plates (1×10^5 cells/well) 24 h before transfection and maintained at 37℃ in a humidified atmosphere of 50 mL/L. HCT116 cells grown to a confluence of 40%-50% were transfected with siRNA using Lipofectamine 2000 (Life Technologies, Inc., Grand Island, NY) according to the manufacturer's recommendations. To detect the transfection efficiency, the cells were analyzed by FACSan (Becton Dickson, San Jose, CA) 6 h after transfection with FITC-labeled siRNA. After transfection, the cells were incubated and then used to various analyses.

MTT assay

Cell viability was examined by routine 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay.

HCT116 cells (1×10^6) were planted in 96-well plates with RPMI1640 in a final volume of 500 μL. On the following day, cells were treated with increasing concentration of siRNA and cultured for 48 h, then cell proliferation was assessed by MTT assay. Following incubation at 37℃ for 3 h, the reaction was stopped by the addition of 150 μL DMSO. After the crystal dissolved, the absorbency of the samples was determined at 492 nm.

Cell counting

HCT116 cells were planted in 24-well plates with RPMI 1640. Cells were treated with increasing concentration of siRNA and cultured for 48 h, then cells were collected by trypsinization, mixed in PBS and trypan blue added. Cells were counted using a microscope counting chamber.

Flow cytometric analysis

At 24 h after transfection, HCT116 cells on 60-mm tissue culture plate were treated with 1 × trypsin-EDTA (Invitrogen, Carlsbad, CA) for 5 min at 37℃; cells were then removed from the plate by gentle scraping, dispersed into cold PBS and washed twice. The cells were resuspended in 1 × binding buffer at a concentration of approximately 1 $\times 10^6$ cells/mL. Five μL of Annexin V- FITC and 10 μL of PI were added to each cell suspension and incubated at room temperature for 10 min in the dark. The cells were subjected to fluorescence estimation using a FACS Calibur flow cytometer. Uninoculated cells stained with Annexin V-FITC and PI were used to determine background levels of apoptosis.

Xenograft model

All animal experiments in this report were performed with approval of the Institutional Animal Care & Use Committee in Ewha Womans University, School of Medicine. The 4-wk-old male BALB/c nude mice were grown in a sanitary room and adjusted for 1 wk before the start of the experiments. Viable HCT116 colon cancer cells (2.0 × 10^6 in PBS/100 μL) were injected subcutaneously into the right flank of the nude mice. Three weeks after tumor cell inoculation with confirmation of successful maturation of tumors, mice were divided randomly into four groups (ten mice per group) and were treated weekly for 4 wk by way of center-intratumoral direct injection at different doses (10, 20, 50 μmol/L) of siRNA manufactured with atelocollagen to achieve effective delivery. To prepare the siRNA/atelocollagen complex, equal volumes of atelocollagen (Atelo-Gene® Systemic Use; Koken, Tokyo, Japan. 0.1% in PBS at pH 7.4) and siRNA solution were combined and mixed by rotation for 20 min at 4℃. In the control group, pure PBS was injected using the same method. The tumors were monitored with a caliper every week over a 4 wk period after siRNA transfection. Tumor volume for each mouse was determined (in cubic millimeter) by measuring in two directions and was calculated as tumor volume = length × (width)^2/2. Also, body weight of each mouse was monitored and recorded. Five weeks after the last siRNA injection, all mice were sacrificed according to the animal experi-

Figure 1 Transfection efficiency. Successful transfection of small interfering RNA was detected with fluorescence staining in HCT116 cell line. A: HCT116 cell culture; B: HCT116 cell with transfection.

mental guidelines and the xenografted tumors were excised and prepared with a routine pathological procedure. Tumor sections were deparaffinized and subjected to Hematoxylin and Eosin staining in the usual manner.

Statistical analysis

Each experiment was repeated three times or more. Bands from RT-PCR were quantified with Quantity One software (Bio-Rad, Hercules, CA). mRNA levels were calculated by referring them to the amount of b-actin. The difference between means was performed with analysis of variance. All statistical analyses were performed using SPSS 11.0 software (SPSS, Inc., Chicago, IL). Statistical significance was considered when the *P* value was less than 0.05.

RESULTS

Transfection of siRNA-Livin to HCT 116 cell line

To identify whether Livin expression was affected by siRNA, we transfected siRNA at different concentrations (25, 50, 100, 150 and 200 μmol/L) to HCT 116 cell line, and then detected Livin density at 18, 24 and 30 h after transfection by RT-PCR.

Successful transfection of siRNA was detected with fluorescence staining (Figure 1) and expression of Livin gene was compared to β-actin. Control HCT 116 cells expressed Livin very well and this expression was dramatically decreased after siRNA transfection. But this effect was attenuated with time and Livin expression was re-

Figure 2 Change of Livin expression after small interfering RNA transfection. This figure shows Livin expression (%) in HCT116 cells at 18, 24 and 30 h post-transfection with 25, 50, 100, 150 and 200 μmol/L of siRNA. Livin expression was compared with β-actin by Western blotting. A: Livin expression at 18 h post-transfection. It was effectively suppressed by 25 μmol/L of siRNA, but this suppression was not dose-dependent; B: Livin expression at 24 h post-transfection; C: Livin expression at 30 h post-transfection; It was retrieved 30 h after transfection.

Figure 3 Cell counting after small interfering RNA transfection in HCT116 cell line. We estimated cell count (%) of each groups in HCT116 cells after Livin silencing with 25, 50, 100, 150 and 200 μmol/L of siRNA. The cell count at 18 h after transfection was the most effectively reduced, but this effect was not time-dependent or dose-dependent. A: Cell count at 18 h post-transfection was significantly reduced as compared with control. (*P* < 0.01); B: Cell count at 24 h post-transfection; C: Cell count at 30 h post-transfection.

trieved 30 h after transfection. Livin expression was most effectively suppressed at 25 μmol/L of siRNA, but this suppression was also not dose-dependent (Figure 2).

Reduction of viable cell numbers with siRNA to Livin

First, we estimated cell counts of each group to evaluate tumor cell growth after Livin silencing. We analyzed cultured cells grown in three dishes per group at one time, and repeated this study three times. As seen in Figure 3, the cell count at 18 h after transfection was significantly reduced as compared with control (*P* < 0.01), but tended not to decrease proportionally depending on transfected dose or relapsing time.

Suppression of cellular proliferation by SiRNA

To quantify the cellular viability, MTT assay was performed. The MTT assay showed that, compared with controls, the proliferation of cells transfected with siRNA was remarkably inhibited at 18 h after transfection (*P* = 0.04), but the inhibitory effect disappeared thereafter, which indicated that the number of viable cells began to increase.

There was no significant difference in cellular proliferation depending on siRNA dose (Figure 4).

Induction of apoptosis by SiRNA

Flow cytometric analysis after Annexin V staining was performed to investigate whether Livin-silencing induces apoptosis resulting in reduction of cell count or suppression of cellular proliferation as per the above findings. As a result, the apoptotic rate was increased continuously since 50 μmol/L of siRNA was treated. The apoptotic rate in control was 3.91%, the apoptotic rate of cells transfected with siRNA 50 μmol/L was 30.32%. The apoptotic rates of cells transfected with siRNA 100 μmol/L, 150 μmol/L and 200 μmol/L increased to 32.88%, 36.91% and 45.08%, respectively (Figure 5). The apoptotic rate was increased dose-dependently, but the necrotic portion was also increased. So, it was thought low dose siRNA was more effective in the clinical setting.

Change of tumor volume in vivo after siRNA treatment

Next, we designed a xenograft model to identify the po-

Figure 4 MTT assay after small interfering RNA transfection in HCT116 cell line. A: The proliferation of cells transfected with siRNA was remarkably inhibited at 18 h post-transfection ($P = 0.04$); B and C: Cellular proliferation at 24 and 30 h post-transfection. The inhibitory effect shown A disappeared, cellular proliferation was similar with control.

Figure 5 Results of Annexin V staining after small interfering RNA transfection in HCT116 cell line. The apoptotic portion (right lower quadrant) was increased continuously after siRNA transfection, but the necrotic portion (right upper quadrant) was also increased. A: The apoptotic rate of staining was 0.26%; B: The apoptotic rate of control was 3.91%; C: The apoptotic rate of cells transfected with siRNA 50 μmol/L was 30.32%; D: The apoptotic rate of cells transfected with siRNA 100 μmol/L was 32.88%; E: The apoptotic rate of cells transfected with siRNA 150 μmol/L was 36.91%; F: The apoptotic rate of cells transfected with siRNA 200 μmol/L was 45.08%.

tential *in vivo* effects of siRNA on inhibition of the proliferation of colon cancer cells. Viable HCT 116 colon cancer cells were injected subcutaneously into the right flank of the nude mice.

In the first series of experiments, the inoculated mice were divided randomly into four groups of ten mice each and were treated with different doses of siRNA (control, 10, 20 and 50 μmol/L) weekly, for 4 wk. Over a 4 wk period after siRNA injection, the tumor volumes were estimated every week. As seen in Figure 6, the rates of tumor growth significantly decreased in higher than 20 μmol/L transfected groups with siRNA as compared with the control group 2 wk following treatment ($P = 0.03$). How-

ever, there was no difference in antitumor effect between 20 μmol/L and 50 μmol/L in the transfected group.

In the first study series, we detected that siRNA 20 μmol/L was the most effective dose for reduction of tumor growth in xenograft models. Thereafter, in the second series of experiments, we divided the inoculated mice randomly into two groups (control group and siRNA 20 μmol/L treated group) of ten mice per group. The mice of the siRNA 20 μmol/L treated group were injected with siRNA daily for 4 wk, and then the tumor volumes were measured every week during that period. The result was similar with the previous experiment; the mean volume of tumors decreased in transfected groups with siRNA

Figure 6 Tumor volume after small interfering RNA intratumoral injection *in vivo*. The inoculated mice were divided into four groups and were treated with different doses of siRNA (10, 20 and 50 μmol/L) weekly for 4 wk; tumor volumes were checked every week. In higher than 20 μmol/L siRNA, the tumor volumes were significantly decreased as compared with control group from 2 wk after transfection (P = 0.03).

20 μmol/L as compared with control groups (Figure 7).

To evaluate the toxic effect of siRNA *in vivo*, the body weights of mice were taken during the experimental period. The body weight of mice in all groups slightly increased over the entire experimental period; there were no significant body weight changes after siRNA injection compared to the control group. Histologic examination was performed with tissues taken from sacrificed mice after experiment completion. It revealed no significant toxic reaction in kidney, liver and brain of siRNA treated mice compared with the control group (data not shown).

DISCUSSION

Eight human IAP molecules have been reported to date; NAIP (BIRC1), c-IAP1 (BIRC2), c-IAP2 (BIRC3), X-linked IAP (XIAP, BIRC4), Survivin (BIRC5), Apollon (BRUCE, BIRC6), Livin/ML-IAP (BIRC7), and IAP-like protein 2 (BIRC8)[12]. They are categorized as IAP by the presence of a baculovirus IAP repeat (BIR) protein domain, which forms a zinc-fold, a critical motif for regulating apoptosis. Many in this family also harbor a COOH-terminal RING finger domain. The BIR domain constitutes the zinc-fold, which is the important motif in delivering the anti-apoptotic signals[9]. It has been proposed that endogenous Livin has a minor direct effect on caspase activity whereas its anti-apoptotic effect could be ascribed to its antagonizing activity on the XIAP-Smac/DIABLO interaction and has been regarded as counteraction molecules against apoptosis through the blocking the terminal effectors such as caspases, thus far[12]. That the IAPs are highly conserved from yeast to mammals suggests the importance of this family in maintain life[11]. There are numerous reports on overexpression of the IAP family in cancer tissues to normal counterparts. The role of Survivin and Livin, in particular, in carcinogenesis has been well confirmed to date.

Livin was reported in 2001 as a novel IAP family protein[9]. The overactivity of Livin was regarded as a predic-

Figure 7 Tumor xenograft in nude mice. The inoculated mice were divided into two groups (control and siRNA-20 μmol/L treated group), and then tumor volume was measured in the the same manner as described in Figure 6. A: Control group; B: siRNA-20 μmol/L treated group. The tumor volume was dramatically decreased as compared with control.

tor of poor prognosis in cancer patients and a resistance factor to chemotherapeutic agents or radioactive drugs in several cancers[13,14]. The overexpression of Livin mRNA has been found in some tumors including melanoma, breast, cervical, colon and prostate cancers, as well in leukemia, in lymphoma and in hepatoma cell lines[12]. Moreover, researchers have shown that only overexpression of Livin-α isoform is correlated with high risk of relapse in bladder cancer[10].

In the previous study, Livin gene was expressed well in the stools of colon cancer patients as opposed to the healthy control group. This finding suggests that the exfoliated cancer cells from the gastrointestinal tumors were contained in the patients' stool and overexpressed tumor related genes such as Livin were detected from the stool. Based on this result, we chose Livin gene as a treatment target in this experiments.

In recent years, numerous genetic engineering techniques were introduced in drug development markets worldwide such as antisense oligonucleotides, aptamer (single stranded nucleic acids), use of ribozymes, dominant negative mutant construction and siRNA. We focused on siRNA technology because of its target sequence-specific degradation ability and relatively simple application procedure.

In higher organisms, defense mechanisms are more complex but long dsRNAs should not be used as an experimental tool to trigger RNAi in mammalian cells. Long dsRNAs are processed by the endonuclease Dicer

into short 21 bp duplexes with siRNA instead of direct suppression[15]. RNA interference is a post-transcriptional regulation process which exploits a complex pathway that regulates gene expression and includes machinery for sequence specific mRNA degradation[8,16].

But there are still some limitations to overcome in applying siRNA in clinical fields. The greatest interference is the short half-life of the delivered siRNA *in vivo* due to renal clearance. Another is a normally existing RNase activity that can degrade siRNA administered artificially. The next key to successful *in vivo* application of siRNA is the delivery system. Transfering the siRNA into target tissues and into the cell cytoplasm is not easily achieved and a most delicate process is required to get the therapeutic potential. Usual methods to achieve maximum therapeutic effects are lipid or protein carriers, liposomes, antibody promoter fusions, cyclodextrin nanoparticles, fusogenic peptides, aptamers, biodegradable polylactide copolymers and polymers[17].

There are several reports on siRNA targeting Livin treatments for cancer in the literature. Crnkovic-Mertens *et al*[18] first reported the induction effects of apoptosis with Livin targeted-siRNA in a HeLa cell line. Their results suggested that the possibility of intracellular interference with Livin gene expression sensitized human tumor cells to apoptosis. Recently, Wang *et al*[19] investigated the apoptotic susceptibility of the SGC-7901 gastric cancer cell by shRNA-mediated silencing of the Livin gene. When Livin gene was silenced, the reproductive activity of the gastric cancer cells was significantly lower than the control groups ($P < 0.05$). The study also showed that IC50 of 5-FU and cisplatin on gastric cancer cells treated by shRNA decreased and the cells were more susceptible to proapoptotic stimuli (5-FU and cisplatin) ($P < 0.01$). In another study[20], it was reported that expression of Livin was downregulated by siRNA in dose- and time-dependent manners, and silencing Livin promoted apoptosis in malignant melanoma LiBr cells. They also demonstrated that silencing Livin by siRNA leads to cell cycle arrest at the G0/G1 phase, reducing the rate of DNA synthesis or resulting in apoptosis. With these promising results, a combination treatment of Livin-targeting siRNA with proapoptotic drugs appears to be more effective in clinical perspectives.

In this study, we confirmed that silencing of Livin gene expression with siRNA was well documented in HCT116 colon cancer cells associated with an increased apoptotic response. In preliminary experiments, we tested the expression of Livin immediately, 2, 6, 12 and 24 h after treatment of siRNA (data not shown). The decrease of Livin expression was notable from 2 h after treatment but the effect was not much different before 24 h, so we extended the time to 30 h after treatment of siRNA. Testing dosage was arranged from 25 to 200 μmol/L, but the silencing effect of siRNA was not proportional in order of concentration. It was possible that a very small amount of siRNA could create the action to achieve the silencing of Livin gene in the cell line. Unfortunately, the silencing effect weakened from 24 h after treatment, which means duration of siRNA to Livin is very short and time limited.

Another consideration is the proliferation of the cells not influenced by siRNA affected the total expression of the Livin with time. On the other, the cell count decreased 45% with 25 μmol/L siRNA at 18 h after treatment and lasted for 30 h and cellular proliferation counted by MTT assay revealed the same results with cell counting. Proliferation was more influenced by siRNA treatment in the early phase compared to the decrease of total cell count numbers. With this phenomenon apoptosis increased 24 h after treatment with dose dependent manner. To integrate the full results, silencing of Livin in colon cancer cell was easily achieved with siRNA treatment into the induction of apoptosis from minimal dosage only in *in vitro* environment.

We used the mouse xenograft model to identify the antitumor effect of siRNA to Livin *in vivo*. We selected the direct intratumoral injection method to verify the direct effect on tumors. In the clinical setting, it is very difficult to use the infected cells of siRNA before confirmation of drug safety regulation, so direct implication to the tumor itself would be more readily applicable to the human body. Because of the limitation of uptake of siRNA, we adopted atelocollagen in this experiment to obtain maximal therapeutic effects. Atelocollagen is derived from type I collagen of calf dermis by pepsin digestion. A telopeptide that is an amino acid sequence of N- and C-terminal of the collagen contains the most antigenicity. Atelocollagen has limited antigenicity because of a lack of telopeptides, so it is more easily applicable to drug delivery processes. It is well confirmed that atelocollagen-siRNA complexes are taken up into cells to achieve a silencing effects. Also, atelocollagen-siRNA complexes are resistant to nucleases, which is another important advantage in siRNA application *in vivo*[8]. Several reports were found in the database revealing siRNA effects with atelocollagen complex. Atelocollagen is one of the more useful DDS available in clinical settings. Kawata *et al*[21] reported PLK-1 (polo-like kinases-1) siRNA with atelocollagen in hepatic metastatic cells from lung cancer. Takeshita *et al*[22] demonstrated the evidence of tumor targeted delivery of systemically administered siRNA with atelocollagen, injected siRNA intracardiac to luciferase and luciferase-expressing bone-metastatic tumor models. In another study, a therapeutic effect *via* atelocollagen-mediated systemic administration of siRNA targeting Bcl-xL into pregrown PC-3 xenografts was reported[17].

A number of studies have reported antitumor effects of siRNA *in vivo*. Verma *et al*[23] demonstrated that siRNA was effective in reducing growth of HCT116 cells in nude mice. These mice were injected with HCT116 cells intraperitoneally and then were treated with siRNA directed against β-catenin, the regulator of cellular proliferation in colon cancer. There was a significant decrease in the tumor size of cells transfected with siRNA directed against β-catenin[23]. In another study, it was found that transfected HCT116 colon cancer cells with siRNA against Survivin, a type of IAP family such as Livin, significantly decreased in size as compared with controls in xenograft models[24]. In a recent study, it was

Figure 8 Hemorrhagic necrosis in small interfering RNA injection site. The inoculated mice were injected with siRNA *via* the intratumoral route; there was local hemorrhagic necrosis in the direct injection site of siRNA.

observed that siRNA against Survivin remarkably induced apoptosis in SW480 cell as a consequence of the inhibition of Survivin and led to significant inhibition of tumor growth *in vivo*[1].

In our xenograft model, the rates of tumor growth were significantly decreased in higher than 20 μmol/L transfected groups with siRNA as compared with control groups. This antitumor effect tended to be greater at a higher dose of siRNA but the differences between each group were not statistically significant. So it would be expected that a low dose of siRNA showed a satisfactory effect on tumor suppression. In addition to the antitumor effect, toxic effects of treatment should be considered. Some therapeutics have been associated with toxic side effects such as weight loss and other organ injury. These systemic toxicities may be related with higher morbidity and lower response rate, resulting in poorer survival. Thus, if there are systemic toxicities caused by drugs, no matter how effective, they should not be used. In this study, measured body weights of mice had no differences, and there were no significant pathologic findings on tissues withdrawn from siRNA-treated group. For these reasons, it could be thought that siRNA targeting Livin can be used in colon cancer therapy without systemic toxic effects *in vivo*. In our present study, another interesting finding was detected despite an effective reduction of tumor size with siRNA. Local hemorrhagic necrosis was seen in the intratumoral injection site of siRNA with syringe, this finding was not identified in other studies (Figure 8). If there are local side effects such as this, even though there is no evidence of systemic toxicity of siRNA, we should carefully determine administration routes to develop antitumor treatments using siRNA.

In conclusion, siRNA-mediated downregulation of Livin expression can induce apoptosis in colon cancer *in vitro* and *in vivo*, which implies new potential cancer therapeutics using siRNA in colon cancer.

COMMENTS

Background

Colon cancer is one of the most common malignancies and has increased in incidence in recent years. Several treatment modalities have been used, especially in metastatic diseases. Several studies have been reported to implicate gene therapy for metastatic colon cancer. Livin, a type of inhibitor of apoptosis, protects cells from various proapoptotic stimuli. So Livin is an effective target for colorectal cancer treatment.

Research frontiers

The overexpression of Livin has been reported in colorectal cancer. However, the direct tumor regression effect of Livin silencing has not been unequivocally addressed. In this study, the authors investigate the effect of silencing *Livin* gene expression with siRNA to apoptosis and proliferation in colon cancer cell line.

Innovations and breakthroughs

There are several reports on siRNA targeting Livin treatments for cancer. But these studies were nearly all performed *in vitro* and there were few studies about colorectal cancer. In this study, the authors confirmed that silencing of Livin gene expression with siRNA was well documented *in vitro* and *in vivo*, especially in colorectal cancer.

Applications

siRNA-mediated downregulation of Livin expression can induce apoptosis in colon cancer *in vitro* and *in vivo*, which may imply new potential cancer therapeutics using siRNA in colorectal cancer.

Terminology

Livin is a 280 amino acid-protein and a member of the mammalian type of inhibitor of apoptosis. It inhibits apoptosis by binding to caspase 3, caspase 7 and caspase 9. Its overexpression protects cells from various proapoptotic stimuli, and is shown in numerous cancers. RNA interference is a fundamental protective process in eukaryotic cells, which is able to block harmful signals by targeting complementary mRNA and cleaving it. The role of RNAi is supposed to be a defense mechanism against deleterious genomic instability.

Peer review

The experiments are properly performed, and findings support their conclusion.

Abstract

AIM: To investigate the proteins involved in colonic adaptation and molecular mechanisms of colonic adaptation in rats with ultra-short bowel syndrome (USBS).

METHODS: Sprague Dawley rats were randomly assigned to three groups: USBS group (10 rats) undergoing an approximately 90%-95% small bowel resection; sham-operation group (10 rats) undergoing small bowel transaction and anastomosis; and control group (ten normal rats). Colon morphology and differential protein expression was analyzed after rats were given post-surgical enteral nutrition for 21 d. Protein expression in the colonic mucosa was analyzed by two-dimensional electrophoresis (2-DE) in all groups. Differential protein spots were detected by ImageMaster 2D Platinum software and were further analyzed with matrix-assisted laser desorption/ionization-time-of-flight/time-of-flight-mass spectrometric (MALDI-TOF/TOF-MS) analysis.

RESULTS: The colonic mucosal thickness significantly increased in the USBS group compared with the control group (302.1 ± 16.9 μm *vs* 273.7 ± 16.0 μm, *P* < 0.05). There was no statistically significant difference between the sham-operation group and control group (*P* > 0.05). The height of colon plica markedly improved in USBS group compared with the control group (998.4 ± 81.2 μm *vs* 883.4 ± 39.0 μm, *P* < 0.05). There was no statistically significant difference between the sham-operation and control groups (*P* > 0.05). A total of 141 differential protein spots were found in the USBS group. Forty-nine of these spots were down-regulated while 92 protein spots were up-regulated by over 2-folds. There were 133 differential protein spots in USBS group. Thirty of these spots were down-regulated and 103 were up-regulated. There were 47 common differential protein spots among the three groups, including 17 down-regulated protein spots and 30 up-regulated spots. Among 47 differential spots, eight up-regulated proteins were identified by MALDI-TOF/TOF-MS. These proteins were previously reported to be involved in sugar and fat metabolism, protein synthesis and oxidation reduction, which are associated with colonic adaption.

CONCLUSION: Eight proteins found in this study play important roles in colonic compensation and are associated with sugar and fat metabolism, protein synthesis, and molecular chaperoning

INTRODUCTION

Short bowel syndrome (SBS) is a chronic malabsorptive syndrome resulting from extensive small bowel resections[1]. Residual small bowel less than 30 cm from proximal end or distal end is termed ultra-short bowel syndrome (USBS)[1]. It occurs when the bowl is less than 200 cm *in situ*[2]. The estimated population prevalence is approximately one per million[3]. In adults, SBS usually results from resection of unviable intestine secondary to vascular insufficiency, Crohn's disease, malignancy or radiation[3]. In children with congenital intestinal anomalies, such as gastroschisis or atresia, necrotizing enterocolitis leads to insufficient intestinal length[4]. Malabsorption of macronutrients and micronutrients may predominate as a clinical manifestation, whereas other patients may struggle to maintain fluid and electrolytes homeostasis[5]. These patients may become dependent on parenteral nutrition (PN) support to maintain their energy balance. A study showed that the colon could undergo adaptation like the small intestine[6]. Epithelial hyperplasia occurred 24-48 h after small intestinal resection in experimental models[7-9]. Animal models showed that adaptation process is stimulated by enteral nutrition for enterocyte reproduction, resulting in the release of trophic factors[10]. Our previous studies have also found changes in morphology and ultrastructure of rat colon and adaptation of absorption functions[11]. However, the proteins and molecular mechanisms associated with the colonic adaptation are still unknown. In this study, we used a proteomics approach to identify the proteins associated with colonic adaptation in USBS rats, and discussed the molecular roles of the identified proteins in colonic adaptation.

MATERIALS AND METHODS

Laboratory animals grouping

Thirty healthy male Sprague Dawley rats (aged 3-4 mo, weighing 250-300 g) were randomly assigned to three groups (10 rats in each group): USBS group undergoing an approximately 90%-95% small bowel resection; sham-operation group undergoing small bowel transaction and anastomosis; and normal control group.

USBS model and postoperative feeding

On the day of operation, animals were fasted from solid food, but with unrestricted access to water. Animals in the USBS group were anesthetized with chloral hydrate (0.3 mL/100 g) for surgical resection of the small bowel. The entire small intestine was resected from 1 cm distal to the Treitz ligament to 1 cm proximal to the ileocecal valve. End-to-end anastomosis of the jejunum to the ileum was performed.

After recovery from anesthesia, rats were fed Peptisorb (Holland Nutricia). The nutrient fluid had an osmotic pressure of 410 mosm/L and a concentration of 25.2%. The nutrient mix could provide 413.82 J of energy per 100 mL. The fluid contained carbohydrates and 85% protein made up the short-chain hydrolytic lactalbumin, including 50% medium-chain triglycerides and 50% long-chain triglycerides. Both the USBS group and sham-operation group were fed with 12.6% Peptisorb on days 1-3 after surgery. Intake was increased to 16.8% on days 4-6 and to 25.2% from day 7 after surgery to the end of the experiment on day 21. Rats were fed 80 mL nutrient mixture daily using a special bottle. Diphenoxylate (0.75 mg/kg daily) was added to the feeding solution to reduce diarrhea.

Morphologic observation

All rats were anesthetized using chloral hydrate (0.3 mL/100 g) prior to a terminal surgical procedure. A 0.5 cm colon was resected from near the ileocecal valve and HE stained in paraffin. The thickness of tunica mucosa coli and the height of plica were measured with an automatic image analysis. Five non-serial sections were measured from each specimen. Average value and standard deviation (SD) were calculated.

Extraction of colonic mucosa

A 1-cm segment of colon was removed from near the ileocecal valve and incised longitudinally after enteral nutrition for 21 d. After being repeatedly washed with double-distilled water, the colon was quickly scraped with glass slides in an ice bath to collect intestinal mucosa. The intestinal mucosa were stored at -80℃ or used for immediate schizolysis to extract protein.

Protein extraction and quantification

Total mucosa was obtained by mixing colonic mucosa from rats in each group. The combined intestinal mucosa was then triturated in liquid nitrogen and lyzed in ice-cold lysis buffer (7 mol/L urea, 2 mol/L thiourea, 4% (w/v) CHAPS, 1 mmol/L DTT, 10 mmol/L PMSF and protease inhibitor cocktail). The cellular lysate was centrifuged at 13 200 r/mim for 30 min. The supernatant was collected and stored at -80℃. Protein concentration was determined using the Bradford assay, as previously described (REF).

Two-dimensional electrophoresis (2-DE) analysis

Protein from intestinal mucosa (150 μg) was applied by 2-DE analysis. 2-DE was performed as previously described. Briefly, one-dimensional isoelectric focusing (IEF) was performed on 13-cm gel strips, pH 3-10 NL (Amersham Ettan IPGPhor IEF system). The following IEF protocol was used at 20℃: rehydration at 30 V for 16 h; 500 V for 1 h; 1000 V for 1 h; and 8000 V for 64000 Vh.

After IEF, the strips were incubated for 15 min with 10 mL equilibration solution A [2% sodium dodecyl sulfate (SDS), 50 mmol/L Tris-HCl pH 8.8, 6 Murea, 30% v/v glycerol, 0.002% bromophenol blue, and 100 mg dithiothreitol (DTT)]. The strips were further equilibrated for 15 min with equilibration solution B, which was identical to solution A except that 250 mg iodoacetamide replaced the DTT. Samples were then transferred onto 12.5% SDS-PAGE for 2-D separation. Proteins in 2-DE gels were stained with silver. Images were scanned using Image-scanner. Each sample was analyzed three times.

Gel image analysis

The protein spots and their differential expressions were analyzed using ImageMaster 2D Platinum software. USBS group gel was compared with the other two groups. Two groups of differentially acquired protein spots were compared to find common differential protein spots. Protein spots achieving a > 2-fold increase in spot intensity and observed in three replicate gels from three independent experiments were scored and subjected to matrix-assisted laser desorption/ionization-time-of-flight/time-of-flight-mass spectrometric (MALDI-TOF/TOF-MS) analysis.

In-gel digestion and protein identification by mass spectrometry

The differential protein spots were in-gel digested, with minor modifications. In brief, the differential protein spots were destained using 15 mmol/L $K_4Fe(CN)_6$ and 50 mmol/L sodium thiosulfate. Spots were digested with trypsin at 37℃ for 16 h. Peptide mixtures were extracted from the gel spots. The extracted peptide mixtures were dried using the SpeedVac Centrifuge.

The peptide mixtures were analyzed on an ABI 4800 plus MALDI-TOF/TOF-MS (ABI, CA). Each spectrum was produced by accumulating the data from 500 consecutive laser shots in the mass range of 900-3500 Da. Seven maximum precursor ions with a signal-to-noise ratio > 50 were chosen for tandem mass spectrometry (MS-MS). The obtained MS and MS-MS data were processed by GPS Explorer software (V3.6). Proteins were identified by the MASCOT search engine (V2.1) in the IPI mouse database based on these MS and MS/MS spectra. Proteins were considered a match if the error for peptide mass was 100 ppm or lower and the mass accuracy was 0.2 Da or lower. Scores > 59 were considered statistically significant ($P < 0.05$).

Class of differentially expressed proteins

Using information from the European Bioinformatics Institute (http://www.ebi.ac.uk), the differential proteins were classified based on function. The relationship between protein expression and biological function in the USBS group was further analyzed, as described below.

Bioinformatics analysis of protein-protein interaction network

The protein-protein interaction network was analyzed by the Search Tool for the Retrieval of Interacting Genes/Pro-

teins (STRING) system. The following sets of STRING programs were employed: organism, required confidence (score), interactions, and additional nodes shown as "homo sapiens," "low confidence (0.150)," "no more than 10 interactions," and "0." For other parameters, default settings were used.

Statistical analysis

One-way analysis of variance and the Student-Newman-Keuls test were performed using SPSS 13.0 statistical software. Data were expressed as mean ± SD. *P* values less than 0.05 were considered statistically significant.

RESULTS

Colonic plica and thickness increased in USBS rats

Among USBS rats, the survival rate was over 90%. Only one rat died of intestinal obstruction 6 d after operation. Rats were observed with dull coats and severe hair loss, especially within the first two weeks after the operation. Rats gradually regained a dense, shiny coat. Rats experienced severe diarrhea, rectal eversion, perineal eczema and infections, and perianal and tail skin ulcers forming ringtail disease.

The colonic mucosal thickness was 302.1 ± 16.9, 276.6 ± 19.1 and 273.7 ± 16.0 μm in the USBS group, sham-operation group and control group, respectively. The colonic mucosal thickness was significantly higher in the USBS group than in other two groups (F = 7.46, P = 0.003). The colonic mucosal thickness was not significantly different between the sham-operation and control groups (P = 0.717). The height of colon plica of the three groups was 998.4 ± 81.2 μm, 893.7 ± 20.2 μm, and 883.4 ± 39.0 μm, respectively. The height of colon plica markedly improved in the USBS group compared with the control group (F = 13.96, $P < 0.001$). There were no significant differences in plica height between sham-operation and control groups (P = 0.665, Figure 1).

Proteome profile alterations in ultra-short intestine mucosa

To identify the proteins involved in colonic adaptation, total proteins isolated from colonic mucosa of the three groups were separated on a 2-D gel (pH 3-10 NL), respectively. The gels were visualized by silver staining (Figure 2). In total, approximately 700 protein spots were detected in each of the silver-stained gels using ImageMaster software. Differential spots were scored when there was a > 2-fold change in spot intensity in three replicate gels from three independent experiments. The analysis revealed 141 differential protein spots, including 49 increased spots in USBS group and 92 decreased spots in the control group; and 133 differential protein spots, including 103 increased spots in USBS group and 30 decreased spots in the sham-operation groups. Among these differential protein spots, 47 differential protein spots were frequently observed in all three groups, including 30 increased spots and 17 decreased spots.

Identification of proteins associated with colonic adaptation

Protein spots were subjected to in-gel digestion with trypsin. Protein identities were determined with MS and MS-MS by searching the IPI mouse database using the MASCOT program. This allowed us to identify eight proteins from 43 differential spots, including protein disulfide-isomerase A3, phosphoglycerate kinase 1, pyruvate kinase isoforms M1/M2, alcohol dehydrogenase class-3, mitochondrial ribosomal proteins, pancreatic triacylglycerol lipase, Hnrph1, and Lambda-crystallin homolog. These proteins are listed in Table 1, along with their IPI accession number, molecular weight, isoelectric point, scores and fold changes among the groups.

Functional classification of differential proteins

Eight differential proteins were preliminarily classified by functions using the European Bioinformatics Institute Bioinformatics Database (http://www.ebi.ac.uk). Protein disulfide-isomerase A3 is associated with molecular chaperoning. Phosphoglycerate kinase 1 and pyruvate kinase 3 isoforms M1/M2 are associated with glucose metabolism. Pancreatic triacylglycerol lipase is associated with fat metabolism. Lambda-crystallin homolog and alcohol dehydrogenase class-3 are associated with oxidation and reduction. Hnrph1 protein, and mitochondrial ribosomal protein L12 are associated with protein synthesis.

Table 1 Differential proteins identified by mass spectrometry

No.	Spot No.	Protein name	Accession No.	Protein MW/PI	Protein score	FD (24 h)
1	528	Phosphoglycerate kinase 1	IPI00231426	44510 /8.02	243	1 000 000
2	725	Pancreatic triacylglycerol lipase	IPI00198916	51407/36.31	60	1 000 000
3	946	Hnrph1 protein	IPI00650124	20567/3 5.2	172	1 000 000
4	331	Protein disulfide-isomerase A3	IPI00324741	57043 /5.88	391	2.4 ± 0.2
5	599	Pyruvate kinase isoforms M1/M2	IPI00231929	57938.9/6.63	67	2.0 ± 0.5
6	603	Alcohol dehydrogenase class-3	IPI00568787	39550.2/7.45	70	2.2 ± 0.3
7	746	Lambda-crystallin homolog	IPI00213610	35318/5.94	222	2.1 ± 0.4
8	1033	Mitochondrial ribosomal protein L12	IPI00203773	29422/99.7	122	2.3 ± 0.2

Protein names and accession numbers are from the International Protein Index rat database. MW: Molecular weight; PI: Isoelectric point; FD: The average fold change among; USBS group: Sham-operation group and control group.

Figure 3 Protein-protein interaction networks involved in colonic adaptation predicted by the STRING program.

Protein-protein interaction networks involved in colonic adaptation

STRING is a system for mapping protein-protein interaction networks. We used the STRING system to construct the protein-protein interaction network of the differential proteins associated with colonic adaptation. Five (phosphoglycerate kinase 1, Hnrph1, protein disulfide-isomerase A3, pyruvate kinase 3 isoforms M1/M2, and alcohol dehyogenase 5) of the eight identified proteins were directly involved in the protein-protein interactions (Figure 3). Notably, phosphoglycerate kinase 1 was found to be a signal node in the network, suggesting that phosphoglycerate kinase 1 may be crucially involved in colonic adaptation. Previous studies have shown that the five proteins played an important role in energy metabolism in cells. It is well known that quickly-grown cells frequently exhibit increases in glycolytic metabolic pathway for adenosine triphosphate (ATP) generation to meet their energetic needs. Therefore, over-expression of these five proteins resulted in increased ATP production, rapid growth of colonic musocal cells and thickness of colonic musocal thickness.

DISCUSSION

Experiments have demonstrated that the colon can compensate after the extensive removal of the small intestine, with thickening of the colonic mucosa and heightening of the colon plica[1,5]. Epithelial hyperplasia was found 24-48 h after small intestinal resection[7-9]. Adaption process is stimulated by enteral nutrition by providing energy for enterocyte reproduction, stimulating the release of trophic factors[10]. Our previous experiments have shown that nutritional absorption of the colon can be increased by adaptation, and microvilli became more abundant, longer and thicker[11]. The colon may adapt to the absorption of a large volume of solutes[12-14]. Absorptive cell hyperplasia of colonic mucosa was found in the USBS rats assessed under electron microscope. These results showed that the colonic absorption area was greatly increased in the USBS rats. There were less apoptosis, less goblet cells and more absorptive epithelial cells in the USBS rats under transmission electron microscope. Adjacent cell membranes merged tightly and formed a rugged structure. There was an increase in cell connections and connection complexes in USBS rats. The junctions, bridge corpuscles, endoplasmic reticulum, Golgi apparatus, and mitochondrion were all increased. This resulted in improvement in the absorptive functions of water, xylose and 15N-glycine[15].

In this study, the entire small intestines of rats were removed to ensure maximum colonic adaptation. We tried to determine how the colon could compensate when the small intestine was lost. We found that USBS rats could survive using colonic compensation after all small intestines were lost, since rats were fed only with enteral nutrition and had a postoperative survival rate over 90%. The length, diameter and height of the mucosal fold in the mucosal thickness of the colon were increased in the USBS rats compared with the control group.

The colon can undergo adaptations in USBS patients and rats. Some materials have been shown to improve the adaptation. In recent years, the more studies of intestinal compensation have focused on compensatory mechanisms, adsorptive function, and cellular hyperplasia of short bowel syndrome (SBS) remnant intestines. Understanding of the mechanisms and ultimate treatment of the

disease will eventually be reflected in protein expression levels and changes in post-translational modifications. We used a proteomics approach to observe differential protein expressions to fully understand the molecular mechanisms of colon adaptation in an attempt to help develop drugs that can promote colon compensation.

The term proteome was first proposed by Mac Wilkins and Keith Williams in 1994[16] to describe the complete set of proteins that are expressed and modified by an entire genome or cell. The intracellular and dynamic changes in protein composition, expression levels and modification states should be analyzed to observe protein-protein interactions and relationship with the disease, revealing the protein functions and activities important in the disease development.

In the diseases of the digestive system, proteomics have not been as widely used to study the USBS as gastric cancer, esophageal cancer and liver cancer[17-20]. A number of other growth and trophic factors have been implicated in animal models including enteroglucagon, epidermal growth factor, glutamine, growth hormone, chole-cysto-kinin, gastrin, neurotensin, leptin and insulin-like growth factors[21-23]. Fat-stimulated glucagon-like peptide-Ⅱ may lead to hyperplasia[24,25]. In this study, 47 protein spots were found to be expressed nonrepetitively, including 30 upregulations and 17 downregulations. Their functions were reported to be associated with metabolism of sugar, protein and fat, oxidation-reduction and molecular chaperones. This implied that multiple proteins might affect the metabolism pathway involved in increasing absorptive functions and compensation.

Among these up-regulated proteins, protein disulfide-isomerase A3 is a special multifunctional protein rich in the endocytoplasmic reticulum. It has a strong non-specific peptide binding ability, and acts as both an enzyme and a chaperone[26]. As an enzyme, protein disulfide-isomerase A3 can assist in protein folding by catalyzing covalent bond changes that directly affect protein folding and functional conformations.

As a chaperone, protein disulfide-isomerase A3 may have acquired a new function during evolution to increase catalytic efficiency and assist in protein folding. It was up-regulated in carcinoma of the large intestine[27]. Ryu *et al*[28] found that protein disulfide-isomerase A3 was over-expressed when gastric cancer and paraneoplastic mucosal biological markers were studied with proteomics. This study indirectly demonstrated that protein disulfide-isomerase A3 is associated with hyperplasia of mucosa. Our previous experiments demonstrated that the endoplasmic reticulum in USBS rat colon was rich in protein disulfide-isomerase A3, suggesting that it was closely related to the adaptation of tunica mucosal coli cells and compensation of the colon.

Another up-regulated protein is pyruvate kinase, which participates in the last step of glycolysis, catalyzing phosphoenolpyruvate and adenosine diphosphate (ADP) into pyruvate and adenosine triphosphate (ATP). Pyruvate can generate ATP by zymolysis or by entering tricarboxylic acid

(TCA) circulation. In animals, pyruvate kinase may serve as a gene, promoter, mRNA splicer, and signal transducer with polyadenylic acid. In this study, the pyruvate kinase was up-regulated in ultra-short intestinal mucosa. This implies that pentose phosphate shunts may be improved by pyruvate kinase. The excessive ribose-5-phosphate and one carbon unit produced by protein decomposition synthesize purine nucleosidase, improving the hyperplasia of tunica mucosa coli cells.

In this study, phosphoglycerate kinase 1 was richly expressed. Phosphoglycerate kinase 1 is the key enzyme of glycolysis and is also an essential enzyme for living. The main function of phosphoglycerate kinase 1 is to participate in the glycolysis procedure. It can catalyze 1,3-di-phosphoglyceric acid into 3-phosphoglyceric acid. Some studies have shown that phosphoglycerate kinase 1 can affect DNA replication and repair the cell nucleus. It can also serve as an mRNA binding protein[29]. Other studies showed that phosphoglycerate kinase 1 up-regulation can cause carcinoma and vascularization. The oxidation status of larvaceous intra-cellular protein is a biological marker in human colon carcinoma[30]. These studies indicated that overexpressed phosphoglycerate kinase 1 can promote cellular proliferation, suggesting that phosphoglycerate kinase 1 is involved in colon compensation by inducing cell proliferation. The bioinformatics analysis in this study showed that phosphoglycerate kinase 1 acts as a hub in the protein-protein interaction networks involved in colon adaptation, suggesting that phosphoglycerate kinase 1 played a key role in colon adaptation and compensation.

Mitochondrial ribosomal proteins were also richly expressed in this study. Some studies have shown that mitochondrial ribosomal proteins can be regulated in translation as chondriogene mRNA. Up-regulation of mitochondrial ribosomal proteins is related to dell differentiation in tunica mucosal coli and colon carcinoma[31]. It has also been implied that mitochondrial ribosomal proteins participate in colon compensation since the number of chondriosomes is markedly increased in USBS rats.

Bioinformatics analysis and previous reports showed that eight proteins were closely related to sugar, fat metabolism, protein synthesis, redox, and molecular chaperones. These proteins likely play an important role in colonic compensation in USBS rats. Further studies to understand the characteristics of these differential proteins will help elucidate the molecular mechanisms of colonic compensation in USBS, and develop drugs to promote adaptation and alimentation.

ACKNOWLEDGMENTS

COMMENTS

Background

People with short small bowel may have difficulties in nutritious absorption and may struggle to maintain nutritious balance. The increased morbidity in intestinal tumors, traumas and mesenteric vascular thrombosis resulted in the increased incidence of short small bowel. It has been evidenced that rats can live without small intestine for a long period as their colon can undergo compensation.

Research frontiers

More studies of intestinal compensation have focused on compensatory mechanisms, adsorptive function and cellular hyperplasia of remnant intestines. Mechanism and treatment of the disease will eventually be reflected in the protein expression levels and changes of post-translational modifications.

Innovations and breakthroughs

The protein expression changes in normal rats and short bowel rats have been studied based on mass spectrometric analysis and other advanced technologies. Eight proteins were found to be closely related with sugar, fat metabolism, protein synthesis, redox, and molecular chaperone. They might play important roles in nutritious absorption, and treatment of short bowel patients.

Applications

The authors offered the methodology for exploring the proteins in short bowel rats. Besides mass spectrometry, immunohistochemistry may be also a smart choice. Once the mechanism is clear and the therapeutic target is established, the malabsorption resulting from extensive small bowel loss will be hopefully solved.

Terminology

Short bowel syndrome is a chronic malabsorptive syndrome resulting from extensive small bowel resections. Mass spectrometry is an analytical technique that measures the mass-to-charge ratio of charged particles. It is used for determining masses of particles, the elemental composition of a sample or molecule, and for elucidating the chemical structures of molecules, such as peptides and other chemical compounds.

Peer review

This study combines proteomics with short bowel syndrome systematically. And it may form the theoretic foundation for treating short bowel syndrome.

Abstract

Non-cirrhotic portal hypertension is a poorly understood condition characterized by portal hypertension in the absence of conventional hepatic cirrhosis and described in association with blood coagulation disorders, myeloproliferative and immunological diseases and with exposure to toxic drugs. Very recently, precise classification criteria have been proposed in order to define four distinct subcategories. The present case highlights how the clinical presentation, the confounding results from imaging studies, and the difficulties in the histological evaluation often render cases of non-cirrhotic portal hypertension a real diagnostic challenge. It also underscores the classification problems which can be faced once this diagnosis is performed. Indeed, the different subcategories proposed result from the prevalent subtypes in a spectrum of hepatic regenerative responses to a variety of injuries determining microcirculatory disturbances. More flexibility in classification should derive from this etiopathogenic background.

INTRODUCTION

Non-cirrhotic portal hypertension (NCPH) is a poorly understood condition characterized by the presence of portal hypertension in the absence of conventional hepatic cirrhosis (defined as diffuse nodules totally surrounded by fibrous septa). Its greatest prevalence has been observed in India, where it represents 20%-25% of the cases that bleed due to esophageal varices[1]. It has been described in association with blood coagulation disorders and myeloproliferative diseases[2,3], with exposure to toxic substances or to drugs[4,5], and with immunological diseases[6,7]. Most of the cases present with thrombosis or sclerosis of the intrahepatic portal venous system, with variable involvement of the prehepatic portal system[8]. Several clinical and pathological pictures are included within this syndrome.

The liver morphology of patients with NCPH shows greatly varying alterations which frequently include archi-

tectural distortion associated with irregular hyperplastic lesions[9,10]. Considering the features of architectural distortion, hyperplastic nodules and fibrosis, an attempt was made to classify each liver into one of 4 diagnostic categories, following the terminology for hepatic nodular lesions recommended by an International Working Party and the definitional criteria used by Nakanuma *et al*[11,12]: idiopathic portal hypertension, diffuse nodular regenerative hyperplasia (NRH), partial nodular transformation, and incomplete septal cirrhosis. Differential diagnosis between these categories is often difficult because single cases frequently do not match the estimated definitions, suggesting that each case of NCPH represents the peculiar pattern of expression of a spectrum of lesions with a common or similar etiopathogenetic background[10].

Here we report a case of NCPH with large regenerative nodules, which highlights the difficulties both in reaching the diagnosis and in classifying the single case into one of the proposed categories.

CASE REPORT

In July 2009, a 62-year-old Italian man was admitted to the Clinical Medicine and Hepatology Unit of our Hospital for recurrent melena.

He had been in good general condition until November 2008, when a first episode of melena occurred in the absence of hematemesis and abdominal pain. Therefore, he was admitted to another hospital, where a severe anemia was found (hemoglobin 5.5 g/dL). A pancolonscopy was negative. Upper intestinal endoscopy showed esophageal varices (not better classified), portal hypertensive gastropathy, and the presence of coagulated blood in the stomach. Upper abdominal ultrasonography revealed hepatomegaly, with caudate lobe hypertrophy, a diffusely dishomogenous echotexture due to the presence of multiple hypoechoic nodules, mainly in the left lobe, the biggest of which was 3 cm in diameter, and mild splenomegaly (transverse diameter: 13.2 cm). Since the patient had no history of chronic liver disease and presented normal liver enzymes and function tests, a transjugular catheterism was performed in order to measure the hepatic pressure venous gradient (HPVG), which confirmed severe portal hypertension (23 mmHg), and to obtain a transjugular liver biopsy, which was negative for cirrhosis-the report of which was the following: "Mild hepatocyte regenerative activity". The patient had been discharged without a definite diagnosis and with the indication to a strict clinical, biochemical and radiological follow-up.

At the admission to our hospital, laboratory tests showed anemia and leucopenia (hemoglobin 9.9 g/dL, hematocrit 32.9%, leucocyte count 2680/μL, platelets 162 000/μL), a good renal function (urea 36 mg/dL, creatinine 0.78 mg/dL), and normal liver enzymes and hepatic function tests: AST 24 U/L [upper normal limit (u.n.l.) 35 U/L], ALT 21 U/L (u.n.l. 45 U/L), alkaline phosphatase 59 U/L (u.n.l. 120 U/L), GGT 18 U/L (u.n.l. 55 U/L), total bilirubin 0.7 mg/dL, total protein 6.6 g/dL, albumin 58%, gamma-globulins 17.1%, INR 1.1.

The patient had no history of associated diseases and was not taking any medication. The blood tests performed in the last few years were also reassessed and showed only impaired glucose tolerance and intermittent mild elevation of the GGT (1.5-2 X u.n.l.).

Viral serology was negative for hepatitis B surface antigen and antibodies to hepatitis C virus. To rule out autoimmune hepatitis, primary biliary cirrhosis, α-1-antitrypsin deficiency, Wilson's disease, and hemochromatosis, antinuclear, anti-mitochondrial, anti-smooth muscle, and antiliver and kidney antibodies, α-1-antityripsin, serum iron, transferrin and ferritin, ceruloplasmin, cupremia and cupruria were assessed and found to be negative or within the normal ranges. Also serum α-fetoprotein level was within the normal ranges (1.7 ng/mL, u.n.l. 8.1 ng/mL). Upper intestinal endoscopy confirmed esophageal varices (F2 blue, without cherry red spots, hematocystic spots or diffuse redness, but with red wale markings ++/+++), and severe portal hypertensive gastropathy.

Contrast-enhanced computed tomography (CT) and magnetic resonance (MR) of the upper abdomen were performed. On CT, several slightly hypodense liver lesions (almost 10, on both hepatic lobes) were visualized, showing an inhomogeneous contrast uptake due to the presence of a hypodense central core. On MR, liver morphology was not that of a cirrhotic liver. In basal conditions, the hepatic parenchyma was heterogeneous due to the presence of multiple nodules, the biggest of which was 3 cm in diameter, hypointense on T1-weighted sequences and slightly hyperintense on T2-weighted images (Figure 1). Nodules were better represented after gadolinium injection, showing mild signal hyperintensity. The very first radiological impression was that of multiple liver metastases from endocrine tumor, melanoma or renal cell carcinoma. The lesions were also compatible with large regenerative nodules in a radiologically noncirrhotic liver. The hypothesis of hepatocellular carcinoma was also considered, but not supported by the poor hypervascularization in the arterial phase and by the lack of hypointensity in portal venous and delayed phases.

In order to rule out malignancy, a US-guided liver biopsy was performed on the 2-cm-sized lesion in the second hepatic segment. Histologically, small foci of necrosis of isolated hepatocytes with focal accumulation of macrophages and other inflammatory cells, and infiltration of portal tracts by scattered mononuclear cells, were observed. The inflammatory infiltrates slightly involved some portal tracts, and were not accompanied by piecemeal necrosis or fibrosis. As recommended in cases of non-cirrhotic portal hypertension, the silver impregnation stain was performed and did not show any architectural alteration. The final histological diagnosis was nonspecific mild chronic hepatitis. In addition, sections from the transjugular liver biopsy performed in the first Hospital were obtained and reassessed by silver impregnation stain (Figure 2). A vaguely nodular arrangement of liver parenchyma was detected, in which areas with hyperplastic hepatocytes, arranged in plates more than one cell thick, were alternated with areas in which the

Figure 1 Magnetic resonance images before and after gadolinium injection. Half fourier acquisition single shot turbo spin echo T2-weighted sequences showed slightly hyperintense nodules (panel A), which were hypointense on T1-weighted sequences (panel B). After gadolinium injection, lesions were better represented, showing a mild signal hyperintensity (panels C and D). The white arrow in each panel indicates the biggest lesion, 3 cm in transverse diameter, on the caudate lobe.

Figure 2 Liver biopsy, reticulin silver impregnation, original magnification, 100 ×. Hyperplastic parenchymal nodules with thickened liver-cell plates are seen (black star), whereas the parenchymal cells adjacent to the nodules are compressed and atrophic (black arrow). This growth pattern is not accompanied by fibrosis.

trabeculae were compressed and atrophic. The interface between nodules was not defined by fibrous septa. There was only minimal inflammation and no evidence of degenerative changes of hepatocytes. Histologically, the diagnosis was NRH. Clinically, the diagnosis was NCPH, in the form of NRH associated with large regenerative nodules.

As NCPH has been described in association with blood coagulation disorders, myeloproliferative diseases, immunological alterations, systemic or intra-abdominal infections and exposure to toxic substances or to drugs, all these

conditions were evaluated and excluded by questioning the patient and performing the appropriate investigations. In particular, the complete panel for hereditary thrombotic risk factors was performed. Lupus anticoagulant, protein-C, protein-S, antithrombin, homocysteine, cardiolipin IgG and IgM antibodies, and anti-β2-glycoprotein-I antibodies were in the normal range. The molecular study was negative for factor V H1299R and G1691A, methylenetetrahydrofolate reductase C677T and A1298C, Plasminogen Activator Inhibitor-1 4G/5G, and for prothrombin G20210A gene polymorphisms. In order to rule out myeloproliferative diseases, the V617F Janus kinase-2 gene mutation was investigated and found to be negative. Bone marrow aspiration was not performed due to the lack of sufficient clinical suspicion justifying the procedure.

A first-degree atrioventricular block partially contraindicated beta-blocker therapy and the patient underwent band ligation of esophageal varices. An upper intestinal endoscopy was repeated after one month, revealing persistence of two F1 varices with red wale markings +/+++, which were band-ligated again. A third endoscopic control, performed after another month, was finally negative.

At present, after nearly 1 year of follow-up, the patient is in good clinical condition. The last image studies, MR in January 2010 and ultrasonography in June 2010, did not show significant modifications of the hepatic picture. The last upper intestinal endoscopy, performed in August 2010, showed only one F1 esophageal varix without red wale markings, hematocystic spots or diffuse redness. A

long-term clinical, radiological and endoscopic follow-up is warranted.

DISCUSSION

The present case highlights how the clinical presentation, the confounding results from imaging studies, and the difficulties in the histological evaluation often render cases of NCPH a real diagnostic challenge. It also underscores the classification problems which can be faced once the diagnosis of NCPH is performed.

Even if the exact prevalence and clinical load of NCPH are not known, there are a number of non-cirrhotic patients with long-standing portal hypertension of unknown etiology. Several clinical and pathological pictures are included within this syndrome. Among these, there are some that are morphologically very similar and, differing from country to country and author to author, they have been called idiopathic portal hypertension[13], hepatoportal sclerosis[14], and non-cirrhotic portal fibrosis[15]. In them, the hepatic architecture is mildly distorted due to the existence of irregular distances between the portal venous and hepatic venous structure[16], and nodular regenerative foci are frequently found[17]. In other types of NCPH, greater architectural distortion and prominent regenerative nodulation are found[12]. Only very recently, precise classification criteria have been proposed in order to define only 4 distinct subcategories: idiopathic portal hypertension, diffuse NRH, partial nodular transformation, and incomplete septal cirrhosis[11,12].

The clinical presentation of our case is typical of NCPH, bleeding from esophageal varices, and laboratory data correspond, since liver enzymes are usually normal or slightly elevated and hepatic function is preserved. As in the present case, in needle biopsies of the liver the changes of regeneration and atrophy may be very subtle on routine hematoxylin-eosin stains, and any case of suspected NCPH should be investigated further using reticulin stains[18]. Even the lack of coexisting diseases which are usually associated with NCPH is not infrequent[10]. However, the dominant finding in all the imaging studies performed in our case, i.e. multiple nodules ranging from a few millimetres to 3 cm in diameter, should not be considered typical of NCPH. Indeed, this picture is neither consistent with partial nodular transformation, where macronodules are concentrated around the hepatic ilus[12], nor with NRH, where nodules are usually too small to be radiologically detectable[19]. NRH is characterized by a diffuse nodular transformation of the hepatic parenchyma, without fibrosis separating the nodules. These histological features, consisting of diffuse hyperplastic nodules composed of cells resembling normal hepatocytes, and little or no inflammation or cholestasis, are concordant with the histological findings in our case. However, nodules characterizing NRH are usually 1-3 mm in size, and, although clusters of nodules up to 10 mm in diameter centered on a large portal tract are occasionally found[11], many nodules found in the liver of our patient are significantly bigger.

Therefore, in the present case, on the histological background of NRH, nodules much larger than the typical NRH ones were detected by imaging studies.

It has been suggested that all the categories constituting NCPH could represent the same lesional spectrum, the different stages of the same disease or the final stage common to different diseases with varying etiologies. Probably, personal anatomy, patterns of vascularization and damage location influence the final picture. The nomenclature proposed, in many cases, provides an inadequate description of the hepatic morphology, and combinations of morphological patterns are often reported in literature. For example, as Nakanuma et al[12] evidenced in their study, nodular parenchymal hyperplasia without fibrous rim was prominent in all cases of NRH but was found also in one fourth of idiopathic portal hypertension cases, in all partial nodular transformation cases, and in one third of incomplete septal cirrhosis cases, in which it was present in a mild degree and with a focal distribution. Moreover, Ibarrola et al[10] were able to classify only 3 out of their 9 NCPH patients according to accepted terminology, using combined terms to describe the hepatic morphology of another 3 cases, and coined the descriptive terms of "irregular architectural transformation" for the last 3 cases, which showed very grossly deformed livers with irregularly distributed nodules of variable size.

In conclusion, the present case highlights the typical difficulties encountered in the diagnostic and classification processes of NCPH. The different categories of NCPH represent the prevalent subtypes of hepatic regenerative response to a variety of injuries determining microcirculatory disturbances. More flexibility in classification should derive from this etiopathogenic background.

World Journal of Gastroenterology

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT
All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including t-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (n). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the P value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS
Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables
Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES
Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI
Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data
Write as mean ± SD or mean ± SE.

Statistical expression
Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units
Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, ρ (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations
Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics
Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS
Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office
World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Theodora CP, Filippos K, Georgios P, Stefanos P. Helicobacter pylori neutrophil activating protein as target for new drugs against Helicobacter pylori inflammation. *World J Gastroenterol* 2011; 17(21): 2585-2591

http://www.wjgnet.com/1007-9327/full/v17/i21/2585.htm

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Helicobacter pylori (*H. pylori*) infection is among the most common human infections and the major risk factor for peptic ulcer disease and gastric cancer. Within this work we present the implication of C-terminal region of *H. pylori* neutrophil activating protein in the stimulation of neutrophil activation as well as the evidence that the C-terminal region of *H. pylori* activating protein is indispensable for neutrophil adhesion to endothelial cells, a step necessary to *H. pylori* inflammation. In addition we show that arabino galactan proteins derived from chios mastic gum, the natural resin of the plant *Pistacia lentiscus var. Chia* inhibit neutrophil activation *in vitro*.

INTRODUCTION

The *Helicobacter pylori* (*H. pylori*) neutrophil activating protein (HPNAP) is one of a number of virulence factors produced by the bacterium *H. pylori*[1]. This protein originally purified from aqueous extracts of *H. pylori*, was shown to induce neutrophil adhesion to endothelial cells *in vitro*[1] as well as *in vivo*[2], to increase the adhesion of neutrophils to endothelial cells[3], to induce migration and activation of human neutrophils and monocytes[4,5] and to be a potent stimulant of mast cells[6]. Its binding to neutrophil-glycosphingolipids[7] and mucin, a component of the stomach mucus layer[8], has also been reported. HPNAP induced reactive oxygen intermediates (ROI) production involves a cascade of intracellular activation events, including increase of cytosolic calcium ion concentration and phosphorylation of cytosolic proteins, leading to the assembly of the superoxide-forming nicotinamide adenine dinucleotide phosphate-oxidase (NADPH) oxidase on the neutrophil plasma membrane[5,9,10].

Free radicals produced by neutrophils are a key component of the innate immune system and an effective antimicrobial agent against *H. pylori* as well as a factor that perpetuates mucosal damage and gastritis. Activation of neutrophils results in NADPH oxidase-mediated superoxide anion production which is highly destructive for the gastric mucosa, induces oxidative DNA damage and leads to substantial mucocal disruption. NADPH oxidase targeting is disrupted such that active enzyme complexes are present in patches at the cell surface but not on *H. pylori* phagosomes. Consequently, superoxide accumulates in the extracellular space but not near ingested bacteria. By this unusual mechanism, *H. pylori* evades oxidative killing and promotes tissue damage and ulceration. A possible blocking of reactive species production may lead to improvement of *H. pylori* induced chronic gastritis and reduction of signs of inflammation.

THE TWO ROLES OF HPNAP

Bacterial protection

HPNAP is a dodecameric protein consisting of 17 kDa monomers with a central cavity where iron can bind[11,12]. The observation that its synthesis is not affected by the iron content of the growth medium, led to the proposal that the primary role of HPNAP *in vivo* may not be to scavenge iron[13]. The primary sequence and overall structure of HPNAP[14] is similar to those of Dps family of iron-binding and DNA-protecting proteins[15]. Dps family proteins protect DNA from oxidative damage through direct interaction. Dps and DNA form a highly ordered and stable nucleoprotein complex called a biocrystal so that DNA is "sheltered" from the attack of the free oxidative radicals[16] by preventing the production of hydroxyl radicals produced by the Fenton reaction[17]. These proteins are present in many prokaryotes[18-22]. They bind ferrous ions and some of them lack the ability to bind DNA *in vitro*[12,19,23].

The role of HPNAP in protecting *H. pylori* from oxidative damage was first suggested by the observation that loss of alkyl hydroperoxide reductase (AhpC) leads to a concomitant increase in HPNAP expression[24]. Like other Dps proteins, HPNAP production is maximal in stationary-phase cells, and an *H. pylori* napA mutant survives less than the wild type strain upon exposure to oxidative stress conditions[25].

Our previous studies[26] revealed that HPNAP does not bind to DNA and therefore protection of the bacterial DNA by means of ferroxidase activity ensues by a mechanism similar to that suggested for other non DNA binding Dps. Molecular dynamics simulations (MDS) revealed that the ferroxidase site amino acids are indispensable for dimer formation and that ferrous ions contribute extensively to the stability of the dimers in solution.

HPNAP's inflammatory role

The inflammatory role of HPNAP concerns the attraction and activation of neutrophils. In particular, the 150 kDa oligomeric protein isolated from *H. pylori* has been found to promote neutrophil adhesion to endothelial cells[1,11]. This protein was designated the HPNAP because of its ability to induce neutrophils to produce reactive oxygen radicals[5,11]. HPNAP is released in the medium, probably after cell lysis, and binds to the bacterial surface where it can act as an adhesin, mediating binding to mucin or to polymorphonuclear leukocyte sphingomyelin[7,8]. Purified recombinant HPNAP has been produced in *Bacillus subtilis* to avoid contamination by *Escherichia coli* lipopolysaccharide. This purified material was found to be chemotactic for human neutrophils and monocytes *in vitro*[5]. Moreover, using intravital microscopy, it has recently been demonstrated that in rats HPNAP is able to cross the endothelia efficiently and to promote rapid neutrophil adhesion *in vivo*[27]. HPNAP-induced adhesivity depends on the induction of expression and on the acquisition of a high-affinity state of β2-integrin on the plasma membrane of PMNs[5,27]. This conformational change requires a functional p38 mitogen-activated protein kinase (MAPK). Collectively, these observations suggest that HPNAP plays a central role in the accumulation of leukocytes at the site of infection[5,11,27]. HPNAP stimulates PMNs to synthesize and release several chemokines, including CXCL8 (interleukin-8), CCL3 (MIP-1α) and CCL4 (MIP-1β)[27]. Because neutrophils rapidly migrate in large numbers at infection sites, the fact that they also serve as a chemokine source may contribute to the generation of the conditions necessary for both the recruitment and activation not only of additional neutrophils, *via* CXCL8, but also of monocytes, dendritic cells, and lymphocytes through CCL3 and CCL4. After crossing epithelial monolayers, HPNAP is also able to activate the underlying mast cells to release tumor necrosis factor-α (TNF-α) and other pro-inflammatory molecules[6,13].

NEUTROPHIL ACTIVATION IN FOCUS

According to the literature HPNAP is the only protein of the DPs family capable of activating human leukocytes. Zanotti *et al*[14] investigated this unique property of HPNAP by analyzing not only its surface but also the surfaces of the structurally similar Flp, Dlp-1 and Dlp-2 which failed to activate human neutrophils. That was an attempt to identify regions located on the surface of these proteins whose different properties could account for such biological difference. They found that the surface of HPNAP was characterized by a large presence of positively charged residues, a property that was not shared by the other members of Dps family. The strong prevalence of positive charges of the electrostatic surface potential of HPNAP conferred a basic character on it. By taking into account the fact that positively charged residues of several proteins, including those of some chemokines which was believed to play a role in the activation of neutrophils[28,29] they suggested that the presence of the large number of basic residues on the HPNAP dodecamer surface was responsible for its neutrophil activating property.

However according to Kottakis *et al*[26] by replacing His25, His37, Asp52 and Lys134, that are located within the ferroxidase site, with Ala, a total loss of ferroxidase activity, dodecamer formation and DNA protection in

Figure 1 Ferroxidase site of *Helicobacter pylori* neutrophil activating protein. A: The "ferroxidase site" in the equilibrated wild type. The iron ion (pink) is kept in position by Asp52, Glu56, His25 and His37. Two water molecules are attracted by Fe(II); B: The same site in the equilibrated mutant. The ferrous ion is attracted one-sidedly by Glu56 and Asp53 (not shown) loosing its ability to stabilize the dimer. Four water molecules are attracted by Fe(II).

Figure 2 Schematic representation of exposed helices of *Helicobacter pylori* neutrophil activating protein. *Helicobacter pylori* neutrophil activating protein dimer in stand up (A) and top view (B) with the exposed helices H3 and H4 (therefore possible candidates for interacting with the neutrophils) colored in violet and orange respectively.

environments rich in free radicals was observed.

MDS revealed that dimer formation was highly unlikely following mutation of the above amino acids, since the ferrous ion is not attracted equally strongly by both subunits (Figure 1A and B). These findings indicate that iron plays an important role in the conformation of HPNAP by initiating the formation of stable dimers that are indispensable for the ensuing dodecamer structure. In addition, according to our experiments both HPNAP wild type as well as HPNAP mutant were able to activate neutrophils. In particular, by incubating neutrophils separately with the above proteins we observed a similar degree of activation for both cases[26]. Very surprisingly, neutrophil activation was stimulated by structural elements that are localized within the broad C-terminal region of both HPNAPmut and dodecamer HPNAP-wild type. In particular, it was found that the dodecamer conformation was not necessary for activation and that helices H3 (Leu69-Leu75), H4 (Lys89-Leu114) or the linking coils (His63-Thr68 and Thr76-Ser88) were critical in stimulating neutrophil activation (Figures 2 and 3).

It was recently reported that HPNAP promotes a Th1 immune response by inducing the expression of IL-12 and IL-23 in neutrophils and monocytes, and also elicits an antigen-specific Th1-polarized T cell response in gastric mucosa of *H. pylori*-infected patients *in vivo*[30]. It has been shown that HPNAP is able to shift antigen activated human T cells from a Th2 to a Th1 cytotoxic phenotype characterized by production of IFN-γ and TNF-α. Since HPNAP is a powerful stimulant for the production of ROS, mediating damage to DNA and enhancing cell turnover[19], it may be a risk factor for *H. pylori*-associated gastric cancer. Considering the upregulatory effects of HPNAP on the innate immune system, it could possibly be argued that the chronic inflammatory response mediated by HPNAP may be associated with an increased danger of occurrence of gastric cancer in view of the fact that *H. pylori* is classified as class 1 carcinogen. As a matter of fact, a recent impressive work[31] studied the serum positivity and mean absorbance value of HPNAP-specific antibodies in patients with gastric cancer in comparison to patients with chronic gastritis. Interestingly, HPNAP antibodies were significantly higher in the gastric cancer group indicating a possible pathogenetic role of HPNAP in gastric carcinogenesis.

ACTIVATED NEUTROPHILS ATTACH TO ENDOTHELIAL CELLS

Human neutrophils were separately incubated with HPNAP-6xHis, HPNAP$_{1-57}$-6xHis (N-terminal region) and HPNAP$_{58-144}$-6xHis (C-terminal region) on micro wells with pre attached endothelial cells and their attachment was quantified by using the myeloperoxidase (MPO) assay[32]. Besides the entire protein and its truncated forms neutrophils were also incubated by the same manner with the neutrophil stimulator formyl-Met-Leu-Pro peptide (fMLP) in order to control their "bioactivity". In addition, a synthetic hexa-histidine peptide (6xHis) was also used for neutrophil activation in order to exclude the possibility that the obtained activation was attributed to the existence of the tailed histidines. Figure 4A shows that HPNAP-6xHis and the C-terminal region display almost the same ability to promote neutrophil adhesion to endothelial cells while the N-terminal region lacks this ability.

Considering the existence of lipopolysaccharides (LPS)

Figure 3 Neutrophil activation by *Helicobacter pylori* neutrophil activating protein. A: Neutrophil activation by *Helicobacter pylori* neutrophil activating protein (HPNAP)-wt and HPNAPmut. Bar 1, activation by formyl-met-leu-pro peptide (fMLP) (control), bar 2, activation by HPNAPwt, bar 3, activation by HPNAPmut; B: Neutrophil activation by HPNAPwt-hexa-histidine peptide (6xHis), HPNAP1-57-6His, HPNAP58-144-6His and 6His peptide. Bar 1, activation by fMLP (control), bar 2, activation by HPNAPwt-6His, bar 3, activation by HPNAP1-57-6His, bar 4, activation by HPNAP58-144-6His, bar 5, activation by 6His peptide; C: Values after subtraction of "6His" value from these of "HPNAPwt", "HPNAP1-57" and "HPNAP58-144".

and their involvement in the activation it is clearly shown that even after their removal the activation effects did not change significantly (Figure 4A). These results are consistent with previously published data[26], indicating that the 58-144 region of the HPNAP protein is the key component in neutrophil recruitment, activation and subsequent adhesion to endothelial cells, leading to oxidative burst and inflammation during *H. pylori* infection. Considering recently published data[33], on the safety and immunoge-

nicity of an intramuscular vaccine comprising VacA, CagA and HPNAP, we suggest that the obtained neutrophil activation by the C-terminal region of HPNAP opens new ways for drug design dealing with *H. pylori* inflammation.

NEUTROPHIL ATTACHMENT INHIBITION BY ARABINO-GALACTAN-PROTEINS FROM CHIOS MASTIC GUM

Chios mastic gum (CMG) and its derivatives were largely used in traditional medicine to ease the discomfort in patients suffering from gastric pain. Its *in vitro* antibacterial properties against a great variety of bacteria are well established[34,35]. In this study we demonstrate that AGPs extracted from CMG as described in[34] inhibit the neutrophil attachment to endothelial cells caused by the HPNAP and its C-terminal region. In particular, human neutrophils were incubated with either HPNAP-6xHis or HPNAP58-144-6xHis both in the presence and in the absence of AGPs and their attachment to endothelial cells was investigated as above. Figure 4B shows the inhibition of neutrophil attachment to endothelial cells after co-incubation of entire HPNAP and its truncated forms (N-terminal and C-terminal) with the AGPs. In particular, bar 3 shows the absence of any influence of AGPs on neutrophil attachment to endothelial cells. The designation "control" on the figure represents the found attachment of isolated neutrophils to endothelial cells after incubation, without any other addition of proteins or AGPs. The marked percentages of all other combinations are calculated by taking into account the control values. Thus, comparison of the bars 4 (HPNAP entire) to 5 (HPNAP entire plus AGPs) and 6 (HPNAP58-144) to 7 (HPNAP58-144 plus AGPs) reveals that neutrophil activation and their subsequent attachment to endothelial cells is inhibited by the AGPs from CMG.

A recent study[36] focused on HPNAP mediated neutrophil activation before and after 2 mo of per os administration of CMG. According to this work, CMG induces a significant reduction in neutrophil activation when incubated with AGP plus HPNAP in *H. pylori*-infected patients and controls. CMG also induces a significant reduction in neutrophil activation when incubated with HPNAP in *H. pylori*-infected patients. These results indicate a substantial down-regulation of the innate cellular immune effectors, which - according to unpublished clinical data in the context of this study - are accompanied by a significant clinical improvement of the patients' complaints (dyspepsia, epigastric discomfort, distention). However a demonstration of the histopathological improvement of the patients' chronic gastritis would provide even more valuable evidence, concerning the potential anti-inflammatory and gastritis-suppressive effects of CMG.

Summarizing our results presented within this work we evidenced that the broad C-terminal region of HPNAP stimulates neutrophil adhesion and that the AGPs from CMG disrupt the process of neutrophil-endothelial cell attachment caused by HPNAP, an effect that should

Neutrophil adhesion to endothelial cells + AGPs

Figure 4 Neutrophil adhesion to endothelial cells. A: Neutrophil adhesion to endothelial cells. Black bars indicate neutrophil adhesion to endothelial cells prior to lipopolysaccharides (LPS) removal while grey bars indicate the adhesion after LPS removal. The data represent triplicates from at least three independent experiments. Error bars indicate standard deviation (SD). Statistical evaluation was performed by Mann-Whitney test. Significant differences with the control values are marked by ([b]$P < 0.001$) bar 1, control, bar 2, formyl-met-leu-pro peptide (fMLP), positive control of the procedure, bar 3, *Helicobacter pylori* neutrophil activating protein (HPNAP)wt-hexa-histidine peptide (6xHis) effect on neutrophil adhesion to endothelial cells before and after LPS removal, bar 4, HPNAP58-144-6xHis effect before and after LPS removal, bar 5, HPNAP1-57-6xHis effect before and after LPS removal, bar 6, 6xHis effect; B: Effect of arabino galactan proteins (AGPs) on neutrophil adhesion to endothelial cells, bar 1, control, bar 2, fMLP, positive control of the procedure, bar 3, effect of AGPs, bar 4, HPNAPwt-6xHis effect before and after LPS removal, bar 5, HPNAPwt-6xHis and AGPs co-effect, before and after LPS removal, bar 6, HPNAP58-144-6xHis effect before and after LPS removal, bar 7, HPNAP58-144-6xHis and mastic gum extract co-effect, before and after LPS removal, bar 8, 6xHis effect.

FAILURE OF ANTIBIOTIC THERAPY AND RECURRENCE OF *H. PYLORI* INFECTION - IS *H. PYLORI* AN INVINCIBLE ENEMY?

Triple as well as quadruple treatment regimens are so far a well established therapy of *H. pylori* infection. Eradication rates of over 80% (triple therapy) and 96% for the quadruple regimen with bismuth or ecabet sodium are documented[37,38]. However, a significant number of mutants is emerging-especially in developing countries - which confers resistance to standard antibiotics (amoxicillin, metronidazole, clarithromycin)[39-41] as well as to fluoroquinolones. Resistance rates of 35% for clarithromycin and 26% for fluoroquinolones are documented, a very worrying fact, which limits considerably the future perspectives of successful antibiotic treatment of *H. pylori* infection.

be further investigated and maybe exploited in a future anti-inflammatory therapy for *H. pylori* patients.

Moreover, a high prevalence of recurrence of *H. pylori* infection in adults as well as in children could possibly render our efforts to eradicate this pathogen futile[42-45]. Indeed, an incidence of *H. pylori* annual recurrence of 2.67% and 13.00% in developed and developing countries respectively is documented in a recent study[46]. In view of these data, alternative methods of treatment as adjunct or main therapy regimens should be considered. HPNAP, a major stimulant of neutrophil recruitment and activation could be effectively targeted by natural agents that reduce inflammation (due to their activity as antioxidants) or suppress the production of inflammatory cytokines that attract neutrophils[47-50]. On the other side, the advent of the structure oriented drug design era would eventually provide us with valuable weapons to fight the *H. pylori* infection by the direct inhibition of HPNAP *in vivo*. The identification of structural elements at the C-terminal region of HPNAP monomer as a stimulus for neutrophil migration through endothelial cells and subsequent release of ROIs[26,51] renders this region eligible for drug mediated

inhibition of its immunological effects upon neutrophils. Indeed, additional studies should be carried out in order to validate this assumption and open the way for new and alternative perspectives to fight this ubiquitous pathogen.

INTRODUCTION

Early gastric cancer (EGC) is defined as gastric carcinoma confined to the mucosa or submucosa, regardless of the presence of regional lymph node metastases[1]. In the 1980s, surgery was typically used to treat early gastric cancer. However, the development of endoscopic devices and skills has resulted in a different approach to treatment. Endoscopic mucosal resection (EMR) is a procedure for the resection of gastrointestinal (GI) neoplasms that was first introduced in Japan. However, since it is difficult to achieve *en bloc* resection of specimens larger than 20 mm with EMR, this procedure has recently been replaced by endoscopic submucosal dissection (ESD)[2,3]. The improvement in ESD technique has led to extension of the indications for endoscopic treatment to that of early gastric cancer. In Korea, ESD has become an effective alternative treatment method to manage early gastric cancer. In this review, we provide an overview of ESD in Korea.

THE DEVELOPMENT OF ENDOSCOPIC RESECTION

Endoscopic therapy has been in continuous development since the injection of saline into submucosal tissue for cutting sessile rectal polyps by Dehyle in 1973[4] In 1984, strip-off biopsy (strip biopsy) was introduced for gastric cancer treatment in Japan[5]. Although successfully used to

Abstract

The early diagnosis of gastric cancer allows patients and physicians to pursue the option of endoscopic resection, which is significantly less invasive than conventional surgical resection. In Korea, the use of endoscopic submucosal dissection (ESD) has been increasing, and many reports on ESD have been published. In addition, Korean gastroenterologists from several hospitals performing ESD have conducted formal meetings to discuss useful information regarding ESD. Here, we discuss the Korean experience with ESD, including outcomes and prospects of endoscopic treatments.

Table 1 Endoscopic mucosal resection/endoscopic submucosal dissection therapeutic outcomes

Author	Yr	*n*	Method	Complete resection (%)	Local recurrence (%)	Bleeding (%)	Perforation (%)
Lee	1996	19	Strip biopsy	37.8	28.6

EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; EMR-C: EMR by cap-fitted panendoscope; EMR-L: EMR with ligation; EMR-P: Precutting followed by snare resection.

treat early gastric cancer, strip biopsies cannot be used to resect depressed ulcers or neoplasms. In the 1990s, EMR by cap-fitted panendoscope (EMR-C) and EMR with ligation (EMR-L) methods were developed in Japan for resection of early gastric cancer[6,7]. However, lesions larger than 2 cm cannot be removed *en bloc* with these techniques. Because piecemeal resection carries a high risk of recurrence and does not facilitate exact pathological staging, ESD was developed to remove early gastric neoplasm *en bloc*[8].

ESD was introduced in the late 1990s and allows direct dissection of the submucosa. ESD allows for certain histological diagnoses and reduces the rate of recurrence compared to EMR. The *en bloc* resection of large lesions is possible with insulation-tipped (IT) electrosurgical knives[9], as well as hook, flex, triangle and flush knives[8].

THE DEVELOPMENT AND OUTCOMES OF ENDOSCOPIC RESECTION IN KOREA

EMR for early gastric cancer was performed for the first time in Korea in 1996 by Hyun[10]. Several small-scale studies of ESD and EMR have been performed in Korea since then[11] (Table 1).

A large-scale, multicenter, retrospective study of EMR treatment was reported in 2007[12]. From January 2000 to December 2002, 514 EGCs in 506 patients were treated by EMR at 13 institutions. The most commonly used procedure was circumferential precutting followed by snare resection (EMR-P, *n* = 269, 52.3%). Complete resection and incomplete resection after EMR were confirmed in 399 lesions (77.6%) and 103 lesions (20.0%), respectively. In the completely resected mucosal cancer group (*n* = 399), local recurrence was detected in 24 cases (6.0%) with a median interval between EMR and recurrence of 17.9 mo (range, 3.5-51.7 mo). There were 3 cases of perforation and 71 cases of bleeding. There were no deaths related to the recurrence of gastric cancer during the overall median follow-up period of 39 mo[12].

The use of ESD has increased in many Korean hospitals over the last 5 years, accompanied by a subsequent increase in published reports about ESD treatment. Park *et al*[13] initially reported 27 cases of ESD treatment using the IT knife in Korea in 2004, after which use of the ESD procedure increased rapidly in Korea. The Korean Society of Gastrointestinal Endoscopy (KSGE) organized an ESD research group in 2003 to exchange professional opinions and develop ESD techniques. The KSGE held hands-on courses to introduce ESD procedures and devices using animal models. Live international ESD demonstrations have been held over a telemedicine network since 2006[14].

In 2009, a large multicenter study of ESD treatment was published[2]. From January 2006 to June 2007, 1000 early gastric cancers in 952 patients (502 men, 450 women; mean age 62.1 years, range 43-90 years) were treated by using ESD at six Korean ESD study group (KESG)–related university hospitals in Korea. The rates of *en bloc* resection, complete *en bloc* resection, vertical incomplete resection, and piecemeal resection were 95.3%, 87.7%, 1.8% and 4.1%, respectively. The rates of delayed bleeding, significant bleeding, perforation, and surgery related to complications were 15.6%, 0.6%, 1.2% and 0.2%, respectively. The rates of *en bloc* resection differed significantly based on the location of the lesions (upper portion *vs* middle portion *vs* lower portion of the stomach, 88.6% *vs* 95.2% *vs* 96.0%, respectively; $P = 0.002$), presence of a scar (no *vs* yes, 96.0% *vs* 89.5%, respectively; $P = 0.002$), and histologic type (low-grade adenoma *vs* high-grade adenoma *vs* differentiated early gastric cancer *vs* undifferentiated early gastric cancer, 95.8% *vs* 94.6% *vs* 96.2% *vs* 83.8%, respectively; $P = 0.007$)[2]. The results of this study suggested that the ESD techniques used in Korea achieve high rates of complete resection (87.7%) with an acceptable rate of complications. In addition, ESD outcomes from several hospitals show that *en bloc* and complete resection rates are 87%-100%, which are superior to those of conventional EMR treatment[15] (Table 2).

Table 2 Endoscopic submucosal dissection outcomes

Result of resection	*n* (%)
Complete resection	877 (87.7)
En bloc resection	953 (95.3)
Free margin of *en bloc* resection	901 (90.1)
Failure of *en bloc* resection	6 (0.6)
ESD time (min), mean ± SD	47.8 ± 38.3
Submucosal invasion of tumor	74 (7.4)
Lymphovascular invasion of tumor	30 (3.0)

ESD: Endoscopic submucosal dissection.

THE CHALLENGE OF ESD IN KOREA

Currently accepted classical indications for EMR according to the gastric cancer treatment guidelines published in 2001 by the Japanese Gastric Cancer Association are: (1) well-differentiated elevated cancers less than 2 cm in diameter; (2) small (< 1 cm) depressed lesions without ulceration; (3) moderately- or well-differentiated cancers confined to the mucosa; and (4) no lymphatic or vascular involvement[8,16]. However, the classical indications for EMR may be too strict and lead to unnecessary surgery[8].

Japanese studies have expanded the indications for endoscopic treatment of gastric cancer[8,17]. ESD has been developed to allow dissection directly along the submucosal layer using electronic knives. Gotoda *et al*[8,18] defined the risk of lymph node metastasis in patients with EGC using a large database of more than 5000 patients who underwent gastrectomy with meticulous R2 level lymph node dissection. This group of patients was characterized by having either no risk or a lower risk of lymph node metastasis compared to risk of mortality from surgery. Thus, expanded criteria for endoscopic resection were proposed: (1) mucosal cancer without ulcer findings, irrespective of tumor size; (2) mucosal cancer with an ulcer < 3 cm in diameter; and (3) min (< 500 μm from the muscularis mucosa) submucosal invasive cancer < 3 cm in size.

Ryu *et al*[19] investigated surgery as indicated for non-curative endoscopic resection in EGC in Korea. Neither residual cancer nor lymph node metastasis was found in patients with less than 500 μm submucosal invasion without margin involvement in ER specimens. An *et al*[20] studied predictive factors for lymph node metastasis in EGC with submucosal invasion. They concluded that lymphatic involvement and tumor size are independent risk factors for lymph node metastasis in EGC with submucosal invasion. Minimally invasive treatment such as EMR may be feasible for highly selective submucosal cancers with no lymphatic involvement, SM1 invasion, and tumor size < 1 cm. In addition, Park *et al*[21] reported that EGC with signet ring cell histology can be treated by endoscopic mucosal resection, if it is smaller than 25 mm, limited to the SM2 layer, and does not involve the lymphatic-vascular structure. Another Korean study showed that poorly differentiated EGC confined to the mucosa or with minimal submucosal infiltration (< or = 500 μm) could be considered for curative EMR due to the low risk of lymph node metastasis[22]. However,

extending the indications for ESD remains controversial because the long-term outcomes of these procedures have not been fully documented.

Histopathologic diagnosis of EMR/ESD specimens is very important, but the diagnostic criteria, terminology and grading systems differ between the East and the West. Most Western pathologists focus on structural invasion to diagnose carcinoma, but Japanese pathologists emphasize severe dysplastic cytologic atypia irrespective of the presence of invasion[23,24]. In 2000, the Vienna classification was proposed to reduce diagnostic discrepancies between Japanese and Western pathologists[25]. However, there is still confusion about the pathological diagnosis of gastric epithelial lesions[26]. In Korea, gastroenterologists and pathologists did not have clear guidelines for diagnosis, and efforts were made to improve consensus. Korean ESD techniques have been influenced by Japan, but Korean doctors are also influenced by advances in Western medical science in general.

Pathologic diagnosis of gastric cancer tissue obtained by ESD was discussed among gastroenterologists and pathologists at a joint symposium of the Gastrointestinal Pathology Study Group of Korean Society of Pathologists (GIPS-KSP) and the ESD study group held in Korea in 2007. This collaboration continues, with the goal of establishing consensus for ESD indications in Korea, as well as internationally.

The following criteria have been suggested for the pathological diagnosis of gastric epithelial lesions: (1) standardization of the number of biopsy specimens (introduction of the number of biopsy specimens according to the size of the lesion); (2) introduction of criteria for determination of the adequacy of a biopsy specimen (marking of muscularis mucosa, submucosa); (3) establishing criteria for diagnosis of advanced adenomas (including nuclear findings and structural abnormalities); and (4) establishing criteria of lamina propria invasion and submucosal invasion[27].

THE PROSPECTS OF KOREAN ESD

Improvements in the ability to endoscopically identify and distinguish cancer and the development of diagnostic tools will enable the diagnosis of ultra-early lesions. The detection of these ultra-early lesions will eventually result in more active use of ESD for treatment.

The rapid evolution of ESD has allowed the procedure to be more widely indicated. In addition, new diagnostic and therapeutic techniques have become available. One example is natural orifice transluminal endoscopic surgery (NOTES), by which abdominal operations are performed with an endoscope passed through a natural orifice (e.g. mouth, urethra, anus) and then through an internal incision in the stomach, vagina or colon[28]. This procedure allows extension of a flexible endoscope to reach organs outside of the lumen of the bowel. NOTES is minimally invasive compared to open surgery and is associated with fewer risks. EMR and/or ESD can be combined with laparoscopic/thoracoscopic sentinel node

mapping to allow successful endoscopic treatment of gastrointestinal cancers with a potential risk of lymph node metastasis using NOTES[29]. The KSGE organized a NOTES research group to discuss, investigate and spread information about the use of NOTES.

Since the KSGE organized the Korean ESD study group, there have been several meetings of gastroenterologists and gastroenteropathologists from hospitals where ESD is performed to discuss standardization of the pathology. The short- and long-term outcomes of ESD for the treatment of early gastric cancer have also been discussed at these regular meetings regarding the progress and outcomes of ESD in Korea[2,12]. However, these evaluations are limited by their retrospective methods, and the absence of an international focus on long-term outcomes. There is agreement that multicenter clinical studies are necessary to obtain prospective results. Therefore, the National Evidence-Based Health Care Collaborating Agency (NECA) and KSGE suggested the prospective study of short-term and long-term clinical outcomes of EGC treated by ESD. Many tertiary university hospitals have been involved in this study, which is expected to provide indications for endoscopic treatment of EGC in Korea and worldwide.

CONCLUSION

ESD is a useful method for complete resection of EGCs, but has many limitations. To improve the safety and efficacy of ESD, many Korean research groups are currently concentrating on the development of new techniques and devices.

Abstract

Endoscopic submucosal dissection (ESD) is the most advanced and representative technique in the field of therapeutic endoscopy and has been used for the treatment of gastrointestinal neoplasms, including early gastric cancer. The major difference and advantage of ESD compared to existing endoscopic resection techniques, such as endoscopic mucosal resection (EMR) and polypectomy, are the width and depth of the resection. Newly developed cutting devices, distal attachable endoscopic accessories, and an advanced electrosurgical unit have helped to overcome the limitations of therapeutic endoscopy in terms of lesion size, location, presence of fibrotic scarring, and accompanying ulcers. As a result, the indications for ESD have been expanded from the classical indication for EMR and polypectomy, and there is now support for a further expansion of ESD indications. At present, the most critical factor to consider in the decision of whether to perform ESD is the probability of unexpected lymph node metastasis. The guidelines for ESD are continually being updated and debated. In this review, we discuss the strengths and weaknesses of the expanded guidelines, based on evidence found in the literature.

INTRODUCTION

Early gastric cancer (EGC) is defined as a gastric cancer that is confined to the mucosa or submucosa, irrespective of the presence of regional lymph node metastasis[1,2]. Endoscopic submucosal dissection (ESD) is a novel endoscopic treatment that enables a clinician to resect a target lesion en bloc. For the last ten years, ESD has been performed in Korea for the management of early gastric cancer[3,4]. ESD for EGC is comparable to conventional surgery in many aspects, and it has the advantage of being less invasive and more economical. In this article, we

introduce the absolute and expanded indications of ESD and discuss their usefulness, safety, and limitations.

ABSOLUTE AND EXPANDED INDICATIONS OF ESD FOR EGC

The curability of EGC depends on the complete removal of the cancerous lesion and its metastatic lymph nodes. Fortunately, because a significant proportion of EGC has no lymph node metastasis, limited surgery, such as ESD, can be legitimately performed in many countries.

Traditionally accepted indications for endoscopic resection of EGC are small intramucosal EGCs of intestinal histology type. The rationale for this recommendation is based on the knowledge that larger lesions or diffuse histology lesions are more likely to extend into the submucosal layer and thus have a higher risk of lymph node metastasis. In addition, resection of a large lesion was not technically feasible until the ESD procedure was developed. Therefore, at present, the accepted indications for endoscopic mucosal resection (EMR) according to the gastric cancer treatment guidelines published in 2001 by the Japanese Gastric Cancer Association are: (1) well-differentiated elevated cancers less than 2 cm in diameter; and (2) small (< 1 cm) depressed lesions without ulceration. These lesions must also be moderately or well-differentiated cancers confined to the mucosa, and have no lymphatic or vascular involvement[5,6]. However, it has been clinically observed that currently accepted indications for EMR may be too strict, leading to unnecessary surgery[7].

Further studies by Gotoda *et al*[8] have defined new criteria to expand the indications for endoscopic treatment of gastric cancer. The ESD method has been developed to dissect directly along the submucosal layer using specialized devices. Preliminary studies have been published on the advantage of ESD over conventional EMR for the removal of larger or ulcerated EGC lesions en bloc. Thus, ESD allows the precise histological assessment of the resected specimen and may prevent residual disease and local recurrence. Gotoda *et al*[8] analyzed 5265 EGC patients who underwent gastrectomy with lymph node dissection. They provided important information on the risks of lymph node metastasis, wherein the differentiated gastric cancer with a nominal risk of lymph node metastasis was defined. They proposed expanded criteria for endoscopic resection: (1) mucosal cancer without ulcer findings, irrespective of tumor size; (2) mucosal cancer with an ulcer $\leq$ 3 cm in diameter; and (3) minimal ($\leq$ 500 μm from the muscularis mucosa) submucosal invasive cancer $\leq$ 3 cm in size (Figure 1)[8,9]. However, extending the indications for ESD remains controversial because the long-term outcomes of these procedures have not been fully documented.

RECENT EVIDENCE FOR EXPANDED INDICATIONS OF ESD FOR EGC

Over the past 20 years, intraluminal endoscopic surgery,

Figure 1 Guideline criteria for endoscopic mucosal resection (A) and expanded criteria for endoscopic submucosal dissection proposed by Gotoda *et al*[8] and Soetikno *et al*[9] (B). EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection.

referred to as EMR, has been advanced in Japan and Korea. Recently, EMR and ESD have been widely used to treat EGC without lymph node metastasis. EMR is indicated when the risk of lymph node metastasis is minimal and when the tumor can be removed en bloc with a loop snare. Therefore, in the guidelines issued by the Japanese Gastric Cancer Association (JGCA), differentiated mucosal cancers measuring less than 2 cm in diameter best fit the above criteria. However, endoscopic resection has also been used for larger lesions without lymph node metastasis. In addition, improved techniques featuring ESD, which involve incision of the mucosa around the lesion followed by direct dissection of the submucosal layer, can provide en bloc resection, regardless of the tumor size. Therefore, provided that there is no metastatic lymph node, and the cancer is confined to mucosa and upper submucosal layer, endoscopic resection featuring ESD can be advocated as a proper management strategy for EGC.

To establish a safe and confident criteria and indication for ESD, we have to classify EGC with and without metastatic lymph nodes and to analyze long-term follow-up data after EMR and ESD. In a recent study of patients who had undergone radical gastrectomy for EGC, none of the 1230 well differentiated mucosa-confined cancers smaller than 3 cm in diameter had associated lymph node metastasis, regardless of the presence of ulceration[8]. Regarding the presence of ulceration in all EGC patients, the probability of lymph node involvement significantly

increases in EGC containing an ulcer (3.4%) compared to EGC without an ulcer (0.5%)[8]. In subgroup analysis, cancer that is confined to the mucosa without an ulcer has no lymph node involvement, regardless of size (95% CI, 0%-0.4%). Mucosal cancer with an ulcer showed a size limitation up to 30 mm to be free of lymph node involvement (95% CI, 0%-0.3%). Thus we can conclude that presence of an ulcer and size are factors for indication of ESD for EGC. However, such characterization of EGC based on morphological feature poses certain problems. First, we should consider the life cycle of a malignant ulcer[10]. About one-third of EGCs with depressed morphology can change over time[11]. An EGC with ulceration on initial EGD can change into non-ulcerative EGC with an antisecretory agent. In addition, EGCs with ulceration, which had not appeared ulcerous on previous examination, are sometimes encountered. Nevertheless, there is no evidence in the literature regarding the outcome of ESD for EGC with healing ulcers and fibrotic scarring. In practice, the decision of ESD for EGC with a shallow ulcer often depends on the timing of the diagnosis and on the willingness of the operator. Regarding the division of ulcerative and non-ulcerative as a criterion for ESD[8], there has not been sufficient research to allow a definite decision. Second, there can be inter-observer variation in defining an ulcer in EGC. By definition, ulcers measure 5 mm or larger in diameter and are on exposed submucosa. However, in real endoscopic examination, the differentiation between ulcer and erosion is not always clear. Third, the size of a lesion can be different according to the method of measurement. An endoscopic ruler or a standard size disc patch can be applicable but, in most cases, a lesion is measured by eye in comparing to opened grasp of forceps. Thus, a standard reliable measurement method is required.

Another factor for expanded indication of ESD concerns the invasion depth of EGC. Although the absolute indication for EMR is applicable to only mucosal cancer, there have been some studies of ESD in submucosal cancer. Of the 145 well-differentiated tumors that had invaded less than 500 μm into the submucosa, and were smaller than 30 mm in diameter, none showed evidence of lymph node metastasis, provided that there was no lymphatic or venous invasion. Based on these findings, it was suggested that the criteria for ESD for EGC could be expanded[12-16].

From the surgical literature, the risk of lymph node metastasis appears to depend on the presence of ulcer rather than on the depth of invasion of EGC. A retrospective analysis of patients who underwent surgery for EGC in Korea reported that, among 129 cases of mucosal cancer compatible with expanded indications for EMR or ESD, three patients (2.3%) had lymph node metastasis and, among 52 submucosal cancer cases that met the expanded indications for EMR or ESD, two patients (4%) had lymph node metastasis[17]. The authors suggest that if EMR or ESD had been performed in these patients, it would not have been curative. However, even in this report, differentiated mucosal cancers without ulcers did not have lymph node metastasis, irrespective of size.

Thus, these data suggest that a well-differentiated mucosal cancer of any size without ulcer may be considered as an expanded indication for ESD.

Even in the expanded criteria, undifferentiated cancer an indication for surgery. However, studies on feasibility of ESD on undifferentiated EGC have been continuously performed and reported. Ye *et al*[18] reported that EGC with undifferentiated histology has no lymph node involvement, provided that the cancer is smaller than 25 mm, is confined to the mucosa or upper third of the submucosa, and has no lymphatic involvement. A similar study for signet ring cell carcinoma was reported by Park *et al*[19]. EGC with signet ring cell histology is a high risk for nodal and organ metastases, while smaller cancers of less than 25 mm that are confined to the SM2 layer and have no lymphatic-vascular involvement have no lymph node involvement. With regard to poorly differentiated EGC, a Korean study reported a somewhat lower risk of lymph node metastasis than expected[20]. On this retrospective analysis of 234 patients with poorly differentiated EGC who underwent radical gastrectomy with D2 lymph node dissection, half of the cases (*n* = 116) showed submucosal invasion in the resection specimen and 25.9% (30/116) of those were limited to the upper third (SM1). Lymph node metastasis was found in 3.4% (4/118) of mucosa-confined cancer. For patients with minor submucosal infiltration (SM1), the lymph node metastasis rate was non-existent (0/30). However, with SM2/3 invasion, the lymph node metastasis rate increased sharply to around 30%. Another Korean study[21] focusing on endoscopic resection for undifferentiated-type cancer, such as poorly differentiated adenocarcinoma and signet ring cell carcinoma, showed interesting results. In this study, 58 lesions with undifferentiated EGC (17 poorly differentiated; 41 signet-ring cell) were treated by endoscopic resection. The en bloc and complete resection rates in poorly differentiated cases were 82.4% and 58.8%, respectively, whereas those in signet ring cell were 85.4% and 70.7%. The recurrence rate was 5.1% in complete resection during the follow-up period. Therefore, the authors suggested that endoscopic resection might be a feasible local treatment for undifferentiated EGC if complete resection can be achieved. Although the studies so far are still insufficient to form a conclusion, we could take poorly differentiated cancer with mucosa or minimal submucosal invasion into consideration as a possible candidate for ESD in high-risk surgical patients.

A prospective comparative study was reported in Japan[6] concerning the clinical outcomes of absolute and expanded indication of EMR and ESD. A total of 589 EGC lesions were divided into the guideline group and the expanded group. En bloc, complete, and curative resections were achieved in 98.6 and 93.0, 95.1 and 88.5, and 97.1 and 91.1% of the guideline and expanded criteria lesions, respectively, and the differences between the two groups were significant. The complication risks, such as procedure associated perforation and bleeding, were significantly higher and the completeness of resection was statistically superior in the expanded indication group. However, the overall survival was equally adequate in both groups, and the disease-specific survival rates were 100% in both groups.

LIMITATIONS OF ESD

Lymph node micrometastasis and delayed cancer dissemination after ESD is one of the concerns about endoscopic resection including ESD. Walter *et al*[22] reported a fulminant case in a 67-year-old male patient with EGC of 12 mm and moderate differentiation. The depth of submucosal invasion was 2.3 mm and the cancer free margin could not be established. The patient underwent gastrectomy and the postoperative stage was pT1 (sm3), pN0 (0/58), cM0, L0, V0, G2 (UICC stage Ia). Three months later, an ultrasound revealed a new mass in the liver, and biopsy showed a rapidly growing metastasis of the gastric adenocarcinoma. This case highlights the risk of affected lymph nodes in early gastric cancer and the consequent risk of metastasis, which increases with greater depth of infiltration into the submucosa. Micrometastasis can be a reason for cancer recurrence even after curative surgery[23-27]. According to Cai *et al*[25], tumor size, macroscopic type, accompanying ulcers, and depth of invasion are strongly associated with micrometastasis in lymph nodes. Therefore, tumors with suspected submucosal invasion, large size, accompanying ulcers, and undifferentiated histology might have a risk of recurrence owing to micrometastasis, which would be contraindicated for EMR or ESD.

LONG-TERM FOLLOW UP DATA

Long-term follow up data are needed for the clinical application of the expanded criteria of ESD. One Japanese study[28] from the National Cancer Center Hospital involving 1955 EGC patients enrolled from January 1999 to December 2005 showed that there were no significant differences in the overall five-year survival rates between the curative resection group, as defined by the expanded indication, and the non-curative resection group, following additional surgery. This data suggest that ESD using the expanded criteria can show an excellent long-term outcome.

CONCLUSION

ESD makes it possible to perform complete resection for lesions larger than 20 mm, as well as those with ulceration, regardless of location. Many clinical data suggest that ESD might be adequate for lesions that fit both the current guidelines and the expanded criteria. In the near future, when long-term follow-up data accumulate and newer technology is available, endoscopic resection, including ESD, will be employed in the treatment of EGC with more expanded indications. However, we must keep in mind that accurate diagnosis, characterization of the lesion, and proper appreciation of technical aspects are most essential in therapeutic endoscopy.

Abstract

The histopathological diagnosis of gastric mucosal biopsy and endoscopic mucosal resection/endoscopic submucosal dissection specimens is important, but the diagnostic criteria, terminology, and grading system are not the same in the East and West. A structurally invasive focus is necessary to diagnose carcinoma for most Western pathologists, but Japanese pathologists make a diagnosis of cancer based on severe dysplastic cytologic atypia irrespective of the presence of invasion. Although the Vienna classification was introduced to reduce diagnostic discrepancies, it has been difficult to adopt due to different concepts for gastric epithelial neoplastic lesions. Korean pathologists experience much difficulty making a diagnosis because we are influenced by Japanese pathologists as well as Western medicine. Japan is geographically close to Korea, and academic exchanges are active. Additionally, Korean doctors are familiar with Western style medical terminology. As a result, the terminology, definitions, and diagnostic criteria for gastric intraepithelial neoplasia are very heterogeneous in Korea. To solve this problem, the Gastrointestinal Pathology Study Group of the Korean Society of Pathologists has made an effort and has suggested guidelines for differential diagnosis: (1) a diagnosis of carcinoma is based on invasion; (2) the most important characteristic of low grade dysplasia is the architectural pattern such as regular distribution of crypts without severe branching, budding, or marked glandular crowding; (3) if nuclear pseudostratification occupies more than the basal half of the cryptal cells in three or more adjacent crypts, the lesion is considered high grade dysplasia; (4) if severe cytologic atypia is present, careful inspection for invasive foci is necessary, because the risk for invasion is very high; and (5) other structural or nuclear atypia should be evaluated to make a final decision such as cribriform pattern, papillae, ridges, vesicular nuclei, high nuclear/cytoplasmic ratio, loss of nuclear polarity, thick and irregular nuclear membrane, and nucleoli.

INTRODUCTION

Techniques for endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) have been developing rapidly, and pathologists more commonly encounter specimens derived from endoscopic resection. These procedures are sometimes performed for diagnostic purposes but mostly for therapeutic convenience compared with radical surgery. However, for both purposes, pathological diagnosis of gastric biopsies and EMR/ESD specimens is very important, because further treatment plans and a surveillance schedule must be established. The importance of a diagnosis is not only stressed from a clinical viewpoint, but also from an academic perspective. Many studies regarding early gastric neoplastic lesions based on a histopathological diagnosis have been performed, and they focus on various clinical and pathological aspects such as survival, recurrence, surveillance programs, and molecular pathology. However, if the pathological diagnosis is different among pathologists, the results cannot be compared. Additionally, socio-economic problems are also important, because medical insurance is intimately associated with disease severity.

Although these issues are important, it is unfortunate that the definition, diagnostic criteria, and grading system for early stage gastric neoplastic lesions are not completely developed. In particular, it is well known that Eastern and Western pathologists use different criteria to make a gastric carcinoma diagnosis. A structurally invasive focus is necessary to diagnose carcinoma for most Western pathologists. The "Eastern" opinion is actually the "Japanese" concept, and diagnosis of gastric carcinoma is based on the cytological findings. We have realized that Korean pathologists have different diagnostic criteria for gastric epithelial neoplasia than Japanese or Western pathologists. In this article, we discuss the current problems for the pathological diagnosis of gastric neoplastic lesions, the Korean perspectives, and the path we should follow.

TERMINOLOGY: DYSPLASIA, ADENOMA, CARCINOMA *IN SITU*, AND INVASIVE CARCINOMA

Initially "dysplasia" was used for inflammatory bowel disease, but, now it is used throughout the gastrointestinal tract as well as for other organs. Dysplasia means an unequivocally neoplastic but non-invasive lesion distinguished from regenerative changes[1]. The term "gastric dysplasia" was used for the first time by Grundmann in 1975 to describe an exclusively precancerous gastric lesion[2]. Shortly thereafter, a WHO committee published a definition that characterizes dysplasia as cellular atypia, abnormal differentiation, and disorganized architecture[3,4].

Most Western pathologists use the term "dysplasia" to describe a neoplastic premalignant abnormality[1,5-11]. However, in Japan, the terminology for non-invasive neoplastic lesions is different. Since Nakamura *et al*[12] established

GED: Gastric epithelial dysplasia.

specific histological atypical gastric epithelium criteria, which were classified as definitely benign, borderline, or carcinoma, the Japanese Society for Research on Gastric Cancer has recommended that gastric neoplastic lesions be subdivided into one of five categories: normal or benign without cellular atypia, benign with slight atypia, borderline, probable carcinoma, and obvious carcinoma[13,14]. "Atypia" has been used more frequently than "dysplasia" in Japan. Subsequently, Japanese authors suggested the definition of "group 3 or 4 lesions"[14-16] (Table 1).

In addition to the differences in terminology describing premalignant gastric lesions, some confusion exists for the terms adenoma and dysplasia. Originally, adenoma was considered a raised circumscribed lesion, either sessile or pedunculated, in contrast to dysplasia, which arose at flat or depressed mucosa. However, much confusing terminology has been introduced such as "flat adenoma", "depressed adenoma", "elevated dysplasia", and "polypoid dysplasia"[17-31]. Thus, WHO defined adenoma as "a circumscribed benign neoplasm composed of tubular and/or villous structures lined by dysplastic epithelium". In 1998, Lewin *et al*[10] suggested nomenclature using both adenoma and dysplasia; the former meant neoplastic circumscribed benign lesions unassociated with underlying inflammation whether pedunculated, sessile, flat or depressed, and the latter meant benign neoplastic lesions associated with underlying inflammation. Both were subdivided as low and high grade. Although there have been efforts to clarify the definition, a confusing situation still persists[9].

Another confusing concept is carcinoma *in situ*, which means carcinoma without invasion. However, a differential diagnosis of high grade dysplasia/atypia and carcinoma *in situ* is problematic. When cytological atypia and architectural complexity is marked, the term "carcinoma *in situ*" is used by some pathologists, but others do not make a distinction between "high grade dysplasia" and "carcinoma *in situ*" because the behavior and management are the same[10]. In the Japanese classification, there is no disease group describing adenocarcinoma *in situ*. The WHO International References Center for Histological/Classification of Precancerous Lesions of the Stomach met in 1978 and developed a consensus statement that stated that presumed precancerous lesions of the stomach should be termed "dysplasia" and that the term "intramucosal carcinoma" should replace "*in situ* carcinoma" for lesions that have invasive malignant cells confined to the lamina propria[3,4]. However, "adenocarcinoma *in situ*" is categorized in the AJCC and Vienna classifications as a non-invasive intraepithelial carcinoma, resulting in confusion.

The most important and surprising inconsistency between Western and Japanese criteria is in the diagnosis of adenocarcinoma. Japanese pathologists make a diagnosis of cancer based on severe dysplastic cytologic atypia with enlarged vesicular oval nuclei and prominent nucleoli irrespective of the presence of invasion. But, Western pathologists believe there must be evidence of invasion into the lamina propria to make a cancer diagnosis. This inconsistency causes serious problems understanding "early" cancer. Many investigators have pointed out this discrepancy and made some efforts to reduce the confusion. The Vienna classification was developed for common world terminology of gastrointestinal epithelial neoplasia[32]. Some Western pathologists agreed with the Japanese criteria and changed their view points[33].

GRADING SYSTEM

Dysplasia is regarded as a precancerous lesion with increased risk of carcinoma, and the risk increases in parallel with the histological grade of the atypia. Various grading systems have been introduced to predict a prognosis of dysplasia/adenoma with more accuracy (Tables 1 and 2).

Table 2 Differentiation of low and high grade dysplasia and gastric carcinomas

Histology	Feature	Low-grade dysplasia	High-grade dysplsia	Carcinoma
Structural atypia	Gland size	Uniform	Variable	Variable
	Gland arrangement	Regular	Slightly irregular	Irregular
	Glandular crowding	Slight	Moderate	Marked
	Glandular transition to surrounding mucosa	No	No	No
	Glandular branching/budding	Focal	Prominent	Prominent
	Glandular cribriform	No	Yes	Yes
	Surface maturation	No	No	No
Nuclear atypia	Shape	Elongated	Elongated and/or irregular	Oval/round
	Pseudostratification	Basal 1/2	Over basal 1/2	Irregular
	Membrane	Thin	Thick	Uneven
	Hyperchromasia	Hyperchromatic even	Hyperchromatic irregular	Vesicular
	Pleomorphism	No	Mild	Moderate to marked
	Prominent nucleoli	Absent	Present	Present
	Loss of polarity	No	No/yes	Yes
Stroma	Invasion	No	No	Yes

The most popular grading system is the three-tiered (mild, moderate, and severe) or two-tiered (low and high) system; the latter shows better inter-observer agreement[1,33-37], and most management protocols are based on the two-tiered system. There is no distinctive management protocol according to the three-tiered system that is practically significant[1,34-37].

The morphological features of low grade dysplasia/adenoma are characterized by simple tubules with little branching, nuclear stratification below half of the cytoplasm, tall columnar cells with dense spindle-shaped hyperchromatic nuclei, ample amphophilic cytoplasm, and sparse mitotic figures. High-grade dysplasia/adenoma is composed of tubules with elongation and complex budding, cribriform in the most extreme cases, greatly enlarged round to oval nuclei, markedly increased nuclear/cytoplasmic ratio, and loss of nuclear polarity (Table 2).

Although well-established low and high-grade dysplasia criteria are present, there are large scale interobserver or intraobserver discrepancies. Sometimes, regeneration causes serious confusion with carcinoma. The category of "indefinite for dysplasia" is maintained in the Vienna classification[32], and the histopathological finding of regeneration has been well described in many studies[9,10,38].

CURRENT STATUS OF PATHOLOGIC DIAGNOSIS OF GASTRIC EPITHELIAL NEOPLASTIC DISEASE IN KOREA

Korea is geographically close to Japan, and academic exchanges are active. Korean endoscopists introduced the EMR/ESD technique from Japan, and many discussions and cooperation continues. In the pathology field, there are many conferences and collaborations between Japanese and Korean pathologists. Furthermore, Korea's medical science is influenced by that in Western countries. Korean doctors are familiar with Western style medical terminology. As a result, the terminology, definition, and diagnostic criteria for gastric intraepithelial neoplasia are very heterogeneous in Korea.

To promote diagnostic consensus, The Gastrointestinal Pathology Study Group of the Korean Society of Pathologist (GIPS-KSP) established a grading system for gastric epithelial proliferative disease and produced a standardized pathological report for gastric cancer[38,39]. The standard guidelines for grading gastric epithelial proliferative disease are as follows: (1) proliferating gastric epithelium can be divided into hyperplastic and neoplastic; (2) the term "dysplasia" is reserved for the microscopic epithelial changes that are unequivocally neoplastic; (3) biopsy specimens are categorized as regenerative (negative for dysplasia), indefinite (questionable dysplasia), positive (positive for dysplasia) and overt carcinoma; and (4) the positive category is divided into two groups; high-grade dysplasia and low-grade dysplasia[40]. Another important criterion for the differential diagnosis of low and high-grade dysplasia is the extent of nuclear stratification; nuclear stratification below half of the cytoplasm is characteristic of low-grade dysplasia. If nuclear stratification above half of the cytoplasm is present at more than three contiguous glands, it is considered high-grade dysplasia[39]. This criterion is based on the definition of high-grade dysplasia associated with inflammatory bowel disease.

In Korea, most pathologists use the term "tubular/villous/villotubular adenoma with low/high grade dysplasia" to describe intraepithelial precancerous disease. "Dysplasia" is used to describe atypia due to neoplastic etiology, excluding regenerative changes. This concept of dysplasia unassociated with adenoma (foveolar type dysplasia) is not well established and needs further study. The term "carcinoma *in situ*" is used by some pathologists to describe a highly anaplastic lesion without lamina propria invasion, but this is not widely accepted.

At the 8th Japan-Korea Pathologist Symposium in 2008 in Yokohama, Japan, there was a consensus conference to discuss diagnostic differences in gastrointestinal neoplasia, and Japanese and Korean pathologists confirmed their different viewpoints.

In 2009, GIPS-KSP began to establish new Korean diagnostic criteria for gastric epithelial proliferative disease, and the effort is ongoing. We gathered 117 cases of gastric

Table 3 Inter-observer agreement rate before and after consensus conferences

Agreement rate (%)	Before (%)	After (%)
0-50	16 (38.1)	1 (2.4)
51-60	13 (31.0)	4 (9.5)
61-70	3 (7.1)	8 (19.0)
71-80	5 (11.9)	6 (14.3)
81-90	3 (7.1)	6 (14.3)
91-100	2 (4.8)	17 (40.5)
Total	42 (100)	42 (100)

biopsy specimens and ESD specimens from 14 institutes. Six pathologists screened the slides and selected 42 cases, which showed the difficulty of diagnosis. The selected cases were circulated and answers were gathered from 45 pathologists. The answer sheet was composed of five categories of diagnosis; regenerative atypia, low grade dysplasia, high grade dysplasia, carcinoma *in situ*, and carcinoma. In most cases, there was a wide range of interobserver discrepancy. We tried to simplify the diagnostic criteria to enhance diagnostic consistency but realized that it was impossible because determining low-grade dysplasia, high-grade dysplasia, and carcinoma was a complex process based on many kinds of diagnostic criteria. A consensus conference was held eight times and the pathological findings of each case were discussed and voted on anonymously. After the consensus conferences, the agreement rate increased (Table 3). Before the consensus conferences, only 10 cases among 42 showed a high agreement rate (more than 70%). After the conferences, the cases showing high agreement rate increased to 25 cases (Table 3). Although these data were not enough for a conclusion, it was suggested that there could be agreement for a pathologic diagnosis among Korean pathologists.

Many histological factors are helpful for the differential diagnosis of low and high-grade dysplasia, but these factors sometimes conflicted with each other. We attempted to identify a more simple and reproducible way to determine the dysplasia grade. We propose guidelines for differential diagnosis: (1) a diagnosis of carcinoma is based on invasion; (2) the most important characteristic of low-grade dysplasia is a regular distribution of crypts without severe branching, budding, or marked glandular crowding; (3) if nuclear pseudostratification occupies more than the basal half of the cryptal cells in three or more adjacent crypts, the lesion is considered high-grade dysplasia (this rule was based according to the previously mentioned Korean Standard of Pathology Report of Gastric Cancer[39]); (4) if severe cytologic atypia is present, careful inspection for invasive foci is necessary, because the risk of invasion is very high; and (5) other structural or nuclear atypia should be evaluated to make a final decision such as cribriform pattern, papillae, ridges, vesicular nuclei, high nuclear/cytoplasmic ratio, loss of nuclear polarity, thick and irregular nuclear membrane, and nucleoli. Based on these principles, the consensus rate was markedly increased, although not in every case.

Figure 1 Consensus diagnosis of tubular adenoma with low grade dysplasia. A: Regular distribution of small proliferative glands without budding or branching (HE, × 100); B: Elongated nuclei with stratification below half of the cytoplasm (HE, × 200).

EXAMPLES OF CASES PRESENTED AT THE CONSENSUS CONFERENCE

Case 1

An ESD specimen revealed a regular distribution of small proliferative glands without budding or branching (Figure 1A). The nuclei were elongated and stratified below half of the cytoplasm (Figure 1B). Hyperchromasia and mitoses were present; 57.8% and 100% of the pathologists agreed with a diagnosis of tubular adenoma with low grade dysplasia before and after the consensus conference, respectively.

Case 2

An ESD specimen revealed regular distribution of small proliferative glands without budding or branching (Figure 2A). Glandular crowding was mild. The nuclei were ovoid and vesicular with conspicuous nucleoli but nuclear stratification did not exceed the basal half of the cell (Figure 2B); 73.3% and 60.9% of the pathologists agreed with a diagnosis of tubular adenoma with low-grade dysplasia before and after the consensus conference, respectively.

Case 3

An ESD specimen revealed compact small glandular proliferation with some variation in gland size (Figure 3A). Budding or branching was present. The nuclei were elongated and stratified with some ovoid nuclei. More than

Figure 2 Major consensus diagnosis of tubular adenoma with low-grade dysplasia. A: Regular distribution of small proliferative glands without budding or branching (HE, × 100); B: Ovoid and vesicular nuclei with conspicuous nucleoli and nuclear stratification not exceeding basal half of the cell (HE, × 400).

Figure 3 Consensus diagnosis of tubular adenoma with high-grade dysplasia. A: Compact small glandular proliferation with some variation of gland size, budding and branching (HE, × 40); B: Elongated or oval nuclei with stratification above half of the cytoplasm in more than three contiguous glands (HE, × 200).

Figure 4 Major consensus diagnosis of tubular adenoma with high-grade dysplasia. A: Glandular crowding with some variation in gland size and budding (HE, × 100); B: Elongated or oval nuclei with stratification above basal half of the cytoplasm (HE, × 200).

three contiguous glands showed nuclear stratification above half of the cytoplasm (Figure 3B). Hyperchromasia and mitoses were present; 44.4% and 100% of the pathologists agreed with a diagnosis of tubular adenoma with high-grade dysplasia before and after the consensus conference, respectively.

Case 4

An ESD specimen revealed glandular crowding with some variation in gland size and budding (Figure 4A).

The nuclei were elongated and stratified with some ovoid nuclei. Nuclear stratification above the basal half of the cytoplasm was present (Figure 4B). Hyperchromasia and mitoses were noted. Before the consensus conference, 44.4% of pathologists agreed with a diagnosis of tubular adenoma with high-grade dysplasia, which increased to 75% after the conference.

Case 5

An ESD specimen revealed compact small glandular

Figure 5 Major diagnosis of tubular adenoma with high-grade dysplasia. A: Compact small glandular proliferation with variation in gland size, budding and branching (HE, × 100); B: Elongated or oval nuclei with stratification above basal half of the cytoplasm in more than three contiguous glands. Glandular complexity without definite invasion (HE, × 200).

Figure 6 Consensus diagnosis of adenocarcinoma. A: Compact small glandular proliferation without budding or branching. Relatively regular glandular distribution but enlarged, oval to round, and pleomorphic nuclei (HE, × 100); B: Another section showing villous configuration (HE, × 40); C: Hyperchromasia and mitoses with invasion into the lamina propria (arrow) (HE, × 400).

proliferation with variation in gland size, budding and branching (Figure 5A). The nuclei were elongated and stratified with some ovoid nuclei (Figure 5B). More than three contiguous glands showed nuclear stratification above the basal half of the cytoplasm. Hyperchromasia and mitoses were present. Glandular complexity was present but definite invasion was not identified; 42.5% and 62.5% of the pathologists agreed with a diagnosis of tubular adenoma with high-grade dysplasia before and after the consensus conference, respectively.

Case 6

A mucosal biopsy specimen revealed compact small glandular proliferation without budding or branching (Figure 6A). Another section showed a villous configuration (Figure 6B). The glandular distribution was relatively regular but gland size was mildly variable. The nuclei were enlarged, oval to round, and pleomorphic. Nuclear stratification was not severe, but enlarged nuclei occupied more than the basal half of the cytoplasm. Hyperchromasia and mitoses were present. Invasion into the lamina propria was present (Figure 6C, arrow); 22.2% and 100% of the pathologists agreed with a diagnosis of adenocarcinoma before and after the consensus conference, respectively.

Case 7

A mucosal biopsy specimen revealed compact small glandular proliferation with budding or branching (Figure 7A). Glandular size and distribution were irregular. The nuclei

were enlarged, oval to round, with vesicular chromatin. Severe nuclear stratification approaching the top of the cytoplasm in more than three contiguous glands was present. Marked hyperchromasia and mitoses were noted with invasion into the lamina propria (Figure 7B, arrow); 26.7% and 56.3% of the pathologists agreed with a diagnosis of adenocarcinoma before and after the consensus conference, respectively.

PROBLEMS TO BE SOLVED

The rate of agreement markedly increased after many consensus conferences (Table 3). However, this guideline has some limitations; (1) focal invasion into the lamina propria may not be detected on a biopsy specimen, which causes diagnostic discrepancy between a biopsy and resection specimen; and (2) a gray zone due to overlapping or mismatching of diagnostic criteria lowers the agreement rate. We must conduct a further study to verify the hypothesis in expanded cases and to determine that the guideline lowers inter and intraobserver discrepancies and correlates with clinical outcome. If more reliable pathological findings suggesting possible invasion into an adjacent area could be found, it would be very useful for small biopsy specimens. We will attempt to define the pathological criteria in a more simple and subjective way, and we would like to develop a diagnostic algorithm. Education is also important. Symposiums, workshops, and publishing of articles will be helpful.

Figure 7 Major diagnosis after the consensus conference of adenocarcinoma.
A: Compact small glandular proliferation with budding and branching. Regular glandular size and distribution (HE, × 100); B: Severe nuclear stratification approaching the top of the cytoplasm in more than three contiguous glands. Marked hyperchromasia and mitoses with invasion into the lamina propria (arrow) (HE, × 400).

We have additional problems to be solved, such as how to measure the invasion depth if submucosal invasion is present, the diagnostic policy for differentiation, judgment on lymphovascular invasion, and a fixation method for ESD specimens, which are all important decisions to develop a further treatment plan after EMR/ESD.

CONCLUSION

Eastern and Western pathologists have different terminology and diagnostic criteria for gastric intraepithelial neoplasia. In Korea, pathologists experience much difficulty when making a diagnosis, and have made efforts to increase the interobserver agreement rate. As a result, we have achieved improved diagnostic consensus, although it is not yet perfect. We tentatively suggest the guidelines for differential diagnosis: (1) a diagnosis of carcinoma is based on invasion; (2) the most important characteristic of low grade dysplasia is the architectural pattern such as regular distribution of crypts without severe branching, budding, or marked glandular crowding; (3) if nuclear pseudostratification occupies more than the basal half of the cryptal cells in three or more adjacent crypts, the lesion is considered high grade dysplasia; (4) if severe cytologic atypia is present, careful inspection for invasive foci is necessary, because the risk for invasion is very high; and (5) other structural or nuclear atypia should be evaluated to make a final decision such as cribriform pattern,

papillae, ridges, vesicular nuclei, high nuclear/cytoplasmic ratio, loss of nuclear polarity, thick and irregular nuclear membrane, and nucleoli. Further study on the pathological findings and clinicopathological correlations as well as a follow-up study are necessary to increase diagnostic accuracy.

Abstract

The high incidence of gastric cancer has led to the initiation of cancer screening programs. As a result, the number of early gastric cancer cases has increased and consequentially, the cancer mortality rate has decreased. Moreover, the development of minimally invasive endoscopic treatment has been introduced for these early lesions. Endoscopic submucosal dissection (ESD) is now recognized as one of the preferred treatment modalities for premalignant gastrointestinal epithelial lesions and early gastric cancer without lymph node metastasis. We review the results of ESD including experiences in Japan and Korea, as well as western countries.

Peer reviewer: Nageshwar D Reddy, Professor, Asian Institute of Gastroenterology, 6-3-652, Somajiguda, Hyderabad-500 082, India

INTRODUCTION

The high incidence of gastric cancer in Japan and Korea has led to the initiation of national cancer screening programs. As a result, the number of early gastric cancer (EGC) cases has increased dramatically and accounts for up to 50% of all gastric cancer diagnoses[1,2]. In addition, as a result of these programs, the mortality rate from gastric cancer has decreased[3]. Moreover, the development of minimally invasive endoscopic treatment has been introduced for these early lesions.

Initially, EGC was treated using endoscopic mucosal resection (EMR) techniques that included an injection that lifts the lesions, which are then cut. EMR can be used with a cap (EMR-C) and with ligation (EMR-L). These techniques are limited by the size of the lesions; only lesions of a relatively small size (< 2 cm) can be resected *en bloc*, due to the restricted size of the snare, cap and ligation devices. If EMR is attempted for lesions > 2 cm, the risk of piecemeal resection might increase, which makes it difficult to determine whether the lateral resection margins are free of disease. Previous studies of EMR have reported an approximately 75% *en bloc* resection rate. However, there is a high risk of local recurrence (2%-35%) with this procedure, especially when EMR cannot achieve *en bloc* resection[4-7].

To avoid the problems associated with EMR, endoscopic submucosal dissection (ESD) has been introduced

for safe *en bloc* resection. ESD can be used for larger lesions and those with ulceration, regardless of their location[7-9]. Although ESD techniques require advanced skill and might have a higher complication rate, including bleeding and perforation, they increase the rate of *en bloc* resection and complete histological analysis, and might ultimately reduce local disease recurrence rate[7,10].

ESD is now recognized as one of the preferred treatment modalities for premalignant gastrointestinal epithelial lesions and EGC without lymph node metastasis. The ESD procedure starts by making several marking dots around the lesion; a lifting solution is injected into the submucosal layer, followed by endoscopic circumferential incision of the lesion with various knives; dissection starts at the lateral edges, and proceeds through the lifted submucosal layer until the lesion is resected in one piece. According to a PubMed search, a total of 517 articles on ESD have been published up to January 2010. Most of the studies have been published from Asia, mainly Japan; however, recently there have been an increasing number of papers from Korea and China.

In this chapter, ESD for EGC is reviewed, including experiences from Japan and Korea, as well as western countries.

BACKGROUND OF ENDOSCOPIC RESECTION

EGC is defined by tumor invasion confined to the mucosa or submucosa, regardless of lymph node metastasis[11]. According to the outcomes after gastrectomy, 5- and 10-year survival rates for patients that have a diagnosis of mucosal EGC have been reported to be 96% and 92%, respectively[12]. The long-term outcomes after EMR for EGC < 2 cm has demonstrated excellent results with disease-specific 5- and 10-year survival rates of 99% and 99%, respectively; this was even with patients that had major organ complications, who were not good candidates for surgery[13]. Clinical experience suggests that complete resection of the cancer is possible, and cure can be achieved as long as the potential for metastatic spread is accurately excluded.

The accepted indications for EMR and ESD are lesions diagnosed as well-differentiated adenocarcinoma by histology, which are elevated and < 2 cm in diameter, and small (≤ 10 mm), depressed, well-differentiated tumors without ulcer formation[14]. However, these indications are rather strict, which leads to many patients being subjected to unnecessary surgery. Actually, endoscopic resection has also been used for larger lesions without lymph node metastasis by many Japanese investigators. Lymphovascular involvement, ulcer formation, and tumor size > 3 cm are independent risk factors for lymph node metastasis in EGC that is limited to the mucosa[15]. A large study on post-gastrectomy outcomes with lymph node dissection has shown that the overall risk for lymph node metastasis among patients with EGC that involved the mucosa was 2.7%. The risk increased to 18.6% when the cancer invaded the submucosa. The absence of submucosal lympho-

vascular involvement in moderately or well-differentiated adenocarcinoma was found to correlate with a nominal risk for lymph node metastasis. In lesions < 3 cm, the risk of lymph node metastasis is very low regardless of the presence of ulceration. In lesions without ulceration, the risk is unaffected by the size of the tumor[16]. Therefore, according to the *Treatment Guidelines for Gastric Cancer in Japan*, the expanded criteria for ESD are as follows: (1) a differentiated mucosal cancer without ulceration, no lymphatic-vascular invasion, regardless of size; (2) a differentiated mucosal cancer with ulceration, no lymphatic-vascular invasion, tumor < 3 cm; (3) an undifferentiated type of mucosal cancer without ulceration and tumor < 2 cm in diameter, and absence of lymphatic-vascular invasion; and (4) when a differentiated adenocarcinoma, which has not invaded deeper than submucosal level 1 (< 500 μm) and lymphovascular invasion is absent, additional lymph node dissection is not necessary[14].

However, expanding the indications for endoscopic resection remains controversial because the long-term outcomes of these indications have not been fully documented. Several publications have reported lymph node metastasis in EGC that meet the extended criteria[17-19]. Jee *et al*[19] have reported lymph node status in a total of 181 patients who met expanded indications for ESD and had undergone surgical resection. They reported lymph node metastasis in 2.3% of 129 patients with mucosal cancer. This included one ulcerated differentiated cancer < 3 cm in diameter, and two undifferentiated cancers < 2 cm in diameter without ulceration. Also, in a study of lymph node metastasis in 4% of 52 patients with submucosal cancer, those were two differentiated tumors.

Therefore, considering the indications for ESD, surgery is preferentially recommended for undifferentiated mucosal cancer, although several recent studies have shown that the rate of lymph node metastasis is negligible in small and undifferentiated mucosal cancer[20-24].

WORLDWIDE ESD RESULTS

The results of recent studies have suggested that the technique of ESD achieves a high rate of *en bloc* resection (92%-97%) and complete resection (73.6%-94.7%) with various rates of complications including bleeding (0.1%-15.6%) and perforation (1.2%-9.7%). Furthermore, they have revealed excellent long-term outcomes (5-year overall and disease-specific survival rates of 97.1% and 100%, respectively) (Table 1).

Japan

Oda *et al*[6] have performed a multicenter retrospective study to determine the nationwide results of endoscopic resection for EGC. Seven hundred and fourteen EGCs (EMR, 411; ESD, 303) that met the expanded criteria, except for the undifferentiated type of mucosal cancer, from 655 consecutive patients and 11 Japanese institutions were evaluated. Technically, 71.6% of the lesions were resected in one piece. The rate of *en bloc* resection by ESD (92.7%) was significantly higher than by EMR (56.0%). The rate of

[1]Overall 5-year recurrence free rate. LGD: Low-grade dysplasia; HGD: High-grade dysplasia; NA: Not applicable; EGC: Early gastric cancer; ESD: Endoscopic submucosal dissection; EMR: Endoscopic mucosal resection; EMR-P: precutting followed by snare resection.

curative resection by ESD (73.6%) was significantly higher than by EMR (61.1%). Bleeding was found in 0.1% of cases. The frequency of perforation with ESD and EMR was 3.6% and 1.2%, respectively. All complications were managed endoscopically, and there was no procedure-related mortality. The median follow-up period was 3.2 years. The 3-year cumulative residual-free/recurrence-free rate in the ESD group (97.6%) was significantly higher than that in the EMR group (92.5%).

Oka *et al*[7] have reported on a comparative study between EMR and ESD of 1020 EGCs that met the expanded criteria. Eight hundred and twenty-five EMRs and 195 ESDs were performed. In cases without ulceration, the *en bloc* and curative resection rates were significantly higher with ESD (both 92.8%) than with EMR (43.4% and 24.6%), regardless of tumor size. The average operation time was significantly longer for ESD than for EMR (84.4 min *vs* 12.6 min), regardless of tumor size. In addition, the frequency of intraoperative bleeding was significantly higher with ESD (22.6%) than with EMR (7.6%). The frequency of delayed bleeding did not differ. No patient experienced recurrence after ESD.

Imagawa *et al*[8] have analyzed 196 EGCs that met the expanded criteria and were treated by ESD, in relation to lesion size, location and the presence or absence of ulceration. The rate of *en bloc* resection was 93%, the curative resection rate was 84%, with a perforation rate of 6.1%, and a mean procedure time of 68 min. The rate of curative *en bloc* resection differed significantly depending on the location of the lesion (upper *vs* middle *vs* lower, 74% *vs* 77% *vs* 91%), as well as on the size of the lesion (> 20 mm *vs* ≤ 20 mm, 59% *vs* 89%). There were also significant differences in the mean procedure time in relation to the location of the lesion (upper *vs* middle *vs* lower, 105 min *vs* 81 min *vs* 45 min) and the size of the lesion (> 20 mm *vs* ≤ 20 mm, 124 min *vs* 55 min), as well as the presence of ulceration (positive *vs* negative, 97 min *vs* 65 min). They showed that the difficulty of ESD depends on the location and size of the lesion, as well as on the presence of ulceration.

Isomoto *et al*[10] have published the first long-term follow-up results of 589 EGCs treated by ESD, which met the expanded criteria. *En bloc* resection was achieved in 94.9%. Curative resection was achieved in 94.7%. *En bloc* resection was the only significant factor associated with curative ESD. Patients with a non-curative resection developed local recurrence more frequently. The 5-year overall and disease-specific survival rates were 97.1% and 100%, respectively.

Goto *et al*[25] have carried out a retrospective investigation of ESD to determine long-term outcomes. Two hundred and seventy-six node-negative EGCs that met the expanded criteria, except for the undifferentiated type of mucosal cancer, were enrolled. The *en bloc* and complete resection rates were 96.7% and 91.7%, respectively. During a median follow-up of 3 years, there were two local recurrences (0.9%). The 5-year overall and disease-specific survival rates were 96.2% and 100%, respectively.

Nakamoto *et al*[26] have performed a comparative study

of EMR and ESD for 202 EGCs. The overall *en bloc* and complete resection rates were lower in patients undergoing EMR compared to ESD (*en bloc*: 53.8% *vs* 94.3%, complete: 37.5% *vs* 92.6%). The overall 5-year recurrence-free rate was lower in the EMR group than in the ESD group (82.5% *vs* 100%). However, with regard to tumor size, EMR was comparable to ESD for the small lesions (< 5 mm).

Korea

The number of publications on ESD in Korea has been increasing. The results of ESD including the *en bloc* resection rate, complete resection rate, and long-term follow-up survival rates are similar to those from Japan. The Health Insurance Review and Assessment Service of Korea have reported that 74 institutions, mainly tertiary hospitals, have performed ESD in 2008.

Kim *et al*[27] have published the first multicenter retrospective study of endoscopic resection in Korea. They collected 514 EGCs in 506 patients during January 2000 to December 2002 by use of the on-line database registry system. The most commonly used technique was circumferential precutting followed by snare resection (EMR-P, 52.3%). The second most common procedure was the injection and cut technique (24.3%). ESD was used only in 6.6% of cases at that time. Complete resection was confirmed in 77.6% of the lesions, and the mean tumor size was 1.76 cm. However, ESD is now in the mainstream for endoscopic resection of early gastric lesions in Korea.

Jung *et al*[28] have reported an 11-year experience of endoscopic resection performed by a single endoscopist. Seven hundred and seventy-five EMR procedures were performed after precutting (EMR-P) during the first 9 years and 552 ESDs over the following 2 years. The median specimen sizes were 33 mm for EMR-P and 45 mm for ESD. The complete resection rates were 91% and 95.1% and the respective complication rates were 7.1% and 10.7%.

The Korean ESD study group has published a retrospective six university hospital experience with ESD for 1000 gastric neoplasms[29]. The rate of *en bloc* resection and complete resection was 95.3% and 87.7%, respectively. The rate of delayed bleeding and perforation was 15.6% and 1.2%, respectively. The rate of *en bloc* resection differed significantly based on the location of the lesions and presence of a scar. Procedure times were increased in cases in the upper stomach that had a large lesion (> 40 mm), with the presence of an ulcer, and the presence of a scar.

Jang *et al*[30] have reported the results of ESD for 402 gastrointestinal neoplasms at a single hospital. *En bloc* resection and complete resection were achieved in 89.7% and 87.9%, respectively, and the local recurrence rate was 5.1%. The 3-year cancer-free survival rate was 94.9%.

Min *et al*[31] have published a comparative study of ESD and EMR after circumferential precutting (EMR-P) of 346 EGCs. *En bloc* resection and complete resection were achieved in 77.7% and 75.7% of the EMR-P group, respectively, and 95.9% and 88.9% of the ESD group. For EGCs > 20 mm, ESD demonstrated a significantly higher *en bloc* resection and complete resection rate compared to

EMR-P. In cases with completely resected differentiated cancer, neither group showed local recurrence during a median 29 and 17 mo follow-up, respectively.

Taiwan

Chang *et al*[32] have published a retrospective multicenter review of ESD of 70 EGCs in Taiwan. The *en bloc* resection rate was 91.4%. The bleeding and perforation rates were 5.7% and 4.3%, respectively. Emergency surgery was performed in the patients with perforations. The local recurrence rate was 2.8%. Another small study has been published in Taiwan[33]; however, the results have indicated that the procedure requires more experience.

Western countries

As a result of the low incidence of EGC in the west, relatively few institutions use ESD and there have been only a few clinical studies on the outcomes[34-42]. However, the reported outcomes of western studies have not been substantially different from those in eastern countries. Cardoso *et al*[35] have published an initial experience with ESD for 15 EGCs < 30 mm with no ulceration or scaring from Brazil. The mean procedure time was 140 min. The *en bloc* and complete resection rate was 80% and perforations occurred in 20% of cases. Catalano *et al*[36] have published their experience with EMR and ESD on 48 gastric lesions in Italy. After an initial experience with 36 EMRs, the procedure was changed to ESD. Out of 36 EMR procedures, *en bloc* and complete resection were achieved in 72% and 56%, respectively. However, among the 12 ESD cases, the rates both increased to 92%. Bleeding and perforation occurred in one case each. Dinis-Ribeiro *et al*[37] have published the results of ESD for 19 gastric lesions in Europe. ESD was performed under general anesthesia with a 79% *en bloc* resection rate. Probst *et al*[38] have published ESD results for 71 epithelial or submucosal tumors, and have demonstrated a learning curve that resulted in a decrease in the procedure duration and increased rate of complete *en bloc* resection over time (65.7% to 72.2%). Although there have been a limited number of studies outside Asia, the number of endoscopy centers that are performing ESD is slowly increasing worldwide[43].

WHAT IS UNIQUE ABOUT ESD IN EASTERN ASIA?

In Eastern Asia, endoscopic resection methods have been widely accepted as the standard treatment for gastric tumors, and many trained endoscopists are familiar with EMR techniques. Compared to other organs including the esophagus or colon, tumors of the stomach are relatively easy to remove by endoscopic resection. The basic techniques of EMR overlap with those of ESD. This allows for a stepwise approach to a variety of lesions. For example, one might start with the frequently encountered easier lesions in the distal portion of the stomach, move to lesions in the proximal stomach, and then lesions in the esophagus or colon as the final step[9,44]. However, in the

west, because of the lower frequency of gastric cancer, endoscopists have relatively less experience with EMR techniques. In addition, the high incidence of Barrett's esophagus, the treatment for which is technically demanding, makes it difficult for beginners to gain extensive experience with ESD[45]. Training programs specifically aimed at advancing experience with ESD are useful[46,47]. Although data on the learning curve for ESD are limited, Choi *et al*[48] have shown that, for an experienced endoscopist, approximately 40 cases of gastric EMR with a circumferential mucosal incision in a low risk location are necessary for satisfactory training.

Kakushima *et al*[49] have reported a retrospective study on the learning curve for 383 ESD procedures by two principal operators and 11 (< 30 cases) endoscopists with less experience. For the two main operators, there was no significant difference between 25 consecutive patients with regard to the *en bloc* resection and complication rates. The size of the lesions increased as the number of patients increased, whereas the average procedure time decreased significantly. For the endoscopists with less experience, there was a similar treatment outcome and complication rate, mainly due to the easier location of the tumors in their cases. A constant rate of both treatment outcomes and complications was achieved over a 5-year period of experience with ESD. A decrease in the procedure time was found to be a marker for operator proficiency with this technique. Yamamoto *et al*[44] have reported on the learning curve for three resident endoscopists that had already learned the basic procedures. They performed ESD under supervision for 30 consecutive lesions each. They obtained a good overall complete resection rate of 93%, with an acceptable complication rate of 4.4% with appropriate supervision; however, there was difficulty in achieving a sufficient rate of finishing up alone for submucosal dissection.

ESD was first performed in Korea in 1999. The Korean Society of Gastrointestinal Endoscopy (KSGE) organized the ESD research group to investigate and expand the ESD procedure nationwide in 2003. Prior to 2006, only 22 hospitals had the facilities to perform ESD. The KSGE developed ESD hands-on courses and traveled nationwide to introduce the ESD procedure and the devices with animal models on eight occasions[50]. As a result, the number of registered ESD facilities increased to 77 according to data from National Health Insurance Review and Assessment Service in 2008. Furthermore, an international ESD live demonstration has been held every year since 2006. Such support from the KSGE, including the ESD research group, a joint symposium with the Korean Pathology Society, ESD live demonstrations, multicenter studies, and training models for teaching ESD have made it possible to standardize ESD guidelines and techniques in Korea.

ESD EAST TO WEST

Minimally invasive approaches provide a substantially better quality of life compared to conventional open surgery. There is currently not enough long-term follow-up outcome data on ESD compared to open surgery; however,

if careful patient selection is maintained, excellent oncological outcomes with ESD are attainable by experienced endoscopists. Although ESD procedures have not been performed in western countries with as much experience as in eastern countries, improved techniques can be achieved with additional experience. In spite of the low incidence of gastric lesions in the west, there is a relatively high incidence of colon lesions, including large sessile and flat polyps. The novice might start with a modified EMR technique including the adoption of some of the methods used for ESD, such as circumferential marginal incision, which has been used to teach ESD techniques during the past decade in Korea. Furthermore, training programs can be developed to teach ESD[47], and close collaboration between western and Asian centers and attending live demonstrations can help to gain such experience. On the other hand, modern medical science and technology continue to develop at a rapid pace. The recent development of accessories and traction devices might help in the acquisition of the skill and experience needed to make ESD easier to learn and apply[51-53].

CONCLUSION

ESD is an effective and safe therapeutic modality for management of early gastrointestinal tract neoplasms, although it has a relatively longer operation time and high risk of complications. In spite of the late start for ESD in the west, the results have been being similar to those from Japan. In the same manner, although there is a problem to overcome the flat learning curve in view of the low number of detected cases in western countries, close collaboration between western and Asian centers is required for improvement of the ESD technique and its clinical application.

Abstract

Endoscopic submucosal dissection (ESD) is becoming a popular procedure for the diagnosis and treatment of superficial mucosal lesions, and has the advantage of *en bloc* resection which yields a higher complete resection and remission rate compared to endoscopic mucosal resection (EMR). However, the learning process of this advanced endoscopic procedure requires a lengthy training period and considerable experience to be proficient. A well framed training protocol which is safe, effective, easily reproducible and cost-effective is desirable to teach ESD. In addition, the training course may need to be tailored around settings such as ethnicity, culture, workload, and disease incidence. In Asian countries with a large volume of early gastric lesions which need endoscopic treatment, endoscopists would be able to learn ESD expanding their skills from EMR to ESD under the supervision of experts. Whereas, in Western countries due to the low incidence of superficial gastric tumors, trials have utilized simulator mod-els to improve learning. In Korea, the Korean Society of Gastrointestinal Endoscopy (KSGE) is playing an important role in training many gastroenterologists who have shown an interest in performing ESD by providing an annual live demonstration and a nationwide tutoring program. The purpose of this article is to introduce our ESD tutoring experience, review the published papers related to this topic, and propose several suggestions for future directions in teaching and learning ESD.

INTRODUCTION

Endoscopic submucosal dissection (ESD) is an excellent procedure for the diagnosis and treatment of superficial mucosal lesions, but its clinical implementation has limitations due to technical difficulties and the risk of complications[1]. ESD has the advantage of *en bloc* resection, which yields a higher complete resection and remission rate compared to endoscopic mucosal resection (EMR). Because of this advantage, many gastroenterologists have shown an interest in performing ESD. Previous studies have indicated that ESD of gastric neoplasms is technically feasible when it is performed by competent endoscopists[2]. However, similar results from novice endoscopists are not

expected since the learning process of this advanced endoscopic procedure is long and requires considerable experience. This is one of the reasons why a well framed training protocol is necessary for this difficult procedure. It is our understanding that the training program should be tailored around needs based on ethnicity, culture, and/or country since the incidence of disease and working environment may be different. However, the training program should focus on safety, effectiveness, easy reproducibility and cost-effectiveness regardless of conditions. In this article, we describe our teaching experience and revisit published papers related to the teaching and learning of ESD.

ESD TRAINING EXPERIENCE IN KOREA

ESD was introduced in Korea in the late 1990s and is now widely accepted as one of the standard treatment modalities for early cancers and premalignant lesions of the stomach and colorectum. In 2008, according to the reference of the Korean Health Insurance Review and Assessment Service, ESD was performed in 70 tertiary hospitals, 3 community-based hospitals, and 1 primary physician center in Korea.

Live demonstrations have been held annually by the Korean Society of Gastrointestinal Endoscopy (KSGE) since 2004. It is a good opportunity for beginners to observe procedures performed by experts and to obtain information on ESD. However, we have noticed that simple observation of these procedures does not serve the needs of the endoscopists who are in the fellowship training course. For this reason, the ESD study group of KSGE held a nationwide tutoring program (7 provinces, 8 sessions) from January through October 2007. This program was divided into two sections and included a live demonstration of ESD in an *ex vivo* porcine stomach model and a hands-on training course using the same model. The well-irrigated porcine stomach was used in the experiment 24 h after the animal was slaughtered. The outlet portion of the stomach was closed with Kelly. A schematized frame was used for electrical patch attachment and water immersion was used for detection of air leakage. The inlet portion of the stomach was connected to the overtube and fixed within the frame (Figure 1). Before demonstrating the procedure, a mini lecture on the procedure was given to explain the procedure to the attendees. In the first section, tutors performed ESD with elaboration of the procedure. The endoscope was introduced through the overtube and the stomach was inflated with the endoscope. After selecting a target portion, the imaginary lesion was dissected after marking, injection and circumferential precutting. After completion of ESD, the integrity of the stomach wall was investigated by air insufflations with detection of leakage. In the second session, every participant performed this procedure once or twice under the supervision of the tutors. Although this program was not connected to the next step, such as *in-vivo* animal models or human studies, it permitted the trainee endoscopists to gain initial experience in performing this complex procedure and to accumulate knowledge on this

Figure 1 Porcine stomach model for endoscopic submucosal dissection. The stomach was immersed in water of the frame for detection of air leakage. The duodenum was sealed with Kelly. The electrical plate was attached to the bottom of the stomach. Bluish discoloration with light illumination was seen at the stomach antrum area (A); the endoscope was introduced through the overtube, which was fixed to the frame developed for endoscopic submucosal dissection tutoring (B).

therapeutic endoscopic technique. The previously mentioned annual live demonstrations by the KSGE provided valuable information for those who attended the training sessions and for those who led the courses.

JOURNAL REVIEW ON TEACHING AND LEARNING ESD

In Korea, a large volume of cases which need endoscopic therapy, especially in the stomach, enables endoscopists to extend their procedure from EMR to ESD step by step. Some early frontiers of ESD in Korea have accumulated their expertise as the EMR technique has evolved. EMR after circumferential precutting (EMR-P), which was first described as endoscopic resection with local injection of hypertonic saline-epinephrine (ERHSE) by Hirao *et al*[3] for superficial lesions less than 2 cm, was a common challenge towards the next step. With the EMR-P method, lesions are resected by a snare after circumferential precutting and *en bloc* resection of the lesion with low risk of complications is possible. For lesions less than 2 cm in diameter, the rates of *en bloc* resection and complications are comparable for EMR-P and ESD[4]. Choi *et al*[5] demonstrated a learning curve for the EMR-P technique, reporting an increase in the *en bloc* resection rate from 45% to 85% after 40 cases by summarizing their evolving self-taught experience on the EMR-P technique. There

were three perforations in the first 20 procedures (15%) and only one in the remaining 60 procedures (1.7%). They concluded that the trainee would need to perform 20-40 procedures to be able to use the technique safely and effectively. However, in the era of many ESD experts, the self-taught method of learning the EMR/ESD technique described in this study is unlikely to be acceptable as a good model for learning ESD[6].

In recognition of the complexity of ESD, the National Cancer Center Hospital in Japan, which is one of the highest-volume centers of ESD, has developed a rigorous training program. In this hospital, ESD is performed under the close supervision of an experienced endoscopist who offers advice and can complete the procedure when it is necessary for the benefit of the patient. In that setting, Gotoda *et al*[6] reported that experience of at least 30 cases is required for a beginner to gain early proficiency in this technique. In addition, they suggested that a major portion of the ESD training must be devoted to avoiding and managing its potential complications such as bleeding[7]. Recently, Yamamoto *et al*[8] reported a study on the assessment of the feasibility and learning curve in ESD performed by supervised residents. Before entry into this study, three supervised residents had experience of at least 1500 regular esophagogastroduodenal procedures and more than 10 EMRs. In addition, they had assisted ESD procedures performed by senior doctors for at least 1 year, and then attended a lecture on ESD techniques, using a manual and videos, by an experienced endoscopist. Each of them performed 30 consecutive ESD procedures for differentiated-type mucosal early gastric cancer without ulcers or scars, and smaller than 2 cm. Among the 90 procedures, there was a good overall complete resection rate of 93%, with an acceptable complication rate of 4.4%. The distribution of complete resection and complication rates were similar between operators. The self-completion rate and operation time were significantly worse for submucosal dissection than mucosal incision, which was mostly related to uncontrolled hemorrhage. Median operation time for mucosal incision did not change markedly and remained around 30 min for all operators. The median operation time for submucosal dissection became shorter than 30 min for one operator whose self-completion rate increased, but did not decrease for the other two operators. In this study, the authors stressed the importance of the assisting period. Trainees acquire the skills needed to troubleshoot various situations while assisting experienced endoscopists. Moreover, since most of the difficulties surrounding the procedure were related to uncontrollable hemorrhage, obtaining expertise in hemostasis before starting ESD is recommended. Kakushima *et al*[9] reported a learning curve for ESD for gastric epithelial neoplasms on the basis of the clinicopathological data from 383 ESD procedures by thirteen endoscopists. In study 1, the performance of the two principal operators (one performed 188 ESDs and the other performed 118 ESDs) was assessed every 25 cases. The endoscopist's experience did not affect either the treatment efficacy or the safety profile. However, the procedure time decreased

with experience, regardless of the increase in lesion size and the increase in resected specimen size. In study 2, the performance of all thirteen operators (11 operators experienced fewer than 30 cases) was assessed according to their experience. There was no significant difference in treatment efficacy and complication rates between the operators throughout the study period. The lesions were mainly located in the lower part of the stomach in the procedures performed by the 11 less experienced endoscopists. The procedure times shortened as experience in the method increased. In this study, the authors were not able to demonstrate an optimal number of cases required to gain adequate experience. However, they suggested that a beginner could start to treat lesions in the lower part of the stomach independently after performing about 30 supervised ESD procedures.

One prospective study on ESD using a porcine model was reported in Hong Kong[10]. Before entry into the study, an ESD training workshop was held. It consisted of three components: (1) three days of an advanced intensive endoscopic course providing lectures on the basics of ESD; (2) a live demonstration of ESD performed for gastric, esophageal, and colonic lesions; and (3) a hands-on practical session of ESD using a porcine model under the supervision of local and overseas faculties. Twenty-four endoscopists were included and performed gastric and esophageal ESD using a porcine model. The mean procedural times were 52.1 ± 24.7 min for gastric ESD and 32.5 ± 8.5 min for esophageal ESD. Surprisingly, during gastric ESD, 15 participants (65.2%) encountered perforations, whereas bleeding occurred during 13 ESDs (56.5%). There were two procedure-related mortalities. The initial performances of ESD were associated with a high incidence of complications, the risk of which was not dependent on previous experience in endoscopy. The majority of the participants in this study agreed that the porcine model would be an appropriate simulation of human ESDs. Live porcine *ex vivo* or computer simulation models have gained much acceptance for training in upper endoscopy, and some evidence suggests that prior training with these simulation models enhances skill acquisition[11,12]. The use of simulation models may be helpful in attaining the skills required for safe performance of ESD, especially in the areas of a low volume of ESDs. From our experience and that of endoscopists in Palo Alto, California, USA[6] and Hong Kong[10], harvested porcine organs and live porcine models seem to provide a potential solution for learning ESD. Harvested porcine organs are a ready-to-use and inexpensive means of becoming proficient in a novel technique. Multiple large resections of the esophagus and the stomach may be practiced before the use of a live porcine model. The live model simulates a more realistic setting for endoscopic procedures and provides the opportunity to respond to and to treat potential complications such as bleeding and perforation. The use of models allows endoscopists to obtain knowledge in a relatively short time period, with a tutor on site. Further mentoring during the subsequent initial clinical experience would complement the animal model experience. Nevertheless, it

should be recognized that these simulation workshops are a means of augmenting training in skills in low-volume centers but will not replace patient-based training[11].

Vázquez-Sequeiros *et al*[13] from Spain reported their experience of learning and performing ESD in the absence of experts on ESD in their country. Four endoscopists with no experience in ESD underwent a four-step training program: (1) review of the literature and acquisition of theoretical concepts of ESD; (2) training in an *ex-vivo* animal model; (3) training in an *in-vivo* animal model; and (4) ESD of a gastric tumor in a patient. The four participants performed a total of 6 experiments using 6 porcine stomachs and esophagus for *ex-vivo* training. Six supervised ESDs were performed in a live porcine model under general anesthesia. After that, an ESD procedure in a patient was performed under general anesthesia in the operating room with a surgical team available. The procedure was successful but took quite a long time (210 min) and the resected specimen was 35 mm in size.

SUGGESTIONS ON TEACHING AND LEARNING ESD

It has been reported that closely supervised trainees can perform advanced surgery such as esophagogastrectomy, hepatectomy[14], or pancreatectomy[15] with similar outcomes to consultant surgeons. In those studies, surgeons with a large workload encouraged trainees to accept more opportunities to participate in such complex operations, with appropriate supervision, because this improved their learning of the surgical methods and did not jeopardize patient care. Similarly, proficiency in ESD cannot be achieved without the availability of a highly experienced supervisor[8], because a significant number of cases were not completed by the trainee alone and complications such as perforations were generally managed by the supervisor.

In Asian countries such as Korea and Japan where there is a large volume of early gastric lesions which need endoscopic treatment, endoscopists can learn ESD expanding their skill from EMR to ESD under the supervision of experts. Initial experience in ESD with a simulator model and accumulation of experience during the assisting period and supervised EMR-P and ESD procedures for easier sites such as the gastric antrum would be right step.

On the other hand, it is difficult to overcome a flat learning curve due to a low case volume in Western countries. According to previously published data, Western countries report a lower rate of complete resection and higher morbidity following ESD compared to most trials in Asian countries[14]. In these countries more time should be devoted to indirect learning with literature and videos. ESD videos are available at some web sites such as DAVE Project (http://daveproject.org/) and published papers with videos. When available, unedited full length videos of other operators may be more valuable for learning purposes. Attending live demonstrations or learning from a DVD which explains ESD technique (such as the one edited by the American Society of Gastrointestinal

Endoscopy) is also helpful. In addition, the target lesion for ESD is different in Western countries and ESD could be more frequently used for resection of neoplasia in Barrett's esophagus or the colon due to their higher incidence compared with early gastric cancer[16,17]. Hence, *ex-vivo* and *in-vivo* training for esophageal and/or colonic ESD may be essential for Western trainees since ESD of these lesions is more difficult than gastric ESD[18].

CONCLUSION

ESD is a beneficial procedure which achieves higher rates of *en bloc* resection and complete resection for early cancer. However, training with a high enough volume to become proficient in ESD requires considerable time and patience especially in Western countries. A well structured training program is essential for the trainee, because the outcome of ESD is dependent on the experience of the endoscopist. Novice endoscopists can learn ESD by utilizing a simulation model, observing and/or assisting procedures performed by experts. The training course would be designed differently for Asian and Western countries according to the workload and incidence of disease. Close collaboration between Western and Asian countries will be helpful to improve ESD technique for various sites and to benefit patients who are suffering from early gastric, esophageal or colorectal cancer.

INTRODUCTION

Gastrointestinal cancers represent the leading cause of cancer-related death worldwide. Prevalence and mortality rate of gastric cancer in malignant tumors is high in Asia, especially Korea and Japan. The diagnosis of early gastric cancer (EGC) is therefore of great interest because its endoscopic and surgical treatment presents the best chance for a cure. Advances in image-enhanced endoscopy allow improved visualization of lesions and can be used to gain insight into the pathology of the lesion, which, in turn, provides guidance to select the optimal treatment[1].

CURRENT STATUS OF ENDOSCOPIC SUBMUCOSAL DISSECTION IN KOREA

Prevalence of EGC is increased due to nationwide mass screening for gastric cancer in Korea, and patients have the opportunity to be treated with curative resection of the tumor by endoscopic therapy. This allows the patients to retain their organs and maintain their quality of life without surgical complications. Endoscopic mucosal resection (EMR) was performed in small-sized, differentiated mucosal EGC. But large scale surgical data reported the possibility of an increased indication of endoscopic resection, and technical and instrumental development enabled endoscopic submucosal dissection (ESD).

Since the early nineties, EMR has been performed as

Abstract

The diagnosis of early gastric cancer (EGC) is of great interest because its endoscopic and surgical treatment presents the best chance for a cure. With technical development, endoscopic submucosal dissection (ESD) has been widely performed for the curative treatment of EGC in Korea. Multinational studies of ESD for EGC will be the next missions that overcome these limitations and global guidelines will be processed for ESD for EGC.

Key words: Endoscopic submucosal dissection; Early gastric cancer

Peer reviewer: Dr. Dinesh Vyas, Department of Minimally and

a treatment modality of gastric neoplasia and ESD was first performed in Korea in 1999, with endoscopists performing ESD gradually. The Korean Society of Gastrointestinal Endoscopy (KSGE) organized an ESD research group in 2003 to discuss, investigate and spread ESD nationwide. Before 2006, only 22 hospitals had ESD facilities. The KSGE planned to hold a six session nationwide lecturing tour, with ESD hands-on courses to introduce the ESD procedure and devices with animal models. After that, the numbers strikingly increased in 2007, and the number of registered ESD facilities rose to 77 according to data from National Health Insurance Review & Assessment Service in 2008. Also, an annual international ESD live demonstration, *via* a telemedicine network, has been held since 2006, with more than a thousand endoscopists registered as audiences each year[2].

TROUBLESHOOTING THE LIMITATION OF ESD

Therapeutic and long-term outcomes of ESD for EGC were acceptable with absolute and expanded indications[3-6]. This revealed that, as described above, that ESD is a powerful technique with therapeutic efficacy for patients with EGC, which enables preservation of organs, increases the quality of life, and allows the complete removal of the primary tumor as an *en bloc* resection with a cancer cell-negative lateral and vertical margin regardless of the tumor location[7-9]. But, ESD has its limitations in that (1) it also cause additional gastrectomy if the depth of invasion is deeper than the SM2 layer, and (2) local resection can be less accurate at evaluating the exact status of lymphovascular invasion and lymph node metastasis than surgery. Current staging workup with endoscopic ultrasound, CT scan and PET-CT is also limited in its correct diagnosis of EGC[10-15]. Furthermore, gastric cancer generally shows greater histologic diversity than other types of cancer. Even tumors confined to the mucosa show histologic diversity, which tends to increase with deeper invasion and increased tumor diameter[16-19]. For these characteristics, additional gastrectomy was performed after pathologic mapping results of the ESD specimen revealed the possibility of lymph node metastasis. Endoscopists, surgeons and radiologists should discuss and overcome these situations to appropriate treatment for patients with EGC.

In Korea, the National Evidence-based Health Care Collaborating Agency and the KSGE have plans for prospective studies into the short term and long term clinical outcomes of EGC treated by ESD. More than eleven tertiary university-affiliated hospitals will be involved in this study. This will be the key to establishing when endoscopic treatment of EGC should be used.

EGC with potential node metastasis might also be treated by a laparoscopic lymph node dissection without a gastrectomy after ESD. Abe *et al*[20] previously demonstrated that this combination enabled the complete endoscopic resection of the primary tumor and histo-logic determination of lymph node status. However, remnant cancer cells in lymphatic and/or venous vessels in the gastric wall could potentially cause a cancer recurrence. Natural Orifice Transluminal Endoscopic Surgery (NOTES) has been applied to treat EGC with several case reports[21-25]. In Korea, Endoscopic Full-Thickness Gastric Resection (EFTGR) with laparoscopic lymph node dissection with hybrid NOTES has been performed and the data was reported to the NOSCAR conference in Boston, 2009. This consisted of five procedures; (1) marking around the lesion safety margin; (2) applying the ESD technique; a circumferential incision as deep as the submucosal layer was made around the lesion; (3) circumferential endoscopic full-thickness resection around the lesion through the submucosal incision line under laparoscopic guidance; (4) laparoscopic full-thickness resection around the remaining lesion through the EFTGR incision line inside the peritoneal cavity; and (5) laparoscopic closure of the resection margin. NOTES enables minimal tumor resection using the ESD technique, and a laparoscopic lymphadenectomy can be performed simultaneously during EGC, although there is a risk of lymph node metastasis. This procedure may be the bridge between ESD and gastric surgery[26].

CONCLUSION

In summary, ESD has become one of the mainstream methods for the treatment of EGC. Although long-term clinical outcomes of previous reports are promising, there still seem to be many obstacles to overcome in order to progress and stabilize the therapeutic range of endoscopic therapy. Multinational, prospective studies of therapeutic outcomes and survivals will be the next target that will overcome these limitations and global guidelines will be processed for ESD for EGC.

Abstract

AIM: To investigate the diagnostic accuracy of hepatobiliary scintigraphy (HBS) in detecting biliary strictures in living donor liver transplantation (LDLT) patients.

METHODS: We retrospectively reviewed 104 adult LDLT recipients of the right hepatic lobe with duct-to-duct anastomosis, who underwent HBS and cholangiography. The HBS results were categorized as normal, parenchymal dysfunction, biliary obstruction, or bile leakage without re-interpretation. The presence of biliary strictures was determined by percutaneous cholangiography or endoscopic retrograde cholangiopancreatography (ERCP).

RESULTS: In 89 patients with biliary strictures, HBS showed biliary obstruction in 50 and no obstruction in 39, for a sensitivity of 56.2%. Of 15 patients with no biliary strictures, HBS showed no obstruction in 11, for a specificity of 73.3%. The positive predictive value (PPV) was 92.6% (50/54) and the negative predictive value (NPV) was 22% (11/50). We also analyzed the diagnostic accuracy of the change in bile duct size. The sensitivity, NPV, specificity, and PPV were 65.2%, 27.9%, 80% and 95%, respectively.

CONCLUSION: The absence of biliary obstruction on HBS is not reliable. Thus, when post-LDLT biliary strictures are suspected, early ERCP may be considered.

INTRODUCTION

Following the first adult-to-adult right lobe living donor liver transplantation (LDLT) in 1994[1], > 90% of organs for liver transplantation in Asian countries have come from live donations because of the shortage of cadaveric organ donation[2]. Even with the development in various refinements in surgical techniques, multiple biliary reconstruc-

tions and smaller bile ducts make right lobe LDLT difficult in comparison with cadaveric whole-size liver transplantation[2]. Although there has been overall improvement in the graft survival rate with advances in the organ preservation method and immunosuppressive management, the postoperative biliary complications have become the focus of concern.

A biliary stricture is one of the most common biliary complications following liver transplantation. The reported incidence of biliary strictures after right lobe LDLT is 28%-43%, which varies according to the type of biliary reconstruction, and with a higher incidence in patients undergoing duct-to-duct anastomosis[3-8]. The short-term consequences of biliary strictures are associated with cholangitis or sepsis, and long-term consequences are related to graft loss, re-transplantation, or even death[9].

Hepatobiliary scintigraphy (HBS) using technetium-99 attached to iminodiacetic acid is a physiological imaging method that is useful for detecting biliary obstruction[10]. There have been some studies to support the diagnostic role of hepatic iminodiacetic acid (HIDA) scans in liver-transplanted patients, mainly emphasizing that the abnormal HIDA scan results can predict the biliary complications[11-15]. The subjects in these studies were a relatively heterogeneous group of patients transplanted with different operative techniques (duct-to-duct or end-to-side anastomoses, cadaveric liver transplantation, or LDLT) and different biliary and non-biliary postoperative complications (biliary strictures, bilomas or bile leakage, and vascular compromise). Moreover, these studies were based on retrospective re-interpretations of the HIDA scans, and did not regard the usefulness of the HIDA scan in real clinical decision making. The purpose of the current study was to determine the usefulness of HIDA scans for detecting biliary strictures; specifically in patients with right lobe LDLT by duct-to-duct anastomosis.

MATERIALS AND METHODS

Patients and evaluation of biliary strictures
This study included 104 LDLT recipients who had HIDA scans and cholangiograms by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous cholangiography (PTC) for suspected biliary strictures between January 2001 and December 2009. The main clinical presentations that led to the evaluation were abnormal blood chemistry at the time of routine visits, or the appearance of symptomatic jaundice or cholangitis. Mebrofenin (bromo-2,4,6-trimethylacetanilidoiminodiacetic acid) was used as a radiopharmaceutical agent for HBS. All 104 LDLTs were performed using the right lobe of the living related donor, and the bile ducts were reconstructed by duct-to-duct anastomosis. The presence of significant biliary strictures on the cholangiogram was regarded as the diagnostic gold standard. We also made a diagnosis of biliary stricture only when a patient had showed improvement after endoscopic or percutaneous intervention, or biliary reconstructive surgery. We reviewed the medical records,

and collected the clinical, radiological and laboratory data. In analysis of the ultrasonography (US) or computed tomography (CT) data, intrahepatic duct (IHD) dilatation of new onset or of progression in comparison with previous imaging studies was regarded as a significant change in bile duct size. The study protocol was approved by the Ethics Committee of Samsung Medical Center and the study was conducted in accordance with the principles of the Declaration of Helsinki.

Classifications of HIDA scan results
Based on the nuclear physician's original interpretation, the results of HIDA scans were classified without retrospective re-interpretation. They were categorized as normal functioning grafts, parenchymal dysfunction, biliary obstruction, or bile leaks. A normal functioning graft was diagnosed when there was an immediate demonstration of hepatic parenchyma, followed sequentially by activity in the intra- and extrahepatic biliary duct system, gallbladder, and upper small bowel within 1 h[16]. Parenchymal dysfunction was considered to be present when abnormal hepatic uptake and/or abnormal excretion was noted. Scintigraphic diagnosis of biliary obstruction was made when bowel activity was not detected within 4 h, regardless of hepatic uptake. Bile leakage was diagnosed when accumulation of tracer was noted at an abnormal physiological site[12].

Statistical analysis
To describe the baseline patient characteristics, the mean ± SD was used for continuous variables with a normal distribution, and the median value was used for continuous variables without a normal distribution. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were used to investigate the accuracy as a diagnostic tool.

RESULTS

Baseline characteristics of the study subjects
Detailed baseline clinical characteristics of the study subjects are presented in Table 1. The mean age was 51.5 years, and there was a male predominance. Hepatic failure and hepatic malignancy constituted one-half of the indications for liver transplantation. Hepatitis B virus (HBV)-related hepatocellular carcinoma and HBV-related hepatic failure accounted for 39.4% and 31.7% of the cases, respectively. Other causes of hepatic failure not shown in Table 1 included drug-induced liver injury, chronic alcoholism, autoimmune hepatitis, and primary biliary cirrhosis. Other hepatic malignancies that led to LDLT were hepatocellular carcinoma associated with chronic alcoholism and hepatic angiosarcoma. The interval between LDLT and HIDA scan ranged between 25 and 1490 d (median: 294.5 d). Table 2 describes the baseline laboratory characteristics of the patients. All 104 patients had imaging studies (US or CT) for evaluation of biliary strictures, and 61 patients (58.7%) had significant changes in bile duct size. Cholangiograms were taken by

Table 1 Baseline clinical characteristics of the patients

Variable	Result
Age (yr), mean ± SD	51.5 ± 8.25
Male/female, *n* (%)	82/22 (79/21)
Indication for liver transplantation, *n* (%)	
Hepatic failure	52 (50)
HBV infection	33 (31.7)
HCV infection	5 (4.8)
Others	14 (13.5)
Malignancy	52 (50)
HCC, HBV-related	41 (39.4)
HCC, HCV-related	7 (6.7)
Others	4 (3.9)
Interval between LDLT and HIDA scan, d, median (range)	294.5 (25-1490)

HBV: Hepatitis B virus; HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma; LDLT: Living donor liver transplantation; HIDA: Hepatic iminodiacetic acid.

Table 2 Baseline laboratory characteristics of the subjects

Laboratory test	Result
Bilirubin, mg/dL, median (range)	3.7 (0.6-44)
AST, U/L, median (range)	85 (15-336)
ALT, U/L, median (range)	132 (6-798)

GGT, U/L, median (range)	297 (28-1491)
Change of bile duct size, *n* (%)	
Present	61 (58.7)
None	43 (41.3)
Stricture on the cholangiogram, *n* (%)	
Present	89 (85.6)
None	15 (14.4)

AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; GGT: γ-glutamyl transferase.

ERCP in 56 patients (53.8%) and by PTC in 48 patients (46.2%), and a total of 89 patients (85.6%) had significant biliary strictures. Management of biliary stricture was successful using an endoscopic or percutaneous approach in 80 patients. However, interventions failed in nine patients and they required Roux-en-Y hepaticojejunostomy, eventually. The median value of the interval between the day of LDLT and the diagnosis of biliary stricture in 89 patients was 309 d (range: 37-1490 d).

Results of HIDA scans and cholangiograms

The results of HIDA scans and the presence of significant biliary strictures on the cholangiograms were matched, as in Table 3. Of 89 patients with biliary strictures, HIDA scans suggested a normal functioning liver graft (Figure 1) in six patients (6.7%), parenchymal dysfunction (Figure 2) in 32 (35.9%), biliary obstruction (Figure 3) in 50 (56.2%), and the presence of bile leakage in one (1.2%). The HIDA scans suggested the presence of biliary obstruction in four of 15 patients with no significant biliary strictures on cholangiograms as presented in Figure 4. All four patients with false-positive results on HIDA scans were confirmed to have allograft rejection after liver biopsy. Three of them received intravenous steroid pulse therapy

Table 3 Results of hepatic iminodiacetic acid scans and cholangiograms

	Normal	Parenchymal dysfunction	Biliary obstruction	Bileleakage	Total
	8 (7.7)	41 (39.4)	54 (51.9)	1 (1)	104 (100)
Stricture on cholangiogram	6	32	50	1	89
No stricture on cholangiogram	2	9	4	0	15

Data expressed as the number (%).

Table 4 Diagnostic accuracy of the change in bile duct size in detecting post-living donor liver transplantation biliary strictures

	Stricture on cholangiogram (+)	Stricture on cholangiogram (-)	Total
Change in bile duct size (+)	58	3	61
Change in bile duct size (-)	31	12	43
Total	89	15	104

and maintained graft function. However, one patient developed hepatic failure in spite of medical therapy, and he underwent re-transplantation.

Diagnostic accuracy of HIDA scans and changes in bile duct size to detect biliary strictures

The sensitivity, specificity, PPV, and NPV of HIDA scans to detect post-LDLT biliary strictures were 56.2% (50/89), 73.3% (11/15), 92.6% (50/54), and 22% (11/50), respectively. All 104 patients had imaging studies with US or CT in the evaluation process. When using the change in bile duct size on US or CT as a diagnostic tool (Table 4), the sensitivity, specificity, PPV, and NPV were 65.2% (58/89), 80% (12/15), 95% (58/61), and 27.9% (12/43).

DISCUSSION

Although there are various etiologies for liver function test abnormalities in liver transplant patients, rejection and biliary strictures are the most common and important causes of morbidity and mortality. These two conditions require different treatment strategies, so accurate differentiation is essential for proper management.

HBS using a radionuclide agent is a diagnostic imaging study that evaluates hepatocellular function and patency of the biliary system by tracing the production and flow of bile from the liver through the biliary system into the small intestine[16]. As a result of its non-invasiveness and convenience, HBS is commonly used to evaluate the presence of biliary strictures[3]. Even though older studies have concluded that HBS can differentiate intrahepatic cholestasis from pure hepatocyte damage in liver transplant patients[17,18], HBS cannot distinguish between cholestasis and rejection[18]. In the current study, the specificity, PPV, sensitivity, and NPV of HIDA scans in detecting post-LDLT biliary strictures were 73.3%, 92.6%, 56.2%, and 22%, respectively. Thus, HIDA

Figure 1 Hepatic iminodiacetic acid scan suggested normal graft function based on the normal hepatic uptake and normal excretion into the bile duct and bowel (A-C). However, the cholangiogram (D) obtained by endoscopic retrograde cholangiopancreatography showed a tight stricture (black arrow) at the anastomosis site.

Figure 2 Hepatobiliary scintigraphy showed decreased hepatic uptake and normal excretion within 60 min, which suggested parenchymal dysfunction of the graft (A-C). However, the cholangiogram (D) revealed a significant anastomotic stricture (black arrow).

Figure 3 By Hepatic iminodiacetic acid scan, no bowel activity was noted after 19 h (A-C). Based on this finding, endoscopic retrograde cholangiopancreatography was performed (D), and a localized anastomotic stricture (black arrow) was demonstrated.

Figure 4 Hepatobiliary scintigraphy showed no clearance of the radiotracer into the bowel on the 24-h image (A-C), therefore, biliary obstruction was strongly suggested. However, no significant stricture was found on the cholangiogram (D).

scans cannot predict the presence of biliary obstruction in about 50% of the patients with significant biliary strictures. Surprisingly, six of eight patients with normal HIDA scan results were shown to have biliary strictures on cholangiograms. The normal HIDA scan results in patients with biliary strictures might be a reflection of post-LDLT biliary strictures that represent low-grade partial biliary obstruction. In the case of high-grade obstruction, there is usually prompt hepatic uptake, but no secretion of the radiotracer into biliary ducts after 4 h[12,13], and sometimes even after 24 h[10,16]. However, the typical scintigraphic imaging find-

ings with low-grade or partial biliary obstruction include good hepatic uptake, normal secretion into the biliary ducts, and slightly delayed secretion into the bowel[10,16]. Another remarkable finding in the current study was that 32 of 41 patients who had parenchymal dysfunction on HIDA scans had biliary strictures on the cholangiograms. With prolonged biliary obstruction, concomitant hepatic dysfunction may occur, so decreased hepatic uptake of radionuclide trace can be seen prominently[16]. As shown in Table 3, four patients with no biliary strictures on cholangiograms had allograft rejection. Similar findings have been reported in previous

studies, and some patients with rejection and severely elevated serum bilirubin levels have scintigraphic findings of total biliary obstruction[12,17]. A possible explanation for this phenomenon is that the histological finding of rejection is characterized by the diagnostic triad of portal inflammatory mixed infiltrates, venous endotheliitis, and bile duct injury, and lack of hepatolysis as a dominant feature[19,20]. This result again confirms that HIDA scans do not have a role in the differential diagnosis of rejection and biliary strictures; the most important clinical situations.

Considering the relatively good PPV, the presence of biliary obstruction on HIDA scans can be quite reliable, and might offer a good rationale for clinicians proceeding to the next step (ERCP or PTC to confirm the presence of biliary strictures) and to initiate definitive treatment. The real problem in clinical practice occurs when the HIDA scan shows negative results, parenchymal dysfunction, or a normal functioning graft. This false negativity may guide the clinician to proceed to another diagnostic modality, most commonly a liver biopsy, and can create a delay in the proper diagnosis and management.

Cholangiography, either by ERCP or PTC, is considered to be the gold standard for post-liver transplantation biliary strictures, not only in establishing the diagnosis, but also in allowing therapeutic intervention in the same setting. ERCP has an advantage over PTC in that it is not only more physiological, but also less invasive. Moreover, recent studies have demonstrated an approximately 70% overall success rate for endoscopic treatment of post-LDLT biliary strictures with duct-to-duct anastomosis[5-9,21,22]. Biliary drainage with the percutaneous approach can be considered as a second option for cases not suitable for endoscopic management[22].

The suspicion for post-LDLT biliary strictures often begins with abnormal liver function tests or clinical evidence of obstructive cholangitis[9,23]. When a biliary stricture is suspected, imaging studies are commonly performed first because of non-invasiveness and convenience. The first step in establishing the diagnosis is usually US of the abdomen[9], which has the advantage that additional information about hepatic vascular patency is provided. However, US evaluation of the biliary tree is known to be of limited value because bile duct dilatation in liver transplant patients can be a non-specific postoperative finding, and the absence of dilatation has been noted to be an unreliable indicator of biliary obstruction[24]. The low sensitivity of US in evaluation of the biliary tree of 38%-66% has been the major drawback to US serving as a meaningful modality in the decision-making process[3]. However, these studies primarily reflect the outcomes during the period of cadaveric liver transplantation. There have been no recent data about the usefulness of change in bile duct size on US or CT in detecting post-transplantation biliary strictures in patients with LDLT. In the present study, to identify specifically clinically relevant changes in bile duct size, we only considered IHD dilatation of new onset or of marked progression. The sensitivity of this criterion was 65.2% and the NPV was 27.9%, which is still lower

than that for a good diagnostic modality, but a higher rate than for HIDA scans. The specificity and the PPV were 80% and 95%, respectively, and again suggested that a significant change in bile duct caliber is mandatory to proceed in ERCP or PTC.

Recently, some studies have indicated that magnetic resonance cholangiography is a non-invasive and promising diagnostic modality with a sensitivity and specificity rate > 90%[25-27]. However, it has a limitation in that the therapeutic intervention is impossible, so cost-effectiveness is of concern. Also, it needs further validation in LDLT recipients by duct-to-duct anastomosis.

In conclusion, HIDA scans had relatively reliable specificity and PPV for detecting post-LDLT biliary strictures, but the sensitivity and NPV were poor. The absence of significant biliary obstruction on HBS cannot be a reliable marker for clinicians. Therefore, early performance of ERCP or PTC may be necessary to diagnose and treat biliary strictures, even though the HIDA scan results are negative, considering the successful outcome of ERCP or PTC in the treatment of biliary strictures.

COMMENTS

Background
Living donor liver transplantation (LDLT) has become the mainstream for liver transplantation to overcome the shortage of cadaveric donors. However, the higher risks or biliary complications remain the primary concern. Stricture is one of the most common biliary complications after LDLT.

Research frontiers
Hepatobiliary scan (HBS) is a diagnostic modality that is useful for detecting biliary obstruction and evaluating hepatocellular function. Several studies have evaluated the role of HBS for detecting biliary stricture in transplanted liver. However, the information is limited and insufficient because most of the studies were performed in the period of cadaveric LT.

Innovations and breakthroughs
To evaluate the role of HBS in real clinical settings, the authors included 104 patients who underwent LDLT and HBS. The HBS results were used without re-interpretation. Although HBS showed relatively reliable specificity and positive predictive value for detecting post-LDLT biliary strictures, the sensitivity and negative predictive value were poor. In particular, it did not distinguish between biliary stricture and rejection.

Applications
Even though the HBS results do not suggest the possibility of biliary obstruction, early performance of cholangiography may be necessary to diagnose and treat biliary strictures.

Peer review
The paper shows that scintigraphy is not a good indicator of modality in post-transplant biliary strictures.

Abstract

AIM: To investigate the effect of keratinocyte growth factor (KGF) gene therapy in acetic acid-induced ulcerative colitis in rat model.

METHODS: The colitis of Sprague-Dawley rats was induced by intrarectal infusion of 1 mL 5% (v/v) acetic acid. Twenty-four hours after exposed to acetic acid, rats were divided into three experimental groups: control group, attenuated *Salmonella typhimurium* Ty21a strain (SP) group and SP strain carrying human *KGF* gene (SPK) group, and they were separately administered orally with 10% NaHCO₃, SP or SPK. Animals were sacrificed and colonic tissues were harvested respectively on day 3, 5, 7 and 10 after administration. Weights of rats, colonic weight/length ratio and stool score were evaluated. Histological changes of colonic tissues were examined by hematoxylin and eosin (HE) staining method. The expression of KGF, KGF receptor (KGFR) and TNF-α were measured either by enzyme-linked immunosorbent assay or Western blotting. Immunohistochemistry was used to detect the cellular localization of KGFR and Ki67. In addition, superoxide dismutase (SOD) activity and malondialdehyde (MDA) contents in the homogenate were measured.

RESULTS: Body weight and colonic weight/length ratio were declined in SPK group compared with SP and control groups (body weight: 272.78 ± 17.92 g *vs* 243.72 ± 14.02 g and 240.68 ± 12.63 g, $P < 0.01$; colonic weight/length ratio: 115.76 ± 7.47 *vs* 150.32 ± 5.99 and 153.67 ± 5.50 mg/cm, $P < 0.01$). Moreover, pathological changes of damaged colon were improved in SPK group as well. After administration of SPK strain, KGF expression increased markedly from the 3rd d, and remained at a high level till the 10th d. Furthermore, KGFR expression and Ki67 expression elevated, whereas TNF-α expression was inhibited in SPK group. In the group administered with SPK, SOD activity increased significantly (d 5: 26.18 ± 5.84 *vs* 18.12 ± 3.30 and 18.79 ± 4.74 U/mg, $P < 0.01$; d 7: 35.48 ± 3.35 *vs* 22.57 ± 3.44 and 21.69 ± 3.94 U/mg, $P < 0.01$; d 10: 46.10 ± 6.23 *vs* 25.35 ± 4.76 and 27.82 ± 6.42 U/mg, $P < 0.01$) and MDA contents decreased accordingly (d 7: 7.40 ± 0.88 *vs* 9.81 ± 1.21 and 10.45 ± 1.40 nmol/mg, $P < 0.01$; d 10: 4.36 ± 0.62 *vs* 8.41 ± 0.92 and 8.71 ± 1.27 nmol/mg, $P < 0.01$), compared with SP and control groups.

CONCLUSION: KGF gene therapy mediated by attenuated *Salmonella* ameliorates ulcerative colitis induced by acetic acids, and it may be a safe and effective treatment for ulcerative colitis.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic inflammatory disorder in gastrointestinal tract mainly involving ulcerative colitis (UC) and Crohn's disease (CD). It is characterized by tissue edema, inflammatory response and increased gut epithelial permeability[1,2]. Although many studies of IBD *in vivo* and *vitro* have been reported, the pathogenesis of IBD is still not completely understood. As it is reported, IBD may be related to a complex interaction of immune system, genetic and environmental factors[3,4]. Conventional drugs, such as corticosteroids and 5-aminosalicylate preparations, are effective in the treatment of IBD, however, long-term medication would induce severe side effects that have harmful impact on life quality of patients[5-7]. Hence, it is necessary to develop new approaches with fewer side effects for treatment of IBD.

Keratinocyte growth factor (KGF), a member of the fibroblast growth factor family (FGFs), could specifically stimulate proliferation and differentiation of various epithelial cells of different organs by a paracrine fashion including skin, lung, intestine and bladder[8]. In patients with IBD, which was mainly located in the lamina propria of gastrointestinal tract, endogenous KGF expression was increased markedly[9,10]. Previous studies indicated that KGF could promote proliferation and differentiation of intestinal epithelial cells both *in vivo* and *in vitro*, and protect the intestine[11,12]. Therefore, KGF may be a potential cytokine to ameliorate IBD. However, the recombinant protein of cytokines is limited in clinical application because of their instability, high dosage and repeated administration which increased the incidence of side effects[13]. We attempted to develop an oral gene therapy of KGF mediated by attenuated *Salmonella typhimurium* to improve the rat acetic acid-induced colitis, which has similar characteristics to human ulcerative colitis[14].

MATERIALS AND METHODS

Establishment of SPK and SP strains

Attenuated *Salmonella typhimurium* Ty21a strain (SP) and SP strain carrying human *KGF* gene (SPK) were constructed by electrotransformation with empty pCDNA3 plasmid (Invitrogen, Carlsbad, CA, USA) or recombinant pCDNA3 plasmid carrying human KGF gene.

Animals

Female Sprague-Dawley rats (aged 8-12 wk, n = 80, weighing 250-300 g), were purchased from the Animal Experimental Center of Lanzhou University (Lanzhou, China). They were housed in wire-bottom cages in a temperature-controlled room with a 12 h light-dark cycle. Rats were acclimatized to the environment for 7 d before experiment. All animal experiments were conducted following the institutional guidelines and approved by the Ethical Committee for Animal Care and Use, the General Hospital of Lanzhou Military Command.

Experimental protocol

Six rats were randomly assigned into normal group and 74 rats into experimental groups. Animals of experimental groups were anesthetized by intraperitoneal injection with pentobarbital sodium (30 mg/kg). A plastic catheter was inserted into the colon at 8 cm proximal to the anus, and 1 mL of 5% (v/v) acetic acid was infused into the rat colon. After 30 s, 2 mL saline was infused to remove the residual acid. Twenty-four hours after exposure to acetic acid, the rats were randomly divided into three groups: control group (n = 24), SP group (n = 25) and SPK group (n = 25). They were treated respectively with 1 mL solvent of 10% NaHCO$_3$, 1.0×10^8 colony forming unit (CFU) of SP strains, or SPK strains by gavage once every other day. Six rats of each group were sacrificed separately on day 3, 5, 7 and 10 after the first administration. The colons were quickly removed, freeze-clamped and dropped in liquid N$_2$ for various assays

Stool examination

The stool examination of each group was scored daily from day 1 to day 10 after drug administration. The score of stool was defined as 1 for normal, 2 for soft stool and 3 for watery diarrhea.

Histological examination

Histological analysis of rat tissues was performed on day 10. The colon tissues were fixed in 10% formalin, embedded in paraffin and sectioned at a thickness of 6 μm. Sections were stained with hematoxylin and eosin (HE) and evaluated under light microscope.

Detection of KGF and TNF-α by Enzyme-linked immunosorbent assay

The colon tissues were homogenized with nine-fold volume of ice-cold phosphate-buffered saline (PBS) using a glass homogenizer at 4℃. The homogenate was centrifuged at $855 \times g$ for 10 min at 4℃ to remove the cell debris and the supernatant was obtained to determine the KGF and TNF-α content with Enzyme-linked immunosorbent assay (ELISA) kits (R and D, Minneapolis, MN, USA) according to the manufacturer's instructions. The optical density was detected at 450 nm with a microplate reader (Thermo, Pittsburgh, PA, USA).

Immunohistochemistry

Immunohistochemistry for KGFR and Ki67 was per-

formed as follows. The slides were incubated with a rabbit anti-rat primary antibody to KGFR (1:500, R and D, Minneapolis, MN, USA) or Ki67 (1:500, R and D, Minneapolis, MN, USA) in PBS at 4℃ overnight. After 3 washes in PBS, the sections were incubated with a horse radish peroxidase (HRP)-conjugated goat anti-rabbit antibody (Beijing Zhongshan Biotechnology, Beijing, China) at a 1:1000 dilution in PBS at 37℃ for 2 h. The sections were then incubated with an avidin-biotin-peroxidase complex (Beijing Zhongshan Biotechnology, Beijing, China), followed by DAB (Beijing Zhongshan Biotechnology, Beijing, China) to induce a color reaction. The expression and localization of the KGFR and Ki67 were examined under light microscope (Olympus, Japan), and a brown color was indicated as positive.

Western blotting

To determine the effect of SPK strain on the KGFR in colon tissues, we detected the expression of KGFR using Western blotting techniques. The colonic homogenates were obtained as previously described, and the total protein in homogenates was quantified with the bicinchoninic acid (BCA) protein assay kit (Beijing Biosynthesis Biotechnology Beijing, China). Twenty μg of the total protein was resolved in SDS-PAGE, and protein was transferred onto PVDF membrane (Milipore, Temecula, CA, USA) electrophoretically at 80 mA for 2 h at 4℃. The membranes were blocked in 5% skim milk (w/v, in Tris-Buffered Saline with Tween-20 (TBST) for 2 h at room temperature. After 3 washes with TBST, the membranes were incubated with a rabbit anti-rat KGFR (1:500, R and D, Minneapolis, MN USA) and a rabbit anti-rat β-actin antibody (1:1000, R and D, Minneapolis, MN USA) overnight at 4℃, respectively. After 3 washes with TBST, the membranes were incubated with a HRP-conjugated goat anti-rabbit antibody (Beijing Zhongshan Biotechnology, Beijing, China) at a 1:2000 dilution for 3 h at 37℃. Bands on the membranes were imaged by X-ray with chemoluminescence reagents (Beijing Solarbio Science and Technology, Beijing, China). Finally, the bands were scanned and quantified using the Image-Pro Plus 6.0 software (Media Cybernetics, Bethesda, MD, USA).

Measurement of oxidative stress

The colonic homogenates were performed as mentioned above, and superoxide dismutase (SOD) activity and malondialdehyde (MDA) contents were determined by spectrophotometry according to the manufacturer's protocol. SOD and MDA detection kits were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China).

Statistical analysis

The data from different groups at various time points were analyzed using one-way ANOVA with SPSS 11.5 software (IBM, Chicago, IL, USA). $P < 0.05$ was considered statistically significant, and data were presented as mean ± SD.

Table 1 Changes of body weight and colonic weight/length ratio

Group	Body weight (g)	Colonic weight/length ratio (mg/cm)
SPK	272.78 ± 17.92[a,b]	115.76 ± 7.47[a,b]
SP	243.72 ± 14.02	150.32 ± 5.99
Control	240.68 ± 12.63	153.67 ± 5.50
Normal	286.64 ± 18.95[a,b]	82.35 ± 4.63[a,b]

Data are presented as mean ± SD, $n = 6$. [a]$P < 0.05$, *vs* control group, [b]$P < 0.01$, *vs* SP group. SP: Attenuated *Salmonella typhimurium* Ty21a strain; SPK: Attenuated *Salmonella typhimurium* Ty21a strain carrying human *KGF* gene.

Figure 1 Stool score in each group after administration. Stool score decreased significantly on day 5 in SPK group, and recovered to normal on day 9. Data are presented as mean ± SD, $n = 6$. [a]$P < 0.05$, [b]$P < 0.01$ *vs* SP group; [c]$P < 0.05$, [d]$P < 0.01$ *vs* control group at the indicated time point. SP: Attenuated *Salmonella typhimurium* Ty21a strain; SPK: Attenuated *Salmonella typhimurium* Ty21a strain carrying human *KGF* gene.

RESULTS

Changes of symptoms in rat ulcerative colitis

The rat body weight on day 10, as shown in Table 1, was significantly reduced ($P < 0.05$) in the SP and control groups, compared with the normal group. However, the body weight loss almost recovered in SPK group. The increase of the colonic weight/length ratio, an index of colonic edema associated with acetic acid-induced inflammatory reaction, was inhibited in SPK group compared with the SP and control groups ($P < 0.01$, Table 1). However, it was still higher than that in normal group ($P < 0.05$, Table 1).

Stool score

Diarrhea is one of the clinical signs of intestinal inflammation, so the effect of administration of SPK on the stool score was investigated. After treatment with acetic acid, diarrhea occurred in all groups on day 1. However, administration of SPK strain resulted in an obvious improvement of stool score on day 5 ($P < 0.05$, Figure 1), and a normal level was achieved on day 9 in SPK group.

Figure 2 Histological sections of the colon on day 10 after treatment. Inflammatory cell infiltration and edema decreased evidently in attenuated *Salmonella typhimurium* Ty21a strain carrying human keratinocyte growth factor gene (SPK) group compared with attenuated *Salmonella typhimurium* Ty21a strain (SP) and control groups. Glands arranged more regularly and there was not obvious hyperemia in the lamina propria in SPK group. A: A representative colon from SPK group; B: A representative colon from SP group; C: A representative colon from control group; D: A representative colon from normal group (HE stain, × 200).

Figure 3 Keratinocyte growth factor concentrations in the homogenate of colon tissues. The concentration of keratinocyte growth factor (KGF) in the homogenate was measured by Enzyme-linked immunosorbent assay after administration, and the expression of KGF increased obviously in attenuated *Salmonella typhimurium* Ty21a strain carrying human *KGF* gene (SPK) group. Data are presented as mean ± SD, $n = 6$. [b]$P < 0.01$ *vs* SP group at the same time point; [d]$P < 0.01$ *vs* control group at the same time point. SP: Attenuated *Salmonella typhimurium* Ty21a strain.

Histological assessment

Histological sections were examined separately by two experienced observers. In SP and control groups, remarkable inflammatory cell infiltration and edema of the lamina propria were observed. The number of goblet cells dramatically decreased. Moreover, severely damaged mucous glands and thinner mucous layer were found in these two groups, and local hyperemia with thicker lamina propria was presented as well (Figure 2B and C). In contrast, the histological damage induced by acetic acid was improved by administration of SPK strain. Hyperemia was not found in the lamina propria, and inflammatory cell infiltration and edema were decreased in SPK group. The intestinal architecture recovered and glands arranged more regularly, as compared with the SP and control groups (Figure 2A).

Expression of KGF and KGFR in colon tissues

To investigate whether KGF could be expressed effectively in this gene therapy, the KGF concentration in the homogenates was measured by ELISA. In SPK group, the KGF concentration increased significantly at all time points, and peaked on day 5 (514.73 ± 103.30 pg/mg, Figure 3). The high level of KGF expression maintained between days 3 and 10. The result of high expression of KGF in SPK group demonstrated that *Salmonella typhimurium* Ty21a was an effective vector in the gene therapy on ulcerative colitis.

The effect of SPK on the expression of KGFR was confirmed by both Western blotting and immunohistochemistry. After exposure to acetic acid, the expression of KGFR in the colon tissues increased by more than 2-folds of the normal level (Figure 4). In SPK group, the expres-

Figure 4 Western blotting of keratinocyte growth factor receptor in colon tissues. The expression of keratinocyte growth factor receptor (KGFR) in the colon tissues was measured by Western blotting after drug administration. The expression of KGFR on days 7 and 10 increased obviously in attenuated *Salmonella typhimurium* Ty21a strain carrying human keratinocyte growth factor gene group (SPK) compared with attenuated *Salmonella typhimurium* Ty21a strain (SP) and control groups. A: Western blotting analysis of KGFR. N: normal group; 3C, 3P and 3K represents control, SP and SPK groups, respectively, on day 3 of drug administration; 5C, 5P and 5K, on day 5; 7C, 7P and 7K, on day 7; 10 C, 10P and 10K, on day 10; B: Analysis of Western blotting of KGFR. The density of the bands was quantified using image-pro plus 6.0 software, and the data are presented as mean ± SD, n = 6. [a]P < 0.05, [b]P < 0.01 *vs* control group; [d]P < 0.01, *vs* SP group at the same time point.

sion of KGFR increased significantly on day 7 compared with the SP and control groups (P < 0.05, Figure 4B), and it increased by approximately 5-folds of the normal level on day 10 (P < 0.01, Figure 4B). As shown by immunohistochemistry, the expression of KGFR was located mainly in the epithelial lamina, and it was kept high in all groups, which was consistent with that detected by Western blotting (Figure 5).

Ki67 expression

To detect whether administration of SPK strain could promote intestinal epithelial cells proliferation, Ki67 expression, one of the markers of cell proliferation, was investigated by immunohistochemistry. Ten days after administration of SPK, the Ki67 expression in the epithelial lamina increased significantly compared with the SP and control groups (Figure 6).

Control	11.37 ± 1.23	11.03 ± 0.87	10.45 ± 1.40	8.71 ± 1.27
Normal	2.54 ± 0.67			

Data are presented as mean ± SD, n = 6. [b]P < 0.01, *vs* SP and [d]P < 0.01, *vs* control group at the indicated time point. SP: Attenuated *Salmonella typhimurium* Ty21a strain; SPK: Attenuated *Salmonella typhimurium* Ty21a strain carrying human keratinocyte growth factor gene.

Changes in SOD activity and MDA contents in colon tissues

As revealed in Table 2, the decreased SOD activity induced by acetic acid was inhibited significantly by administration of SPK strain on day 5 (P < 0.01), and the SOD activity of SPK group became similar to the normal group on the 10th d. MDA contents increased significantly due to the inhibition of SOD activity induced by acetic acid, and reached to 4-folds approximately of the normal level (Table 3). However, administration of SPK strain resulted in a remarkable decrease of MDA contents (P < 0.01, Table 3) on day 7, compared with the SP group and control group. The decrease of MDA contents maintained until day 10, although they were still higher than normal levels (P < 0.01, Table 3).

Expression of TNF-α in colon tissues

To examine the effect of SPK strain on the expression of proinflammatory cytokine, the TNF-α level in colon was measured by ELISA. The TNF-α level of colon tissues elevated dramatically after exposure to acetic acid (Figure 7). However, administration of SPK strain significantly inhibited the overexpression of TNF-α between days 5 and 10, as compared with the SP and control groups (P < 0.01, Figure 7).

DISCUSSION

Ulcerative colitis is one of the refractory diseases, and there are still no specific and ideal drugs and therapies for this disease. In this study, we focused on the gene therapy of KGF mediated by attenuated *Salmonella typhimurium*

Figure 7 Tumor necrosis factor-α concentration in homogenate of colon tissues. The concentration of tumor necrosis factor (TNF)-α in the homogenate was measured by enzyme-linked immunosorbent assay after administration. The expression of TNF-α decreased significantly in attenuated *Salmonella typhimurium* Ty21a strain carrying human keratinocyte growth factor gene (SPK) group from day 5 to day 10. Data are presented as mean ± SD, $n = 6$. [a]$P < 0.05$, [b]$P < 0.01$ *vs* attenuated *Salmonella typhimurium* Ty21a strain (SP) group; [d]$P < 0.01$ *vs* control group at the same time point.

Ty21a. Our results showed that oral administration of SPK strain ameliorated the colitis induced by acetic acid in rat model. Furthermore, no side effects induced by administration *Salmonella typhimurium* Ty21a, were detected. This gene therapy is potential for the treatment of ulcerative colitis.

Keratinocyte growth factor receptor (KGFR/FGFR2-Ⅲb), a splice variant of FGFR2, is a transmembrane tyrosine kinase receptor encoded by the *bek* gene[15]. KGFR, with a high affinity to KGF, expresses mainly in epithelial cell lineages, so KGF specifically stimulates epithelial cells *via* binding with KGFR. KGF promotes the intestinal epithelial cell proliferation and differentiation in a paracrine fashion[11]. KGF may help maintain and restore the integrity of the intestinal mucosa after injury[16]. And local administration of KGF could alleviate the inflammatory and promote the re-epithelialization and adaptive process after proctocolectomy[10]. In addition, the expression of KGF and KGFR in the intestinal tissues of IBD patients was enhanced significantly [16], suggesting that the interaction of KGF and KGFR may play a crucial role in the progress of IBD. In this study, we found that the expression of KGF increased remarkably compared with the control group at all time points after administration of SPK strain, and the expression of KGFR in SPK group also elevated obviously on day 7. The expression of Ki67, one of the markers of cell proliferation[17], in the epithelial lamina increased in SPK group, which indicated that KGF might directly promote the restoration of intestinal epithelial cells *via* binding with KGFR in the ulcerative colitis.

Many factors are involved in the process of the pathogenesis of IBD, although the accurate mechanisms are still unclear. The damage induced by reactive oxygen species (ROS) is one of the important factors. Accumulation of ROS in ulcerative colon tissues stimulates inflammation responses and secretion of proinflammatory cytokines, such as TNF-α, IL-1 and IL-6[18,19]. ROS also impairs the integrity of the intestinal epithelial cells and increases the intestinal mucosal permeability, which subsequently attenuates the barrier function and host defense to exogenous bacteria and microorganisms[20,21]. In addition, ROS could induce DNA damage and stimulate activation of NF-κB that plays an important role in inflammation responses[19,22]. As it was reported previously, ROS levels increased significantly in IBD patients[23]. There are two main reasons for the ROS increase. The first one is that the release of ROS from lymphocytes, macrophages and neutrophils increases in the process of IBD; and the second one is the endogenous antioxidant enzymes, such as SOD and GSH, reduce and lead to the accumulation of ROS[22]. SOD is able to counteract ROS by catalyzing ROS to oxygen (O_2) and hydrogen peroxide (H_2O_2) which is subsequently decomposed to water (H_2O) and oxygen (O_2)[24]. At present, many therapies based on SOD have been applied in treatment of IBD. Suzuki *et al*[25] reported that PC-SOD (40 mg or 80 mg daily) is able to improve UC rapidly. In addition, SOD gene therapy mediated by *Lactobacillus gasser* also ameliorates the IBD in IL10-deficient mice *via* reducing the infiltration[26].

The present study showed that the SOD activity increased significantly on the 5th d after administration of SPK strain compared with the SP and control groups ($P < 0.01$, Table 2). The increase of SOD activity may be associated with KGF-induced promotion of the proliferation and repairing of intestinal epithelial cells[16], which secreted SOD in regenerative intestinal tissues[26]. MDA, one of the direct products of ROS, induces lipid peroxidation and its contents are usually used as a marker for free radicals-induced lipid peroxidation[19]. In this study, MDA contents in SPK group decreased significantly on day 7, accompanied with the increase of SOD activity. These results demonstrated that administration of SPK strain could protect intestinal tissues from damages induced by ROS.

TNF-α, mainly from activated macrophages in the gastrointestinal tract, plays an important role in the pathogenesis of IBD. It directly induces apoptosis of epithelial cells, promotes production of oxygen free radicals (ROS), interferes with the intestinal epithelial barrier, activates neutrophils and macrophages, and causes inflammation as well[27,28]. Moreover, by activating transcription factor nuclear factor κB (NF-κB) signal pathway, TNF-α indirectly induces production and secretion of many inflammatory cytokines and chemokines involving IL-6, IL-12, IL-18, IFN-γ and MMPs[27,29,30]. The expression of TNF-α in IBD patients increases dramatically, and Infliximab, an anti-TNF-α monoclonal antibody, has been applied clinically to treat Crohn's disease and ulcerative colitis[31]. The TNF-α levels in colon tissues are often used as a biomarker of the severity of colitis[29]. Similarly, the expression of TNF-α increased dramatically in the damaged

colonic tissues induced by acetic acids in this study. However, in SPK group, TNF-α level decreased significantly on day 7, which demonstrated that administration of SPK strain could ameliorate rat ulcerative colitis resulting from inhibition of TNF-α secretion. It has been reported that TNF-α could induce excessive expression of KGF in the intestinal tissues[32]. KGF, in return, could down-regulate the TNF-α expression in the lung or intestinal tract injury induced by bone marrow transplantation[33,34]. This is consistent with the results in this study. All these suggest that there may be a negative feedback mechanism between TNF-α and KGF.

Attenuated *Salmonella typhimurium* is one of the prevalent bacterial vectors in gene therapy and oral DNA vaccines, which could transfer multiple exogenous gene into host cells effectively[35,36]. *In vivo*, live attenuated *Salmonella* strains penetrate into the intestinal epithelial barrier *via* M cells and macrophages, and reach the Peyer's patches, where the targeting gene would be expressed. The exogenous gene would subsequently be expressed in the host cells[37]. Attenuated *Salmonella* has been proved to be a simple, effective and safe vector in gene therapy[36,38]. In addition, production of bacteria is relatively simple and low in cost compared with other vectors, such as virus and liposome. We chose the attenuated *Salmonella typhimurium* Ty21a as the vector of KGF gene therapy, an aroA mutant strain that is safe and effective for human and has been approved for human use by the U.S. FDA[39,40]. In the present study, no adverse effects were observed in the animals administrated orally with SPK and SP strain. Therefore, this attenuated *Salmonella* strain is safe for treatment of ulcerative colitis.

In conclusion, the oral gene therapy of KGF could improve the colitis physiologically and pathologically in rat model and this therapy may be a potential, safe and efficient for ulcerative colitis.

ACKNOWLEDGMENTS

COMMENTS

Background

Inflammatory bowel disease (IBD) is a chronic inflammatory disorder in gastrointestinal tract mainly involving ulcerative colitis (UC) and Crohn's disease (CD). It is characterized by tissue edema, inflammation and diarrhea. Although conventional drugs, such as corticosteroids and 5-aminosalicylate preparations, are effective in the treatment of IBD, long-term medication would induce severe side effects, affecting the life quality of patients. Keratinocyte growth factor (KGF), a member of the fibroblast growth factor family (FGFs), could specifically stimulate proliferation and differentiation of various epithelial cells of different organs including skin, lung, intestine and bladder. So, the authors hypothesized that KGF could repair the damaged intestinal mucosa and relieve the inflammation.

Research frontiers

Previous studies indicated that KGF could promote proliferation and differentiation of intestinal epithelial cells both *in vivo* and *in vitro*, and protect the intestine. However, the recombinant proteins of cytokines are limited in clinical usage because of their instability.

Innovations and breakthroughs

To avoid the disadvantages of protein drugs, the authors attempted to develop an oral gene therapy of KGF mediated by attenuated *Salmonella typhimurium* to improve the ulcerative colitis in rats with acetic acid-induced colitis.

Applications

The oral gene therapy of KGF could improve the colitis physiologically and pathologically in rat model, and this therapy may be potential, safe and efficient for ulcerative colitis.

Peer review

Oral administration of the attenuated *Salmonella typhimurium* Ty21a strain carrying *KGF* gene could effectively relieve the ulcerative colitis induced by acetic acid, through promoting the proliferation of intestinal mucosal cells, inhibiting the expression of tumor necrosis factor-α, a inflammatory factor, and protecting the intestinal tissues from the damage of reactive oxygen species.

Abstract

AIM: To evaluate the possible relationship between varicocele and chronic constipation.

METHODS: Between April 2009 and May 2010, a total of 135 patients with varicocele or constipation and 120 healthy controls were evaluated. Patients were divided into two groups. In both groups detailed medical history was taken and all patients were examined physically by the same urologist and gastroenterologist. All of them were evaluated by color Doppler ultrasonography. All patients with constipation, except for the healthy controls of the second group, underwent a colonoscopy to identify the etiology of the constipation. In the first group, we determined the rate of chronic constipation in patients with varicocele and in the second group, the rate of varicocele in patients with chronic constipation. In both groups, the rate of the disease was compared with age-matched healthy controls. In the second group, the results of colonoscopies in the patients with chronic constipations were also evaluated.

RESULTS: In the first group, mean age of the study and control groups were 22.9 ± 4.47 and 21.8 ± 7.21 years, respectively ($P < 0.05$). In the second group, mean age of the study and control groups were 52.8 ± 33.3 and 51.7 ± 54.3 years, respectively ($P < 0.05$). In the first group, chronic constipation was observed in 8 of the 69 patients with varicocele (11.6%) and 3 out of 60 in healthy controls (5%), respectively. In this regard, there was no statistical significance between varicocele patients and the healthy control ($P = 0.37$). In the second group, varicocele was observed in 16 of the 66 patients with chronic constipation (24.24%) and 12 out of 60 in healthy controls (20%) respectively. Similarly, there was no statistical significance between chronic constipation and healthy controls ($P = 0.72$). Internal/external hemorrhoids were detected in 4 of the 16 patients with chronic constipation and varicocele, in the second group. In the remaining 50 patients with chronic constipation 9 had internal/external hemorrhoids. In this regard, there was no statistical significance between chronic constipation and healthy controls ($P = 0.80$).

CONCLUSION: Chronic constipation may not be a major predictive factor for the development of varicocele, but it may be a facilitator factor for varicocele.

INTRODUCTION

Varicocele, the most common surgically correctible cause of male infertility, is characterized as abnormal tortuosity and dilation of the pampiniform plexus within the spermatic cord[1]. Although the exact etiology of varicocele is not known[2], the pathogenesis may be associated with various factors resulting in increased retrograde blood flow or increased pressure in the pampiniform plexus and internal spermatic vein[3].

Constipation is a common, often chronic, gastrointestinal motility disorder described by such symptoms as straining, difficult stool, and infrequent defecation[4]. The prevalence in children ranges from 0.7% to 30%. In adults, constipation affects between 2% and 28% of the general population[5].

In this study we aimed to evaluate the possible relationship between varicocele and chronic constipation.

MATERIALS AND METHODS

Between April 2009 and May 2010, a total of 135 patients with varicocele or constipation and 120 healthy controls were evaluated. Patients were divided into two groups.

The first group was consisted of 69 patients with left varicocele and 60 age-matched healthy volunteers, and the second group was consisted of 66 patients with chronic constipation and 60 age-matched healthy volunteers.

Patients who were admitted to the outpatient clinic with complaints of scrotal pain and/or infertility were requited in the first group. In this group, the age-matched healthy controls were the people who were admitted to the outpatient clinic with no varicocele.

In the second group, patients diagnosed with chronic constipation by a gastroenterologist were consulted to the urology outpatient clinic and examined for varicocele. The age-matched healthy controls were the people who were admitted to the outpatient gastroenterology clinic with no constipation.

In both groups a detailed medical history was taken and all patients were examined physically by the same urologist and gastroenterologist in attention to those associated with varicocele and constipation. Afterwards, all of them underwent a standard gray scale and color Doppler ultrasonographic examination of the scrotum, which was performed by the same radiologist. For the ultrasonographic examination, a color Doppler scanner (GE Logic 9, Milwaukee, Wisconsin, USA) equipped with a 5- to 10-MHz linear transducer was used. The transverse diameter of the biggest vein in the pampiniform plexus was measured 3 times by a transducer probe with

a frequency of 7.5-10 MHz during normal breathing, and the Valsalva maneuver. The arithmetic mean value of the diameters measured was used for the assessment. Patients with a varicose spermatic vein larger than 2.0 mm or having reversal flow during the Valsalva maneuver were included in the study group as a varicocele patient.

In the second group, patients were included according to the scope of the Rome III criteria. The Rome III criteria system was developed to classify functional gastrointestinal disorders based on clinical symptoms.

In this regard, patients who had straining and incomplete evacuation and hard stools more than 25% of the time, as well fewer than 3 bowel actions in a week were defined as "chronically constipated". The patients were questioned in terms of systemic diseases and other medications. Anal tonometry was performed to assess the colonic transit time. Colonoscopy and anoscopy was performed in the same session. The presence of hemorrhoid was confirmed. The patients in whom no reason for constipation was detected by colonic transit, anorectal manometry, anoscopy or colonoscopy studies, were enrolled in the study. The hemorrhoid was diagnosed by anoscopy. The other studies were performed for the other etiologies except hemorrhoids. The control group of Group-2 consisted of patients who underwent colonoscopy because of gastrointestinal symptoms other than constipation. All colonoscopies were performed by the same gastroenterologist with a Olympus Q160 AL 160 cm video colonoscope. During the colonoscopy 4 mg midazolam were given to all the patients for anesthesia.

Patients with drug use such as diuretics, hypotensive drugs, anticonvulsants anal fistulas and abscesses, and neurogenic and endocrine disorders associated with constipation such as paraplegia and hypothyroidism, were excluded. Due to the possible effects to spermatic veins, patients with a past medical history of inguinal or scrotal surgery were excluded from the study.

In the first group, we determined the rate of chronic constipation in patients with varicocele and in the second group, the rate of varicocele in patients with chronic constipation. In both groups, the rates of these diseases were compared with age-matched healthy controls. In the second group, the results of colonoscopies in the patients with chronic constipations were also evaluated.

Informed consent was obtained from all participants, and the study was approved by the local Ethical Committee.

SPSS for Windows Version 15 was used for statistical analysis. Statistical analysis was based on χ^2 test. Results are reported as mean ± SD where $P < 0.05$ was considered to be statistically significant.

RESULTS

In the first group, mean age of the study and control groups were 22.9 ± 4.47 and 21.8 ± 7.21 years, respectively. There was no statistical significance between the mean ages of the study and control groups ($P = 0.83$).

In the second group, mean age of the study and control groups were 52.8 ± 33.3 and 51.7 ± 54.3 years, respectively. There was no statistical significance between

the 16 patients with chronic constipation and varicocele, in the second group. In the remaining 50 patients with chronic constipation 9 had internal/external hemorrhoids. In this regard, there was no statistical significance between chronic constipation and healthy controls (*P* = 0.80). Total colonoscopy findings in the second group is summarized in Table 3 and Figure 3.

No complication was observed during the colonoscopy procedure.

DISCUSSION

Varicocele, which is defined as the dilatation of veins of pampiniform venous plexus, is found in approximately 15% of the general population, 35% of men with primary infertility and 80% of men with secondary infertility[6].

Although the exact etiology has not been identified yet, several mechanisms have been proposed in the pathophysiology of varicocele involving insufficiency or absence of venous valves[6], anatomic inclination due to raised pressure in the left renal vein[7], "nut-cracker" phenomenon due to compression of left renal vein between aorta and superior mesenteric artery and oxidative stress[8].

Constipation may be clarified as having two of the following symptoms of straining, difficult stools, sensation of incomplete discharging, sensation of anorectal obstruction/blockage, requiring manual maneuvers to evacuate the stools, and having less than 3 evacuations per week using the Rome III criteria[9]. For the constipation to be described as chronic, the Rome criteria need to have been met for the previous 3 mo, with the attack of symptoms 6 mo prior to diagnosis[10]. In our study the group was formed by patients with symptoms of constipation for at least 8 wk. A longer follow-up period is needed to evaluate the relationship between the duration

of constipation and varicocele. Therefore; in this study, the relation of the duration of constipation and varicocele was not investigated. This issue may to be another subject of study.

Several mechanisms have been proposed for the physiopathologic mechanism of chronic constipation, but the following 2 major disturbances are commonly accepted as related to the development of constipation: "colonic inertia"[4], causing a delay in the passage of the fecal material through the colon; and "outlet inertia" or "anorectal dysfunction"[11], by which the defecatory mechanism is disturbed, causing difficulty in ejected stool from the distal colon to the anus[12].

In the literature on the urinary tract abnormalities and constipation are extensive. The first study reported[13] that 31% of children with functional constipation had megaureter, and then they recommended that the cause would be a mechanical pressure phenomenon. Afterwards, several authors linked constipation to dysfunctional voiding patterns[14-16]. Moreover, higher rates of dilatation of the upper urinary tract and urinary tract infections in constipated patients were showed in some studies[14,15]. These results were ascribed to mechanical compression of the urinary tract by the distended rectum, due the anatomic proximity of the bladder and urethra to the rectum[16]. Also, constipation in children was showed by Fein *et al*[17] as a cause of scrotal or testicular pain, which was ascribed to direct neural stimulation by a fecal mass in the rectum. In this regard, the posterior sacral nerve, ilioinguinal nerve, or genital branch of the genitofemoral nerve has been involved in this neural association[18].

To our knowledge, there is only one study in the literature which investigates the prevalence of chronic constipation in patients with varicocele. According to this study, varicocele was determined in almost 50% of patients with chronic constipation which is suggested to be an important causative factor for the development of left varicocele[19]. The authors demonstrated the statistically significant relationship between the chronic constipation and varicocele, and had proposed a routine ultrasonographic evaluation for the possible development of varicocele in men who have pain or who are otherwise symptomatic[19]. Our study will be the second in the literature demonstrating the relationship between chronic constipation and varicocele.

Generally, the incidence of chronic constipation is reported as 3% in the young population[20]. In the first group of our study, chronic constipation rates were 5% and 11% in the control group and varicocele patients, respectively. These rates may support the relationship between the urinary tract and intestinal system[13-15].

Varicocele may be associated with underlying venous pathological conditions[7]. A study proved that a left varicocele may be two sides disease caused by an inadequacy of the one-way valves in the internal spermatic veins, connected to persistent pathological hydrostatic pressure in the long vertical spermatic veins and venous by passes[21]. Another researcher has been explained that patients with coronary artery ectasia had an increased

prevalence of varicocele compared with coronary artery disease[22]. Also, the increased prevalence of peripheral varicose veins has been reported with coronary artery ectasia by Androulakis *et al*[23]. Lately, Koyuncu *et al*[24] have shown that the rate of saphenofemoral insufficiency has been found to be statistically higher in patients with primary varicocele, compared to healthy men. In addition, many of the studies in the literature have shown a close relationship among varicocele, hemorrhoid and venous diseases[25-27]. This relationship suggests that etiopathogenesis of varicocele and hemorrhoids may be a common venous pathology[28]. According to our colonoscopies results, hemorrhoids were found in 25% of patients with varicocele and 18% of patients with no varicocele. As a result, the rational relationship between varicocele and hemorrhoid was similar within the literature. To our knowledge, this is the first study evaluating the relationship between varicocele and chronic constipation by detailing the colonoscopic findings.

Varicocele may be attributable principally to the accompanying distention of the sigmoid colon and distal part of the descending colon, with resultant compression of the left testicular vein in the retroperitoneum, as well as repeated increased intra-abdominal pressure due to chronic straining[19].

In the literature, it has been shown that the incidence of varicocele is 9% at the second decades, 15% at the third decades and 18% at the fourth decades[25]. Contrary to these, we showed that the incidence of varicocele is 24% at the fourth decades in which the chronic constipation is seen more frequently. Therefore, this finding may support the possible relation between the intestinal system and urinary tract.

We anticipate three possible mechanisms for the relation between varicocele and chronic constipation: (1) Anatomic inclination may become more prominent with chronic constipation through the pressure effect to the intra-abdominal organs; (2) Recurrent and abrupt increases in pressure, chronic constipation may cause compression of intra-abdominal organs, eventually contributing to the development of "nutcracker" phenomenon of left renal vein by superior mesenteric artery and aorta; and (3) Chronic constipation may increase oxidative stress with hypoxic attacks and compression of venous return leading to varicocele.

In conclusion, chronic constipation may facilitate the development of varicocele with abrupt recurrent increases in intra-abdominal pressure through mechanisms of compression in intra-abdominal organs and increasing oxidative stress.

However, our study has two limitations. The first is that the number of patients in the study group may be accepted as a limited number and so, in our opinion, these findings should be confirmed with larger series. The other limitation of our study is the difference by means of patient age. The patients group's age should be homogeneous.

In conclusion, there is a rational relationship between varicocele and chronic constipation. However there was no statistical significance between chronic constipation and

varicocele. Therefore, chronic constipation may not be a major predictive factor for the development of varicocele, but it may be a facilitator factor for varicocele. The results of this hypothesis should be confirmed in larger series.

COMMENTS

Background
This study is interesting because there is not much written in literature. Varicocele can cause infertility in men. The etiology of varicocele is still not clear. Chronic constipation is probably a cause of male infertility.

Research frontiers
The study is preliminary working. The duration of constipation associated with varicocele have not been evaluated in this study. This study should be supported in infertile male patients.

Innovations and breakthroughs
To our knowledge, there is only one study in the literature to investigate the prevalence of chronic constipation in patients with varicocele. To our knowledge, this is the first study evaluating the relationship between varicocele and chronic constipation by detailing the colonoscopic findings. Chronic constipation may trigger the development of varicocele. Therefore, defecation habits of patients with male infertility should be asked.

Applications
Scrotum should be examined in male patients with chronic constipation.

Terminology
Specific terminology was not used in this article.

Peer review
This study is interesting because there is not much written in literature.

Abstract

AIM: To evaluate blood concentration of melatonin and urinary excretion of its metabolite, 6-sulfatoxymelatonin (6-OHMS), in functional dyspepsia (FD).

METHODS: Ninety individuals were enrolled in the study: 30 in each study group: patients with postprandial distress syndrome (PDS), epigastric pain syndrome (EPS), and controls. Blood samples were drawn at 02:00 and 09:00 h and 24-h urine collection was performed. Serum melatonin and urinary 6-OHMS concentrations were measured by enzyme-linked immunosorbent assay.

RESULTS: Serum melatonin concentration at night and in the morning was significantly ($P < 0.001$) higher in PDS patients [at 02:00 h-93.3 pg/mL, quartile range (QR): 79.8-116.2; at 09.00 h-14.3 pg/mL, QR: 7.06-19.0] than in EPS (57.2 pg/mL, QR: 42.6-73.1; 8.1 pg/mL, QR: 4.1-9.3) and control patients (57.7 pg/mL, QR: 51.2-62.5; 8.1 pg/mL, QR: 5.4-10.3). A similar relationship was observed for urinary 6-OHMS excretion. Patients with severe PDS symptoms had a higher melatonin concentration than these with moderate syndromes, whereas patients with severe EPS had a lower urinary 6-OHMS excretion than patients with moderate symptoms.

CONCLUSION: Evaluation of melatonin serum concentrations and 24-h urinary 6-OHMS excretion are useful methods for differential diagnosis of various clinical forms of FD.

INTRODUCTION

Melatonin is synthesized by pinealocytes and in the gastrointestinal (GI) tract. Enterochromaffin (EC) cells are widely distributed in the GI tract mucosa, and are a rich source of this hormone, with the total amount of melatonin greatly exceeding that in the pineal gland[1,2]. Melatonin

displays endocrine, paracrine and autocrine properties, which may account in part for its neuroprotective action, and melatonin and its metabolites are powerful antioxidants[3-5]. The hormone also plays a role in the modulation of prostaglandin secretion and nitric oxide generation, as well as stimulation of bicarbonate secretion in the duodenum and pancreas[6-8]. Melatonin exerts an inhibitory effect on gastric acid secretion and myorelaxation effects on the smooth muscles of the GI tract[9,10]. Melatonin anti-inflammatory and immunomodulatory properties may also play a role in its general protective action in the GI tract[11,12].

An obvious question is whether the protective actions of MEL are exerted only in the case of a threat, or whether they are indispensible under physiological conditions. A growing body of evidence suggests the latter possibility and it has become clear that melatonin deficiency plays an important role in the pathogenesis of certain GI diseases[13,14]. Moreover, melatonin may protect gastric mucosa from stress-mediated lesions at a level comparable to or better than ranitidine and omeprazole[15,16].

Patients with duodenal ulcer disease have lower melatonin concentrations in the blood than healthy individuals have. The difference is most pronounced in the autumn and at night, but they it does not depend on the clinical phase (exacerbation or remission) of peptic ulcer disease[17-19]. It has been suggested that fasting and night abdominal pain in ulcer-like dyspepsia could be associated with lower than normal melatonin secretion, but there are some contradictory data[20,21]. Thus, an unequivocal link between melatonin deficiency and occurrence of disease symptoms in the GI tract has not been established. In our previous study, we recommended that patients with GI pain syndromes took 5 mg/d melatonin for 12 wk. In most patients (56.6%), the symptoms resolved after melatonin treatment; in 30% there was some amelioration of symptoms; while only 13.6% reported no clinical effect[22]. These results prompted us to carry out the present study.

The clinical picture of functional dyspepsia (FD) is rather complex. According to the Rome Ⅲ criteria, there are two major forms of this disease: epigastric pain syndrome (EPS) and postprandial distress syndrome (PDS). In patients with EPS, abdominal pain in the epigastrium dominates, but fasting and nocturnal pain also occur. On the other hand, PDS patients rarely suffer from epigastric pain, but they complain of discomfort and distension in the epigastrium after meals, and they often have morning satiety and nausea.

In the present work, we determined the level of melatonin in serum and measured urinary excretion of the main and immediate metabolite of melatonin, 6-sulfatoxymelatonin (6-OHMS), in patients with EPS or PDS.

MATERIALS AND METHODS

Patients

Ninety subjects were enrolled in this study, 58 women and 32 men, aged 19-45 years (mean, 30.9 years). Clinical characteristics of the patients are presented in Table 1. The

Table 1 Clinical characteristics of the study subjects: controls and patients with postprandial distress syndrome and epigastric pain syndrome

	Controls	PDS	EPS
Number	30	30	30
Age (yr), mean ± SD	28.6 ± 9.4	31.8 ± 12.4	32.3 ± 14.1
Sex (M/F)	12/18	14/16	13/17
Normal gastric mucosa	18/30	17/30	15/30
Superficial gastritis	12/30	13/30	15/30

PDS: Postprandial distress syndrome; EPS: Epigastric pain syndrome.

subjects were divided into three groups: healthy persons with no signs of GI dysfunction; patients with EPS; and patients with PDS without symptoms of irritable bowel syndrome (IBS).

Diagnosis of FD was based on the Rome Ⅲ Criteria. To exclude other diseases, all the patients underwent upper GI endoscopy with histopathological evaluation of gastric mucosa biopsy specimens, abdominal ultrasound, and laboratory tests including blood cell morphology, C-reactive protein, glucose, electrolytes, bilirubin, urea, creatinine, cholesterol, triglycerides, thyrotropin, and activity of aspartate transaminase, alanine transaminase, γ-glutamyl transpeptidase, alkaline phosphatase, amylase and lipase. To exclude Helicobacter pylori infection, the urea breath test (UBT; FANCI-2 System, Fisher Instruments, Germany) was performed. Patients on any long-term treatment as well as cigarette smokers were not enrolled. Furthermore, Beck Depression Inventory and Hamilton Depression Scale were used to assess mental status and to exclude patients with psychiatric disease.

Methods

Seven days prior to the start of the study, patients were recommended to stop taking any medication and remain on a similar diet, which contained the same amount of tryptophan-rich products. Symptoms reported were graded according to a 10-point scale and the subjects were grouped into categories with moderate (1-5 points, 14 individuals with EPS, 16 with PDS) or exacerbated (6-10 points, 15/15) symptoms. On the day of the study, the patients were in the room with only red light exposure between 21:00 h to 07:00 h, and on the same liquid diet (Nutri Drinks; Nutricia, Warsaw, Poland) that consisted of 3 × 400 mL, which contained 18.9 g carbohydrate, 6.0 g protein and 5.8 g lipid per 100 mL, with a total caloric value of 1800 kcal. They also consumed 1.5 L isotonic gas-free water. Blood samples were drawn from the antecubital vein at 02:00 h and 09:00 h and serum was frozen at -70℃. At the same time, 24-h urine samples were collected and stored at 4℃. At the end of 24-h urine collection, the volume of urine was measured and the samples were frozen at -70℃. Serum melatonin and urinary 6-OHMS were measured by enzyme-linked immunosorbent assay using IBL antibodies (RE-54021 and RE-54031; Nordic Immunological Laboratories, Tilburg, Holland) and Expert 99 MicroWin 2000 Reader (BMG Labtech, Offenburg, Germany).

Figure 1 **Serum melatonin concentrations at 02:00 h and 09:00 h in healthy subjects (K, clear bar, *n* = 30) and epigastric pain syndrome (grey bar, *n* = 30) and postprandial distress syndrome (dark grey bar, *n* = 30).** Box represents median with 25th and 75th percentiles (lower and upper quartiles, respectively). The ends of the error bars represent the smallest and largest measurements in the study groups. [b]*P* < 0.001. PDS: Postprandial distress syndrome; EPS: Epigastric pain syndrome.

Ethics

The study was conducted in accordance with the Declaration of Helsinki and with the principles of good clinical practice. These studies were approved by the Bioethics Committee of the Medical University of Lodz, Poland (permission no. RNN/26/04/KB). Each patient was acquainted with the aim of the study and gave written informed consent.

Statistical analysis

The Kolmogorov-Smirnov test was used to determine whether data fitted a normal distribution. Differences between groups were evaluated using the Mann-Whitney rank sum test, with $P < 0.05$ regarded as statistically significant.

RESULTS

The median serum melatonin concentration at 02:00 h in patients with PDS [93.3 pg/mL, quartile range (QR): 79.8-116.2] was about two times higher than in the control subjects (57.7 pg/mL, QR: 51.2-62.5, $P < 0.001$) and patients with EPS (57.2 pg/mL, QR: 42.6-73.1, $P < 0.001$) (Figure 1). We observed a similar relationship at 09:00 h when

Figure 2 **Twenty-four-hour urinary excretion of 6-OHMS in healthy subjects (K, clear bar, *n* = 30) and in patients with epigastric pain syndrome (grey bar, *n* = 30) and postprandial distress syndrome (dark grey, *n* = 30).** Box represents median with 25th and 75th percentiles (lower and upper quartiles, respectively). The ends of the error bars represent the smallest and largest measurements in the study groups. [b]*P* < 0.01. PDS: Postprandial distress syndrome; EPS: Epigastric pain syndrome.

melatonin concentration in the PDS group (14.3 pg/mL, QR: 7.060-19.0) was significantly ($P < 0.001$) higher than in the controls (8.1 pg/mL, QR: 5.4-10.3) and in EPS subjects (8.1 pg/mL, QR: 4.1-9.3) (Figure 1). We also observed higher 24-h urinary 6-OHMS levels in patients with PDS (26.8 μg, QR: 13.4-35.6) as compared with controls (14.6 μg, QR: 10.6-19.4) and patients with EPS (16.4 μg, QR: 13.4-30.7) (Figure 2). The PDS patients with severe symptoms displayed a higher melatonin concentration at 02:00 h (100.0 pg/mL, QR: 91.0-115.0) and 09:00 h (16.1 pg/mL, QR: 12.9-23.4) as compared with patients with moderate symptoms (84.0 pg/mL, QR: 66.1-101.7, $P < 0.05$ and 11.9 pg/mL, QR: 5.2-14.4, $P < 0.001$) (Figure 3). The 24-h urinary excretion of 6-OHMS was also higher in these patients (30.3 μg, QR: 22.9-45.7) in comparison with moderate symptom patients (84.0 pg/mL, QR: 66.1-101.7; 11.9 *vs* 17.5 μg, QR: 9.7-28.9, $P < 0.01$) (Figure 4). We also observed that patients with EPS with severe symptoms had a reduced 24-h 6-OHMS urinary excretion as compared with patients with moderate symptoms (13.2 μg, QR: 10.3-16.6 *vs* 22.8 μg, QR: 16.5-43.3; $P < 0.01$) (Figure 4).

DISCUSSION

Clinical studies of melatonin secretion are usually based on its serum concentrations. These values are relatively low during the daytime and increase significantly at night; especially in the absence of white light. The circadian rhythm of melatonin is a result of secretion by the pineal gland. In pinealectomized animals, no night-time rise in blood melatonin levels is observed, and its concentration throughout a 24-h period remains at a low and relatively constant level[23]. The low residual amounts of melatonin are from sources other than pineal gland, for example, mainly from the GI tract. These sources of melatonin are regulated by mechanisms that do not involve the pi-

Figure 3 **Serum melatonin concentrations at 02:00 h and at 9.00 a.m. in patients with epigastric pain syndrome (two shades of light grey, *n* = 30) and postprandial distress syndrome (two shades of dark grey, *n* = 30).** Darker bars represent patients with severe symptoms [*n* = 16 for epigastric pain syndrome (EPS) and *n* = 15 for postprandial distress syndrome (PDS)] and lighter bars, patients with moderate symptoms (*n* = 14 for EPS and *n* = 15 for PDS). Box represents median with 25th and 75th percentiles (lower and upper quartiles, respectively). The ends of the error bars represent the smallest and largest measurements in the study groups. neal gland. Melatonin secretion from EC cells of the gut increases as a consequence of the activity of muscarinic M3 and β-adrenergic receptors, but also after the intake of food[24]. Large meals rich in L-tryptophan cause satiety and sleepiness in humans and they stimulate the release of melatonin from EC cells. Postprandial melatonin peripheral serum concentrations do not rise markedly because melatonin is absorbed into the portal circulation and transported to liver, where 90% of it is metabolized, mainly to 6-OHMS, which is then excreted by kidneys into the urine[25]. It is accepted that evaluation of urinary 6-OHMS excretion is a useful index of the secretory activity of all cells that produce melatonin[26]. Collecting blood every 1-2 h for the purpose of measuring melatonin concentration is troublesome for patients, disturbs their normal circadian rhythms, and increases emotional stress, which may significantly influence their melatonin levels. As a result, it is widely accepted to perform the measurements twice daily: usually at 02:00 h (in darkness) and at 09:00 h (in daylight)[27].

Melatonin, due to its interaction with receptors[28] and because of its antioxidative properties[29,30], plays an

important role in the function of the GI tract and this indoleamine deficiency is likely involved in the pathogenesis of some GI diseases, including gastric and duodenal peptic ulcers[14]. However, the role of melatonin in the etiology of FD has not been established. The diagnosis of FD is still based on patient complaints. Objective indices of this disease are generally lacking. In the current study, the subjects with EPS had melatonin serum concentrations similar to those in healthy controls, but higher urinary 6-OHMS excretion. This suggests enhanced melatonin secretion from the GI tract in these patients. This enhancement might be sufficient to prevent formation of peptic lesions, but not sufficient to prevent the occurrence of dyspeptic symptoms. In this context, increased melatonin release from the GI tract may be a consequence of pathogenic factors such as chronic stress, increased vegetative system tension, and other processes.

We observed a higher concentration of melatonin in PDS patients than in the control subjects; both during the day and at night, but whether this increase was the reason or a consequence of FD is unresolved. A relative melatonin deficiency may have pathogenic implications for the GI tract, as it has in sleep disturbances, depression and in some organic diseases, including cancer. However, elevated melatonin concentrations have been observed in some diseases of the endocrine and reproductive systems[31], liver cirrhosis[32], and anorexia nervosa[33]. The results of the current study show that FD could be one of these diseases. Different melatonin levels in different forms of FD may have diagnostic significance. Melatonin, or its precursor L-tryptophan, could also be administered in cases of their deficiency, or in patients who are receiving gastro toxic drugs. Rapaport *et al*[34] have recommended that melatonin should be taken by patients with duodenal ulcer

disease, after they observed its beneficial clinical effect and ability to heal inflammatory lesions of the gastric antral mucosa. In our previous studies, the therapeutic efficacy of melatonin in patients with ulcer-like dyspepsia has been shown. Moreover, Konturek *et al*[35] have reported a clear gastroprotective effect of L-tryptophan in patients who are taking acetylsalicylic acid. To date, however, melatonin and its analogs have been used mainly in the treatment of sleep disorders and depression[36,37]. Functional diseases of the GI tract are often associated with psycho-emotional disorders. Dyspeptic symptoms are often the main or even the only manifestation of depression, because it is not associated with bad mood. In several cases of sleep disorders, GI complaints and the fear of severe, chronic non-curable disease are markers of depression.

Disturbance of melatonin level is also observed in patients with IBS, which is more likely to share a common background with FD. To date, the role of melatonin in the etiology of IBS has not been established. Melatonin is known to be a regulator of intestinal motility, therefore, it could act by relaxing bowel muscles. It has been observed that melatonin reduces the tone, but not the amplitude or frequency of contractions[38]. This effect is probably due to stimulation of melatonin receptors and regulation of Ca^{2+}/K^{+} channels, and indirectly by the nervous system[39,40]. Other results suggest that melatonin has a peripheral anti-serotonin-like effect[41]. Serotonin (5-hydroxytryptamine; 5-HT) is thought to be a likely contender in the induction and maintenance of visceral hypersensitivity associated with IBS. 5-HT acts mostly at 5-HT3 or 5-HT3-like receptors, and enhances the sensitivity of visceral neurons that project between the gut and central nervous system.

In conclusion, melatonin levels in the peripheral blood are significantly higher in patients with severe symptoms of PDS than in those with EPS. Thus, these levels may be useful in the differential diagnosis of these diseases. Evaluation of 24-h urinary 6-OHMS excretion is a useful method for the estimation of melatonin secretion and may be important in the differentiation of various clinical forms of FD.

COMMENTS

Background
Melatonin is synthesized by pinealocytes and in the gastrointestinal (GI) tract. Melatonin displays endocrine, paracrine and autocrine properties, which may account in part for its neuroprotective action. Moreover, melatonin and its metabolites are powerful antioxidants.

Research frontiers
An obvious question is whether the protective actions of melatonin are exerted only in the case of a threat or whether they are indispensible under physiological conditions. A growing body of evidence suggests the latter possibility, and it has become clear that melatonin deficiency plays an important role in the pathogenesis of certain GI diseases.

Innovations and breakthroughs
This is believed to be the first study to report an association between functional dyspepsia (FD) and melatonin serum level and 6-sulfatoxymelatonin (6-OHMS) urinary excretion.

Applications
By connecting melatonin levels in the peripheral blood with FD, this study may

help to establish the new differential diagnosis of various clinical forms of FD. The authors also proved that evaluation of 24-h urinary excretion of 6-OHMS is a useful method for the estimation of melatonin secretion, and together with melatonin levels in the peripheral blood, may be important for the differentiation of various clinical forms of FD.

Terminology
Melatonin is a naturally occurring compound in animals, plants and microbes. Many biological effects of melatonin are produced through the activation of its receptors, while others are due to its role as a pervasive and powerful antioxidant. FD is a disease without organic evidence that is likely to explain the symptoms. These symptoms include: upper abdominal pain, belching, nausea, abdominal bloating and early satiety. FD is estimated to affect about 15% of the general population in western countries.

Peer review
This was a well-designed study that examined the association between FD and melatonin serum level and 6-OHMS urinary excretion.

Abstract

AIM: To evaluate the efficacy and safety of endoscopic removal and trimming of self-expandable metallic stents (SEMS).

METHODS: All SEMS had been placed for distal biliary strictures. Twenty-seven endoscopic procedures were performed in 19 patients in whom SEMS (one uncovered and 18 covered) removal had been attempted, and 8 patients in whom stent trimming using argon plasma coagulation (APC) had been attempted at Tokyo Medical University Hospital. The APC settings were: voltage 60-80 W and gas flow at 1.5 L/min.

RESULTS: The mean stent indwelling period for all patients in whom stent removal had been attempted was 113.7 ± 77.6 d (range, 8-280 d). Of the 19 patients in whom removal of the SEMS had been attempted, the procedure was successful in 14 (73.7%) without proce-dure-related adverse events. The indwelling period in the stent removable group was shorter than that in the unremovable group (94.9 ± 71.5 d *vs* 166.2 ± 76.2 d, *P* = 0.08). Stent trimming was successful for all patients with one minor adverse event consisting of self-limited hemorrhage. Trimming time ranged from 11 to 16 min.

CONCLUSION: Although further investigations on larger numbers of cases are necessary to accumulate evidence, the present data suggested that stent removal and stent trimming is feasible and effective for stent-related complications.

INTRODUCTION

Placement of self-expandable metallic stents (SEMS) in the palliation of malignant biliary stricture has been increasingly employed in an attempt to prolong the patency period[1,2]. The recent improvement in multidisciplinary therapy that incorporates treatments such as chemotherapy and radio-

therapy has resulted in an increased number of long-term survivors. This has however been accompanied by an increased chance of experiencing stent-related complications. The majority of stent-related complications involve stent occlusion, leading to cholangitis. Displacement of the stent in the duodenal wall, which is another complication, is not only associated with occlusion but also with the formation of erosions and ulcers from mechanical irritation, and serious bleeding and gastrointestinal tract perforation[3-5].

An intervention for stent occlusion is mechanical cleaning, using devices such as a balloon, but, the occlusion recurs in a comparatively short time in many cases[6]. For patients with repeated stent occlusion, the stent-in-stent procedure with plastic stents or SEMS is used. According to some recent reports[7-9], a procedure whereby SEMS are removed and replaced by new SEMS, has been performed as an alternative method for management of occlusion of SEMS. Furthermore, as an intervention in the displacement of a metallic stent, metallic stent trimming by argon plasma coagulation (APC) has been used in cases of stent migration to the duodenum[4,10-13]. In the present study, we retrospectively evaluated the efficacy and safety of endoscopic removal and trimming of SEMS.

MATERIALS AND METHODS

All SEMS had been placed for distal biliary strictures. Twenty-seven endoscopic procedures were performed in 19 patients in whom SEMS removal had been attempted and in 8 patients in whom APC trimming had been attempted at Tokyo Medical University Hospital between February 2004 and April 2009. The APC trimming group included 3 patients in whom stent removal had been switched to trimming because stent removal was impossible.

The ratio of males to females was 17:10 and the mean age was 68.1 ± 13.7 years (range, 43-91 years) (Table 1). Our policy for managing stent-related accidental symptoms is outlined below. When a stent was occluded, our policy was first to clean the occluded stent using a balloon catheter or basket catheter. If cholangitis due to stent occlusion recurred more than a twice, we attempted stent removal. However, even if the SEMS were positioned appropriately but removal was difficult, mechanical cleaning or a stent-in-stent maneuver was performed. Furthermore, if the end tip of the stent had migrated towards the duodenal wall, only stent trimming was performed. If the stent was occluded even after trimming, mechanical cleaning or a stent-in-stent procedure was performed.

Stent removal
The SEMS used for the 19 cases in whom stent removal was attempted are shown in Table 1. The stents used included one uncovered Wallstent (Boston Scientific Japan, Tokyo, Japan) and 18 covered SEMS. Therapeutic duodenoscope (TJF-240, TJF-260V and JF-260V, Olympus Medical Systems, Tokyo, Japan) were used for the removal of stents. Snare forceps (SD-5L-1, Olympus, Tokyo, Japan) were used to grip the end tip of the stent, which was then removed by pulling it towards the working channel. How-

Table 1 Characteristics of patients			
	Total	**Stent removal**	**Stent trimming**
No. patients	27	19	8[1]
Sex (male/female)	17/10	13/6	4/4[1]
Mean age, yr, (range)	68.1 (43-91)	66.9 (43-91)	70.9 (54-90)
Etiology of biliary strictures			
Pancreatic carcinoma	17	12	5
Biliary ductal carcinoma	3	2	1

ever, if removal through the working channel was difficult, the stent was removed by endoscopy while holding it. If a Niti-S Biliary covered stent (Taewoong Company, Seoul, Korea) was used with a removal suture, the removal cord was gripped using biopsy forceps and after pulling the stent a distance of about a third from the papilla, it was removed using snare forceps as previously mentioned.

Stent trimming
An APC system (ENDOPLASMA, PSD-60, Olympus Medial Systems, Tokyo, Japan) was used to perform stent trimming. The settings were: voltage at 60-80 W and gas flow at 1.5 L/min. The APC probe used for all the patients was the front emission elasticity APC probe (MAJ-1011, diameter 2.3 mm, Olympus Medical Systems, Tokyo, Japan). The stent amputation stump margin was set at 5-15 mm from the papilla. A rough distance was maintained so that the tip of the probe would be in minimal contact with the stent. The target line for cutting the stent was a circumferential incision in addition to ablation (Figure 1). In addition, to avoid gut distension due to the retention of excess gas and the accompanying pain, as well as the risk of perforations during the procedure, gas was suctioned periodically. Stent fragments were removed together with the endoscope using a catheter with a retrieval net or by pulling them out while being held by forceps.

RESULTS

Stent removal
The mean stent indwelling period of all SEMS was 113.7

Figure 1 Stent trimming using argon plasma coagulation. A: Endoscopic imaging showing displacement of a Niti-S Biliary ComVi stent to the duodenum; B: Stent trimming was performed using argon plasma coagulation; C: Endoscopic imaging showing the cut down the stent; D: Eventually, the stent fragment was removed from the body.

Table 2 Outcome of removal of metallic stent

19	CP	Niti-S Biliary Covered Stent with removal suture	77	Success	None

ca.: Carcinoma; CP: Chronic pancreatitis; SEMS: Self-expandable metallic stent; MFP: Mass-forming pancreatitis; AIP: Autoimmune pancreatitis.

± 77.6 d (range, 8-280 d). There was no statistical difference between malignant and benign diseases (126.1 ± 80.0 and 78.8 ± 65.2 d, respectively, $P = 0.25$). Of the 19 patients in whom removal of the SEMS was attempted, the procedure was successful in 14 (73.7%) without complications (Table 2). Stent removal was impossible for one patient with an uncovered stent and 4 patients with a covered stent. The indwelling period in the stent removable group was shorter than that in the unremovable group (94.9 ± 71.5 d *vs* 166.2 ± 76.2 d, $P = 0.08$). Of the 14 patients who underwent successful stent removal, the indwelling period for the 10 patients who had a malignant disease was 111 ± 76.1 d (range, 15-232 d) and the period for the 4 patients who had a benign disease was 54.5 ± 41.6 d (range, 8-100 d). There was no statistical difference between the 2 groups ($P = 0.1$).

Of the 14 patients for whom stent removal was possible, covered SEMS were reinserted in 12, and the remaining 2 patients had a benign biliary stricture without additional stent placement because of successful dilation of the stricture.

In 5 patients for whom stent removal was impossible, a stent-in-stent procedure with a covered Wallstent was used for one patient, and trimming was performed for 3 patients as an alternative method (Table 2). For the one remaining patient, the progress was monitored because the stent was found to be open by imaging.

Stent trimming

Stent trimming was successful for all the patients (Table 3). Trimming time was 12 min for the single patient with the uncovered Wallstent, a mean of 14 min (range, 12-16 min) for 3 patients with the covered Wallstent, a mean of 13 min (range, 11-15 min) for 4 patients with the Niti-S Biliary ComVi Stent. Of the 2 patients for whom stent trimming was successful found to have bile duct stenosis and so a stent-in-stent procedure was performed using the covered Wallstent and Niti-S Biliary ComVi stent.

There was self-limiting hemorrhage due to injury to the esophageal mucosa during removal of the stent fragments in one patient. The patient progressed well with conservative treatment.

Table 3 Outcome of stent trimming

No. of case	Disease	SEMS	Procedural time (min)	Additional procedure after trimming
1	Pancreatic ca.	Uncovered Wallstent	12	None

SEMS: Self-expandable metallic stent; BBS: Benign biliary strictures; MBS: Malignant biliary strictures.

DISCUSSION

Nowadays, placement of SEMS has become the gold standard for the treatment of malignant distal biliary stricture[1,2]. In addition, SEMS have recently been used for postoperative bile leaks, benign biliary strictures such as in chronic pancreatitis, or postoperative biliary strictures[14-17]. Nevertheless, stent occlusions do occur. Previously, when we encountered a SEMS occlusion, we used the stent-in-stent technique. Recently, stent replacement by stent removal, which is an alternative to the stent-in-stent technique, has been attempted[7-9]. In reports to date, the rate of complete removal of covered SEMS is 95.5% (169/177), which has been described as having a comparatively high rate of success (Table 4). However, an uncovered metallic stent is usually impossible to remove as a result of it being embedded in tissue, regardless of whether the disease is benign or malignant. There are also reports of a stent being removed by breaking it up with forceps[18-20], but this is time consuming and there is also the possibility of the channel being damaged by stent fragments. Therefore, this procedure is unlikely to become popular. In the present study, the rate of success for complete removal of the covered metallic stents was 77.8%, while that of the uncovered metallic stents was 0%, showing a comparatively good result for the rate of complete removal of the covered metallic stent. However, even with covered metallic stents, 22.2% were not removable, showing that in fact, there is a limitation to this technique's total success rate. In reports to date, one of the reasons why it is difficult to remove covered metallic stents is said to be severe tissue growth over the uncovered part[8]. In addition, it has been reported that tumor growth causes duodenal stenosis, making it impossible to approach papillary areas[6,7].

In the present study, although there was no statistical significance, the mean indwelling period of removable SEMS was shorter than those of unremovable SEMS, suggesting that the length of the indwelling period may affect the successful removal of SEMS. Structural properties of

the stent were also shown to affect the possibility of stent removal. For the covered Wallstent, the entire diameter was found to shrink and straighten when the stent was held and pulled towards the biliary axis. However, for the Niti-S Biliary ComVi stent, only the part that was held was found to shrink and even the straightening was inadequate, making it difficult to transmit force. Therefore, compared to the covered Wallstent, it was our experience that it was slightly difficult to remove. However, these possible correlations are unclear because of the small number of patients.

Another problem with the covered metallic stent is displacement of the stent towards the duodenum. Covered SEMS are easier to remove than uncovered SEMS. However, they migrate more easily than uncovered SEMS[21,22]. In future, the risk of stent displacement due to shrinkage of tumors in patients that respond to chemotherapy and radiotherapy is likely to increase. In cases where the prolapsing part is extremely long and cannot be held with a snare or holding forceps, it is sometimes effective to use recovery methods such as the wire loop technique[23]. Recently, stent trimming has occasionally been used. Basically, the purposes of trimming are to resolve any occlusion as a result of burial of the stent tip towards the duodenal wall, eliminate mechanical irritation of the duodenal wall, and ensure an accessible route to the bile duct. In particular, trimming using APC is known to be inexpensive and simple. Presently, the safety and usefulness of APC trimming have been confirmed in experimental[24] and clinical[4,10-13] studies. However, its indication, method of intervention, and settings have not yet been established because there are no uniform conditions for setting APC in trimming. From various studies, settings for the high frequency wave output ranged from 60 to 85 W, and gas flow from 0.8 L/min to 2.0 L/min, showing notable variation. The main reports to date are presented in Table 5[4,10-13]. In this study, gas flow was set at 1.5 L/min and the output was started at 60 W and gradually increased while observing the results of the trimming. However, at 60 W, the ablation effect was often inadequate; at 80 W, trimming could be done effectively and smoothly. In addition, even at 80 W, the trimming could be done adequately and safely without any major complications. Therefore, setting the output at 80 W initially con-

tributed to a reduction of unnecessary testing time. With regard to the maximum output, there has been histological evaluation in animal models[24] but its status in the human body is unknown. Standardization of a safe and effective setting of the output would be ideal.

There are various types of SEMS in use and these include Elgiloy, which is a cobalt alloy as in the Wallstent (Boston Scientific Co., Tokyo, Japan), other stainless steel stents, and recently, Nitinol, which is made up of a shape-memory alloy as in the Niti-S stent (TaeWoong Medical Co., Seoul, Korea). To date, there are reports on APC trimming with the uncovered metallic stents, Elgiloy and Nitinol, stating that trimming can be done with no major complications[4,10-13]. In the present study, the trimming time was about 15 min (range, 11-16 min) for all the patients, with no significant difference in time. With regard to the differences between the uncovered and covered metallic stents, Vanbiervliet *et al*[10] and Christiaens *et al*[13] were unsuccessful at trimming the covered metallic stents, and the reason given was poor generation of the heat required for trimming due to hindrance of the flow of electricity to the stent by the coated polyurethane resin membrane. However, Chen *et al*[24] reported there was no difference in technique or time required for trimming covered *versus* uncovered stents. This result was different from the results in clinical reports. Presently, no conclusion can be reached regarding the differences. In addition, food residue that attaches to the periphery of stents can also be considered a hindrance to the discharge of electricity[12]. As a pre-trimming intervention, adequate removal of food residue may shorten the time of the procedure.

In conclusion, although further investigations on larger numbers of cases are necessary to accumulate evidence, the present data suggest that stent removal and stent trimming is feasible and effective for stent-related complications.

ACKNOWLEDGMENTS

COMMENTS

Background

Recently, self-expandable metallic stents (SEMS) removal has been performed as an alternative management method of occlusion of SEMS. Furthermore, metallic stent trimming by argon plasma coagulation (APC) has been used in cases of stent displacement or migration to the duodenum.

Research frontiers

In reports to date, the rate of complete removal of covered SEMS was 95.5% (169/177), which has been described as having a comparatively high rate of success. However, an uncovered metallic stent is usually impossible to remove. In the present study, of the 19 patients in whom removal of the SEMS had been attempted, the procedure was successful in 14 (73.7%) without complications. The rate of success for complete removal of the covered metallic stents was 77.8% (14/18), while that of the uncovered metallic stents was 0% (0/1). In addition, stent trimming was successful in all patients. Trimming time ranged from 11 to 16 min. The present data suggested that stent removal and trimming is feasible and effective for stent-related complications.

Innovations and breakthroughs

The present study showed a comparatively good result for the rate of complete removal of the covered metallic stent. However, even with covered metallic stents, 22.2% (4/18) were unremovable, showing that there is a limitation to this technique's total success rate. This report suggests that the indwelling period length and structural properties of the stent may also affect the successful removal of SEMS. There are few reports about stent trimming of biliary covered SEMS. In addition, several investigators have reported no success in trimming the covered metallic stent. Meanwhile, in the present study, stent trimming was successful for all covered SEMS.

Applications

Stent removal and trimming is feasible and effective for stent-related complications.

Terminology

Covered SEMSs can be removed theoretically, because the membrane of SEMS prevents embedding caused by tumor ingrowth or tissue hyperplasia.

Peer review

This is a well written paper on removal and trimming of self expandable metal biliary stents with good results. The technique and setting used are useful for the readers.

Abstract

AIM: To determine the association between serum levels of growth-related gene product β (GROβ) and clinical parameters in esophageal squamous cell carcinoma (ESCC).

METHODS: Using enzyme-linked immunosorbent assay, serum GROβ levels were measured in ESCC patients ($n = 72$) and healthy volunteers ($n = 83$). The association between serum levels of GROβ and clinical parameters of ESCC was analyzed statistically.

RESULTS: The serum GROβ levels were much higher in ESCC patients than in healthy controls (median: 645 ng/L *vs* 269 ng/L, $P < 0.05$). Serum GROβ levels were correlated positively with tumor size, lymph node metastasis, and tumor-node-metastasis (TNM) staging, but not with gender or the histological grade of tumors in ESCC patients. The sensitivity and specificity of the assay for serum GROβ were 73.61% and 56.63%, respectively.

CONCLUSION: GROβ may function as an oncogene product and contribute to tumorigenesis and metastasis of ESCC.

Clinical significance of serum expression of GROβ in esophageal squamous cell carcinoma. *World J Gastroenterol* 2011; 17(21): 2658-2662 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i21/2658.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i21.2658

INTRODUCTION

Esophageal squamous cell carcinoma (ESCC) is one of the most aggressive malignancies in China, South Africa, and some other developing countries[1,2]. In China, patients with ESCC have a poor prognosis, with an average 5-year survival rate of less than 30%[3-5]. It is thus imperative to find new markers, especially serum protein markers, to facilitate the early detection and diagnosis of ESCC.

CXC chemokine receptors are integral membrane proteins that specifically bind and are activated by cytokines

of the CXC chemokine family, a group of small cytokines[6] involved in the response to injury[7] and inflammatory reactions[8] as well tumorigenesis, cancer progression, and metastasis[9,10]. CXCL16 expression is increased in multiple tumor tissues and cell lines, and upregulation is associated with tumor progression and metastasis[11]. The plasma levels of CXCL4 and CXCL6 are much higher in patients with osteosarcoma than in healthy controls, and elevated plasma CXCL4 and CXCL6 levels are associated with poor prognosis[10]. Growth-related gene product (GRO) is a member of the CXC chemokine family, which is composed of GROα, GROβ and GROγ[12,13]. GROα is highly expressed in a variety of tumors and plays an important role in tumor proliferation[14], angiogenesis[15], and metastasis[16]. Compared with GROα, the roles of GROβ in tumors are poorly understood.

Recently, authors from South Africa reported that GROβ is highly expressed in ESCC tissues and cell lines[17]. Although this suggests that GROβ may be secreted from tumor tissues into the extracellular milieu, no report has yet investigated serum GROβ expression levels in human ESCC. In this study, we measured the serum levels of GROβ in ESCC patients and healthy controls by enzyme-linked immunosorbent assay (ELISA), and analyzed the association between clinical parameters of ESCC and serum GROβ levels.

MATERIALS AND METHODS

Clinical specimen collection and preparation

Serum samples were collected from 72 ESCC patients [52 males and 20 females; mean age, 61 ± 7.7 years (SD); range 41-76 years] and 83 healthy controls [45 males and 38 females; mean age, 57 ± 8.4 years (SD); range 41-70 years] after the informed consent was obtained. Pathological diagnosis was independently conducted by two senior pathologists. The healthy individuals were negative for hepatitis B virus, hepatitis C virus, and human immunodeficiency virus. Abdominal ultrasound examination, routine blood tests, and biochemistry tests were performed for the healthy controls, and the results were within normal ranges. Sample preparation was referred to the reference[18]. The clinical characteristics of the serum samples are shown in Table 1.

ELISA for GROβ

A human GROβ ELISA development kit (PeproTech, Rocky Hill, NJ, USA) was used to measure GROβ in human serum. Briefly, 96-well ELISA microplates were coated overnight with 100 μL GROβ antibody (PeproTech, Rocky Hill, NJ, USA) at a final concentration of 0.25 mg/L in PBS. After washing with PBS/0.05% (w/v) Tween-20 (PBST, pH 7.4), the wells were blocked with blocking buffer at room temperature for 1 h. Then, 100 μL diluted serum samples (at 1:5 dilution) were added and incubated at room temperature for 2 h. Similarly, 100 μL PBST lacking antibody was used as a negative control. Following three washes with PBST, 100 μL antibody diluted to a concen-

tration of 0.25 mg/L was added. After incubation at room temperature for 2 h, 100 μL avidin-horseradish peroxidase-conjugated secondary antibody (at 1:2000 dilution) was added, and plates were incubated at room temperature for 30 min. The excess conjugate was removed by washing the plates three times with PBST. The amount of bound conjugate was determined by adding ABTS liquid substrate solution to each well, and plates were incubated at room temperature for color development. The absorbance was measured at 405 nm using a Model 680 microplate reader (Bio-Rad Lab. Inc., Hercules, CA, USA). All analyses were performed in triplicate. The coefficient of variation was lower than 15% between analyses.

Statistical analysis

Statistical significance was determined with the nonparametric Mann-Whitney *U*-test (differences between two groups) and the Kruskal-Wallis nonparametric test (differences among more than two groups) with SPSS 16.0 software (Chicago, IL, USA). Values of *P* < 0.05 were considered statistically significant.

RESULTS

Serum GROβ levels in ESCC patients and healthy controls

A total of 155 participants were enrolled in this study. The serum levels of GROβ in ESCC patients (*n* = 72) and healthy controls (*n* = 83) were assessed by ELISA.

Figure 1 Correlations between serum growth-related gene product β level and clinicopathological parameters in esophageal squamous cell carcinoma. Serum growth-related gene product β (GROβ) levels were measured in esophageal squamous cell carcinoma (ESCC) patients (*n* = 72) and healthy volunteers (*n* = 83) using enzyme-linked immunosorbent assay. Serum levels of GROβ were significantly increased in ESCC patients (A). Serum levels of GROβ were correlated positively with tumor-node-metastasis stage (B), tumor size (C), and lymph node (LN) metastasis (D), but not with histological grade (E) or gender (F) in ESCC patients. The boxes represent the distribution of the 25th and 75th percentile data (the line in the box is the median, and the dots are the outlying points).

Serum concentrations of GROβ ranged from 146 ng/L to 3721 ng/L (median = 645 ng/L) in ESCC patients, and from 0 ng/L to 2781 ng/L (median = 269 ng/L) in healthy controls. GROβ levels were significantly higher in ESCC patients than in healthy controls (Mann-Whitney *U*-test, *P* < 0.001, Figure 1A). The sensitivity and specificity of serum GROβ were 73.61% and 56.63%, respectively.

Association between serum concentrations of GROβ and clinical parameters in ESCC

We assessed the potential correlations between serum levels of GROβ and clinical parameters, including tumor-node-metastasis (TNM) stage, tumor size, lymph node metastasis, histological grade, and gender. The median levels of GROβ in the ESCC patients at different stages were: stage I, 284 ng/L (range, 146-1141 ng/L); stage Ⅱ, 360 ng/L (range, 211-2453 ng/L); and stage Ⅲ, 966 ng/L (range, 165-3721 ng/L)". The serum GROβ levels were significantly different (Kruskal-Wallis nonparametric test, *P* = 0.006) among the three TNM stages, and significantly higher in patients at stage Ⅲ than in those at stage Ⅱ (Mann-Whitney *U*-test, *P* = 0.041, Figure 1B) and stage I (Mann-Whitney *U*-test, *P* = 0.004, Figure 1B). However, there was no signif-

icant difference between stage I and stage Ⅱ (Mann-Whitney *U*-test, *P* = 0.135). Furthermore, patients with tumor diameters ≥ 5 cm had higher serum levels of GROβ (median = 786 ng/L; range, 191-3721 ng/L) than those with smaller tumors (median = 456 ng/L; range, 146-2008 ng/L; Mann-Whitney *U*-test, *P* = 0.016; Figure 1C). Serum levels of GROβ in patients with lymph node metastasis (median = 819 ng/L; range, 165-3721 ng/L) were significantly higher than those without lymph node metastasis (median = 330 ng/L; range, 146-2453 ng/L; Mann-Whitney *U*-test, *P* = 0.020; Figure 1D). However, there was no significant difference between serum levels of GROβ in patients with poorly differentiated tumors (median = 607 ng/L; range, 191-2705 ng/L) and well-differentiated tumors (median = 1178 ng/L; range, 239-3721 ng/L; Mann-Whitney *U*-test, *P* = 0.110, Figure 1E). Serum levels of GROβ were not gender dependent (Mann-Whitney *U*-test, *P* = 0.650, Figure 1F).

DISCUSSION

Identification of targets for early detection of ESCC is important to improve the prognosis of the patients with this pernicious disease. Currently, carcinoembryonic antigen, cytokeratin 19 fragments, and squamous cell carcinoma-associated antigen are routinely used as serum markers for detection of ESCC. Due to the low sensitivity and specificity of detection of these markers[19], additional serum markers must be established for early detection and diagnosis of ESCC.

GROβ, also known as the chemokine CXCL2, is a member of the CXC chemokine family and shares the same receptor with interleukin (IL)-8, interleukinIL-8RB/CXCR2. GROβ is widely expressed in the central nervous system[20] and possesses important functions, such as attracting neutrophils to sites of inflammation, mobilizing stem cells[21-25], and modulating neurotransmitter release[26]. The roles of GROβ in tumor formation and development have been investigated[27], and a recent report described significant elevation of GROβ mRNA in colon cancer tissues[28]. Upregulation of GROβ promotes colony formation by melanocytes in soft agar and tumor formation in nude mice[13,29]. Conversely, decreased expression of GROβ inhibits the proliferation and colonization capacity of esophageal cancer cells[30]. Through binding to its receptor CXCR2, GROβ forms an autocrine loop that activates the Ras-Erk1/2 signaling pathway, which is important for cell proliferation[17,25,26,31]. This pathway in turn activates the transcription and expression of the early growth response 1 gene (*egr1*), a transcription factor that regulates the expression of downstream factors related to cell growth and cell cycle regulation (p65, p27), thereby promoting tumor growth[32-34].

Using cDNA microarray analysis, authors from South Africa showed that GROβ was highly expressed in ESCC tissues and cultured cells[17]. As a chemokine, GROβ may be secreted into the extracellular matrix. However, no report has investigated the clinical significance of serum GROβ levels in ESCC. To compare the levels of serum GROβ in patients with ESCC and healthy controls, we measured

serum GROβ concentrations with ELISA. The level of serum GROβ was much higher in patients with ESCC than in healthy controls, which supported the hypothesis that GROβ may function as an oncogene in ESCC.

We assessed the potential correlations between serum levels of GROβ and several clinical parameters of ESCC, including tumor size, TNM stage, lymph node metastasis, histological grade and gender. Serum levels of GROβ were correlated significantly with tumor size and the extent of metastasis. Patients with larger tumors ($\geq$ 5 cm in diameter) had higher levels of serum GROβ than those with smaller tumors ($P < 0.05$). Likewise, serum GROβ levels in patients with lymph node metastasis were significantly higher than those without lymph node metastasis ($P < 0.05$). The elevation of serum GROβ in ESCC patients may therefore reflect the enhanced potential of tumor cells to proliferate and metastasize, which is consistent with TNM staging[35]. Indeed, GROβ serum levels were significantly increased in stage III patients compared with stage II and stage I patients ($P < 0.05$). The histological grade of tumors is also an important indicator associated with the development and prognosis of cancer[36]. However, no significant differences were found in the serum levels of GROβ in ESCC patients with different histological tumor grades ($P > 0.05$) in our study. Because our study involved a relatively small number of ESCC patients and the sensitivity and specificity of our assay to measure serum GROβ were not sufficiently high, further confirmation in a larger sample size is warranted.

In conclusion, we found that serum GROβ levels were increased in ESCC patients and correlated positively with tumor size, TNM stage and lymph node metastasis, but not with gender or the histological grade of ESCC. GROβ may function as an oncogene product and play a role in tumor formation, progression and metastasis. Examining and monitoring serum GROβ levels may be useful in estimating the prognosis of ESCC.

ACKNOWLEDGMENTS

COMMENTS

Background
Esophageal squamous cell carcinoma (ESCC) is one of the most aggressive malignancies in China, South Africa and some other developing countries. In China, prognosis of the patients with ESCC is poor, with a 5-year survival rate of less than 30%. It is important to find new markers, especially serum protein markers to facilitate the early detection and diagnosis of ESCC.

Research frontiers
Growth-related gene product β (GROβ) was reported to be highly expressed in ESCC tissues and cell lines. As a chemokine, GROβ could be secreted from cells to extracellular matrix. But no report has yet investigated serum GROβ expression levels in human ESCC. In the present study, serum level of GROβ between patients with ESCC and healthy controls were firstly measured, and

the association between clinical parameters of ESCC and serum GROβ levels were also analyzed.

Innovations and breakthroughs
The serum level of GROβ was increased in ESCC patients and was positively correlated with tumor size, tumor-node-metastasis staging and lymph node metastasis of the patients. GROβ might serve as an oncogene and contribute to tumorigenesis and metastasis of ESCC.

Applications
Examining and monitoring serum GROβ levels are useful in estimating the prognosis of ESCC patients.

Terminology
GROβ, also known as CXCL2 chemokine, is a member of the CXC chemokine family. It is widespread in the central nervous system and involved in many important functions, such as attracting neutrophils to inflammation sites, mobilization of stem cells and neurotransmitter release modulation.

Peer review
GRO, a member of the CXC chemokine subfamily, plays a major role in inflammation and wound healing. CXC chemokines have been found to be associated with tumorigenesis, angiogenesis and metastasis. The roles of GROβ in tumor formation and development were unclear. The papers from tumor cell lines, animal and human studies on this field showed controversial results.

Abstract

AIM: To examine the effects of 2,4-dihydroxybenzophenone (BP-1), a benzophenone derivative used as an ultraviolet light absorbent, on acetaminophen (APAP)-induced hepatotoxicity in C57BL/6J mice.

METHODS: Mice were administered orally with BP-1 at doses of 200, 400 and 800 mg/kg body weight respectively every morning for 4 d before a hepatotoxic dose of APAP (350 mg/kg body weight) was given subcutaneously. Twenty four hours after APAP intoxication, the serum enzyme including serum alaine aminotransferase (ALT), aspartate aminotransferase (AST), lactate dehydrogenase (LDH) were measured and liver histopathologic changes were examined.

RESULTS: BP-1 administration dramatically reduced serum ALT, AST and LDH levels. Liver histopathological examination showed that BP-1 administration antagonized APAP-induced liver pathological damage in a dose-dependent manner. Further tests showed that APAP-induced hepatic lipid peroxidation was reduced significantly by BP-1 pretreatment, and glutathione depletion was ameliorated obviously.

CONCLUSION: BP-1 can effectively protect C57BL/6J mice from APAP-induced hepatotoxicity, and reduction of oxidative stress might be part of the protection mechanism.

INTRODUCTION

Acetaminophen (APAP), which is also named paracetamol, is a widely used antipyretic and analgesic drug. However, it can cause hepatic necrosis and even death in human and experimental animals when taken in overdose[1]. Overdose of APAP can lead to acute liver injury and histopathological changes characterized by centrilobular necrosis[2,3]. Most of APAP is cleared by glucuronic acid or sulphate combination while a part of APAP is metabolized by cytochrome P450 system and generates reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI). NAPQI can be conjugated by glutathione and hence excreted from the body as sulfhydryl adducts. If the formation of NAPQI is beyond the clearing capacity of reduced glutathione (GSH), NAPQI combined with liver cellular protein will cause liver cell injury[4,5]. APAP has been widely used to establish acute liver injury models for liver protective agent research. Since C57BL/6J mice were more susceptible to APAP, C57BL/6J mice were used in the present study.

2,4-dihydroxybenzophenone (BP-1), a benzophenone derivative, is often used as an ultraviolet light absorbent. BP-1 has also been used in some products such as nail polish, polish remover, shaving cream, body cleanser and so on. Previous researches about BP-1 mainly focused on its estrogenic activities. Matsumoto *et al*[6] demonstrated that BP-1 exhibited estrogenic activities by estrogen receptor using MCF-7 (a human breast cancer cell line) cell proliferation assay. In this study, we examined the effects of BP-1 in APAP-induced hepatotoxicity in mice.

MATERIALS AND METHODS

Chemicals

BP-1 was purchased from Huangshi Meifeng Chemical Company (Huangshi, China) and APAP from Jiaozuo Xin' an Science and Technology Company (Jiaozuo, China). BP-1 suspension was prepared with 1% Tween80 from Amresco Company (Solon, USA). TBARS assay kit was purchased from Cell Biolabs (San Diego, USA). Glutathione assay kit was purchased from Calbiochem (Darmstadt, Germany).

Animals and treatment

Healthy and clean male C57BL/6J mice weighing 18-22 g were used in all experiments. They were bought from Peking University Laboratory Animal Department. Mice were housed in a well-ventilated room and fed adaptively for 3 d before experiment. Room temperature was controlled at 21-25℃ with a 12 h/12 h light-dark cycle and humidity at 65%-70%. All mice were allowed free access to water and fed with forage supplied by Laboratory Animal Center of Academy of Military Medical Sciences.

Thirty mice were randomly divided into 5 groups. Group 1 was vehicle control group and Group 2 was APAP alone group, both of which administered intragastrically with 1% Tween80 for 4 d. Groups 3, 4 and 5, administered intragastrically with BP-1 at doses of 200, 400 and 800 mg/kg body weight respectively for 4 d. On the 4th day, all mice except those in vehicle control group were injected with APAP (350 mg/kg body weight) subcutaneously 30 min after the final administration. Twenty-four hours after APAP injection, blood samples were collected from orbital venous plexus. Then all mice were sacrificed, and livers were moved out immediately and washed with saline, dried on a filter paper and weighed. Liver samples were prepared for further tests. The animal experiments and surgical procedures were all performed in compliance with the Guidelines for Animal Care and Use issued by Peking University.

Biochemical test

The serum enzyme levels including serum alaine aminotransferase (ALT), aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) were determined by HITACHI-7170A automatic analyzer. Liver homogenization was carried out in ice-cold KCl solution (0.15 mol/L) or phosphate buffered solution to yield a 5% (w/v) tissue

Figure 1 Effects of 2,4-dihydroxybenzophenone administration on serum levels of alaine aminotransferase, aspartate aminotransferase and lactate dehydrogenase in mice. Acetaminophen (APAP) was administered at 350 mg/kg sc and 2,4-dihydroxybenzophenone (BP-1) was administered ig at doses of 200, 400 and 800 mg/kg respectively 4 d before acetaminophen treatment. Alaine aminotransferase (ALT), aspartate aminotransferase (AST) and lactate dehydrogenase(LDH) levels were measured 24 h after acetaminophen treatment. Results were expressed as mean ± SE and data was analyzed by one-way analysis of variance using SPSS 13.0 software. [a]$P < 0.05$ *vs* acetaminophen group; [c]$P < 0.05$ *vs* control group.

homogenates for malonaldehyde (MDA) and GSH tests. The MDA, GSH and oxidized glutathione (GSSG) levels in liver tissues were determined according to the manufacturer's protocols. GSH/GSSG ratio was calculated.

Histological examination

The left liver lobes were cut out and fixed in 10% formalin solution. After pathological sectioning and HE staining, liver histopathologic changes were examined under inverted phase contrast microscope.

Data treatment and statistical analysis

Data were expressed as mean ± SE. Statistical comparison between groups was performed by one-way analysis of variance (ANOVA) with SPSS 13.0 software. Significance was accepted at $P < 0.05$.

RESULTS

BP-1 administration reduced ALT, AST and LDH

Twenty-four hours after a single dose of APAP (350 mg/kg body weight), serum levels of ALT, AST and LDH increased significantly ($P < 0.05$), showing characteristic acute liver injury induced by APAP. Compared with APAP group, BP-1 groups lowered serum levels of ALT, AST and LDH dramatically. At a dose of 200 mg/kg body weight, the difference was not significant; at doses of 400 and 800 mg/kg body weight, there were significant differences between BP-1 groups and APAP group ($P < 0.05$). The effect of BP-1 was dose-dependent and serum levels of ALT, AST and LDH in the highest dose groups were comparable to that of vehicle control group ($P > 0.05$) (Figure 1).

Figure 2 Liver histology of all groups 24 h after acetaminophen treatment (350 mg/kg). Hematoxylin-eosin-stained liver sections displayed representative hepatocellular morphological changes. Original magnification × 200. A: Liver section in the vehicle control group showed a normal lobular structure; B: Liver section in acetaminophen alone group showed large areas of centrilobular necrosis, vacuolar degeneration and inflammatory cell infiltration; C: Liver section in the 200 mg/kg group showed necrosis with the same degree as in acetaminophen group; D: Liver section in the 400 mg/kg group showed a significant alleviation of liver injury; E: Liver section in the 800 mg/kg group showed absence of necrosis and almost normal lobular structure.

Table 1 Effects of 2,4-dihydroxybenzophenone administration on malonaldehyde level and GSH/GSSG ratio in mice

Groups	MDA (μmol/g)	GSH/GSSH ratio
Control	0.30 ± 0.27	10.5 ± 2.7
Acetaminophen	0.90 ± 0.70[c]	7.1 ± 2.1[c]
BP-1 (200 mg/kg)	1.08 ± 0.68	5.1 ± 1.4[a]
BP-1 (400 mg/kg)	0.58 ± 0.33	6.8 ± 1.5
BP-1 (800 mg/kg)	0.50 ± 0.10	9.6 ± 1.9[a]

[a]$P < 0.05$ *vs* acetaminophen alone group; [c]$P < 0.05$ *vs* control group. BP-1: 2,4-dihydroxybenzophenone; MDA: Malonaldehyde.

Effect of BP-1 administration in liver tissue MDA and GSH/GSSG ratio

Compared with vehicle control group, MDA content in liver tissue of APAP alone group increased while the ratio of GSH/GSSG decreased dramatically ($P < 0.05$), indicating an oxidation stress and depletion of GSH. With increasing dose of BP-1, MDA level decreased and GSH/GSSG ratio increased. In the highest dose group (800 mg/kg body weight), the MDA and ratio of GSH/GSSG were close to the normal level as shown in vehicle control group (Table 1).

BP-1 alleviated pathological injury induced by APAP

Observed by naked eyes, the livers of vehicle control group were deep red, moist, glossy and resilient. In APAP group, the livers lost luster and yellow necrosis foci were often found on the surface. Liver injury of BP-1 pretreated mice was attenuated dramatically in a dose-dependent manner.

Under light microscope, liver lobular structures in vehicle control group were clear and regular, and single layer of hepatocytes arranged around the central vein in a radical pattern. There were abundant basophilic granular cytoplasms in the hepatocytes (Figure 2A). In APAP-intoxicated mice, normal liver lobular structures were damaged and collapsed. The hepatocytes showed vacuolization, sinusoidal dilation and congestion. Infiltration of inflammatory cells and loss of cell boundaries were also observed (Figure 2B). Pre-administration of BP-1 showed mild injuries in a dose-related manner. BP-1 at 200 mg/kg could not effectively prevent the damage (Figure 2C). There was a moderate injury in the 400 mg/kg group (Figure 2D) while in the 800 mg/kg group liver lobular structure was well comparable to that in the vehicle control group (Figure 2E).

DISCUSSION

APAP is often used in animal experiments to establish acute liver injury models. Our previous researches found that C57BL/6J mice were more susceptible to APAP[7], so C57BL/6J mice were chosen in the present study as experimental animals. The serum levels of ALT, AST and LDH are the main indexes which reflect liver injury[8]. Our study demonstrated that BP-1 protected mice from APAP-induced acute liver injury as shown by the significant decrease in serum ALT, AST and LDH. BP-1 could also antagonize tetrachloromethane-, cocaine- and thioacetamide-induced acute liver injuries, which was evidenced by reduced serum ALT, AST and LDH levels, as

well as ameliorated pathological changes in the liver (data not shown).

BP-1 showed a broad protective effect in hepatotoxic chemicals-induced acute liver injury, implying that it may target on the oxidative stress, which was the key event in liver injuries caused by these hepatotoxic chemicals. To confirm the hypothesis, we examined the content of MDA in liver tissues which was often used as a biomarker to measure the level of oxidative stress in organisms[9], as well as the GSH/GSSG ratio which indicated the capability to antagonize the oxidative injury[10]. The results demonstrated that, MDA levels in APAP-intoxicated mice increased obviously and GSH/GSSG ratio decreased, implying the existence of oxidative damage and depletion of GSH. However, pre-administration of BP-1 decreased the MDA level and increased GSH/GSSG ratio in a dose-dependent manner. The results indicated that the hepatoprotective effect of BP-1 was associated with its antioxidant activity.

COMMENTS

Background
Acetaminophen (APAP)-induced acute liver injury model has been widely used as hepatoprotective agent screening. The authors have conducted the screening for hepatoprotective agents for a long time. To the best of their knowledge, there has been no report about the hepatoprotective effects of 2,4-dihydroxybenzophenone (BP-1) up to date.

Innovations and breakthroughs
This study shed a light on the hepatoprotective effects of BP-1. The results indicated that the hepatoprotective effect of BP-1 was associated with its anti-oxidant activity.

Applications
This study provided evidence for the protective effect of BP-1 against APAP-induced liver injury, which implied that BP-1 might be a promising agent for acute liver injury in human. Of course, before possible clinical use, more researches are needed to confirm that BP-1 is both effective and safe for humans.

Peer review
The authors investigated the effect of BP-1 pretreatment on APAP-induced hepatotoxicity in mice. The results demonstrated that: BP-1 pretreatment antagonized APAP-induced liver pathological damage; BP-1 pretreatment reduced APAP-induced hepatic lipid peroxidation; and BP-1 pretreatment ameliorated glutathione depletion.

Abstract

AIM: To investigate the silencing effects of pAd-shRNA-pleiotrophin (PTN) on PTN in pancreatic cancer cells, and to observe the inhibition of pAd-shRNA-PTN on neurite outgrowth from dorsal root ganglion (DRG) neurons *in vitro*.

METHODS: PAd-shRNA-PTN was used to infect pancreatic cancer BxPC-3 cells; assays were conducted for knockdown of the *PTN* gene on the 0th, 1st, 3rd, 5th, 7th and 9th d after infection using immunocytochemistry, real-time quantitative polymerase chain reaction (PCR), and Western blotting analysis. The morphologic changes of cultured DRG neurons were observed by mono-culture of DRG neurons and co-culture with BXPC-3 cells *in vitro*.

RESULTS: The real-time quantitative PCR showed that the inhibition rates of PTN mRNA expression in the BxPC-3 cells were 20%, 80%, 50% and 25% on the 1st, 3rd, 5th and 7th d after infection. Immunocytochemistry and Western blotting analysis also revealed the same tendency. In contrast to the control, the DRG neurons co-cultured with the infected BxPC-3 cells shrunk; the number and length of neurites were significantly decreased.

CONCLUSION: Efficient and specific knockdown of PTN in pancreatic cancer cells and the reduction in PTN expression resulted in the inhibition of neurite outgrowth from DRG neurons.

Yao J, Zhang M, Ma QY, Wang Z, Wang LC, Zhang D. PAd-shRNA-PTN reduces pleiotrophin of pancreatic cancer cells and inhibits neurite outgrowth of DRG. *World J Gastroenterol* 2011; 17(21): 2667-2673 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i21/2667.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i21.2667

INTRODUCTION

Pancreatic cancer is one of the most aggressive and intractable human malignant tumors[1,2]. Perineural invasion extending into the pancreatic nerve plexus is a histopathologic characteristic of pancreatic cancer. However, the mechanisms contributing to the invasion of intrapancreatic nerves and spread of cancer cells along extrapancreatic

nerves in the course of pancreatic cancer are still poorly understood. A family of proteins consisting of neurotrophic factors is of interest due to recent experimental data that showed their involvement in the neural invasion of pancreatic cancer[3,4].

Pleiotrophin (PTN) is a type of neurotrophic factor and is also known as a neurite growth-promoting factor. Human, mouse and rat PTN proteins are identical, and they share a 45% amino acid similarity with midkine-another member of this family[5,6]. PTN could promote neurite outgrowth in primary cultures of cortical neurons[7] and neuronal survival[8]. PTN is mainly expressed during early embryogenesis. In human adult tissues, PTN is markedly down-regulated and present only at minimal levels in very few tissues. It is not expressed in normal pancreatic tissues, but highly expressed in pancreatic cancer cells[9]. Kinnunen *et al* found a high expression level of PTN in 78% of the tumor samples from pancreatic cancer patients[10]. PTN and N-syndecan act as a receptor-ligand pair in neurite outgrowth. Anti-N-syndecan antibodies added to the culture media had an inhibitory effect on PTN-induced neurite outgrowth[11]. Therefore, PTN may play an important role in the neural invasion of pancreatic cancer.

RNA interference (RNAi) is a process during which double-stranded RNA induces the homology-dependent degradation of cognate mRNA[12]. In some organisms, the introduction of double-stranded RNA has been proven to be a powerful tool for suppressing gene expression through a process known as RNAi[13]. However, in most mammalian cells, it provokes a strong cytotoxic response[14]. This nonspecific effect could be circumvented using synthetic small interfering RNA (siRNA), which could mediate strong and specific suppression of gene expression[15]. Transfection of chemically synthesized siRNA is routinely used for gene silencing[16]. To circumvent the high cost of synthetic siRNA and establish stable gene knock-down cell lines by siRNA, several adenovirus vector systems, such as the BLOCK-iT™ Adenoviral RNAi Expression System, have been designed to produce siRNA intracellularly. The BLOCK-iT™ Adenoviral RNAi Expression System combines Invitrogen's BLOCK-iT™ RNAi and ViraPower™ Adenoviral technologies to facilitate the creation of a replication-incompetent adenovirus that delivers a synthesized short hairpin RNA (shRNA) of interest to dividing or non-dividing mammalian cells for RNAi analysis. These RNAi expression vectors are highly efficient for *in vitro* and *in vivo* gene transfer into a variety of mammalian cells and tissues and have been used in functional and gene therapy studies[17,18].

In this study, we investigated the silencing effects of pAd-shRNA-PTN on the *PTN* gene in the pancreatic cancer cell line BxPC-3, and observed the inhibition of neurite outgrowth from dorsal root ganglion (DRG) neurons *in vitro*. Our results demonstrated efficient and specific knockdown of *PTN* in the BxPC-3 pancreatic carcinoma cell line, and suggested that PTN is an attractive new target for the study of neural invasion in pancreatic cancer gene therapy.

MATERIALS AND METHODS

Cell lines, medium and reagents

The BLOCK-iT™ Adenoviral RNAi Kits (pAd/BLOCK-iT™-DEST Gateway^R Vector Kit; Gateway^R LR Clonase™ Enzyme Mix; 293A Cell Line; and BLOCK-iT™ U6 RNAi Entry Vector Kit) and Lipofectamine™ 2000 were purchased from Invitrogen Corp. (Carlsbad, California, USA). Monoclonal mouse antihuman PTN, anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) antibodies, and the secondary antibody (peroxidase-coupled goat anti-mouse IgG) were purchased from Santa Cruz Biotechnology (Santa Cruz, California, USA). The human pancreatic cancer cell line BxPC-3 was purchased from the American Type Culture Collection. The BxPC-3 cells were maintained in Dulbecco's modified Eagle's medium (DMEM) obtained from Life Technologies (Carlsbad, California, USA). Fetal calf serum (FCS) and Ham's F$_{12}$ medium were purchased from Gibco BRL (Carlsbad, California, USA).

Construction of recombinant adenovirus pAd-shRNA-PTN

The construction procedure for recombinant adenovirus pAd-shRNA-PTN has been described previously[19]. Briefly, according to data on the human pleiotrophin mRNA (GenBank accession no. NM002825), four pairs of complementary single-stranded oligonucleotides (ss oligos) were designed and synthesized using the Invitrogen's RNAi Designer online. Then, the ss oligos were annealed to create double-stranded oligonucleotides (ds oligos). The four ds oligos were cloned into the pENTR/U6 vector to produce four shuttle plasmid pENTR/U6-shRNAs that were transduced into the BxPC-3 cells by Lipofectamine™ 2000 after sequencing, to identify and select the shuttle plasmids showing optimal silencing effect. Oligo-3 was proven to have an optimal silencing effect. The sense and antisense strands of oligo-3 were 5'-CACCGCCAGAAGACTGTCACCATCTCGAAA-GATGGTGACAGTCTTCTGGC-3' and 5'-AAAAGC-CAGAAGACTGTCACCATCTTTCGAGATGGTGA-CAGTCTTCTGGC-3'. Then, the attL and attR (LR) recombination reaction was performed. Recombinant adenovirus pAd-shRNA-PTN was produced and amplified in HEK 293A cells; the viral titers were determined by TCID50 assays[20]. The construction of pAd-shRNA-PTN was confirmed *via* electron microscopic observation.

Procedure for infecting the BxPC-3 cells

The BxPC-3 cells were placed at a concentration of 1 × 10^6 cells per well into a 6-well plate, and 2 mL of normal DMEM along with 10% FCS was added into each well. On the day of infection (Day 0), 5 μL adenoviral stock (1 × 10^{10} pfu/mL) was added into a 2 mL fresh culture medium with 2% FCS (at a multiplicity of infection (MOI), i.e. an MOI of 50). Then, we removed the previous culture medium from the cells, mixed the medium containing virus gently, added it to each cell, and incubated it at 37℃ overnight. The following day (Day 1), we removed

the medium containing virus and replaced it with fresh DMEM containing 2% FCS. The cells were harvested on the 0th, 1st, 3rd, 5th, 7th, and 9th d after infection and assayed for knockdown of the *PTN* gene by immunocytochemistry, real-time quantitative polymerase chain reaction (PCR), and Western blotting analysis. In this study, we regarded the cells harvested on the 0th d after infection as the control.

Immunocytochemistry

Immunostaining of the human pancreatic cancer cell line BxPC-3 was performed on the 0th (control), 3rd, and 5th d after infection. The BxPC-3 cells were grown on glass slides and fixed with acetone; endogenous peroxidase was blocked by incubation with 0.3% H_2O_2 in methanol. The sections were washed and incubated overnight with a 1:20 dilution of anti-PTN antibody at 4℃. After subsequent wash in phosphate buffered saline (PBS), the secondary antibody was added and incubated for 1 h at room temperature. After another wash in PBS, the peroxidase activity was localized by staining with diaminobenzidine as the substrate. Then, the sections were rinsed in water, dried, and covered.

Total RNA isolation and real-time quantitative PCR

On the 0th, 1st, 3rd, 5th, 7th, and 9th d after infection, the medium was removed from each well. Total RNA from each plate of BxPC-3 cells was extracted (RNeasy Mini Kit, Qiagen). The extracted RNA was quantified by measuring the absorbance at 260 nm. The purity of the RNA was verified by calculating the ratio between the absorbance values at 260 and 280 nm. This ratio ranged between 1.83 and 2.00, demonstrating the high quality of the RNA. Reverse transcription reactions were performed at 50℃ for 30 min. The reaction mixtures were heated to 95℃ for 15 min to activate HotStarTaq (Qiagen). The forward and reverse primers of PTN were 5'-TCCTAG-TATTTTTTTCCTCAG-3' and 5'-CTTGTTTTCTGC-CAATAG-3', respectively; the forward and reverse primers of GAPDH were 5'-TCATCCCTGCCTCTACTG-3' and 5'-TGCTTCACCACCTTCTTG-3', respectively. PCR amplification was performed in a total volume of 20 μL: 4.4 μL PCR master mix (TaKaRa Ex Taq R-PCR Version, TaKaRa), 10 pmol of each primer, 2 mmol MgCl₂, 2 μL (1:15 000 dilution) SYBr Green Ⅰ (SYBr Green Ⅰ Nucleic Acid Gel Stain, Takara), and distilled water. PCR was performed using the ABI PRISM 7700 Sequence Detection System under the following conditions: 95℃ for 30 s and 35 cycles at 95℃ for 0 s for instrument setting to 0 s, 57℃ for 5 s, and 72℃ for 10 s. Cycle threshold (CT) values were obtained from the BIO-RAD iQ5 2.0 Standard Edition Optical System Software (BIO, RAD, USA). Data were analyzed using the ΔΔCT method and GAPDH served as an internal control.

Western blotting analysis

The cells were harvested on the 0th, 1st, 3rd, 5th, 7th, and 9th d after infection, washed once with cold PBS (pH 7.0), and lysed in a lysis buffer (150 mmol/L NaCl, 50 mmol/L Tris-HCl (pH 7.4), 2 mmol/L EDTA, and 1% NP-40) containing protease inhibitors (Boehringer Mannheim, Germany). The analysis was performed on all the lysates with equal amounts of protein (20 μg per lane), quantified by colorimetric detection based on the bicinchoninic acid (BCA) test. The samples were heated at 95℃ for 5 min and loaded on a 12% sodium dodecyl sulfate (SDS)-polyacrylamide gel. Following electrophoresis, the separated protein fractions were transferred onto a methanol-activated polyvinylidene fluoride (PVDF) membrane and incubated with anti-PTN and anti-GAPDH antibodies, followed by incubation with the corresponding secondary antibodies. The bands were visualized using the enhanced chemiluminescence system.

Monoculture of DRG neurons and their coculture with BxPC-3 cells

DRG neurons were dissociated from a 16-d rat fetus. An average of approximately 300 DRG neurons were plated on the poly-L-lysine (200 μg/mL)-coated glass cover slips (13 mm in diameter) placed in a 6-well plate and maintained overnight at 37℃ in a humidified incubator gassed with 5% CO_2 in air. Following this overnight setting period, co-cultures of the DRG neurons and BxPC-3 cells were prepared. BxPC-3 cells plated at a concentration of 1×10^5 cells per well in a 6-well plate and 2 mL of DMEM/F₁₂ medium with 10% FCS were added into each well. On the day of infection (Day 0), 50 μL adenoviral stock and 2 mL fresh DMEM/F₁₂ medium containing 2% FCS (at an MOI of 50) were added to the infected groups and 2 mL fresh DMEM/F₁₂ medium containing 2% FCS but without adenoviral stock was added to the control (uninfected) group. The previous culture medium was removed from the cells, and the fresh medium was added to each cell. The plate was swirled gently to disperse the medium. After incubating at 37℃ for 6 h, the glass cover slips with 300 DRG neurons were plated on it. The two cell types were cocultured for 7 d in the DMEM/F₁₂ medium containing 2% FCS and maintained at 37℃ in a humidified incubator with 5% CO_2 in air.

Statistical analysis

The images obtained from the Western blotting were scanned and analyzed using the Quantity One software. The ratios of PTN to GAPDH were calculated. The statistical significance between the control and infected groups was calculated using one-way ANOVA test. $P < 0.05$ was considered to indicate statistical significance.

RESULTS

Transmission electron microscopy

Two days after infection, we were able to find characteristic morphological changes. There were lots of scattered virus capsids in the nucleus, next to the nuclear membrane cytoplasm with few virus capsids (Figure 1A). At highest magnifications ($\times$ 60 000), the capsids showed no

Figure 1 Morphological changes of recombinant adenovirus pAd-shRNA-pleiotrophin in HEK 293A cells. Scale bars: 600 nm (A) and 200 nm (B).

Figure 2 Pleiotrophin immunostaining of BxPC-3 human pancreatic cancer cells (× 400).

connection to each other. Virus capsids were 50-70 nm with an almost round appearance (Figure 1B).

PTN expression in pancreatic cancer cells

Using immunocytochemistry, we found a strong staining pattern for PTN in the cytoplasm of normal BxPC-3 cells (control, Figure 2A). The silencing rate was determined in comparison with the control alone. The expression rate of the PTN protein on the membrane was decreased by 30% (3 d, Figure 2B) and 70% (5 d, Figure 2C).

Down-regulation of PTN mRNA expression in the pancreatic cancer cell line BxPC-3

The efficacy of pAd-shRNA-PTN with regard to knock-down of PTN mRNA was confirmed through real-time quantitative PCR analysis. The melting temperature range of PTN was 86.5-87.5℃, and the melting temperature range of GAPDH was 89.5-90.5℃. No nonspecific amplification was observed. High expression levels of PTN mRNA were observed in the control. The inhibition rates of PTN mRNA expression in the BxPC-3 cells were 20%, 80%, 50%, and 25% on the 1st, 3rd, 5th and 7th d after infection. The PTN mRNA level was decreased on the 1st d, and down-regulation of PTN mRNA expression was most obvious on the 3rd post-infection day. On the 5th d, the PTN mRNA level increased gradually, and the PTN mRNA expression approximately returned to the level of normal BxPC-3 cells on the 9th post-infection day (Figure 3).

Western blotting analysis of the down-regulation of PTN protein expression in the pancreatic cancer cell line BxPC-3

Western blotting analysis of the anti-PTN-specific antibodies revealed that PTN protein expression in BxPC-3 cells infected with pAd-shRNA-PTN was markedly suppressed on days 3-7 compared with the control (0 d). The inhibition rates of PTN protein expression were 47.5%, 80.5% and 20%, respectively, on the 3rd, 5th and 7th d following pAd-shRNA-PTN infection. The maximal knockdown level was observed on the 5th post-infection day. The PTN protein levels began to rise on the 7th post-infection day (Figure 4).

Co-cultures of DRG neurons and BxPC-3 cells

Healthy DRG neurons began to adhere and extend their processes within 3 h of plating. Within 24 h, the neurons were mainly adherent. On the 1st d, the DRG neurons of the monoculture were mostly adherent, and were round or elliptical in shape and approximately 25 μm in diameter. Decades of them gathered together, and no neurite outgrowth was observed from DRG neurons; glial and Schwann cells were also not observed (Figure 5A). During cultivation, morphological changes in the DRG neurons were not obvious. On the 7th d, the number of neurons decreased, and very few neurons extended neurites (Figure 5B); these neurites were significantly shorter than those extending from the neurons co-cultured with normal BxPC-3 cells

Figure 3 Inhibitory effects on pleiotrophin mRNA expression in the pancreatic cancer cell line BxPC-3. PTN: Pleiotrophin.

Figure 4 Inhibitory effects on pleiotrophin protein expression in the pancreatic cancer cell line BxPC-3. PTN: Pleiotrophin.

(Figure 5D). On the 7th d after co-culture with BxPC-3 cells, the control (co-cultured with normal BxPC-3 cells) DRG neurons were larger in size and irregular in shape. Robust neurite outgrowth was observed, with extensive outgrowth forming reticulate links and neural networks (Figure 5C). In contrast to the control, the DRG neurons co-cultured with the infected BxPC-3 cells shrunk; the number of neurons that extended neurites was significantly decreased, as was the length of the neurites. No neural networks were formed (Figure 5D).

DISCUSSION

Pancreatic cancer is characterized by perineural invasion[21], early lymph node metastasis, and poor prognosis[22,23]. Perineural invasion is an important cause of local recurrence, but little is known about its mechanism. The perineural invasion originates from not only the extrapancreatic nerve but also the intrapancreatic nerve in pancreatic carcinoma[24]. It is likely that as a neurite growth-promoting factor, PTN acts synergistically to promote the development of perineural invasion in pancreatic cancer. Weber *et al*[9] showed that PTN is expressed in gastrointestinal and, particularly, in pancreatic cancer cells. Using immunocytochemistry, 10 different human pancreatic cancer cell lines were analyzed for PTN expression. Six cell lines were positively stained for PTN: A816-4, BxPC-3, Panc-Tu1, SW850, Panc89, and Colo357[9]. In this study, we also found that PTN was clearly expressed in BxPC-3 cells.

In cancer gene therapy, the success of a strategy depends on its cancer specificity and efficient delivery into mammalian cells. In this study, the RNAi technique and recombinant adenovirus were used to achieve this. The availability of a high virus titer and infection of a broad spectrum of cell types makes adenovirus the vector of choice for siRNA delivery. For example, oncogenic K-ras and other genes could be specifically and stably inactivated in human pancreatic cancer cells using a viral RNA interference (RNAi) vector, leading to loss of tumorigenicity[25]. The construction of recombinant adenovirus was confirmed *via* electron microscopic observation. The pAd/BLOCK-iT™ adenoviral construct is replication-

incompetent and does not integrate into the host genome. Therefore, once transduced into mammalian cells, the shRNA of interest will be expressed as long as the viral genome is present. In the actively dividing cells, the adenovirus genome is gradually diluted as cell division occurs, resulting in an overall decrease in shRNA expression over time, i.e. the target protein levels generally return to background levels within 1-2 wk following transduction. For reducing the dilution, we cultured BxPC-3 cells in DMEM/F$_{12}$ medium containing 2% FCS to reduce cell division. Besides, we used an MOI of 50 to obtain the optimal degree of target gene knockdown. In this study, we found that *PTN* gene knockdown in BxPC-3 cells might be detectable (20%) by real-time quantitative PCR on the 1st post-infection day, with maximal knockdown levels (80%) observed on the 3rd post-infection day. On the 5th d, as the adenovirus genome was diluted, the level of PTN mRNA was increased gradually and the PTN mRNA expression returned to the level observed in control BxPC-3 cells on the 9th post-infection day. Immunocytochemistry and Western blotting analysis also revealed the same tendency, except that the maximal knockdown levels of PTN protein were observed two days later; this may be related to the translation process of the protein.

In the nervous system, PTN has been shown to induce neurite outgrowth from dopaminergic neurons[8,26]. PTN and its receptor, N-syndecan, are important in promoting neurite outgrowth. N-syndecan expression was stronger in both the brain and spinal cord during the later developmental period (days 14-16 of gestation); N-syndecan isolated from a 16-d-old rat fetus bound strongly to PTN[27]. Anti-N-syndecan antibodies bound to the surface of the neurites and also perturbed neurite growth[28]. PTN was also involved in the peripheral nerve regeneration following nerve injury and functional recovery following neural transplantation in rats[29,30]. Taken together, the available

Figure 5 Morphological changes in dorsal root ganglion neurons. A: Monoculture of dorsal root ganglion (DRG) neurons on the 1st d (× 400); B: Monoculture of DRG neurons on the 7th d (× 400); C: Co-culture of DRG neurons and infected BxPC-3 cells (× 200); D: Co-culture of DRG neurons and normal BxPC-3 cells (× 200). Scale bars: 25 μm (A, B) and 50 μm (C, D).

evidence suggests that PTN bound to N-syndecan can promote neurite outgrowth from DRG neurons. In this study, we selected DRG neurons for investigation because they may play a role in the neural invasion of pancreatic cancer[31]. We dissociated DRG neurons from a 16-d-old rat fetus for monoculture or co-culture with BxPC-3 cells. The results indicated that pAd-shRNA-PTN could also be used to infect the BxPC-3 cells and suppress *PTN* gene expression efficiently. In contrast to the number of control cells, the number of DRG neurons co-cultured with infected BxPC-3 cells and extended neuritis significantly decreased. These results were in agreement with those of our previous studies[19].

In conclusion, the adenoviral construct pAd-shRNA-PTN showed efficient and specific knockdown of *PTN* in the pancreatic cancer cell line BxPC-3, and the inhibition of neurite outgrowth from DRG neurons was observed *in vitro*. Therefore, the *PTN* gene and pAd-shRNA-PTN may be very important for the research on the neural invasion of pancreatic cancer. We will set up a model of pancreatic cancer *in situ* in nude mice in the future studies. By injecting pAd-shRNA-PTN stock, we can investigate the effects of the *PTN* gene and adenoviral construct pAd-shRNA-PTN on the neural invasion of pancreatic cancer.

COMMENTS

Background

Pancreatic cancer is still one of the most aggressive and intractable human malignant tumors. Perineural invasion extending into the pancreatic nerve plexus is

a histopathologic characteristic of pancreatic cancer. However, the mechanisms contributing to the invasion of intrapancreatic nerves and spread of cancer cells along extrapancreatic nerves in the course of pancreatic cancer are still poorly understood. As a neurite growth-promoting factor, pleiotrophin (PTN) and its receptor, N-syndecan, may play a very important role in tumor growth and neural invasion of pancreatic cancer. Therefore, the authors of this study used recombinant adenovirus pAd-shRNA-PTN to investigate the silencing effects of PTN in pancreatic cancer cells and to observe the inhibition of pAd-shRNA-PTN on the neurite outgrowth from dorsal root ganglion (DRG) neurons *in vitro*.

Research frontiers

Perineural invasion extending into the pancreatic nerve plexus is a histopathologic characteristic of pancreatic cancer. The neural invasion of pancreatic cancer leads to local recurrence, metastasis and poor prognosis, which have been brought difficulty to diagnosis and treatment of pancreatic cancer.

Innovations and breakthroughs

In recent years, researches of pancreatic cancer have focused on the biological characteristics, especially perineural invasion. This study explored the effects of pAd-shRNA-PTN on PTN of pancreatic cancer cells and neurites outgrowth of DRG neurons, which might reveal the relative mechanism of the neural invasion.

Applications

The study indicates that PTN appears to be an attractive target for nerve infiltration of pancreatic cancer gene therapy.

Terminology

PTN is a type of neurotrophic factor and is also known as a neurite growth-promoting factor. N-syndecan is a transmembrane protein and a high- affinity receptor for PTN. PTN and N-syndecan are important in promoting neurite outgrowth. RNA interference (RNAi) is a process during which double-stranded RNA induces the homology-dependent degradation of cognate mRNA. RNAi has been proven to be a powerful tool for suppressing gene expression.

Peer review

The study investigated the silencing effects of recombinant adenovirus pAd-shRNA-PTN on PTN gene in pancreatic cancer cells, and observed the inhibition of pAd-shRNA-PTN on the neurite outgrowth from DRG neurons *in vitro*. The subject is important because very little is known about the molecular mechanism of perineural invasion in pancreatic cancer, that is to say, this study

has revealed the role of *PTN* gene in perineural invasion using pAd-shRNA-PTN. The study is well designed.

Abstract

AIM: To investigate the contribution of periostin in nicotine-promoted gastric cancer cell proliferation, survival, invasion, drug resistance, and epithelial-mesenchymal transition (EMT).

METHODS: Gastric cancer cells were treated with nicotine and periostin protein expression was determined by immunoblotting. Periostin mRNA in gastric cancer cells was silenced using small interfering RNA (siRNA) techniques and periostin gene expression was evaluated by quantitative reverse transcription-polymerase chain reaction. Gastric cancer cells transfected with control or periostin siRNA plasmid were compared in terms of cell proliferation using the methylthiazolyldiphenyl-tetrazolium bromide assay. Cell apoptosis was compared using annexin V-fluoresceine isothiocyanate and propidium iodine double staining. Tumor invasion was determined using the Boyden chamber invasion assay, and the EMT marker Snail expression was evaluated by immunoblotting.

RESULTS: Nicotine upregulated periostin in gastric cancer cells through a COX-2 dependent pathway, which was blocked by the COX-2-specific inhibitor NS398. Periostin mRNA expression was decreased by ~87.2% by siRNA in gastric cancer cells, and stable periostin-silenced cells were obtained by G418 screening. Periostin-silenced gastric cancer cells exhibited reduced cell proliferation, elevated sensitivity to chemotherapy with 5-fluorouracil, and decreased cell invasion and Snail expression ($P < 0.05$).

CONCLUSION: Periostin is a nicotine target gene in gastric cancer and plays a role in gastric cancer cell growth, invasion, drug resistance, and EMT facilitated by nicotine.

INTRODUCTION

Gastric cancer is malignant and has a high occurrence. It originates from normal gastric epithelial cells that undergo various precancerous diseases, such as chronic atrophic gastritis and intestinal metaplasia, and then eventually cancer[1].

The relationship between smoking and gastric cancer has received increasing interest. A large population epidemiological investigation revealed that previous and current smokers had a 43% and 57% higher incidence of gastric cancer than non-smokers, respectively[2]. Therefore, smok-

ing is the most important behavioral factor leading to gastric cancer[3]. About 60% of tobacco components are carcinogens, including conjugated aromatic chemicals, nitric amines, aromatic amines, trace metals, and nicotine[4]. Nicotine is the most active carcinogen in cigars, and has been shown to promote gastric cancer cell proliferation and neoangiogenesis *in vivo* and *in vitro*[5]. Nicotine activates β-adrenoceptors and the downstream protein kinase C-β, extracellular signal-regulated kinases 1/2, and cyclooxgenase-2 (COX-2) signaling pathways in gastric cancer cells, thus promoting gastric cell mitosis and proliferation[6]. In addition, nicotine contributes to the invasion and metastasis of gastric cancer through the activation of COX-2 and vascular endothelial growth factor receptors in gastric cancer cells[7]. Therefore, COX-2 is an important nicotine-regulated molecule in gastric cancer cells and an important oncogene in the pathogenesis of gastric cancer. Tumor invasion means that malignant cells penetrate the basal membrane, migrate away from primary tumor sites and invade surrounding tissues. Tumor invasion results from the interaction between tumor cells and surrounding mesenchymal cells, leading to further spreading and the malignant advancement of tumors. During the invasion of epithelial-originated malignant tumors, the polarity of the epithelial cells disappears and their migration and mobility increase. Subsequently, epithelial cells are transformed into mesenchymal cells, which is known as the epithelial-mesenchymal transition (EMT).

Periostin, or osteoblast-specific factor 2 (OSF-2), is a newly discovered adhesion molecule that is over-expressed in various tumors, including oral cancer, thyroid cancer, breast cancer, and gastric cancer, and is correlated with tumor invasion, distant metastasis, and angiogenesis[8-11]. Periostin is a mesenchyme-specific protein expressed and secreted by tumor mesenchymal cells. Transfection and over-expression of the periostin gene in 293T cells has been shown to cause EMT as well as cell migration, invasion, and adhesion[12]. Moreover, metastatic loci were formed when recombinant cells over-expressing periostin were transplanted into immune-deficient mice[12].

Although facilitation by nicotine of the invasion and EMT of tumor cells has been confirmed by numerous investigators[5-7], to the best of our knowledge, the relationship between nicotine and the EMT-marker periostin has not been reported. We studied the expression of periostin induced by nicotine treatment in gastric cancer cells *in vitro*, silenced the periostin gene using small interfering RNA techniques and investigated the effects of nicotine on the growth, apoptosis, and invasion of gastric cancer cells. Our study suggested that periostin might be a downstream target gene regulated by nicotine in gastric cancer cells and may significantly contribute to nicotine-induced proliferation, metastasis, and EMT in gastric cancer cells.

MATERIALS AND METHODS

Reagents and equipment

The 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), annexin V-fluoresceine isothiocyanate (V-FITC), propidium iodine (PI), nicotine, and the COX-2-specific inhibitor NS 398 were from Sigma (St. Louis, MO, USA). The fetal bovine serum was from Sijichun Bioengineering Materials, Inc. (Hangzhou, Zhejiang, China). The DMEM culture media was from Invitrogen-GIBCO (Carlsbad, CA, USA). Vectors for periostin siRNA were constructed by lab co-workers. LipofectAMINE-2000 and TRIzol were from Invitrogen. The reverse transcription-polymerase chain reaction (RT-PCR) kits were from Treasure Biological, Inc. (Dalian, Liaoning, China). The forward and reverse primers were from Shanghai Bioengineering Inc. (Shanghai, China). The flow cytometer (FACS-440) was from BD Biosciences (Franklin Lakes, NJ, USA). The inverted phase contrast microscope (CK-40) was from Olympus (Center Valley, PA, USA). The gastric cancer cell line SGC-7901 was from the cell bank of the Shanghai Biological Institute of the Chinese Institute of Science. The T4 DNA Ligase was from Takara Bio Inc. (Otsu, Shiga, Japan) and the Boyden chamber was from Corning Costar Corp. (Cambridge, MA, USA).

Cell culture

Gastric cancer cell line SGC-7901 was cultured in DMEM media (high glucose) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin. Cells were maintained at 37℃ and 5% CO_2 in an incubator, and the culture medium was changed every 2-3 d. SGC-7901 cells were treated with nicotine at 200 ng/mL for 24 h before lysing for immunoblotting experiments. To determine if periostin upregulation by nicotine was related to the COX-2 pathway, the COX-2-specific inhibitor NS 398 was applied to SGC-7901 cells 6 h before nicotine treatment.

Construction, transfection, and screening of siRNA plasmids

Targeting sequences (complimentary oligonucleotides) for siRNA of periostin were designed from the human periostin sequence (GenBank accession number NM_006475.2) based on general design principles of siRNA. Forward primers for U6 promoter amplification and reverse primers (at bp 136, 246, and 268) for periostin amplification were used for 2-step PCR to amplify siRNA expression cassettes at 94℃ for 30 s and 72℃ for 90 s over 40 cycles. PCR end products were ligated with precut plasmid pRNAT-U6.1 and T4 DNA ligase at 16℃ overnight. Ligation products were transformed into competent *Escherichia coli* DH5α, followed by blue-white screening, enzyme digestion confirmation, and glycerol storage for gene sequencing at Shen You, Inc. The pRNAT-U6.1-periostin plasmid with the correct sequence was used to prepare and purify a large amount of plasmid DNA.

The gastric cancer cell line SGC-7901 was recovered, subcultured, and plated in 6-well plates at a density of 4×10^5/mL 24 h before transfection, such that the cells were 90% confluent at transfection. SGC-7901 cells were transfected with either pRNAT-U6.1-periostin siRNA plasmid or pRNAT-U6.1 control plasmid. Cells were observed separately for the periostin gene and protein expression by RT-PCR and immunoblots 48 h after transfection. SGC-7901 cells with successful transient pRNAT-U6.1-

periostin siRNA transfection and optimal periostin siRNA were selected, and culture medium with G418 at 400 and 800 µg/mL was used for concentration increase screening.

RT-PCR for detection of periostin mRNA

Total RNA was isolated from SGC-7901 cells with different treatments 48 h after transfection, and RT-PCR was performed to quantify periostin mRNA expression normalized against GAPDH. Five micrograms of RNA was used to synthesize cDNA, followed by PCR.

The periostin forward primer was 5'-GCACTCT-GGGCATCGTGGGA-3' and the periostin reverse primer was 5'-AATCCAAGTTGTCCCAAGCC-3'. The GAPDH forward primer was 5'-CTGCACCACCAACT-GCTTAG-3' and the GAPDH reverse primer was 5'-TGAAGTCAGAGGAGACCACC-3'.

The amplicons for periostin and GAPDH were 132 and 407 bp, respectively.

The thermal profile of PCR for periostin and GAPDH mRNA detection was 94℃ for 4 min over 1 cycle, 94℃ for 30 s, 57℃ for 30 s, and 72℃ for 1 min over 33 cycles, followed by 72℃ for 7 min over 1 cycle.

The PCR products were electrophorized on 1.5% agarose gel in Tris-acetate-EDTA (TAE) buffer. The bands of the PCR products were quantified by grayscale readings using a gel imaging system. The ratios of the grayscale readings of the band for periostin *vs* those for GAPDH using the same samples were calculated as the relative mRNA expression of periostin. Periostin suppression rate (%) = (1 - periostin mRNA relative expression in the pRNAT-U6.1-periostin siRNA group/periostin mRNA relative expression in pRNAT-U6.1 control group) × 100%.

Immunoblots

Proteins were isolated from SGC-7901 cells and the protein concentrations were determined. The proteins were separated using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) gels (polyacrylamide concentration 100 g/L) and electrophoretically transferred to PVDF membranes. The PVDF membranes were blocked with 3% BSA at 37℃ for 1 h and probed with the primary antibody mouse anti-human periostin, Snail (1:100), or β-actin (1:1000) monoclonal antibody for 2 h. The bound antibody was detected by horseradish peroxidase-conjugated goat anti-mouse IgG (1:5000) and enhanced chemiluminescence. The blots were washed with 1 × Tris-buffered saline with Tween buffer for 10 min, 3 times between each step. The density of the targeted bands was quantified using the Developer 100 Plus Imaging Analysis System.

Cell growth assay

The cell growth rate was determined using the methylthiazolyldiphenyl-tetrazolium bromide (MTT) assay and growth curve depictions. Cells with pRNAT-U6.1-periostin siRNA or control plasmid (2×10^5 cell/mL) were seeded onto 96-well plates with 100 µL in each well, cultured with DMEM media supplemented with 10% fetal bovine serum, and observed for cell proliferation at 24, 48, and 72 h after seeding. For the cell viability and growth assay, 10 µL

of MTT solution (5 mg/mL) was added into each well and incubated at 37℃ for 4 h, and the reaction terminated with a detergent solution to lyse the cells and solubilize the colored formazan crystals. The supernatant was centrifuged at 3000 r/min for 10 min to obtain a formazan pellet. The supernatant was removed, and the pellet was dissolved completely with 100 µL DMSO and observed at a wavelength of 570 nm using an ELISA plate reader.

Cell apoptosis assay

Cell apoptosis was analyzed by annexin V-FITC and PI double staining. Cells with pRNAT-U6.1-periostin siRNA or control plasmid were evaluated for apoptosis after 24, 48, and 72 h of culture. From each well, 2×10^5 cells were harvested, and the supernatant was collected by centrifugation at 2000 r/min for 5 min. The pellet was washed with PBS buffer once, resuspended in 100 µL 1 × binding buffer, supplied with 2.5 µL annexin V and 5 µL PI (final concentration of 10 µg/mL), incubated for 15 min in the dark, and assayed for cell apoptosis by flow cytometry. The results were analyzed using Lysis software.

Tumor invasion assay

The Boyden chamber invasion assay was used to evaluate the ability of tumor cells to invade. Tissue culture plates with 24 wells and Transwell filter membranes were used for the experiments. Cells with pRNAT-U6.1-periostin siRNA or control plasmid were cultured in the presence or absence of nicotine for 4 days, harvested at 3×10^6/mL, and seeded onto the upper part of the Transwell chamber at 100 µL/well. The basement membrane matrix preparation, Matrigel, served as the matrix barrier and the lower part of the Transwell chamber was filled with 500 µL of culture medium as a chemoattractant. The chamber was kept at 37℃ in a 5% CO_2 incubator for 24 h before regular fixation and Trypan blue staining. The cells on the upper surface of the filter membrane were removed with a cotton swab, and the number of cells migrating through the membrane was determined. Three parallel membranes were counted for each condition. The number of cells migrating through the Matrigel was normalized to those through the non-Matrigel to obtain an index of relative percent migration, indicating the ability of tumor cells to invade *in vitro*.

Statistical analysis

Statistical analysis was performed using commercially available software (SPSS version 14.0). Data are presented as the mean ± SE. Means of 2 groups were compared using the Student's *t* test (unpaired, two tailed). Means of more than 2 groups were compared using one-way analysis of variance (ANOVA) followed by post-hoc testing using the Least-Significant-Difference test. $P < 0.05$ was considered statistically significant.

RESULTS

Nicotine induced periostin upregulation in gastric cancer cells via a COX-2 dependent pathway

Immunoblotting showed that 200 µg/mL nicotine at

Figure 1 COX-2 inhibitor NS398 showed inhibitory effects on nicotine (200 ng/mL)-induced periostin expression after 24 h of treatment. COX-2-specific inhibitor NS398 (10 μmol/L) was applied to SGC-7901 cells 6 h before nicotine (200 μg/mL) treatment. A: Western blotting bands of periostin protein in four groups of gastric cancer cells; B: Quantification analysis demonstrated significantly higher relative expression of periostin in the nicotine group than in the other three groups ($P < 0.05$). Notes: CON: Control; Nicotine: Treated with nicotine; NS398: Treated with COX-2-specific inhibitor NS398; Ni + NS: Combined treatment with nicotine and NS398.

24 h significantly upregulated periostin protein expression in SGC-7901 cells, suggesting that periostin could be a downstream target of nicotine in gastric cancer cells. Pretreatment with the COX-2-specific inhibitor NS 398 almost completely blocked the upregulation of periostin by nicotine in SGC-7901 cells. NS 398 also reduced periostin protein expression in the absence of nicotine in SGC-7901 cells (Figure 1).

Effects of periostin siRNA on its mRNA expression
The mRNA level of periostin was significantly reduced in all groups (S1-S4) and was most evident in S2 at 87.2% *vs* the plasmid control, suggesting that the periostin gene was successfully silenced by siRNA. SGC-7901 cells with successful transfection of the siRNA S2 plasmid were further screened in culture medium supplemented with increasing concentrations of G418 at 400 or 800 μg/mL. The stably silenced cells were finally maintained in culture media with 400 μg/mL G418 (Figure 2).

Inhibitory effects of periostin siRNA on nicotine-induced gastric cancer cell proliferation
SGC-7901 cells with successful transfection of the control plasmid (siRNA-C) showed slow growth in the MTT assay, but growth was significantly accelerated by nicotine treatment. SGC-7901 cells with successful transfection of the periostin siRNA plasmid (siRNA-P) showed much slower growth *vs* siRNA-C under both the basal and nicotine-stimulated conditions. Additionally, siRNA-P showed increased proliferation in response to nicotine stimulation, indicating that nicotine-induced cell proliferation could not be fully blocked by silencing periostin in SGC-7901 cells (Figure 3).

Figure 2 Relative expression of periostin mRNA 48 h after transfection by siRNA plasmid. The silencing effect of the transfection of periostin siRNA plasmid in SGC-7901 cells was confirmed by quantitative reverse transcription-polymerase chain reaction 48 h after transfection. Four representative results are shown (S1-S4). SiRNA-C indicates gastric cancer cells with control plasmid. Control indicates gastric cancer cells without transfection. [a]$P < 0.05$ *vs* control. The Y ordinate indicates the ratio of periostin mRNA normalized to that of house-keeping genes. Notes: siRNA-S1, siRNA-S2, siRNA-S3, siRNA-S4: four representative results of periostin siRNA transfection; siRNA-C: vacant siRNA-control; control: SGC-7901 cells without transfection.

Figure 3 Periostin siRNA inhibited nicotine-promoted cell growth in gastric cancer cells. SGC-7901 cells with stable expression of siRNA-periostin (siRNA-P) and vacant siRNA-control (siRNA-C) were treated with nicotine. Cells were then lysed to analyze cell viability using the methylthiazolyldiphenyl-tetrazolium bromide assay at 0, 24, 48, and 72 h of treatment, and growth curves were constructed. The viability of the siRNA-C+nicotine group was significantly higher than those of the other three groups at the 48 and 72 h time points ($P < 0.05$), which is indicated by "a". Notes: siRNA-C: vacant siRNA-control; siRNA-P transfected with periostin.

Stimulatory effects of periostin siRNA on chemotherapy-induced apoptosis of gastric cancer cells
SiRNA-P showed higher sensitivity to 5-fluorouracil (5-FU, 50 mg/L) treatment than did siRNA-C, as revealed by flow cytometry. After 24 h of 5-FU treatment, the apoptotic rate did not differ between the two groups (4.36% *vs* 6.06%, siRNA-P *vs* -C). However, after 48 and 72 h, siRNA-P had a significantly higher apoptotic rate than did siRNA-C (13.3% *vs* 22.1%, 20.5% *vs* 39.7%) (Figure 4).

Effects of periostin siRNA on invasion and the expression of the EMT marker Snail in gastric cancer cells
SiRNA-P showed a significantly lower index of invasion (21.8% ± 4.11%) than did siRNA-C (55.4% ± 2.64%), in-

Figure 4 Periostin siRNA increased the sensitivity of gastric cancer cells to 5-fluorouracil-induced apoptosis. SGC-7901 cells with stable expression of siRNA-periostin (siRNA-P) and vacant siRNA-control (siRNA-C) were treated or not with chemotherapy agent 5-FU. siRNA-periostin significantly increased the sensitivity of 5-FU treated gastric cancer cells both at 48 h and 72 h ($^a P <$ 0.05). Notes: siRNA-C: Vacant siRNA-control; siRNA-P: Transfected with periostin; 5-FU: 5-fluorouracil (50 mg/L).

Figure 5 The effect of periostin siRNA on the ability of gastric cancer cells to invade. SGC-7901 cells with stable expression of siRNA-periostin (siRNA-P) and vacant siRNA-control (siRNA-C) were treated with nicotine and evaluated for cell invasion using the Boyden chamber invasion assay.

Figure 6 The inhibitory effect of periostin siRNA on nicotine-induced Snail protein expression. A: Western blotting bands of Snail protein in four groups of gastric cancer cells. B: Relative expression of Snail in the above four groups. Nicotine significantly increased the relative expression of Snail protein in gastric cancer cells ($P < 0.05$). However, there were no significant differences in Snail expression between the siRNA-P group and the siRNA-P+nicotine group ($P > 0.05$). Notes: siRNA-C: vacant siRNA-control; siRNA-P: Transfected with periostin; Ni: Treated by 200 ng/mL nicotine.

dicating that silencing of periostin can reduce the capability of gastric cancer cells to invade. Similarly, with nicotine treatment, siRNA-P also showed significantly less invasion (29.5% ± 3.11%) than did siRNA-C (29.5% ± 3.11%) (Figure 5).

The expression of the EMT marker, Snail, was determined in siRNA-P and siRNA-C by immunoblotting. The Snail protein was significantly decreased in siRNA-P compared to the siRNA-C group, both in nicotine-treated and nicotine–untreated groups. Nicotine treatment significantly increased Snail protein expression in siRNA-C, but not in siRNA-P (Figure 6).

DISCUSSION

We observed that nicotine can upregulate periostin protein expression in gastric cancer cells in a COX-2-dependent pathway, which can be blocked by the COX-2-specific inhibitor NS 398. Periostin mRNA expression was significantly decreased by 87.2% in siRNA-P, which was stably silenced with G418 screening. Cell proliferation in siRNA-P was significantly inhibited compared to siRNA-C. Nicotine can promote gastric cancer cell growth, which can be partially blocked by periostin siRNA. Furthermore, siRNA-P had a significantly increased sensitivity to apoptosis induced by the chemotherapy reagent, 5-FU, compared to siRNA-C, especially after 48 and 72 h. Nicotine increased the ability of gastric cancer cells to invade *in vitro*, and siRNA-P showed decreased invasion in the presence or absence of nicotine compared to the controls. EMT is an important underlying mechanism used by epithelial cancer cells to invade and metastasize. We found that the EMT marker, Snail protein expression, decreased in siRNA-P *vs* siRNA-C with or without nicotine treatment, indicating that periostin expression could be required for EMT in gastric cancer cells.

Our study revealed that periostin expression was controlled by nicotine. As the most active carcinogen in tobacco, nicotine is well known to promote lung cancer, and its relation to other types of tumors has come under increasing scrutiny. Nicotine has been shown to activate COX-2 in gastric cancer cells, which is related to the growth, survival, invasion, and metastasis of gastric cancer cells[5,7,12]. COX-2 is also an important prognostic factor for gastric cancer. The higher the expression of COX-2 in gastric cancer cells is, the worse the prognosis is[13]. We also found that the regulation of periostin by nicotine was COX-2 dependent. Inhibition of COX-2 almost completely blocked the upregulation of periostin by nicotine, and inhibition of COX-2 itself downregulated periostin expression in gastric cancer cells. These findings indicate that the regulation of periostin by nicotine is completely COX-2 dependent and

that periostin expression is partially dependent on COX-2 in gastric cancer cells. Currently, there are only a few reports on the relationship between COX-2 and periostin. It has been shown that activation of the signaling molecule Wnt can concurrently upregulate COX-2 and periostin in mammary epithelial cells[14]. That both COX-2 and periostin are expressed at the same time in gastric cancer cells, along with the relationship of COX-2 to the prognosis of gastric cancer, warrants further investigation to determine whether periostin can serve as a prognostic indicator for gastric cancer.

Our research indicated that periostin gene silencing could significantly increase the sensitivity of gastric cancer cells to 5-FU. A hypoxic environment has been shown to upregulate periostin expression and promote cell survival *via* activation of the downstream Akt/PKB signaling pathway in non-small cell lung cancer cells[15]. In pancreatic cancer cells, periostin promoted resistance to hypoxia-induced apoptosis through binding to integrin on the cell membrane and activation of the downstream PI3K-AKT signaling pathway, which promotes cell survival[16]. At diagnosis, patients with gastric cancer usually have micro-metastasis of gastric cancer cells into non-gastric areas, such as the liver, abdominal cavity, bone marrow, and peripheral circulation[17-20]. Chemotherapy that does not completely remove these latent cells leads to distant metastasis and the recurrence of tumors. This indicates that tumor cells with metastatic potential may have resistance to apoptosis, and periostin could be an underlying mechanism used to promote invasion, metastasis, and drug resistance in cancer cells *via* a complex intracellular signaling network.

Our findings suggest that periostin expression is required for the EMT of gastric cancer cells. Periostin is a mesenchyme-specific gene[21] expressed and secreted by tumor mesenchymal cells[22] and associated with the EMT of tumor cells. In fact, EMT induced by nicotine has been the subject of numerous publications. Nicotine-induced cell invasion and EMT has been shown to relate to the nicotinic acetylcholine receptors on the surface of lung cancer cells[23,24]. Nicotine was recently shown to induce EMT in gastric cancer cell lines through the activation of 5-lipoxygenase[25]. During EMT, epithelial markers decrease, mesenchymal markers increase, and periostin mainly resides in mesenchymal cells[26]. It could be that nicotine-induced periostin upregulation results from EMT, leading to fewer epithelial cells and more mesenchymal cells. However, our results showed that in gastric cancer cells with the periostin gene downregulated by siRNA, there was significant downregulation of the EMT marker gene, Snail, with nicotine treatment, along with the inhibition of cell growth, drug resistance, and tumor invasion. This suggests that periostin changes in gastric cancer cells are not a result of EMT and that, instead, periostin contributes to EMT *via* a specific pathway.

In this *in vitro* study, the concentration of nicotine was 200 ng/mL, this was chosen as the most appropriate concentration from our preliminary results. In smokers, venous nicotine levels range from 5 to 15 ng/mL, which is much lower than the level used in our *in vitro* study[27]. Nicotine, which can be absorbed *via* respiratory tissues, the skin, and the gastrointestinal tract, takes part in the initiation and promotion of carcinogenesis in the gastrointestinal tract. Because this is a gradual process, a lower *in vivo* nicotine concentration could enhance the detrimental effects of other carcinogens over a long period of time. In fact, the *in vitro* effects of nicotine on periostin expression were only observed up to 24 h in this study. Whether this effect is longer lasting will be investigated in subsequent *in vivo* animal experiments.

In summary, we showed that periostin is a nicotine-regulated gene that contributes to nicotine-induced cell growth, drug resistance, invasion, and EMT in gastric cancer cells. These findings may lead to a new target for the prevention of nicotine-induced gastric cancer.

ACKNOWLEDGMENTS

COMMENTS

Background

Gastric cancer has a high occurrence and its relationship with smoking has been a focus of recent research. As the most active carcinogen in cigars, nicotine has been shown to promote gastric cancer cell proliferation and neo-angiogenesis *in vivo* and *in vitro*. Periostin is a mesenchyme-specific protein that is over-expressed in gastric cancer cells and is related to invasion, distant metastasis and angiogenesis in many tumors.

Research frontiers

During the invasion of epithelial-originated malignant cancers, the polarity of epithelial cells disappears along with an increase in migration and mobility, which is known as the epithelial-mesenchymal transition (EMT). Nicotine can enhance invasion and EMT in various tumor cells; however, the relationship between nicotine and EMT-marker periostin has not been unequivocally addressed. In this study, the authors demonstrate that the expression of periostin can be induced by nicotine treatment in gastric cancer cells and that proliferation, drug resistance and invasiveness in gastric cancer cells is induced by nicotine.

Innovations and breakthroughs

Recent reports have highlighted the importance of the EMT and its related molecules, including Snail, in gastrointestinal carcinogenesis and progression. In gastric cancers, EMT is enhanced. This is the first study to report that EMT-related periostin is upregulated by nicotine in gastric cancer cells. Furthermore, The authors' *in vitro* studies suggest that this protein may be the cause of the proliferation, drug resistance and invasiveness induced by nicotine in this cancer.

Applications

By understanding how periostin is induced and by silencing its expression, this study may represent a future strategy for therapeutic intervention in patients with nicotine-associated gastric cancer.

Terminology

Periostin and Snail are proteins involved in a process called the EMT. EMT occurs when epithelial cells lose polarity and increase migration and mobility. Such a mechanism is crucial in the invasion and metastasis of many epithelial-originated malignant tumors.

Peer review

The study is entitled "Enhanced proliferation, invasion, and epithelial-mesenchymal transition of nicotine-promoted gastric cancer cells by periostin" presents convincing evidence for the effect of nicotine on the induction of periostin and its effect on EMT of gastric cancerous cell lines.

Abstract

Casais *et al* have reported an inverse correlation between serum phosphate and body weight after administration of sodium phosphate at a dose of 60 g. Our group has already described the relationship between body weight and hyperphosphatemia with these preparations, although our study was not quoted by Casais. We performed a pharmacokinetic study involving 13 volunteers who were divided into two groups on the basis of body weight: group I consisting of seven women with a median weight of 60 kg and group II consisting of five men and one woman with a median weight of 119.2 kg. Group I developed higher peak phosphate levels and maintained these levels above the subjects in Group II for a prolonged time period despite adequate hydration being ensured with frequent monitoring of weight, fluid intake and total body weight. Our study demonstrated that adequate hydration does not protect against the secondary effects of hyperphosphatemia. In the study by Casais *et al*, 66% of the study subjects were women, the correlation between serum phosphate and gender in their data also appears to be important. Women are at higher risk of acute phosphate nephropathy due to a diminished volume of distribution of the high dose of ingested phosphate. Decreased volume of distribution in women is due to diminished body weight. This is further compounded by decreased creatinine clearance in females.

Deepak P, Ehrenpreis ED. Lower body weight and female gender: Hyperphosphatemia risk factors after sodium phosphate preparations. *World J Gastroenterol* 2011; 17(21): 2681-2682 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i21/2681.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i21.2681

TO THE EDITOR

Casais *et al*[1] have described an inverse relationship between serum phosphate and body weight after administration of sodium phosphate at a dose of 60 g (90 mL) in 100 consecutive patients. Significantly, adequate hydration was provided to their patients with ingestion of 4 L of clear liquids. Our group has already described the relationship between body weight and hyperphosphatemia after so-

Figure 1 Comparison of serum phosphate levels in a 55 kg from Group Ⅰ and a 100 kg patient from Group Ⅱ.

dium phosphate preparations and determined the pharmacokinetic basis for this observation[2-4], although our studies were not referenced by Casais *et al*[1]. In our study, we administered a single half dose (45 mL) of Fleet Phospho-Soda containing 30 g of sodium phosphate to 13 normal volunteers consisting of two groups. Group I had seven women with a median weight of 60 kg, and Group Ⅱ had five men and one woman with a median weight of 119.2 kg. Multiple serum and urine levels of phosphate, calcium, ionized calcium and other electrolytes were measured for 12 h. Hydration was maintained throughout the study by monitoring the weight, fluid intake, and total body water, with increased intake promoted for declines in any value.

The subjects in Group I developed higher peak phosphate levels and maintained these levels above the subjects in Group Ⅱ for a prolonged time period (Figure 1). The normalized area under the phosphate *vs* time curve was much higher in group I (1120 ± 190 mg/dL per min) than in group Ⅱ (685 ± 136 mg/dL per min), $P < 0.001$. Urinary excretion of calcium was significantly lower in group I (mean 16.4 ± 7.6 mg) than in group Ⅱ (mean 39.2 ± 7.8 mg), $P < 0.001$, and most subjects in Group I had a prolonged time of abnormal ionized calcium levels during the study. Our study demonstrated that individuals, especially women, develop high serum phosphate levels for prolonged periods of time after ingesting sodium phosphate, even under the idealized condition of continuous monitoring of fluids and weight as done in this study. This suggests that adequate hydration does not protect against the secondary effects of hyperphosphatemia, as others have proposed[5,6]. Markowitz *et al*[7] has published 37 cases of acute phosphate nephropathy (APN), 30 (81%) of them were females. In the study by Casais *et al*[1] 66% of the study group were women, the correlation between serum phosphate and gender in their data also appears to be important. Pharmacokinetics demonstrates that women of diminished body weight become extremely hyperphosphatemic based on their diminished volume of distribution for the high dose of ingested phosphate. This is further compounded by decreased creatinine clearance in this group (a function dependent in part on body weight). Despite adequate fluid intake, these subjects are at very high risk for renal damage and acute phosphate nephropathy. Females, especially those of lower body weight should avoid using sodium phosphate laxatives for colonoscopic preparation.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT
All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS
Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office
World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation
The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form
Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers
Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support
For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript
WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases
Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee
WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

ABOUT COVER Veloso FT. Extraintestinal manifestations of inflammatory bowel disease: Do they influence treatment and outcome?
World J Gastroenterol 2011; 17(22): 2702-2707
http://www.wjgnet.com/1007-9327/full/v17/i22/2702.htm

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Hepatitis C virus (HCV) infects more than three million new individuals worldwide each year. In a high percentage of patients, acute infections become chronic, eventually progressing to fibrosis, cirrhosis, and hepatocellular carcinoma. Given the lack of effective prophylactic or therapeutic vaccines, and the limited sustained virological response rates to current therapies, new approaches are needed to prevent, control, and clear HCV infection.

Entry into the host cell, being the first step of the viral cycle, is a potential target for the design of new antiviral compounds. Despite the recent discovery of the tight junction-associated proteins claudin-1 and occludin as HCV co-receptors, which is an important step towards the understanding of HCV entry, the precise mechanisms are still largely unknown. In addition, increasing evidence indicates that tools that are broadly employed to study HCV infection do not accurately reflect the real process in terms of viral particle composition and host cell phenotype. Thus, systems that more closely mimic natural infection are urgently required to elucidate the mechanisms of HCV entry, which will in turn help to design antiviral strategies against this part of the infection process.

INTRODUCTION

Hepatitis C virus (HCV) is an enveloped, positive-polarity RNA virus that belongs to the *Flaviviridae* family and infects mainly hepatocytes[1]. The HCV genome encodes a polyprotein that is processed by host and viral proteases to yield

ten mature products, which include three structural proteins [the capsid protein (core) and two envelope glycoproteins (E1 and E2)], the p7 protein, and the non-structural proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B). The HCV particle consists of a nucleocapsid surrounded by a lipid bilayer harboring the two envelope glycoproteins, which heterodimerize and play a major role in HCV entry[1]. Cellular infection begins with the attachment of the viral particle to the host cell and, after interacting with cell surface molecules, the virus is subjected to clathrin-mediated endocytosis and its envelope is fused with the endosomal membrane, releasing the viral genome into the cytosol[1]. These steps involve a set of attachment factors and cellular co-receptors, including highly sulfated heparan sulfate, the low-density lipoprotein receptor (LDL-R), the scavenger receptor class B type Ⅰ (SR-BI), the tetraspanin CD81, and the tight junction (TJ) proteins, claudin-1 and occludin[2-4]. These molecules are not exclusively present in hepatocytes; therefore, HCV hepatotropism may be determined by other factors, such as the absence of inhibitory proteins[5].

In early reports, the soluble E2 envelope protein was employed as an approach to search for host cell HCV binding factors[6,7]. However, the conformation and function of the soluble glycoprotein may differ considerably from HCV envelope-anchored E2. In addition, envelope-anchored E2 is associated with E1[8], which may have additional implications in terms of receptor recognition and binding. The study of HCV entry was boosted by the use of HCV pseudotyped particles (HCVpp)[9], providing an infection system exclusively relying on the envelope glycoproteins. Since the establishment of a cell culture-derived HCV (HCVcc)[10-12], it has become the most powerful tool for studying HCV because it reflects the complete viral cycle. The use of both HCVpp and HCVcc has been of crucial importance in the discovery of new receptors, and has enabled high-throughput assays to test molecules for their ability to inhibit HCV entry.

INHIBITION OF HCV ENTRY AS A THERAPEUTIC ALTERNATIVE

HCV infection is the most frequent cause of liver failure worldwide[13,14]. Current therapies based on PEGylated interferon-alpha and ribavirin often fail to clear the infection and present a wide spectrum of systemic side effects[15]; therefore, alternative therapeutic options need to be developed. Among the different steps of HCV cycle, viral entry could be considered as a clinical target, especially in the context of orthotopic liver transplantation, where allograft reinfection occurs within hours after reperfusion and is followed by an accelerated chronic disease progression[16]. To date, several molecules have been found to inhibit HCV entry. Matsumura *et al*[17] showed that phosphorothioate oligonucleotides, previously described as HIV entry inhibitors[18], blocked HCV entry *in vivo*. Other inhibitors of HIV entry, such as cyanovirin-N, have also proved effective[19]. Furthermore, serum amyloid A, an acute phase protein mainly produced by the liver in response to different stimuli, including infections, has been demonstrated to

inhibit HCV entry[20,21]. Moreover, the milk thistle (*Silybum marianum*)-derived silymarin and its purified flavonolignans have been recently shown to inhibit HCV infection both *in vitro* and in non-responder patients[22,23], blocking viral entry and transmission[24]. Therefore, increasing evidence suggests that blocking the entry step of HCV infection may be a good therapeutic alternative.

The genetic diversity of HCV contributes to its evasion from the host immune response[25], challenging the development of effective vaccines and virus-targeted inhibitors[26-28]. Nonetheless, this problem could be overcome by developing antiviral strategies aimed at blocking essential host factors for viral infection. To this end, multiple strategies have been pursued to inhibit HCV entry at different levels, including viral attachment, post-binding events, and fusion with the endosomal membrane[4,29]. One of these approaches consists of interfering with the interaction between the viral particle and cell surface co-receptors by the use of glycosaminoglycans, natural ligands, recombinant proteins, or blocking antibodies (Table 1). Notably, it has been demonstrated that antibodies against CD81 can prevent HCV infection of human liver-uPA-SCID mice[16], probably by inhibiting the E2-CD81 binding process[6,16,30]. As a more realistic and economical alternative, small molecules with similar properties could be used instead of blocking antibodies. In search of these compounds, several high-throughput screenings have been performed recently to identify molecules with the ability to inhibit HCV infection at the entry step[31-33]. Importantly, the possible cytopathic effects of these inhibitors should be assayed prior to starting clinical trials and considering them as potential therapeutic options. Chockalingam *et al*[32] developed a cell protection screen where cytotoxicity and inhibition of infection were evaluated simultaneously. As a more practical approach, Gastaminza *et al*[31] performed the screening with a set of drugs that had already been clinically approved.

The study of HCV infection and the search for inhibitory molecules are usually carried out with the use of HCVpp or HCVcc, and a highly permissive cell line, such as Huh7 and its derivatives. However, several conflicting results have arisen when attempting to validate the data in a more pathophysiologically relevant context (Table 1). A soluble form of CD81 was shown to prevent infection of Huh7.5 cells by HCVcc; however, it was not effective when primary human hepatocytes (PHH) were challenged with serum-derived virus[34]. Moreover, infection of hepatoma-derived cell lines with HCVpp and HCVcc does not seem to depend on LDL-R[35-37], whereas it has been demonstrated to participate in the infection of PHH with HCV from human plasma[38]. These facts stress the importance of being cautious with results obtained from HCV surrogates and cell lines, which should be validated *in vivo* whenever possible or at least in systems that more closely mimic real infection.

CELL POLARIZATION, TJ-ASSOCIATED PROTEINS, AND HCV ENTRY

In contrast to "simple" polarized cells, which present the

typical epithelial columnar phenotype with individual basolateral and apical domains, hepatocytic polarity is very peculiar and complex[39]. The plasma membrane of polarized hepatocytes is divided into several basolateral and apical poles, the latter forming a continuous network of bile canaliculi (BC) into which bile is secreted[40]. BC are delimited by TJs, which maintain cell polarity by separating apical from basolateral domains and form the intercellular barrier between bile and blood[41]. Claudin-1 was the first TJ-associated protein to be described as a HCV co-receptor[42]. Soon after, occludin was also shown to participate in HCV entry[43-45]. Despite these discoveries clearly pointing to a role of TJs in HCV cell entry, recent works have reported conflicting data about how cell junctions and polarity influence HCV infection. Perturbation of cellular junctions by calcium depletion promotes opposing effects depending on the system employed, e.g. it decreases viral entry in Huh7 cells[46] but increases it in "simply" polarized Caco-2 cells[47]. Furthermore, junctional accumulation of claudin-1 has been shown to either improve[48] or hinder[49] infection of Huh7.5 and polarized HepG2 cells, respectively. Collectively, these data suggest that the HCV entry process may vary considerably depending on the polarization state of the target cells.

Several studies have questioned the importance of TJ integrity in the function of claudin-1 and occludin as HCV co-receptors. For example, HCV infection is not affected after knocking down other TJ-associated proteins, such as ZO-1 and JAM-A[45], and claudin-1's association with CD81 at the basolateral membrane of HepG2 cells, but not at the TJ, defines HCV entry[50,51]. Furthermore, fluorescent HCV particle internalization generally occurs outside of cell-cell junctions[52], and VEGF induces a reduction of junctional occludin concomitant with an increase of HCV

infectivity[53]. Moreover, claudin-1 and occludin mutants lacking domains that are important for their correct junctional localization and function are still capable of rendering cells susceptible to HCVpp entry[42,54,55]. Finally, HCV infection of HepG2 cells is negatively regulated by cell polarity[49,53], but is not affected by TNF-α- and IFN-γ-mediated TJ disruption[49], and claudin-1 blocking antibodies inhibit HCV infection without perturbing TJs[30,56]. Taken together, these data strongly suggest that the role of claudin-1 and occludin in viral entry is relevant, but not necessarily when these proteins are part of functional TJs, which may indeed be a barrier for HCV infection. Interestingly, it has recently been demonstrated that hepatitis A virus infects HepG2-derived cells from the basolateral domain and that TJ-dependent polarization restricts infection[57].

The mechanisms by which claudin-1 and occludin participate in HCV entry have not been clearly established. In both cases, an extracellular loop of the protein has been shown to be indispensable for infection[42,44,55,58]. Several reports have shown that occludin precipitates with HCV E2 in infected, transfected, or replicon-containing cells[43,55,59], but its direct interaction with viral particles or envelope glycoproteins has not been demonstrated. Additionally, it has been shown that occludin interacts with dynamin Ⅱ, a well known regulator of endocytosis[55]. This observation, along with data obtained from cell-cell fusion experiments[45], suggests that occludin might participate in late steps of the HCV entry process. Interestingly, occludin endocytosis has been implicated in group B coxsackievirus infection, although not by directly interacting with the virus[60]. On the other hand, kinetic studies with blocking antibodies have shown that claudin-1 mediates an HCV entry step closely linked to CD81[30]. Indeed, it has been described that basolateral pools of claudin-1 are associated with CD81 in polarized HepG2 cells[50,51], and that disrupting this interaction, either by site directed mutagenesis or claudin-1 blocking antibodies, neutralizes HCV infection by reducing E2 association with the cell surface[30,51]. However, Cukierman *et al*[54] generated a mutant version of claudin-1 which, in spite of maintaining its interaction with CD81, no longer localized to cell-cell contacts and lost HCV receptor properties. This result suggests that, besides favoring E2 binding to the host cell, additional mechanisms involving claudin-1 participation in HCV entry may exist. Nevertheless, as these experiments were carried out in the non-hepatic, non-polarized HEK cell line, data should be carefully interpreted. This is a good example of how cell polarity may influence the results obtained, especially when studying features of TJ-associated proteins in a hepatocellular context.

LIPID METABOLISM AND HCV ENTRY

Cell polarization is crucial for the correct localization and function of TJ-associated proteins with HCV receptor activity, which could in turn be important for viral entry[41,61]. In addition, polarization may affect other steps of the HCV cycle, such as assembly and egress. Indeed, it has been shown that assembly of RNA enveloped viruses in MDCK cells is closely related to cell polarization[62]. It is also noteworthy that polarization is tightly linked to lipoprotein secretion[63,64], especially because some low density natural HCV particles have been found to be complexed with ApoB and/or ApoE-positive triglyceride-rich lipoproteins[65-67]. This association is believed to take place during viral egress[68] because HCVcc virions were found to be secreted in a manner that parallels the formation of VLDLs[69-71]. Thus, cell polarization may influence lipoprotein secretion, which is important for the generation of correctly assembled HCV progeny. Indeed, non-polarized Huh7-derived cells have been shown to be unable to secrete authentic, ApoB-containing VLDLs[72]. In addition, when HCVcc generated in these cells was subjected to isopycnic gradient ultracentrifugation, it was found to have higher average buoyant density than viral particles obtained from PHH[72]. Interestingly, the density profile of serum-derived viral particles obtained from HCVcc-infected animals was significantly lower than that of the initial HCVcc inoculum[73]. In both reports, specific infectivity of PHH and serum-derived HCV particles was shown to be greatly increased compared to standard HCVcc, and these properties were lost after passaging the virus again in Huh7.5 cells. These findings strongly suggest that HCVcc generated in Huh7-derived cells probably presents a defective lipoprotein association, which may in turn affect viral infection.

The lipoprotein composition and distribution within the viral particle may thus be important for the mechanisms underlying HCV entry[74]. Indeed, several reports have shown that lipoprotein lipase and hepatic triglyceride lipase alter both the physiological characteristics and the infectivity of HCV[75-77]. This notion is supported by the fact that LDL-R participates in the first steps of the entry process[38], and that viral particle density is inversely correlated to infectivity *in vivo*[66]. Additionally, the virus-host interaction could be affected in a context of a lipoprotein-defective viral particle because of changes in the exposure and accessibility of E2 to cellular co-receptors. In fact, this could explain the differences observed between HCVcc and serum-derived HCV infection in terms of inhibition by the soluble CD81 large extracellular loop[34]. Moreover, in contrast to serum-derived HCV[38], infection with HCVcc and HCVpp seems to be LDL-R independent[35-37], probably because of differences in lipoprotein composition.

Therefore, it is necessary to study HCV entry in systems that more accurately mimic the viral cycle in a pathophysiological context, from viral particle generation to target cell infection. The interplay between HCV and hepatocytes seems to be closely related to their particular phenotype (Figure 1); therefore, data obtained from models that do not reflect hepatocellular polarization and lipoprotein secretion should be cautiously interpreted.

TOWARDS A MORE PHYSIOLOGICALLY RELEVANT MODEL

The use of HCVpp and HCVcc has meant a great advance in HCV research. Their adaptability to high-throughput

analysis has enabled genome-wide screening for host proteins involved in the HCV cycle at different stages. In addition, they provide a valuable tool for testing the possible antiviral activity of large chemical libraries of compounds. However, it is important to bear in mind the limitations of these *in vitro* models, as both viral particles and target cells differ notably from serum-derived HCV and polarized hepatocytes, respectively. Thus, results obtained with HCVpp and HCVcc should be validated in systems that more closely mimic real HCV infection before establishing firm conclusions. To this end, significant work is being done by Molina and colleagues, who have already confirmed a role for LDL-R and CD81 in serum-derived HCV infection of PHH[34,38]. This model is considered an accurate *in vitro* system, as cells can be maintained in a differentiated phenotype to retain their polarity and drug metabolizing capacities. In addition, they can be infected with serum-derived HCV of any genotype and, in contrast to what is observed in hepatoma cell lines (e.g. Huh7 cells and derivatives), the innate immune response is fully preserved[78]. However, production of measurable titers of progeny virus in this system has not been achieved[79], indicating that the model fails to reflect the entire HCV cycle. Recently, it has been shown that HCVcc infection of PHH results in the robust production of infectious viral particles, which were in turn able to efficiently infect naïve PHH[72]. This primary cultured-derived HCV (termed HCVpc), compared to HCVcc, exhibited lower average buoyant density and higher specific infectivity, reminiscent of what is seen for virus recovered from the blood of animals infected with HCVcc[72,73]. Therefore, HCVpc infection of PHH emerges as a valuable tool for studying the complete HCV cycle in a more relevant context. Nevertheless, this system presents the drawbacks of working with PHH, such as restricted availability, the difficulty of studying long-term infections, and the heterogeneity of samples and results. Interestingly, Matrigel-embedded 3D cultures of Huh7 cells display a hepatocyte-like polarization and are susceptible to HCVcc infection. Progeny viruses generated by these cultures, similarly to HCVpc, also present a shift towards lower densities (our unpublished observations). This result suggests that if hepatocellular polarity is achieved, it is possible to generate viral particles that more closely mimic real HCV, even when cell lines are used as the source of virus.

Animal models are essential to validate *in vitro* data, because not only hepatocytes, but also the liver as a whole, may determine the mechanisms of HCV cell entry. Indeed, the liver sinusoidal endothelial cell-expressed protein, L-SIGN, has been shown to bind serum-derived HCV[80] and mediate trans-infection of Huh7 cells by HCVpp[81,82]. Additionally, co-culture of PHH with liver sinusoidal endothelial cells significantly increases the expression of the HCV co-receptor LDL-R[83]. Regarding *in vivo* obtained data, CD81 is the only co-receptor that has been demonstrated to participate in HCV infection using the human liver-uPA-SCID mouse model[16]. This system, albeit constituting a useful tool, is limited by the fact that the animals lack a functional immune system. This may be important,

Figure 1 Interplay among cell polarization, lipoprotein secretion, and hepatitis C virus particle assembly, release, and entry into host cells. The correct polarization of hepatocytes, implying the presence of functional bile canaliculi delimited by TJs, may be important for the proper maturation and secretion of lipoproteins. This process is tightly associated with the composition and assembly of hepatitis C virus (HCV) lipoviroparticles and their exit from infected cells. Finally, HCV entry may be affected by the lipoprotein composition of the viral particle, the hepatocellular polarization of target cells, and the localization of the TJ-associated proteins claudin-1 and occludin.

not only for the outcome of the infection, but also for the entry process itself, because DC-SIGN, expressed on dendritic cells, has been shown to capture and transmit HCVpp to Huh7 cells[81,82]. More recently, peripheral blood B cells have been shown to exert a similar function[84]. To date, chimpanzees are the only immunocompetent *in vivo* system for studying HCV infection, but their use is limited by ethical concerns, restricted availability, requirement of special facilities, and very high costs[85]. In search of a small, HCV susceptible and immunocompetent animal model, it has been proposed to combine human liver chimeric models with mice harboring a human hematolymphoid system[85], although this approach depends on the availability of human primary cells. Thus, the ideal model would be an immunocompetent mouse susceptible to HCV infection without the need of harboring human cells. Given that HCV species tropism is restricted to human and primates[58,85], an alternative strategy consists of using an HCV variant able to infect murine cells. Bitzegeio et al. adapted HCVcc to mouse CD81 and identified three envelope glycoprotein mutations which together enhanced infection of cells with mouse or other rodent receptors by approximately 100-fold[86], thus overcoming the species-specific restriction of HCV cell entry. Another possible approach would be to employ genetically engineered mice bearing the human entry factors that confer species specificity[44]. However, mouse hepatocytes fail to initiate viral replication[85]; therefore, these models would not be able to mimic the entire HCV cycle.

CONCLUSION

During HCV infection, hepatocytes almost exclusively constitute both the target and the virus-producer cells. Thus, it is mandatory to perform HCV studies in systems that closely mimic the complex nature of hepatocyte pheno-

type. These models should enable the generation of viral particles that resemble the ones found *in vivo*, and reproduce the hepatocyte physiology as accurately as possible. Only the combination of these two factors will provide the necessary information to establish firm conclusions. Nevertheless, the choice of employing HCVpp, HCVcc, HCVpc, or serum-derived HCV to infect cell lines, PHH, or animals should depend on the stage of the research process: the *in vitro* systems are more adequate for high throughput screenings and the *in vivo* models are essential for validating the data. Once the mechanisms of HCV entry are deciphered in detail, this step of the viral cycle could be an effective target for the development of antiviral compounds. These inhibitors should ideally be effective for a broad range of HCV genotypes and subtypes, and even for other viruses, such as HIV, that might share some entry mechanisms and co-infect some patients. Thus, blocking cellular factors might be a good therapeutic alternative in the fight against viral genetic variability. However, targeting host molecules could alter their physiological functions and result in harmful side effects. In addition, this approach does not rule out the possible emergence of viral variants that would be able to circumvent the specific effect of the entry inhibitor. Moreover, HCV cell-to-cell transmission may bypass the inhibition of cell-free virus entry and allow viral spread. Therefore, clinical strategies based on broad-spectrum compounds or the combination of different therapeutic molecules should be developed to simultaneously interfere with several steps of the viral cycle to efficiently control infection with the minimal side effects.

INTRODUCTION

Inflammatory bowel disease (IBD) is one of the more common chronic illnesses afflicting adolescents, with an estimated prevalence in those younger than 20 years old of 71 per 100 000[1]. Both Crohn's disease (CD) and ulcerative colitis (UC) present day-to-day as well as long-term challenges that can be particularly difficult for the adolescent patient. The developmental and psychosocial changes unique to adolescence, including establishing autonomy, risk-taking behavior, and undue susceptibility to peer influence make managing IBD in this age group more difficult.

MEDICATION ADHERENCE

Adhering to a prescribed medication regimen is difficult for teenagers. Adolescents need to remember to take medications amidst a busy lifestyle with school and extracurricular activities, and to accurately recall the types and number of medications to be taken at various times of the day. They can be particularly resistant to taking medications that cause cosmetic changes, choosing a better appearance over persistent IBD symptoms. The concept of maintenance therapy can also be challenging for teens who, once acute symptoms subside, often decide to stop taking medications "because I don't need them anymore".

A study by Hommel *et al*[2] examined the problem of medication nonadherence in 42 adolescents with IBD. In addition to recording an objective measure of adherence

Abstract

Adolescents with inflammatory bowel disease face daily and long-term challenges that may be difficult for teenagers to manage. The developmental and psychosocial changes unique to this age group include becoming more autonomous and being more vulnerable to peer influence. These changes may lead to problems in medical management such as poor medication adherence and risky behavior. Being aware of these issues will help the medical team provide anticipatory guidance to address these concerns.

using pill count, they further evaluated the problem by determining the adolescents' subjective assessments of their adherence through standardized interviews. Subjects reported that they missed 6% of their 6-mercaptopurine/azathioprine (6-MP/AZA) doses and only 3% of the 5-aminosalicylate (5-ASA) medications. However, pill counts revealed that 38% of 6-MP/AZA and 49% of 5-ASA doses had been missed. Only 14% of patients had therapeutic levels of thiopurine metabolites, further confirming their poor adherence to the prescribed 6-MP/AZA regimen. The subjects who were nonadherent to 6-MP/AZA were also likely to miss 5-ASA doses. The frequent dosing and large quantity of pills per dose were factors associated with poor adherence to 5-ASA treatment.

A survey study by Greenley *et al*[3] of 64 adolescents and their parents found that 48% of teenage patients took one IBD medication or supplement, 36% took two, and 11% took three. Only 65% of adolescents reported perfect adherence. Common barriers to medication adherence included lack of time, medication side effects, feeling well, or belief that the medication was ineffective. Patients on polytherapy had more barriers to successful medication-taking than those on monotherapy. A similar study by Ingerski *et al*[4] found that the most common barriers to medication nonadherence included forgetting, being away from home, and interference with an activity.

Based upon these studies, physicians may help increase medication adherence by minimizing the frequency of doses and number of pills. When prescribing a new treatment, physicians need to carefully explain to adolescents why they need to take their medications as prescribed, especially when patients have low expectations that the therapeutic regimen will be effective, or are likely to experience side effects[3]. Physicians must also clearly communicate the concept of maintenance therapy, both when medications are first prescribed, and more importantly, during routine follow-up visits so that teenagers understand why they need to continue to take medications even when they are feeling well. Suggestions to help teens remember to take their medications include using a pill box, carrying an extra supply of pills, and setting an alarm as a reminder on a watch, cell phone, or portable electronic device.

GROWTH AND DEVELOPMENT

IBD may lead to growth failure and delayed puberty during adolescence. Pfefferkorn *et al*[5] examined growth outcomes in children with CD at diagnosis, 1 year, and 2 years using data from the Pediatric IBD Registry, a prospective, multicenter observational database established in 2002. The study found that the mean height z-scores were approximately -0.50 standard deviations (SD) at each of the three time points despite improvement in disease activity over the course of the observation period. Although the mean height velocity z-score increased between the first and second years, the proportion of

patients with a height velocity z-score less than -1 SD was similar and substantial (45% at 1 year and 38% at 2 years). Furthermore, all subjects in the study were Tanner I to III at diagnosis and at 1 year. At 2 years, 84% (92/110) of patients did not progress to Tanner IV. These data are disturbingly similar to those derived from patients diagnosed in the 1970s and 1980s, in whom periods of significant growth failure were demonstrated in 37% of young adults whose CD had been diagnosed before their adolescent growth spurt[6]. Despite advances in nutritional and anti-inflammatory therapy, promoting normal growth continues to be a significant challenge for the physician caring for adolescents with IBD.

Not only is height adversely affected in children with IBD, but bone mineral density (BMD) is as well. Sylvester *et al*[7] prospectively followed Caucasian children with IBD over a 2-year period from diagnosis. The mean total body BMD z-score at diagnosis was significantly lower for CD patients compared to healthy controls of similar age (-0.78 for CD, -0.46 for UC, and -0.17 for controls). CD patients with a BMD z-score lower than -1 tended to have a lower body mass index (BMI) and higher serum interleukin-6. Despite clinical improvement in the CD and UC patients over the follow-up period, the mean BMD z-score was unchanged for CD. Similarly, the mean BMD z-score for UC patients was unchanged from diagnosis to 1 year, but increased from the first to second year.

Sylvester's study[7] also found that both CD and UC patients had decreased serum concentrations of biochemical markers of bone formation at diagnosis compared to controls. In addition, CD patients had a lower concentration of N-telopeptide of collagen, a marker of bone resorption, compared to controls. Over the course of the study, improvement in clinical status and nutrition was associated with increased concentrations of markers of bone formation but not of bone resorption. However, mineralization rates did not significantly improve, particularly in CD patients.

Dubner *et al*[8] evaluated the bone and muscle of the left tibia using peripheral quantitative computed tomography (pQCT) in pediatric CD patients. pQCT provides a 3-dimensional assessment of trabecular and cortical volumetric BMD (vBMD) and geometry, and a cross-sectional area of muscle and fat. Patients with CD had musculoskeletal deficits (in trabecular vBMD, cortical bone geometry, and muscle mass) at diagnosis compared to healthy controls of similar age. Six months after diagnosis, there was improvement in trabecular vBMD and muscle mass, but worsening of cortical bone geometry. One year after diagnosis, all 3 were still low compared to controls.

In addition to physical appearance, growth failure and delayed puberty may also affect psychosocial aspects of adolescent life. Looking different from peers may render teens to feel self-conscious or "abnormal". Teens may have difficulty "fitting in" with peers or dating because they appear less mature. Having short stature may also affect their ability to participate in or excel at sports, or at least give adolescents this perception. All these

factors may lead teens to become repeatedly frustrated, have low self-esteem, or seclude themselves.

Poor nutrition may contribute to poor growth. Patients may not meet their nutritional requirements because of inadequate caloric intake, malabsorption, or increased metabolic needs from chronic inflammation. Patients with CD are more likely to be malnourished than patients with UC. It is important to monitor nutritional status by anthropometrics, and checking blood for albumin and micronutrient levels (e.g. iron, folate, and B12). Patients who are undernourished or have micronutrient deficiencies should receive supplementation with oral or nasogastric tube feeds, or with specific vitamins or minerals. In addition, it may be beneficial for patients to take a daily multivitamin. Patients receiving sulfasalazine and/or methotrexate should be given folic acid supplements[9]. Patients may also be referred to a nutritionist for evaluation of dietary intake and guidance on how to eat a healthy and appropriate diet.

PEER INFLUENCE

Peer influence is strong during adolescent years. This period is filled with the desire to be accepted, identity formation, intense introspection, and internal conflict. Teenagers may feel embarrassed or self-conscious about their body as a result of IBD, its complications, or side effects from medications. Patients may feel uncomfortable about their short stature, delayed puberty, body habitus (thin from malnutrition or weight gain from corticosteroids), surgical scars, or ostomy. Patients missing school or limiting extracurricular activities due to IBD flares or medical appointments may feel isolated from peers. Teenagers may not want to appear different from friends or raise suspicion about having a medical condition, especially one that involves potentially embarrassing topics such as diarrhea.

When adolescents are ready to share their medical condition with friends or someone they are dating, they must decide when is the appropriate time, and how to do so. Patients may want to let peers realize that disclosing this information demonstrates that patients trust their peers and that their relationship has reached a certain level. Patients may also explain that the disease does not define them as a person. In addition, adolescents should understand that they have the option of sharing only information which they are comfortable disclosing.

RISKY BEHAVIOR

Adolescents may participate in risky behaviors such as practicing unprotected sex, and abuse of alcohol and illicit drugs[10,11]. It is common to hear adolescents explain their risky behavior because they think that bad consequences "won't happen to me." Adolescents with IBD are no exception, but their risky behavior can also take the form of discontinuing their medications without consulting their physician. Therefore, it is important for the physician caring for adolescents with IBD to address risky behavior and provide anticipatory guidance. For example, adolescent IBD patients should be counseled about the importance of using protection if they decide to have sexual intercourse. If the female adolescent patient decides to use oral contraceptive pills, she should be aware of the possible increased risk of thrombosis[12]. It is also important to explain that, although sulfasalazine can lower sperm counts, it should not be considered a method of contraception[13].

If the teenage patient is pregnant, she may want to seek family planning to decide whether to continue the pregnancy. If the decision is to continue the pregnancy, it may be beneficial to transfer her to an adult gastroenterologist because internists have more experience with pregnancy and high-risk obstetrics than pediatricians. Patients should be encouraged to tell their physicians that they are pregnant because some IBD medications such as methotrexate are known teratogens and others may need to be monitored carefully during pregnancy. Conversely, some medications are safe during pregnancy but there may be a popular misconception that they are not (such as infliximab until 28 wk gestation)[14].

Toxic ingestion (including alcohol consumption) and illicit drug use are other risky behaviors that are important to address. Teens may abuse alcohol and illicit drugs for various reasons, such as peer pressure, recreational use, emotional escape, pain control, or appetite stimulation. Regardless of their reason, alcohol and illicit drug use may have multiple adverse health effects including damage to the liver, an organ vital in metabolizing some medications used to treat IBD. In addition, intravenous drug use, unprotected sex, and having tattoos or body piercing are risk factors for contracting hepatitis B and C[15-18]. Adolescents should also be informed that metronidazole must not be taken with alcohol, as it can cause a disulfiram-like reaction[19].

TRANSITION TO AN ADULT GASTROENTEROLOGIST

Transition to an adult gastroenterologist provides older teenagers and young adults with a hospital or clinic environment that is appropriate for their age. In addition, adult gastroenterologists are more experienced than their pediatric counterparts regarding issues frequently encountered in adults such as pregnancy, fertility, and cancer surveillance. In addition, the process of transition promotes independence and better adherence with therapy because patients must learn to take care of themselves, be proactive in their medical care, form decisions, communicate with the medical team, and be a self-advocate[20,21].

The transition may be stressful for everyone involved in the process: patients, parents, as well as pediatric and adult gastroenterologists. Patients and families must relinquish the familiarity of the pediatric medical team and institution to face a new one that may have a different practicing style and expect patients to be independent. The

adult gastroenterologist may subsequently be perceived as less concerned about the needs of the patients and their families. Pediatric gastroenterologists may be reluctant to transfer patients to an adult provider whose medical management may be different or who may be less familiar with the issues of adolescent patients. Adult gastroenterologists may see young adult patients as less mature or self-reliant, and their families as overly involved[20].

Hait *et al*[21] proposed a timeline consisting of competencies patients should achieve and tasks the medical team should implement based on patients' age, to help promote a successful transition. Pre-adolescents (ages 11-13 years) should learn to identify their disease and medications (names, dosages, and major side effects). The medical team should present the idea of independent visits in the future and discuss the effects of exercise, sexual intercourse, and substance abuse on IBD. Young adolescents (ages 14-16 years) should learn to identify their medical team and be knowledgeable about their medical history (including prior procedures and tests), relevant family history, and the risk of medication nonadherence. The medical team should start to help patients to become more independent by addressing patients first and having the family step out of the room for part of the visit. However, it is important to explain that the medical team has a legal obligation to share certain aspects with parents. Patients should be taught how to contact the medical team, schedule appointments, and fill prescriptions. In addition, physicians should inquire about their patients' plans after high school and introduce the idea of transition. Older adolescents (ages 17-19 years) should be able to manage their medical needs, which include scheduling appointments and having a plan to attend them, asking and answering questions during their private conversation with the gastroenterologist, filling prescriptions and picking them up at the pharmacy, and being knowledgeable about their insurance. Physicians should discuss possible difficulties encountered in the transition process and provide names of prospective adult gastroenterologists.

When patients are ready to transfer care, transition is easier when there is stability in their disease and life. Transition is more successful when patients in college are transferred to an adult gastroenterologist after graduation and have acquired a job or started graduate school. Patients who do not plan to attend college may be transferred after securing housing and a job. A medical summary should be provided at the time of transfer[21].

A survey by Hait *et al*[22] illustrated adult gastroenterologists' perspectives of the transition process. The survey of 363 adult gastroenterologists revealed that factors they believed were most important for a smooth transition were often lacking amongst their young adult patients. These factors included patients' knowledge about their medications (name, dose, and major side effects), medical history, and health effects of smoking, drugs, and alcohol. Adult gastroenterologists also considered it helpful that pediatric gastroenterologists should provide a medical summary of their patients. The vast majority of adult gastroenterologists thought it was important

that adult providers be familiar with adolescent medical and developmental issues, but a significantly low proportion felt proficient in this area.

CONCLUSION

In summary, adolescents have unique issues such as poor medication adherence, growth failure, peer influence, and risky behavior, which make managing teenage IBD patients more challenging. It is important for physicians to recognize these issues so that they are prepared to address patients and parents early to help improve adherence to medications, nutritional status, complications of IBD, social well-being, and the transition process.

Abstract

Crohn's disease and ulcerative colitis affect women in their child-bearing years. Family planning has come to be a common discussion between the gastroenterologist and the inflammatory bowel disease (IBD) patient. Disease control prior to desired conception and throughout pregnancy is the most important thing to keep in mind when caring for the IBD patient. Continued medical management during pregnancy is crucial in optimizing outcomes. Studies indicate that quiescent disease prior to conception infer the best pregnancy outcomes, similar to those in the general population. Active disease prior to and during pregnancy, can lead to complications such as pre-term labor, low birth weight, and small for gestational age infants. Although there are no definitive long term effects of pregnancy on IBD, there are some limited studies that suggest that it may alter the disease course. Understanding the literature and its limitations is important in the modern era of IBD care. Educating the patient and taking a team approach with the obstetrician will help achieve successful outcomes for mother and baby.

INTRODUCTION

Approximately fifty percent of patients are less than 35 years of age at the time of diagnosis and twenty five percent conceive for the first time after their diagnosis of inflammatory bowel disease (IBD)[1-3]. Advances in the field of IBD have made successful pregnancy outcomes a reality for many women. It is very important that as a gastroenterologist you have input into the conversation regarding management during pregnancy. It is important to understand the effect of pregnancy on IBD and the effect of IBD on a pregnancy. This review discusses the evidence for the important questions that female patients have in regards to this topic, and recommendations based on clinical experience of the authors has also been included.

HOW DOES IBD AFFECT THE OUTCOMES OF PREGNANCY?

The general consensus agrees that the impact of IBD

on pregnancy depends on disease activity at conception. Studies suggest that quiescent disease throughout a pregnancy leads to similar risks to those of the general population in regards to spontaneous abortion, pregnancy related complications, and adverse perinatal outcomes[4-6]. Disease activity at conception has been associated with preterm births, low birth weight (LBW), and fetal loss[4,7-10]. In addition, active disease during pregnancy results in the greatest risk of adverse perinatal outcomes[3,4,11]. This risk appears to be higher in women with Crohn's disease (CD) than in those with ulcerative colitis (UC). However, severe disease relapses during pregnancy in UC are associated with shorter gestation periods and lower birth weights[12]. In the study by Reddy *et al*[12] there was a higher risk of preterm births among women hospitalized for severe UC, with the mean gestational age being 35 wk *vs* 38.7 wk in the control group (without disease relapse).

In 1997, Kornfeld *et al*[13] studied 756 women with IBD and found that IBD was an independent risk factor for LBW and premature infants. However, they did not differentiate between CD and UC. Studies in the US and Denmark have demonstrated an increased risk of preterm delivery, small for gestational age (SGA), and LBW in infants to CD mothers[8,14,15]. In a study of Danish UC women, 1531 infants were included and there was no difference in rates of pre-term delivery, LBW, or SGA compared to controls[16]. The rate of healthy offspring to UC women was similar to the general population[3,8]. Despite a consistent trend of preterm delivery, most of the deliveries occurred after 35 wk with favorable outcomes[14].

Khosla *et al*[17] examined a cohort of 54 pregnant CD patients, and found that those with active disease at conception had rates of miscarriage up to 35% higher than those of patients who were in remission. In 2007, Nørgård *et al*[18] examined the impact of disease activity on birth outcomes in CD, and reported that activity during pregnancy only increased the risk of preterm birth. Furthermore, Moser *et al*[19] concluded that the presence of ileal disease in CD women was a strong predictor for LBW.

In a study by Dominitz *et al*[14] a greater risk of congenital abnormalities was seen in UC women compared to controls (7.9% *vs* 1.7%, *P* < 0.001). This study, however, failed to take into consideration disease activity or medication use, and this finding has not been replicated by other investigators. Indeed, most studies have found no greater risk of malformations in UC or CD[8,10,20]. For example, Lamah *et al*[21] found that there was no increased risk of spontaneous abortions, perinatal mortality, or congenital malformations in their UC cohort.

Using the 2005 Nationwide Inpatient Sample, Nguyen *et al*[22] examined 2372 CD deliveries and 1368 UC deliveries. In this population-based study, the adjusted odds of a cesarean section were higher in women with CD (aOR 1.72) and UC (aOR 1.29) compared to non-IBD controls. The risk of a venous thromboembolism was also substantially higher in IBD pregnancies. Interestingly, protein calorie malnutrition occurred more frequently in IBD

women, as did blood transfusions in CD deliveries (aOR 2.82). To date, there are no associated complications of hypertension or proteinuria with IBD pregnancy[5].

Beniada *et al*[11] reported a series of 76 cases of women with their first IBD flare during pregnancy, and observed that they were at increased risk for pre-term delivery and/or LBW. The largest study to date on this topic is the meta-analysis by Cornish *et al*[23] that evaluated 12 studies in regard to the impact of IBD on pregnancy. This study comprised a total of 3907 patients with IBD and 320 531 controls. Based on this analysis, women with IBD were more likely to experience adverse pregnancy outcomes, such as premature birth and LBW. In fact, premature delivery was almost twice as likely compared to the general population. Women with IBD were also 1.5 times more likely to undergo cesarean section. Unfortunately, neither medication use nor disease activity was analyzed as a cofounder, which makes it difficult to put the results into proper perspective. The meta-analysis reported a 2.37 fold greater risk of congenital abnormalities (95% CI: 1.47-3.82, *P* < 0.001), but most of the studies included did not differentiate between minor and major malformations[23].

In 2006, a Spanish study of 124 pregnant CD women looked at pregnancies before and after diagnosis. They concluded that the course of IBD did not adversely affect pregnancy or the postpartum time period. The study determined that diagnosis prior to pregnancy did not influence the number of cesarean sections performed or increase the presence of LBW infants[24].

In 2007, Mahadevan *et al*[25] compared pregnancy outcomes between women affected with IBD and those unaffected. The study comprised of 461 pregnant IBD patients and a randomly selected cohort of age matched controls, and represents the largest US study to date. Women with IBD were more likely to have an adverse pregnancy complication compared to those women without IBD, but there was no difference in adverse newborn outcomes or congenital abnormalities. This difference was seen irrespective of the disease activity. The use of IBD medications was not found to be predictive of adverse outcome in this large, non-referral population. There was no statistically significant difference in newborn outcomes between the IBD and control pregnancies.

In the general population, smoking is a known risk factor for LBW infants and for disease activity in CD women[2]. Pregnant CD patients who smoke are at a substantially increase risk for LBW and preterm delivery[2,21]. Conversely, smoking in UC women does not increase their risk of preterm delivery[26]. However, given the known risk of smoking on the individual and the baby, smoking cessation should be encouraged in all scenarios.

Numerous studies continue to associate preterm birth and IBD; however the majority of these "preterm" deliveries occurred after 35 wk of gestation[14,26]. In UC, if resection is needed during pregnancy, Nielsen *et al*[8] found an increased risk of preterm delivery. Many theories have been put forth for this observation, but the etiology is unclear. One hypothesis is that an increase in circulating

prostaglandin levels during a flare could initiate pre-term labor with the induction of smooth muscle contraction[12,27]. Another theory is that the role of increased gut permeability during increased inflammation could alter nutritional and immunological factors affecting labor[12]. In addition, safety concerns for the mother and baby might prompt induction of early delivery, which would bias the end result of an LBW infant. Although each theory is plausible, more data are needed to clarify IBD and preterm infants.

While the data are conflicting at times, it appears that the disease activity is the main impetus of adverse pregnancy outcomes[28], as miscarriages are seen more frequently with active disease[13-15]. In our practice, we encourage women to be in remission before considering conception, and for those who become pregnant, we monitor closely and treat disease activity aggressively.

HOW DOES PREGNANCY AFFECT THE DISEASE COURSE?

A consistent finding in more recent literature is that the rate of disease flare during pregnancy (26%-34%) is similar to non-pregnant flare rates[7,10,29,30]. An exacerbation rate of 34% per year during pregnancy in UC women and 32% per year when not pregnant was observed by Nielsen *et al*[8]. These rates of relapse were similar in the CD population[10]. The Kaiser cohort, previously discussed, included women with inactive disease throughout their pregnancy, with no sudden increase in activity post-partum[25,29].

UC

When conception occurs during a quiescent state, 70%-80% of UC patients will remain in remission[2,8]. The rate of relapse is thus similar to a non-pregnant UC patient. Unfortunately, when flares do occur, the data is unreliable in relation to the stage of pregnancy. It was initially believed that an increase of disease flare occurred in both the first trimester and post-partum, but timing of a flare appears to more related to disease activity at conception and at term. Moreover, disease flare is often related to discontinuation of medical therapy (first trimester) or resuming smoking after delivery (post-partum)[2,11,31]. Active disease at conception can be associated with a worse prognosis. In a cohort of UC patients, Willoughby *et al*[32] noted that active disease during these times was more resistant to treatment.

The patient who has undergone an ileoanal anastomosis procedure presents a special situation. Ravid *et al*[33] examined 67 pregnancies in 38 UC women with ileal pouch anal anastomosis surgery. It was determined that pregnancy was safe with some alteration of pouch function, almost exclusively during the third trimester. For most of the women, the pouch function returned to its pre-pregnancy state. However, there was a small proportion of women that suffered long term disturbance of pouch function. This long- term effect was not related to the method of delivery. Although the mode of delivery in a pouch patient

remains disputed, the method of delivery should not be determined by the presence of a pouch, but by patient and obstetric decisions. There are no long term data on pouch function after vaginal delivery but short-term data showed that pouch function, continence and quality of life are not affected by uncomplicated vaginal delivery[2,34].

CD

CD during pregnancy is similar to patients with UC. As with UC, the key to a good outcome is the disease state at conception and delivery. If the CD is quiescent at conception, 70% of pregnant CD patients will remain quiescent compared to the non-pregnant CD patient[2,17,35]. There has been some suggestion that CD symptoms might improve during gestation and that relapse is more common in the first trimester[2,17,26]. When disease is active at the time of conception, we follow "the rule of thirds". One third of women will get better, one third will stay the same, and one third will worsen. The biological mechanism of this finding has yet to be fully explained, but several studies have suggested that the immune disparity between mother and fetus might play a role in immune regulation, thereby altering immune function and pathology[36].

The recommended mode of delivery in CD patients is still controversial. In comparison to the general population, CD patients undergo cesarean sections more frequently, with the rate of cesareans increasing after diagnosis[37,38]. There are conflicting data on vaginal deliveries and perianal disease. The current recommendation, based on small observational studies, is to avoid vaginal deliveries in the setting of active perianal disease. CD patients with uncomplicated disease should be treated like the general population when deciding on delivery, but episiotomy should be avoided. The presence of a colostomy or ileostomy should not designate delivery choice. Despite the limited data, choice of delivery should be a collaborative decision between the patient, gastroenterologist, and the high-risk obstetrician.

Nursing

Any detriment to maternal health secondary to nursing after delivery is controversial. There have been some reported associations between nursing and increased disease activity, but this is unclear whether this is related to disease course or cessation of medication. Kane *et al*[31] found the odds ratio (OR) of disease flare for women who breastfeed was 2.2 (95% CI: 1.2-2.7) compared to those who did not breastfeed. However, once medication discontinuation was factored in, the OR became non-significant. Moffatt *et al*[39] published a population based study of breastfeeding and found no increased risk of flare in the postpartum period, and a possible protective effect once the discontinuation of medications was taken into account.

Long term effects of pregnancy on IBD

There have not been any data to suggest a long term detrimental effect of pregnancy on IBD and there is

never a role for elective termination. In the specific cases where methotrexate or thalidomide are involved, the decision for a therapeutic abortion may need to be addressed, given that it is a category X drug with known association with fetal abnormalities. Pregnancy has not been shown to definitively alter disease phenotype[38]. Riis *et al*[38] demonstrated that parous IBD patients experienced a reduction in relapse rate in the three years following pregnancy when compared to the three preceding years[2,40]. The rate of relapse decreased in the years following pregnancy in both UC and CD. Riis *et al*[38] looked at 580 IBD pregnancies in a European cohort. The pregnancy itself did not influence disease phenotype or surgery rates, but it was associated with a reduced number of flares in the following years (UC 0.34 flares/year *vs* 0.18 flares/year, *P* = 0.008 and CD 0.76 flares/year *vs* 0.12 flares/year, *P* = 0.004). Nwokolo *et al*[41] demonstrated a negative correlation between increasing parity and number of resections[2]. They found that in parous women with CD, the need for surgical resection was inversely correlated with increasing parity. Castiglione *et al*[42] studied parous IBD women and found that the incidence of relapses in the first three years after pregnancy was lower than that prior to pregnancy. Hormonal changes during and after pregnancy might account for a change in fibrosis and stricture formation[5]. Some studies suggest a down regulation of the immune system with maternal fetal HLA disparity[36]. Maternal immune response to paternal HLA antigens might result in immunosuppression that can in turn affect the maternal immune-mediated response. Kane *et al*[36] looked at 50 pregnancies in 38 women and found 42 disparate (84%) at the DRB1 locus, 34 (68%) at the DQ locus, and 31 (62%) at both loci. A significant difference was found in IBD activity between women mismatched at both loci *vs* only 1 or neither locus (OR 8.4, *P* = 0.01) Improvement of IBD symptoms during pregnancy was associated with disparity in HLA class II antigens between mother and fetus. When logistic regression was performed, pre-partum disease activity and disparity at both DRB1 and DQ were significant predictors of overall disease activity during pregnancy. Pregnancy should never be discouraged or terminated in a patient with IBD, but instead, the goal of care should be early counseling and appropriate medical management.

IBD medications and pregnancy outcomes (Table 1)

It is believed that the greatest risk to IBD pregnancy is active disease and not active therapy. In addition to the effect on disease activity during pregnancy, the fear of a medication's effect on the fetus often prompts physician and patient to discontinue all medications. Pregnancy data on outcomes and disease course are complicated by cessation of drugs. One of the earliest available drugs for the treatment of colitis, sulfasalazine, readily crosses the placenta, but has not been linked to any fetal abnormalities in several large studies. However, patients taking sulfasalazine should be supplemented with folic acid to decrease the risk of neural tube defects. A dose of one milligram twice daily is appropriate.

Table 1 Use of medications during pregnancy in inflammatory bowel disease

Benefit clearly outweighs risk	Limited data	Contraindicated
5-ASA, oral and topical	Olsalazine	Methotrexate
Corticosteroids	Natalizumab	Thalidomide
Metronidazole, amoxicillin		
Azathioprine/6-MP		
Anti-TNF agents		

TNF: Tumor necrosis factor.

Aminosalicylates: The safety of 5-ASA compounds during pregnancy has been demonstrated in a number of trials, despite the fact that mesalamine and its metabolite, acetyl-5-aminosalicylic acid are found in cord plasma[43,44]. In two separate studies, women taking 2-3 g/d for either UC or CD had no increased incidence of fetal abnormalities compared to normal healthy women.

Immunomodulators: In the retrospective chart review by Francella *et al*[45], there were 79 women with 325 pregnancies. The compared patients on 6-MP during conception, those that stopped prior to conception, and patients never exposed to 6-MP were compared. Although they did not look at prematurity or LBW, there were no statistical differences in spontaneous abortions, major congenital abnormalities, neoplasia, or increased infection [RR 0.85 (0.47-1.55), *P* = 0.59]. Moskovitz *et al*[46] looked at IBD medications (including 6-MP and azathioprine) taken during pregnancy. In this age-controlled multivariate analysis of 113 patients with 207 conceptions, there was no evidence that medications affected pregnancy outcomes (abortions, premature birth, healthy full-term birth, ectopic pregnancy, congenital abnormalities, birth weight, or type of delivery). Nørgård *et al*[47] combined two large national data registries with a national prescription database to look at therapeutic drug use in women with CD and birth outcomes. Among the women that were exposed to 6-MP/azathioprine throughout their pregnancies, the risk of preterm birth and congenital abnormalities was 4.2 (95% CI: 1.4-12.5) and 2.9 (95% CI: 0.9-8.9), respectively. Preterm births were more prevalent among steroid and 6-MP/azathioprine exposed women compared to the reference group. However, they were unable to stratify disease activity to adverse birth outcomes due to the low number of hospital admissions. Due to model fitting issues, the authors could not adjust for the "disease activity" when looking at the LBW infants at term[48].

In has been our practice to continue immunomodulator therapy through pregnancy. While classified as an FDA category D medication, it received this designation in the 1950s when originally approved to treat leukemia. The doses used to treat IBD are much smaller and the above cited literature suggests this to be a low risk therapy at these doses. Stopping therapy once pregnancy is diagnosed only puts the mother's disease at risk of flaring, as organogenesis has already occurred at this point and the fetus has been exposed at its most vulnerable-

cessation for safety to the fetus has to be 6-8 wk before conception, not after.

Biologics: Biologics are now more commonly used for more aggressive disease, and sometimes are used as first line in the "top-down" therapeutic approach. The first series of intentional infliximab use throughout pregnancy by Mahadevan *et al*[49] examined outcomes in ten women with active CD during pregnancy. All ten pregnancies resulted in live births, with no congenital malformations. There were three pre-term births and one LBW infant, but these were not unexpected in a population of women with CD significant enough to require biologic therapy. Infliximab has been detected in the infants born to mothers receiving infliximab during the third trimester of pregnancy; however, to date, the long term effect of this placental transfer is unknown[50].

A published report for the successful use of adalimumab in pregnancy describes a patient with severely active disease at conception[51]. She was placed on adalimumab one month prior to conception and delivered of a normal growth infant without visible congenital anomalies. A case series recently presented suggested its safety in fetal outcomes in women treated for CD[52]. More recent data presented in abstract form showed that patients exposed to natalizumab during pregnancy had a spontaneous abortion rate comparable to what is expected in the general population[53]. However, the number of exposed patients was too low to draw any definitive conclusions. Therefore, it is important for the physician to discuss with each patient the risk to benefit ratio of biologic therapy to control disease in pregnancy.

It has been our practice to continue biologics at least through the second trimester of pregnancy. Placental transport of IgG begins around week 20 and increases thereafter. Theoretically therefore, no therapy is reaching the fetus until administrations after week 20. If the last infusion of infliximab is timed to be around week 32, then the next infusion can be after delivery. Adalimumab injections are held after week 36.

Other agents: Corticosteroids have not been associated with teratogenicity in humans and can be used as required to control disease activity. Prednisolone crosses the placenta less efficiently than other steroid formulations, such as betamethasone or dexamethasone. Only limited data are available regarding the safety of antibiotics as treatment for CD. Currently, ampicillin, cephalosporins, and erythromycin are believed low risk, as is ciprofloxacin. Metronidazole has been used to treat vaginitis in women during the first trimester of pregnancy but no controlled trials have definitively demonstrated its safety[54].

CONCLUSION

Over twenty years ago it was recognized that IBD patients flaring at the time of conception had a higher chance of spontaneous abortion, still birth, and premature delivery. The classic Miller[6] paper from 1986 is often referenced.

For patients with active disease, one third will improve, one third will stay the same, and one third will worsen. This leaves two thirds of patients having to live with active disease during pregnancy[48]. Despite conflicting and sometimes confusing data, it is clear that there are potential risks involved with IBD pregnancies. It is crucial to understand the literature and also recognize its limitations. Ideally, conversations with the patient should occur before conception. Furthermore, decisions should be made with an informed approach with a team effort between the patient, the obstetrician, and her gastroenterologist. The key is continued monitoring and aggressive control of the disease prior to conception and throughout, to achieve optimal outcome for mother and baby.

Abstract

Crohn's disease and ulcerative colitis are chronic inflammatory bowel diseases that often involve organs other than those of the gastrointestinal tract. Immune-related extraintestinal manifestations (EIMs) are usually related to disease activity, but sometimes may take an independent course. Globally, about one third of patients develop these systemic manifestations. Phenotypic classification shows that certain subsets of patients are more susceptible to developing EIMs, which frequently occur simultaneously in the same patient overlapping joints, skin, mouth, and eyes. The clinical spectrum of these manifestations varies from mild transitory to very severe lesions, sometimes more incapacitating than the intestinal disease itself. The great majority of these EIMs accompany the activity of intestinal disease and patients run a higher risk of a severe clinical course. For most of the inflammatory EIMs, the primary therapeutic target remains the bowel. Early aggressive therapy can minimize severe complications and maintenance treatment has the potential to prevent some devastating consequences.

Key words: Inflammatory bowel disease; Immune-related extraintestinal manifestations; Treatment

INTRODUCTION

Inflammatory bowel diseases (IBDs) are clinically heterogeneous disorders with the potential for systemic involvement. The clinical spectrum of these extraintestinal manifestations (EIMs) varies from mild transitory to very severe lesions, sometimes more incapacitating than the intestinal disease itself.

Most of the EIMs, such as those that occur in the joints, skin, mouth and eyes, are related to the activity of the bowel disease and, consequently, have been referred to as "inflammatory". Others are associated with autoimmunity, while further manifestations result from nutritional or metabolic dysfunction.

Patients with ulcerative colitis (UC) are considered a more homogeneous group than patients with Crohn's disease (CD). The most important significant variables in UC are the extent of colonic involvement and the activity of disease.

The current clinical practice for management of CD patients should take into account a major number of events, such as age at diagnosis, location, behavior, intestinal complications, EIM symptoms and previous medical or surgical treatment.

The aim of the present manuscript is to review the common immune-related EIMs and to evaluate whether they are important targets of treatment or just an expression of disease activity.

PREVALENCE OF EIMS IN IBD

Globally, about one third of patients with IBD develop inflammatory systemic manifestations. The frequency of these manifestations in previous major studies ranged from 21% to 41%, depending on the patient population and criteria used[1-5]. In our series they were observed in 26% of the patients and were more common in CD than in UC patients. However, during the follow-up period the cumulative probability of developing EIMs increased from 12% at diagnosis up to 30%[2].

We have studied the course of CD according to the Vienna classification and clinical activity[6]. More recently, in this cohort of 480 patients followed from diagnosis, we investigated the cumulative probability of inflammatory EIMs, which varied from 22% at diagnosis to 40% 10 years after diagnosis. Here we showed that a single manifestation occurred in 80 patients, whereas multiple manifestations overlapping joints, skin, mouth, and eyes occurred in 89 patients (Figure 1).

The specific disease entities considered were peripheral and axial arthritis (joints), erythema nodosum and pyoderma gangrenosum (skin), aphthous stomatitis (mouth), and episcleritis and uveitis (eye). Thus, it was confirmed that two or more manifestations in the same patient occurred more frequently than would be expected by chance alone ($P < 0.001$)[2,4].

Patients with one of these EIMs not only run a high risk of a repetition of the same manifestation, but also of having any of the other associated manifestations. In our patients the cumulative probability of a second manifestation was about 70% at 10 years of follow-up.

Moreover, we have also studied the appearance of various EIMs throughout the clinical course and it was observed that some types of manifestations are more likely to appear during the early stages. This was particularly evident for skin manifestations, which tend to occur in most of the patients for the first time during the first 2 years of follow-up (Figure 2).

We have also studied the probability of EIMs in different subsets of CD patients[7]. The location of disease was significantly different between patients who had and who did not have EIMs and was higher in those with colonic involvement ($P < 0.005$) (Figure 3).

To calculate the clinical course, we constructed a Markov model to study the probability of maintaining a similar state during the following year. Patients were divided into two exclusive groups, those who had and those who did not have manifestations. Patients with EIMs ran a higher risk of a severe clinical course ($P < 0.005$)[7].

In UC it is still controversial whether EIMs are correlated with the extent of colonic involvement, although they are usually related to the activity of the disease.

DESCRIPTION OF EIMS

Joint manifestations

Peripheral involvement of the joints is the most common of the EIMs and it affects between 5% and 20% of IBD patients[8-11]. In our series, arthritis occurred frequently, twice

Figure 1 Associations of the four major inflammatory extraintestinal manifestations in 169 of 480 Crohn's disease patients.

Figure 2 Cumulative probability of having a repetition of the same inflammatory extraintestinal manifestations.

Figure 3 Distribution of inflammatory extraintestinal manifestations according to the Vienna classification in 169 Crohn's disease patients.

as often in CD as in UC (20% vs 11%)[2]. The joint involvement is mostly monoarticular, asymmetrical, transitory and migrating. Generally, it is of short duration and is unaccompanied by residual deformity or radiological change.

The diagnosis is based on clinical signs of synovitis, eventually associated with enthesitis. However, using articular scintigraphy, a sensitive indicator of active joint disease, asymptomatic and mild forms of synovitis could be detectable. We have evaluated articular involvement, clinically and by scintigraphy, in forty-two IBD patients. More affected joints have been diagnosed scintigraphically than

clinically, indicating that the prevalence of this complication could be much higher than generally believed[11].

The clinical activity of synovitis tends to parallel that of the intestinal disease. In most instances, the synovitis symptoms follow rather than precede IBD and recurrence is common, frequently coinciding with a flare-up of intestinal disease. Also, they are more common in patients with extensive colitis.

Regarding treatment, the main issue should be to control the clinical activity of the underlying bowel disease. Thereafter, there is agreement that this manifestation generally responds well to medical or surgical treatment targeted to the bowel disease. Conventional treatments for mild to moderate inflamed joints consist of acetaminophen, sulfasalazine, corticosteroids, and if necessary nonsteroidal anti-inflammatory drugs (NSAIDs). Furthermore, the majority of IBD patients with active intestinal disease and peripheral arthritis will notice an improvement of joint symptoms after receiving infliximab[12].

Ankylosing spondylitis, as defined by the Rome criteria, is associated with IBD in 5% of cases and it runs an independent course to the IBD[8-10]. In fact, the onset of ankylosing spondylitis is not related to the onset of IBD and usually precedes it. Also, there is no association between the severity of IBD and axial arthritis.

The proven efficacy of infliximab therapy in CD and rheumatoid arthritis has led to the suggestion that antitumor necrosis factor-α treatment might also be a useful agent in the management of spondyloarthropathies associated with CD.

In several open studies, infliximab has been used in patients with ankylosing spondylitis, leading to clinical, biologic and imaging improvement[12-15].

In our clinical practice the use of infliximab in patients with spondyloarthropaties associated with CD has resulted in an impressive improvement in clinical and laboratory abnormalities. The same has been reported in other uncontrolled studies[12,16]. In a multicentric, randomized, double-blind international trial to evaluate the efficacy of infliximab maintenance therapy in patients with moderate to severe active CD (ACCENT I), it has been reported that maintenance therapy with infliximab is superior to a single dose in resolving arthritis/arthralgia[17].

Clinical data suggest that intensive therapeutic strategies using biologic drugs should be tailored to the individual with severe or refractory articular disease. However, long-term studies with larger numbers of patients will be necessary to determine the patients who are most likely to benefit from these specific treatments. Furthermore, careful attention should be paid to the potential adverse events; mainly infections and malignancy.

Skin manifestations

There is a wide range of dermatological manifestations reported in patients with IBD, of which erythema nodosum is the most common form of reactive eruption. The prevalence of erythema nodosum has been reported to occur in up to 15% of patients[1], although other, more recent studies have reported that the prevalence may be considerably lower[10,18]. In fact, in a previous report from our

Figure 4 Severe lesions of erythema nodosum treated with infliximab.

group it was seen in 8% and 3% of CD and UC patients, respectively[2]. Clinically, erythema nodosum appears in conjunction with symptoms of active bowel disease and is most common in females, patients with large intestine involvement and peripheral arthritis[2].

Erythema nodosum lesions usually respond to treatment with corticosteroids used to control the bowel flare-up. In refractory cases, potassium iodide, colchicine, hydroxychloroquine, and thalidomide have been used[19]. More recently a successful response to infliximab in severe erythema nodosum has also been reported[20]. We have used this treatment in a patient with colonic CD complicated with severe lesions of erythema nodosum and arthritis, refractory to high doses of steroids, which resulted in a rapid and complete resolution of skin and articular manifestations (Figure 4).

Pyoderma gangrenosum is a severe and debilitating skin disorder, characterized by the occurrence of nodules and pustules that rapidly enlarge and ulcerate. Lesions typically occur on the extensor surfaces of the lower extremities, but may also be found elsewhere. Since there is no specific test, the diagnosis can be difficult, only being established when the clinical and histopathological pictures are consistent with pyoderma gangrenosum, and other pustular or ulcerative dermatoses have been excluded.

This chronic ulcerating skin disorder can be found in 0.4%-2% of patients with IBD[10,19]. Patients with severe disease and colonic involvement are most likely to develop this complication. Pyoderma gangrenosum may run a course independent of the IBD, but sometimes coincides with an exacerbation of the underlying intestinal disease.

 Management of pyoderma gangrenosum continues to be a therapeutic challenge and usually requires aggressive local and systemic therapy. High doses of oral prednisone and/or intralesional injections of corticosteroids are generally effective in the management[21]. However, the best form of treatment, particularly in patients with inactive intestinal disease, has not been established yet. Several clinical cases have been successfully treated with intravenous cyclosporine, oral and topical tacrolimus, or mycophenolate mofetil and granulocytapheresis[22-27].

In several reports patients treated with infliximab have shown rapid healing of their lesions[28]. We have successfully treated one patient in this way (Figure 5). In a recent controlled study, 6 of 13 patients with pyoderma

Figure 5 Pyoderma gangrenosum before, during and after treatment with infliximab.

Figure 6 Aphthous ulcers in the buccal mucosa and on the tongue.

Figure 7 Ankylosing spondylitis and uveitis in the same patient.

Figure 8 ERCP showing sclerosing cholangitis and endoscopic view of carcinoma of the colon observed in the same patient.

gangrenosum were successfully treated with infliximab[29]. Thus, infliximab treatment is highly effective in healing refractory lesions and has become the first choice for the treatment of pyoderma gangrenosum.

Oral ulceration

Aphthous ulcers are the most common oral lesions in IBD; they occur in about 10% of patients. Aphthae are shallow, round ulcers with a central fibrinous membrane and erythematous halo (Figure 6). Their onset is usually sudden, coinciding with the flare-up of intestinal disease and occurring simultaneously with other EIMs[2,30].

Many similarities exist between CD and intestinal Behçet's disease. Both diseases have similar EIMs, particularly aphthous ulcers, which are an initial symptom in the majority of patients with Behçet' disease[31].

Oral ulcers usually respond to the treatment of the underlying bowel disease, but sometimes they may be resistant to conventional therapy. In these situations topical applications of steroids or tacrolimus may be of use[32]. Oral thalidomide has been reported to be beneficial in the treatment of aphthous stomatitis related to HIV infection and could be tried for lesions in patients with IBD. Infliximab has also been used in the treatment of patients with CD complicated with gigantic oral ulcers[7].

Eye manifestations

Ophthalmologic complications have been reported to occur in up to 12% of patients according to the published literature and these complications seem to occur more frequently in CD patients[33]. The most common complications are episcleritis, scleritis, and uveitis. Uveitis is the most serious complication and may be the cause of significant morbidity. Often it occurs independently of the bowel disease and is particularly associated with the mus-

culoskeletal EIMs[34] (Figure 7). Specific treatment may include topical and systemic steroids. In the management of ophthalmologic manifestations, immunosuppression is often required. Infliximab has been reported to have a beneficial effect in a few patients suffering from CD with uveitis and spondyloarthropathy, and is increasingly being used in both acute and chronic ocular inflammatory manifestations of IBD[12,35-37].

Hepatobiliary manifestations

Primary sclerosing cholangitis (PSC) is the most common immune-mediated hepatobiliary disease. It is a chronic, progressive, cholestatic disorder characterized by inflammation and fibrosis of the intrahepatic and extrahepatic bile ducts. The prevalence of IBD (mostly UC) is about 75% and PSC complicates approximately 2%-5% of cases of UC and 0.7%-3.4% of cases of CD[10,38].

Most patients with PSC are diagnosed when asymptomatic with abnormal liver function tests performed in routine follow-up. Symptoms of PSC usually consist of fatigue, pruritus, right upper quadrant pain, fever, jaundice, and weight loss. Magnetic resonance (MR) cholangiography is often used for diagnosis of PSC and avoids the complication of endoscopic retrograde cholangiopancreatography. Liver biopsy is not always necessary where typical features are present on MR cholangiography[39].

IBD-PSC patients have a specific phenotype, characterized by extensive, mild disease with a particularly high risk of colonic dysplasia and carcinoma (Figure 8), as well as an increased risk of bile duct cancer. Yearly surveillance

colonoscopy is recommended for those patients with colonic involvement[40,41].

The medical management of PSC remains controversial. Ursodeoxycholic acid is widely used for this indication, and the best results have been obtained with high dose (up to 22-25 mg/kg). Moreover, the evidence that this medication prevents progression of PSC and that it may reduce the high risk of colonic cancer in these patients may become an indication for its use[38]. Liver transplant is the only treatment for patients with advanced PSC, with a 5-year survival rate of approximately 80%. However, the optimum timing for transplantation remains a difficult decision.

CONCLUSION

During the course of IBD, EIMs related to the activity of intestinal inflammation are quite common. Phenotypic classification shows that certain subsets of patients are more susceptible to developing EIMs. They also have a higher probability of maintaining active disease during the clinical course. For most of the inflammatory EIMs, the primary therapeutic target remains the bowel. Early aggressive therapy with biologic drugs may be required for several EIMs and maintenance treatment has the potential to prevent some devastating consequences. Long-term studies with larger numbers of patients will be necessary to determine the patients who are most likely to benefit from specific treatments.

Abstract

The majority of patients with inflammatory bowel disease (IBD) achieve good control of the inflammatory activity using available therapies. When remission is achieved and quality of life recovered, a considerable proportion of IBD patients express their desire to travel abroad, be it for business, academic or leisure purposes. Their physicians should help and encourage them whenever possible. However, preventive measures are warranted to minimize the risk, since IBD patients are exposed to the same infections affecting the general population, plus opportunistic infections (OI) related to the immunosuppression. There are a large number of potential OI that might affect patients with IBD. The true prevalence of these infections is unknown, and can vary from country to country. Therefore, reactivation or *de novo* acquisition of infections such as tuberculosis, malaria, and viral hepatitis will be much more frequent in endemic areas. Therefore, physicians should be aware of these aspects when planning specific preventive measures for patients traveling to a particular country. This includes good control of environmental exposure, chemoprophylaxis when indicated, and the use of a specific vaccination program to prevent endemic infections. In addition, it should be noted that, though the risk of acquiring an infectious disease is probably greater for IBD patients traveling from a developed to a developing country, the inverse situation can also occur; it depends on the previous acquired immunity of the host against infections in any particular environment.

PREVENTIVE MEASURES AND CHECK-UPS BEFORE THE TRIP

Patients traveling abroad should adhere to a specific vaccination program depending on the country to which they are traveling. Specific advice by specialists in tropical medicine might be required at least 4-6 wk before the trip, to allow time for vaccines to take effect and to start taking chemoprophylaxis to prevent malaria when needed. Requirements for visiting/staying in any particu-

lar country can be found on the websites of the World Health Organization (WHO) (http://apps.who.int/tools/geoserver/www/ith/index.html) and of the Centers for Disease Control and Prevention (CDC) (http://wwwnc.cdc.gov/travel/destinations/list.aspx). An interactive map provides information on health risks for travelers to specific countries by clicking on any part of the country or a nearby country.

The vaccination status according to current recommended vaccination program for adult inflammatory bowel disease (IBD) patients[1-3] (Table 1) should be periodically monitored, particularly before the start of a trip. Concerns about the safety of live-attenuated vaccines in immunosuppressed patients have arisen due to the possibility of fatal reactivation of the infectious agent contained in the vaccine. However, there are no data regarding the required time free of immunomodulators for administering these vaccines with confidence. The risk of reactivation, which also occurs with opportunistic infections (OI), probably depends on the type, dose, and duration of immunosuppressants added to a particular host response, for example the existence or not of leucopenia and lymphopenia[4]. Thus, an immunosuppressant washing-out period of 2 mo before and after live attenuated vaccine administration seems to be prudent. Live attenuated vaccines include, among others, varicella and yellow fever vaccines (Tables 1 and 2). Additionally, there is limited information as to whether IBD patients, mainly those under immunosuppressants, acquire adequate levels of protection using the present recommended vaccination schedule. For example, in one study including adult patients with rheumatological diseases and Crohn's disease vaccinated against two strains of influenza (A/H3N3 and B), the majority achieved protective titers $\geq$ 40, irrespective of whether or not they were taking anti-tumor necrosis factor (TNF) therapy[5]. However, impaired response against a single dose of 23-valent pneumococcal polysaccharide vaccine[6] and against standard three doses of hepatitis B vaccine[7] was reported, mainly in those patients treated with combined immunosuppressants and biologics. Therefore, it remains to be established whether higher doses of vaccine and booster administration might afford better immunization against specific infections.

For IBD travelers coming from countries with well-developed immunization programs, vaccination against tetanus, diphtheria, and inactivated poliomyelitis should be administered every 10 years and a booster dose is recommended before traveling. A booster dose against pertussis is also advisable in combination with the former, as a resurgence of pertussis has been documented in many industrialized countries, such as the United States, Australia, and Canada. Estimating rates of pertussis in developing countries is difficult, because of a lack of access to diagnostic methods and under-reporting. However, epidemiologic estimates by the WHO from Asia, Africa, and South America demonstrate that these areas have the highest disease burden, and there is a public health problem in all age groups[8].

Antibodies against hepatitis B should be checked when planning a trip to high prevalence areas (China, Southeast Asia, and tropical Africa) or intermediate prevalence areas (Eastern Europe, the Mediterranean, Russia, and Central and South America). For immunocompromised patients, regular testing and booster administrations, when anti-HBs antibody levels fall below 10 mIU/mL, are recommended[9]. This is important because not only can the response to standard dose of vaccination be impaired, but antibody titters can decrease with time in immunosuppressed patients who have achieved an adequate previous immunization. There is a combined Hepatitis A inactivated and hepatitis B recombinant vaccine for the immunization of adults. The effect of hepatitis A immunization in IBD patients is not known, but it seems to be severely impaired in immunosuppressed patients for other disease conditions[4].

Influenza viruses change rapidly from season to season, consequently Influenza vaccine must be manufactured and administered every year. This vaccine includes the three strains that cause the most illness in the upcoming season based on virus samples and patterns collected from around the world. Influenza viruses circulate worldwide and IBD travelers should be aware of the outbreaks of specific influenza viruses when they plan a trip to a particular country. They should be vaccinated for the specific strain affecting this particular area at a given moment. In this sense, the pandemic caused by the H1N1 swine-derived influenza strain, or the previously emerged avian influenza strains still circulating, constitute good examples of the need for specific protection[10].

One of the biggest problems for IBD patients traveling to tropical areas of South America and Sub-Saharan Africa is how to prevent yellow fever. It is caused by an RNA hepatotropic virus that causes a pansystemic disease, with fever, hepatic, renal and myocardial injury, hemorrhage, shock, and mortality as high as 50%. Vaccination against yellow fever is mandatory when visiting 16 countries and strongly recommended for all endemic countries. Although limited studies indicate that vaccine immunity lasts for at least 45 years, the WHO requires booster immunizations every 10 years to maintain adequate protection. The yellow fever vaccine 17D contains live attenuated virus and is contraindicated for IBD patients who cannot stop immunosuppressants for at least 4 mo. Hence, traveling to endemic areas should be discouraged for patients requiring continuous immunosuppression to keep their IBD under control. However, the long-lasting immunization effect of yellow fever vaccine allows its administration at any time that is convenient for immunosuppressant discontinuation when a trip to endemic areas is expected in the future. Risk of serious adverse events following yellow fever vaccination is very low, but increases with age (4 per 100 000 doses for people aged 60-69 and 7.5 per 100 000 doses for people 70 and older)[11].

Neisseria meningitidis causes endemic meningococcal disease worldwide, with a specific serotype distribution

Table 1 Current recommended vaccination program for adult inflammatory bowel disease patients[1-3]

Illness	Vaccine	Recommendation	Schedule
Tetanus	Purified anatoxin	Recommended	Every 10 yr
Diphteria			
Poliomyelitis	Injectable: inactivated	Recommended	Every 10 yr
Pertussis	Acellular antigen	Authorized	Every 10 yr
Hepatitis B	Recombinant peptide	Recommended	Single/double doses?
			Booster?
Pneumococcal disease	23-valent purified antigen	Recommended	Every 5 yr
			Single/double doses?
			Booster?
Influenza	Inactivated virus	Recommended	Annually
Human papillomavirus infection	Recombinant L1 protein	Authorized	??
Measles,mumps and rubella	Live attenuated	Contraindicated during immunosuppression	??
Varicella	Live attenuated	Contraindicated during immunosuppression	Double dose (4 wk interval)
Haemophilus influenzae B disease	Conjugated capsular polyosidique antigen	Authorized	Single dose

Table 2 World distribution of travel-related preventable illnesses and current recommended vaccination program for adult inflammatory bowel disease patients

Illness	Regions with high and intermediate endemicity	Vaccine/schedule	Recommendation
Hepatitis A	High: Africa South America, Middle East Southeast Asia, China Intermediate: Southern and Eastern Europe	Inactivated virus (every 10 yr)	Authorized
Yellow fever	Africa: Sub-Saharan Africa America: Central and South America	Live attenuated (every 10 yr) 17D strain (17D-204 /17DD)	Contraindicated during immunosuppression
Meningococcal disease	Europe: Serogroups B, C	Conjugate polysaccharide C	Authorized
	Americas: Serogroups B, C, Y	Polysaccharide combined A+C	Authorized
	Africa and Asia: serogroups A, C, W135	Polysaccharide combined A+C+W+Y (single dose among persons aged 11-55)	Authorized
Typhoid	High: Southern Africa Western, Eastern South central and Southeastern Asia Intermediate: Eastern, Middle and Northern Africa, Western Asia, Latin America/Caribbean, Oceania	Vi Capsular polysaccharide (single dose IM. Booster dose every 2-3 yr for those at risk)	Authorized
Cholera	Africa: Congo, Kenya, Mozambique, Uganda, Tanzania and West Africa	Oral Killed (2 doses at 1-6 wk interval with a buffer to protect the B-subunit against stomach acidity)	Authorized
	South and Central America: Peru, Ecuador, Guatemala, Nicaragua Asia: Afghanistan, India, Cambodia, Malaysia, Nepal, Sri Lanka	Oral live	Contraindicated during immunosuppression
Rabies	High: Africa, Asia, parts of Central and South America Intermediate: Eastern Europe, parts of central and South America (Chile, Argentina)	Cell culture-derived vaccine (travellers, not handling animals: 2 doses, at days 0-28. If risk continues booster dose at 6-12 mo)	Authorized
Japanese encephalitis	Southeast Asia Far East	Cell culture-derived vaccine (2 doses, at days 0-28 booster dose?)	Authorized
Tick-borne encephalitis	Europe: Central and Eastern Europe, Russia Asia: China, Siberia, Russian Fareast	Inactivated virus (3 doses at 0,1 and 12 mo)	Use with caution

per continent (Table 2). Polysaccharide vaccines against meningococcal serogroups A, C, Y, and W135 have been available for several decades, but have been little used due to poor immunogenicity and minimal effects on naso-pharyngeal carriage. The recent advent of a quadrivalent conjugate vaccine including A, C, Y, and W135 ensures a broad coverage for travelers and should always be considered before the polysaccharide vaccine[12]. However, effective global prevention of meningococcal disease will not be achievable without the availability of a vaccine against Group B meningitis (predominant in Europe and America), for which outer membrane protein vaccines are under development[13].

Travel to the Indian subcontinent is associated with the highest risk of contracting enteric fever. There are two available vaccines against *S. typhi*: the live attenuated oral vaccine containing the *S. typhi* strain Ty21a (Ty21a vaccine) and the parenteral capsular polysaccharide vaccine based on the *S. typhi* Vi antigen (Vi vaccine). Thus, the Vi vaccine is recommended for IBD patients. It is

available for children ≥ 2 years old, conferring protection 7 d after injection with a maximum neutralizing antibody concentration demonstrated 28 d after vaccination[14]. Percentages of efficacy in immunocompetent individuals range from 55% to 72%, but the figure is unknown for IBD patients taking immunosuppressants. The gastro-enterologist should discuss with the patient the efficacy of the vaccine and reinforce the necessity of strict food and water precautions. The same control measures are required to prevent cholera and all diarrheal illnesses. However, when access to clean water and sanitation are not guaranteed, cholera vaccine should be administered, conferring 85% short-term protection, and 60% protection up to 3 years following vaccination. IBD patients taking immunosuppressants should receive the oral-killed vaccine licensed in more than 20 countries, including the European Union (Dukoral®). Another available oral-killed vaccine (Vabiotech, ORC-Vax®) was initially licensed only in Vietnam[15].

Rabies is a viral zoonosis, almost invariably fatal in humans. Rabies is widely distributed throughout the world and present in all continents. However, the probability of rabies exposure is directly related to the incidence of rabies in the area and the probability of contact with infected animals. In areas of high-risk exposure, such as most parts of Africa, Asia, and Latin America, human rabies occurs from the bite of domestic and stray dogs and cats without owners. By contrast, in low-risk areas (North America, southern Africa, parts of the Caribbean, and Europe), the principal mammalian reservoir species are wild carnivores[16]. Currently, cell-culture derived vaccines are used, and these are authorized for use by IBD patients traveling to high risk areas, particularly where there is limited access to medical care[1,3].

Japanese encephalitis (JE) is a leading cause of viral meningoencephalitis transmitted by *Aedes* mosquitoes in large parts of Asia. It is mainly a problem in rural rice growing and pig farming regions, but can also be found at the outskirts of cities. It occurs more commonly in the rainy season (roughly May-September), when the mosquitoes are most active[17]. Individuals under chronic conditions and under anti-TNF therapy are particularly considered candidates for JE vaccine[18]. A novel inactivated cell culture-derived vaccine (IXIARO®) has recently been licensed in the United States and Europe and can be safely administered to IBD patients.

Tick-borne encephalitis (TBE) is a disease of the central nervous system caused by a tick-borne viral infection. A recent systematic review has demonstrated that the three currently licensed TBE vaccines (Encepur children®, Encepur Adults®, and FSME-IMMUN"new"®) gave seroconversion rates of over 87%[19]. However, the relationship between seroconversion and clinical protection has not been established. As all the vaccines may produce commonly but generally mild adverse effects, their use in IBD patients is authorized with caution. In addition, the TBE vaccine has been suspected of causing an exacerbation of autoimmune diseases, but a cause-and-effect relationship has not been confirmed. Taking all these factors together, risk-benefit should be weighed and vaccine administered to those patients traveling to high-risk rural or forested areas, especially in the spring or summer.

PREVENTIVE MEASURES DURING THE TRIP

Though vaccination or chemoprophylaxis remains the most effective means of traveler infection prevention, some additional measures upon exposure to environmental factors during the trip should be taken. These include the avoidance of insect bites and the ingestion of safe foods and beverages. Insects are vectors of infections such as malaria, dengue, filariasis, Chagas, leishmaniasis, onchocerciasis, and trypanosomiasis, among others. At the WHO and CDC websites there is updated information about diseases that should be prevented per country, the type of insect vector, and the best means of prevention. Some of these diseases may be partly prevented by the application of insect repellents. However, the ideal mosquito repellent remains to be identified. It should repel multiple species of arthropods, have long-lasting effect, cause no local or systemic toxicity, be resistant to abrasion and rub-off, and be greaseless and odorless. DEET (N,N-diethyl-m-toluamide) remains the gold standard of currently available insect repellents[19]. Used at variable concentrations ranging from 10% to 75%, it is considered that a concentration higher than 50% offers no additional benefit. Other measures, such as avoidance of outdoor exposure during the period of maximum insect activity (for example crepuscular periods for malaria mosquitoes), and wearing long-sleeved shirts, long pants, and a hat outdoors, are also advisable.

It is important to prevent animal bites and scratches to avoid rabies. If suspected exposure to rabies occurs, prompt and thorough cleansing of the wound, together with administration of immunoglobulin added to immunization with the above-mentioned vaccine starting immediately after exposure, virtually guarantees complete protection[16].

IBD patients should pay particular attention to preventing traveler's diarrhea (TD), as there is evidence showing that intestinal infections can trigger the disease[20] or induce relapses[21]. However, infection by enteropathogenic bacteria does not appear to be associated with a poorer clinical outcome of the IBD flare[21]. There is no evidence supporting the need for chemoprophylaxis for IBD travelers to prevent diarrhea, and the majority of specialists prefer not to recommend it to travelers[22]. However, a recent expert review included IBD patients as potential candidates for chemoprophylaxis[22]. An intermediate and very reasonable position might be early self-treatment when a gastrointestinal infection is suspected[4,23]. Fluoroquinolones are the drugs of choice in IBD, followed by azithromycin in patients who take fluoroquinolone as a part of their treatment[4]. The efficacy of Rifaximin against enteroinvasive bacteria (*Campilobacter*,

Table 3 Preventive measures for inflammatory bowel disease patients coming from developing countries (mainly while taking immunosuppressants or before starting)

Shigella, and *Salmonella*) has never been proved and consequently it is not an appropriate drug for IBD patients with bloody diarrhea and fever[4,22].

The evidence for the use of vaccines against enterotoxigenic *Escherichia coli* (ETEC) is scarce and it cannot be recommended at the present time for TD prevention. In addition, studies should be performed to demonstrate which foods and beverages have the lowest and the highest risk for TD. Though firm evidence is lacking demonstrating the value of dietary and beverage selection in the prevention of TD, uncooked fruits and vegetables and untreated drinking water are considered to hold the highest risk[22].

PREVENTIVE MEASURES AND CHECK-UPS TO DETECT INFECTIONS HARBORED DURING THE TRIP

Patients with IBD are likely to be treated with steroids, immunomodulators, or biologicals. It has been reported that these therapies can increase the risk of severe infections[24] or OI[25], especially when administered in combination, and even more so in the elderly or when narcotics are also prescribed. Thus, those patients on maintenance therapy with these drugs who travel to developing countries are, at least hypothetically, at increased risk for OI. Of course, the time spent in those countries may be one of the most decisive factors in increasing the risk of such infections, and it should be always taken into account when evaluating these patients. Most OI will present as acute manifestations soon after (or even while) the patient returns home. However, some parasitic or protozoal infections can remain latent for years (e.g. strongyloidosis, Chagas' disease, or histoplasmosis); we must remember this especially in patients who stay for a long period of time in developing countries or, even more importantly, for individuals coming from developing countries who are diagnosed with IBD once in a developed country.

Another important factor is familiarizing oneself with the endemic infections affecting countries from which the patients are returning (Table 3). Depending on the geographic area, our investigations should be directed towards some infective agents or others. However, no specific recommendations are yet available for returning travelers; of course, there is no definition for "long-term" travel or stay in developing countries. Therefore, in this section the authors will try to draw a modest picture of which infections should be investigated, and how.

The most common clinical setting should be that of a patient returning from a short stay in a developing country who presents with diarrhea[26]. In this case, stool samples for microbiological evaluation using conventional cultures (mainly to detect enteric pathogens) should be taken and examination for fecal parasite detection should be carried out. It is important to collect at least three samples from different bowel movements (preferably from different days). If infestation by *Giardia lamblia* or *Criptosporidium parvum* is suspected, immunofluorescence is necessary. The presence of fecal *Entamoeba* cysts must be corroborated by serology; if positive, combined therapy with metronidazole and paromomycin should be started. However, in seronegative patients, paromomycin alone might be sufficient[27].

Among chronic infections, strongyloidosis might reactivate in case of immunosuppression[28]. Infection by *Strongyloides stercolaris* is endemic in tropical and subtropical regions, and it can be also seen anecdotally in Europe, the United States, Japan, and Australia. Evaluation of stool samples remains of paramount importance, although with limited diagnostic yield because of the intermittent presence of ova and larva in feces. Collection of repeated stool samples is strongly warranted, as is the use of concentration techniques or specific cultures that can achieve 80% sensitivity. Although serologic tests are highly sensitive, they do not differentiate past from current infection. Strongyloidosis might present not only by diarrhea, but also by abdominal pain or rectal bleeding. It should be especially suspected in patients coming from endemic areas, with a compatible clinical picture and peripheral eosinophilia[29]. Similarly, schistosomiasis is a prevalent chronic infestation in tropical and subtropical regions. Diagnosis is based in the visualization of ova in urine samples. Chagas' disease, or American trypanosomiasis, is a zoonosis found all over South America. The infection can remain latent for 10 to 30 years, and 30%-40% of individuals will then develop a chronic disease[30]. Interestingly, clinical symptoms will be those

related to the development of visceral involvement; in the case of the GI tract, dysphagia due to megaesophagus and constipation, abdominal pain and bloating due to megacolon make up the most common clinical picture[31]. Parasitological studies are of low diagnostic yield, and serological tests (indirect hemaglutination, indirect immunofluorescence, and ELISA) are preferred; in fact, two positive serological tests are necessary to establish the diagnosis[32]. Although digestive involvement is not usually life threatening, cardiac involvement can result in a fatal outcome.

Malaria and tuberculosis are the most common infectious diseases. *Plasmodium falciparum* can persist as a latent infection for 1 to 5 years, *P. ovale* and *P. vivax* for 3 to 5 years, and *P. malariae* for up to 40 years. Thick drop test in peripheral blood remains the diagnostic test of choice, although PCR tests can be useful in cases of low parasitemia[33,34].

Tuberculosis is nowadays systematically ruled out in patients who might be treated with anti-TNF agents. However, this diagnosis should always be taken into account in IBD patients returning from or coming from developing countries. Tuberculin skin tests and interferon gamma assays can be used for the diagnosis of latent or active TB, as recently stated in the European Crohn's and Colitis consensus[4,35]. Finally, histoplasmosis is widely distributed, although predominantly in America and Africa. Primoinfection is often subclinical, but reactivation can be life threatening. Diagnosis is based on direct observation on microscopy, and it is corroborated by a positive culture of biological samples (sputum, skin lesions, liver biopsy, or bone marrow aspiration). Antigenuria is useful to monitor therapeutic response[36,37].

CONCLUSION

In summary, patients with IBD on immunosuppressanttherapy (including steroids) must be carefully evaluated in case of fever, diarrhea, abdominal pain, or rectal bleeding when returning from or coming from developing countries. Learning about the geographical area and time spent in the area are of paramount importance in identifying one or another OI and appropriately targeting the diagnostic tests. In addition, an accurate medical history, as well as a complete physical examination, will be of great value.

Abstract

Inflammatory bowel disease (IBD) develops in genetically susceptible individuals due to the influence of environmental factors, leading to an abnormal recognition of microbiota antigens by the innate immune system which triggers an exaggerated immune response and subsequent bowel tissue damage. IBD has been more frequently found in families, an observation that could be due to either genetic, environmental or both types of factors present in these families. In addition to expanding our knowledge on IBD pathogenesis, defining the specific contribution to familial IBD of each one of these factors might have also clinical usefulness. We review the available evidence on familial IBD pathogenesis.

Key words: Inflammatory bowel disease; Familial aggregation; Familial clustering; Environmental factors; Genetics; Genome wide association studies

INTRODUCTION

Our present understanding of inflammatory bowel disease (IBD) pathogenesis considers ulcerative colitis (UC) and Crohn's disease (CD) as complex conditions that develop in genetically susceptible individuals due to the influence of various environmental factors[1-6]. An abnormal recognition of certain antigens of the bowel microbiota by elements of the innate immunity is thought to play a key role, leading to an exaggerated immune response, release of pro-inflammatory molecules and, ultimately, bowel tissue damage.

In past decades a greater incidence of IBD cases among UC and CD relatives, referred to as family aggregation or familial IBD, has been clearly demonstrated[7-11]. The reason for such an increased risk is not straightforward, but genes, the environment or a combination of both could, in theory, account for family aggregation, considering their contribution to the development of IBD. A better understanding of the factors leading to familial IBD might result in clinical applications.

FAMILLIAL IBD

Familial aggregation among IBD patients or "familial IBD" is defined by the occurrence of a trait in more fam-

ily members than expected by chance. Multiple population studies have demonstrated that relatives of an IBD patient have a much higher risk of developing the same condition, compared to the general population[7-11]. The magnitude of familial aggregation depends on several factors, including: (1) type of IBD; (2) population studied; and (3) family relationship.

In respect to type of IBD, familial aggregation has been more frequently reported in CD than UC[7,9]. In first degree relatives, the age-adjusted relative risk of developing the same type of IBD ranges from 2-8 for UC and from 5-10 in the case of CD[7-9]. As elegantly demonstrated by Yang *et al*[9], affected relatives can develop both forms of IBD, although the greatest risk is associated with the appearance of the same disease type occurring in the index case. Additionally, CD patients tend to have a much higher frequency of relatives affected with UC when compared to UC patients having relatives affected with CD[7].

In respect to different populations, it has been shown that Jewish families present more than twice the number of multiple affected families when compared to the non-Jewish population[9]. However, we cannot rule out the possibility that differences amongst other geographical populations are due to their study design.

Finally, frequency of familial IBD also varies according to the degree and type of kinship. The prevalence of IBD in second-degree relatives appears to be lower than in first-degree relatives, especially in those with discordant disease[7]. In addition, although only a few studies have estimated the age-adjusted risk of IBD in relatives, it seems that the risk of IBD in offspring is higher than in parents and similar, or even slightly higher, than in siblings[8,9,11]. A potential source of bias could result from underreported cases in second-degree relatives and older generations, which might have influenced these differences.

In addition to an increased risk of developing the disease, first-degree relatives of IBD patients also have an increased likelihood of sharing the same phenotype[8,12]. This seems to be partly true in CD owing to the striking clinical concordance in families, in respect to disease location and behavior. On the contrary, literature is scarce and presents mixed results for CD severity and complications[8,9,13-16]. In UC families, the phenotype concordance data is less consistent, but a high concordance rate related to colonic extent and extra-intestinal manifestations has been reported[12,14].

The possibility that IBD develops at an earlier age in offspring than in their parents, a phenomenon known as anticipation, has been controversial[17-21]. Although different studies have reported such differences in age of onset, it seems that multiple biases could account for these findings. Whether familial IBD is a different clinical entity was the subject of debate. However, in the largest population-based study including 654 sporadic and familial IBD patients, a positive familial IBD history did not significantly influence clinical course or risk of developing IBD-related complications[22].

ROLE OF GENES IN FAMILIAL IBD

Evidences supporting the role of genetic factors in IBD pathogenesis

The fact that IBD is a genetically mediated disease was initially derived from the physician's perception of a higher prevalence of UC and CD cases among the relatives of IBD patients. This hypothesis was initially supported by case report studies showing clustering in IBD families and was subsequently confirmed by several population-based studies[3-7]. In one of these studies, Yang *et al*[9] described a risk of developing UC and CD among first degree relatives of IBD patients of 1.6% and 5.2%, respectively. The risk of developing IBD also varies according to the ethnic origin of individuals, a fact that is likely to be linked to their genetic background. In that regard, the prevalence of IBD among the Jewish population is 2 to 4 times higher than in any other ethnic group, being greater in Ashkenazi than in Sephardic or Oriental Jewish, with no influence from their geographical location[9,11].

Another source of evidence underlying the key role of genetic factors in IBD steams from twin studies. In these studies the greatest IBD concordance rate was found in monozygotic twins, ranging from 20% to 50% in CD and from 14% to 19% in UC twins, whereas in dizygotic twins concordance rates dropped to 0%-7% in both CD and UC twins[23-26]. The degree of monozygotic-dizygotic twin concordance found in CD point towards a genetically mediated condition with a non-Mendelian inheritance pattern. Of note, the concordance rates observed in CD are greater than these found in type 1 diabetes, asthma or schizophrenia, all of them diseases with a well-established genetic background.

Genes involved in CD pathogenesis

Several genome linkage studies identified a number of CD susceptibility regions in chromosomes 1, 3, 4, 5, 6, 7, 10, 12, 14, 16, 19 and X[27-34]. After subsequent confirmation, regions on chromosomes 16, 12, 6, 14, 5, 19 were named IBD1 to IBD7, respectively[35]. Of these 7 original loci, only IBD1 (chromosome 16q12) was replicated in all studies, whereas another three loci, IBD2 (chromosome 12), IBD3 (chromosome 6) and IBD4 (chromosome 14) were replicated in some of the studies[36]. Later on, several CD susceptibility genes, such as NOD2, NOD1, toll-like receptors (TRLs) genes, and novel organic cation transporter (OCTN) genes were identified using either a candidate gene approach or positional cloning techniques[37].

The first and most relevant CD susceptibility gene described to date is NOD2. The carriage of one or more of the three main NOD2 variants (Arg702Trp, Gly908Arg and Leu1007incC) is found in 25%-45% of CD Caucasian patients and in only 15%-20% of healthy subjects[38]. A clear gene-dose effect has been described for NOD2 in CD patients. While the risk of developing CD is increased by 2-3-fold in subjects carrying one NOD2 variant allele, it reaches a 20-40-fold increase in subjects with two or more NOD2 variant alleles. In addition to increasing CD

susceptibility, the *NOD2* gene variants can also influence CD behaviour, phenotypes and need of surgery[39]. Similarly, the carriage of NOD2 variants has also been linked to a slight increase in familial CD risk[40]. In spite of being the most powerful CD susceptibility gene found to date, it must be underlined that the *NOD2* gene only accounts for a small proportion of the genetic inheritance of CD in Caucasians. Moreover, *NOD2* gene variants are infrequent in some geographic areas, such as Scotland, Ireland and Scandinavia, or even completely absent in subjects with an Asian and African-American genetic background[37]. In these cases other genes must account for the genetic predisposition to develop CD. This is in keeping with the highly polygenic nature of this disease.

In the last 3 years, the field of IBD genetics has experienced a dramatic transformation. Completion of the human genome project and development of tools capable of simultaneously studying a great number of genes has resulted in a much higher number of genes influencing CD and UC susceptibility than expected. Several genome-wide association studies (GWAS) have been undertaken in CD patients and healthy controls[41-45] and a meta-analysis has been recently published[46]. In this meta-analysis more than 30 independent loci are found to be convincingly associated with CD, providing an extraordinary insight into CD pathogenesis. Interestingly, most CD susceptibility genes are involved in either recognition of bowel microbiota antigens by the innate immunity, the IL-17/IL-23 pathway or autophagy, suggesting that these molecular mechanisms play a key role in CD pathogenesis.

Several studies have evaluated the frequency of CD-related mutations in affected families[47-49]. Jess *et al*[47] studied NOD2 mutation frequency in a population of Danish twins with IBD. In this study, a high prevalence of NOD2 mutation was observed in both CD twins and their healthy siblings. A Swedish study on monozygotic twin pairs reported a NOD2 frequency in both concordant CD siblings of only 22%, although the prevalence of NOD2 was indeed higher in concordant than in discordant twin pairs[48]. Joossens *et al*[49] investigated the prevalence of genetic markers (NOD2, NOD1, TLR4, CARD8) in multiplex and single-case families, healthy relatives and controls. The authors found a significant correlation between the number of genetic mutations per family and an increasing number of first-degree relatives with CD. However, these results could not discriminate between single-case and multiplex families.

Genes involved in UC pathogenesis

Two studies aimed at describing the influence in UC of the well-established CD susceptibility genes reported very interesting findings[50,51]. It became clear there is a genetic overlap between the two forms of IBD, with some genes involved in the development of both CD and UC (3p21.31, NKX2-3, CCNY). On the contrary, other genes have been only associated with UC, but not CD (ECM1 HERC2, STAT3 and PTPN2). In that regard, a very recently published UC GWAS meta-analysis has demonstrated that

roughly half of the known CD susceptibility gene loci are shared by UC[52]. In addition, more than 20 exclusive UC loci have been recognized to date including, among others, IL10, ARPC2 and ECM1[52-55]. To summarize our present understanding, we believe that some genetic factors influence the global predisposition to develop IBD, whereas other genes are related to the risk of developing either UC or CD, specifically. Such genetic overlap between UC and CD probably contributes to the existence of a 5% of non-classifiable or indeterminate colitis among the IBD population. Similarly, it also contributes to the fact that first degree relatives of CD or UC patients not only have an increased risk of developing the same type of IBD, but also the other form of IBD, although with a lower frequency in the latter case.

EVIDENCE SUPPORTING AN ENVIRONMENTAL AETIOLOGY IN FAMILIAL IBD

Evidences supporting the role of environmental factors in IBD pathogenesis

The remarkable increase in the IBD incidence in the last few decades cannot be explained by changes in the genetic background of a certain population. Instead, it clearly points towards the existence of potent environmental factors playing a key role in IBD pathogenesis. Several studies performed in Europe that have evaluated IBD prevalence in immigrant populations from low IBD risk areas found that immigrants present a similar or higher risk of developing IBD when compared to the indigenous population[56-58]. These results suggest that differences in prevalence are probably associated with lifestyle and environmental factors, and not with a specific genetic background. It is remarkable though that only very few studies have addressed environmental etiologic factors in respect to familial IBD.

Eating habits, pets and previous infections

One of the largest controlled studies addressing the impact of environmental factors on familial IBD was conducted in Belgium by Van Kruiningen *et al*[59] who investigated 21 families with 3 or more first-degree relatives affected with CD. Subjects were interviewed using an extensive questionnaire on potential environmental factors. In this study affected families and controls presented some remarkable differences in eating habits, domestic factors and medical history. IBD patients ate fewer oats, rye and bran, consumed more unpasteurized cheese and drank more well water, compared to controls. Additionally, an increased frequency of smoking habit, appendectomy and fecal-oral transmitted infections was found in a subject who later developed CD. In respect to domestic habits, affected families also presented a lower daily contact with pets during childhood. Taken together, these results point towards a role of certain gastro-intestinal infections as triggering events contributing to the development of IBD, whereas

the contact with pets during childhood seem to have a protective role favoring the immune system modulation.

Another familial aggregation study by the same Belgian group reported on a large Moroccan family with multiple CD cases[60]. Potential environmental, genetic and serological markers were studied in all family members. No differences in CD susceptibility genes or serological antibodies described in Caucasian populations were found between CD patients and healthy subjects. The study of environmental factors revealed the consumption of a large amount of unpasteurized milk in all family members, which was an environmental factor previously associated with occurrence of familial CD[59].

Another questionnaire-based study on environmental factors in a large monozygotic and dizygotic twin population included more than 300 twin pairs who were discordant for IBD diagnosis[61]. Twins with UC and CD reported recurrent gastrointestinal infections more frequently than their healthy siblings. These findings are in keeping with an increased frequency of fecal-oral transmitted infections reported in multiplex CD families[59] and suggest that past gastrointestinal infections might influence the risk of IBD.

Appendectomy
Appendectomy is associated with a lower risk of developing UC, although the exact mechanisms of this protective role are still not elucidated[62]. While controversial, it seems that the effect of appendectomy requires a certain degree of inflammation (appendicitis or lymphadenitis) and also applies to subjects undergoing appendectomy before the age of 20 years[63]. However, in a recently published study evaluating the usefulness of appendectomy as a therapeutic strategy for distal UC, 40% of patients experienced a complete symptoms resolution after elective appendectomy[64]. Conversely to UC, appendectomy seems to be associated with an increased risk of developing CD, although the studies addressing this issue yield conflicting results[65-70]. These discrepancies might be due to the inclusion of appendectomies performed at CD diagnosis or to methodological differences. More recently, data from large Swedish and Danish cohorts and a meta-analysis have demonstrated that the risk of developing CD is markedly increased only during a short period following appendectomy, disappearing after 5 years[71,72]. This behavior suggests that the association of appendectomy with CD might be a diagnostic bias, instead of a true risk factor.

Tobacco
Smoking habit, particularly cigarette smoking, is the most indisputable example of the influence of the environment on IBD[73,74]. Smoking has striking opposite effects on CD and UC, supporting the notion that distinct mechanisms underlie the pathogenesis of each form of IBD[74]. Subjects who have never smoked and former smokers are at a higher risk of developing UC, whereas present smokers have an increased risk of CD. In addition to the impact on disease susceptibility, smoking habit also modifies the

clinical course of disease, increasing the risk of experiencing a relapse and the need for surgery[75-78]. Moreover, it has been demonstrated that tobacco discontinuation improves CD course[79]. Tuvlin *et al*[80] conducted a survey on tobacco use in UC and CD patients in familial IBD. In this study, smokers had double the risk of CD and former smokers had double the risk of UC, in younger age groups. A Danish case-report study on 2 monozygotic female twins with ileo-colonic CD and their non-affected brother and parents showed that though the healthy father. brother and twins all presented a NOD2 variant related to CD, only the affected twins were smokers, had undergone appendectomy and were on oral contraceptive use[81]. To further evaluate the influence of smoking habit in familial IBD, Bridger *et al*[82] analyzed 658 IBD patients, including 339 affected sibling pairs of whom 89 were discordant for smoking when diagnosed. Siblings who were discordant for smoking and IBD type almost always show CD in the smoker and UC in the non-smoker patient. The authors also suggest that the protective effect of tobacco on UC is due to a shift towards development of CD, in subjects prone to undergo bowel inflammation, rather than true protection of from the development of UC.

Oral contraceptive and non-steroidal anti-inflammatory drugs
Several studies have addressed the potential contribution of contraceptive pills to the development of IBD. It has been demonstrated that the risk of IBD in women taking oral contraceptives is greater that in controls, although there is no direct evidence for a causal relationship[83-85]. Data from two meta-analysis suggest a modest association between the use of oral contraceptives and development of IBD, with a pooled relative risk adjusted for smoking habit of 1.46 for CD and 1.26 for UC[86,87]. The most recent meta-analysis also suggests that the risk disappears once the medication is discontinued[87]. Other frequently used types of drug that have also been associated with IBD are non-steroidal anti-inflammatory drugs (NSAIDs)[88-95]. Due to their inhibitory action on protective prostaglandins, these drugs could enhance intestinal permeability facilitating disease activity. A growing body of evidence suggests a true association between NSAIDs and IBD activity, although the existence of multiple confounding factors makes it difficult to establish a formal relationship[96]. These confounding factors include selection of inadequate control groups, publication bias and intestinal tissue damage due not only to IBD activity but also to NSAIDs. Unfortunately, there are no studies evaluating the role of oral contraceptives and NSAIDs in familial IBD.

IBD as an infectious disease
Van Kruiningen *et al*[97] analyzed the pedigrees and time course of IBD development in a group of patients with familial IBD. They found that first-borns and subsequently born siblings were more frequently affected[87,97]. In addition, they described a statistically significant CD clustering that would indicate an infectious etiology supported by

which family members were affected and time to develop symptomatic disease. Another study by Van Kruiningen *et al*[98] assessed 2 French families with multiple CD cases, in an attempt to identify the suspected infectious cause. However, *Campylobacter*, *Yersinia*, *mycobacteria*, *mycoplasma*, *torovirus*, *coronavirus*, *Brucella*, *Influenza* and animal entero-pathogenic infections were all ruled out and no pathogen could be identified. Even though an abnormal recognition of antigens of the intestinal microbiota by innate immunity is thought to play a key role in IBD pathogenesis, there are no studies addressing specifically the interaction between bowel microbiota and familial IBD.

Intestinal permeability

An abnormal gut barrier function, with an increased intestinal permeability, could contribute to CD pathogenesis[99]. It that regard, it has been demonstrated that small intestinal permeability is increased not only in patients with CD but also in their healthy relatives[100,101]. Peeters *et al*[100] reported that 25% of healthy first-degree relatives of CD patients had an increased small intestinal permeability. The mechanisms responsible for these disturbances in bowel permeability are not fully elucidated and its pathogenesis is a much debated topic. In their study in familial and sporadic CD, Peeters *et al*[100] reported no specific genetic pattern accounting for the abnormal permeability found in patients and relatives. In addition, there were no significant differences between families with multiple members affected and families with only one individual affected. Interestingly, almost half of the spouses presented increased intestinal permeability, which clearly suggests that this abnormality is due to environmental and not to genetic mechanisms. In keeping with this finding, Fries *et al*[102] studied the prevalence of intestinal permeability and some CD genetic markers (including NOD2 main variants) in 23 families of CD patients. Authors found no association between increased intestinal permeability and genetic markers in their population. In contrast, other studies have found an association between an abnormal bowel permeability and the presence of NOD2 variations[101,103].

CONCLUSION

IBD is a complex polygenic disorder modulated by a series of environmental factors, some of which are likely yet to be determined. In spite of the significant progress done in the study of both the genetic and environmental factors associated, the exact contribution of each one of the many factors involved is still largely unknown. From a practical point of view, at present no specific recommendations to IBD families, in respect to genetic or environmental counselling, are available. Large, prospective, population-based studies following IBD patients and their healthy relatives will be necessary to untie the knots in this tangled web of genetic and environmental factors.

Abstract

Patients with inflammatory bowel disease (IBD) can be affected by other unrelated diseases. These are called comorbid conditions, and can include any secondary health problem that affects a person suffering from a primary or main disease, and which is neither linked physiopathologically to the primary condition, nor is it due to the treatments used for the primary condition or to its long-term anatomical or physiological consequences. Different comorbid conditions, as well as their influence on IBD, are discussed.

COMORBODITY, THE CONTEXT, DEFINITION

It has always been difficult for physicians to attain a balance between specialization and the possession of general medical knowledge that makes it possible to optimize and expand the quality of care delivered to patients. The amount of information that a physician is supposed to manage is huge, and always growing. This is why, even when information tools are better than ever, we have perhaps reached a point in which Medicine achieves such a deep level of knowledge in specific areas, that sometimes the global perspective is lost. Or at least, is lost by physicians.

Health care professionals entrusted to assist patients with inflammatory bowel disease (IBD) must remember that our patients are also unfortunately exposed to other health problems (Table 1). We are not dealing here with the extraintestinal manifestations of IBD, whose importance we recognize and that we have probably learned to manage in a satisfactory way. Neither are we concerned with the adverse effects caused by the diverse therapies applied to our patients, such as osteoporosis or infections in the immunocompromised patients, or with the long-term consequences of the anatomical and physiological alterations induced by the disease. The problem that now demands our attention relates to a series of health problems that do not have a direct relationship to IBD as such, but that could alter the diagnosis, presentation and management of the intestinal disease. These conditions are generically known as "comorbidities". A working definition of comorbid conditions could include in this concept any secondary health problem that affects a person suffering from a primary or main disease, and which is neither linked physiopathologically to the primary condition, nor is it due to the treatments used for the primary condition or to its long-term anatomical or physiological consequences. The delimitation of what is and is not a comorbid condition is not easy, and we are

sure that many readers will think that this review should have perhaps addressed a different scope of diseases. In fact, agreement between the authors has required some debate. Our selection may be incomplete, but we are sure that all the conditions that we have included deserve important consideration when caring for a patient with IBD.

It is of paramount importance to differentiate comorbidity from multimorbidity. The first concept deals with the association of a group of diseases with a given condition, whereas multimorbidity refers to the association of multiple diseases in a single person[1]. Another term bordering the concept of comorbidity, is that of patient complexity. In this concept, other extramedical factors are taken into account, such as personal, cultural or social situations that might significantly influence the way in which the health system has to take care of a given person.

Why is comorbidity important?

Firstly, it is obvious that comorbid conditions cannot be overlooked in a patient with IBD. The existence of comorbidity can significantly change several scenarios of medical practice[2]. (1) Clinical manifestations of IBD and its activity can be altered or confused by associated diseases; (2) Prognosis of IBD will also be influenced; (3) Whenever a patient with significant comorbidity is seen by us, we step outside the realms of medical evidence. As a rule, randomized controlled trials exclude patients with comorbidity, and so their conclusions are not necessarily applicable to such situations; (4) The use of drugs for the treatment of IBD is limited by the increased importance their pharmacologic or collateral effects can have on a person with comorbid conditions; and (5) Frequently, it is more important than ever to set up multidisciplinary teams to empower patient care, or, at least, to assure that channels of collaboration and mutual consultation are as fluid and reliable as possible.

Is it possible to quantify comorbidity? What are its generic consequences?

Different sets of clinical indices have been developed and proposed for the specific study of comorbidity. Not all of them have been developed in the same way, nor have they been applied to similar populations. This is why they are not always comparable, and to pick one or another must be done very carefully. Charlson's index is widely used[3], probably due to its unique combination of simplicity and performance. However, it has been validated in multiple populations, but not in IBD patients.

In the general population, multimorbidity is associated with a significantly worse quality of life[4-6]. The specific case of IBD has not been addressed yet, but it is known that in other chronic conditions there is an increased cost of care and a higher complexity of medical activities[7], which are accompanied by poorer outcomes and unfavorably influence indices such as emotional impact, ability to cope, mortality, days of admission or postoperative complications[8-11].

What is the quantitative importance of comorbidity in IBD?

Data on the importance of comorbidity in IBD patients are scarce. Its prevalence has been poorly studied, and refers to other related diseases[12] such as pulmonary thromboembolism[13], arthritis[14] or immune-based conditions[15]. These immune-mediated inflammatory disorders, which include IBD itself, associate with each other and determine a higher risk for other chronic diseases, with a corresponding increase in resource costs.

Although the main determinant of quality of life in patients with IBD is activity of the disease[16], other comorbidities not directly related also have an impact on the physical scores, especially cardiovascular diseases[17-20].

It is not known whether the presence of several chronic diseases can determine poorer results following the medical treatment of this disease; however, it has been well described that they strongly influence surgical outcomes, because preoperative comorbidities are, alongside with age, the main predictors of the occurrence of postoperative complications[18-20].

Finally, among the identified causes of mortality in IBD are several processes that reflect the patient's comorbidity, such as postsurgical cardiovascular complications, age and infections[19]. It is true that many factors favor infections in IBD patients, such as immunosuppressants and malnutrition, but both age and comorbidity probably have their corresponding effects[20].

HEPATIC COMORBIDITY

The potential association between primary sclerosing cholangitis (PSC) and IBD is well known. However, we shall not deal with this condition here, and instead will focus on other liver diseases which can be observed in our patients, and may well alter the course of their disease.

During the long-term follow-up of a patient with IBD, a transient elevation in liver function tests is frequently observed. The cross-sectional prevalence of high aminotransferase levels varies between 5% and 50%, but more adjusted figures show, that around 20%-40% of patients have elevated aminotransferases at some time during the course of their disease, whereas a chronic alteration in such values can be detected in approximately 10% of these patients[21-23]. These elevations in liver function tests are usually discrete, in a range below twice the upper normal level[21,24]. There is no clear correlation between the degree of alteration of liver function tests and the presence of active IBD. An investigation of the underlying cause is frequently frustrating and unyielding, with a small percentage of definitive diagnoses[22].

The causes of altered hepatic biochemistry are manyfold, but the most frequent causes are steatosis and drug toxicity[21]. The evaluation of such patients has to be sensible and reassuring. The first step is to categorize the type and degree of altered hepatic biochemistry. Four different situations could perhaps be defined: (1) Slight (< 2

Table 1 Putting comorbidity into context: secondary health problems in patients with inflammatory bowel disease

Extraintestinal manifestations	Adverse effects of treatments	Comorbid conditions	Direct consequences of the disease
Peripheral and axial arthritis	Steroids: cataracts, glaucoma, mood changes, osteoporosis…	Cardiovascular	Abdominal and retroperitoneal scarring: hydrone-phrosis, intestinal obstruction, female infecundity…
Erythema nodosum, pyoderma gangrenosum, oral aphtae	Immunosuppressors: infections, neoplasia, liver toxicity, myelosuppression…	Hepatic, biliary, pancreatic, digestive	Consequences of intestinal resection: malabsorption, short bowel syndrome, oxalate nephrolithiasis
Uveitis, episcleritis, blepharitis	Biologics: infections, neoplasia, demyelinizing disease, infusion	Metabolic: obesity	Persistent inflammation: osteoporosis, amyloidosis
Primary sclerosing cholangitis	Reactions, drug-induced lupus	Neuropsychiatric	

× upper normal level) and transient elevation of amino-transferases (aspartate aminotransferase/alanine aminotransferase), γ-glutamyl transferase, alkaline phosphatase or bilirubin: it is probably appropriate not to alarm the patient and check the altered values after a short period, proceeding to investigate the cause if the alteration persists; (2) Sustained elevation has to be approached as it would in the general population, with special attention to the usual data in the anamnesis (epidemiological sources of exposure, potential liver toxics…) and ordering a battery of tests that could pinpoint the cause of such elevation. No precise indications have been published to determine which tests should be explored, and in what order. A possible selection could include the following: hepatitis B and C serology, and anti-neutrophil-cytoplasma, antitransglutaminase, antinuclear, anti-smooth-muscle and antimitochondrial antibodies; exploring copper and iron metabolism and investigating other less frequent or characteristic causes of altered liver function tests, could be left for a second step. A liver ultrasound should be obtained at an early stage, to explore the presence of a bright pattern, indicative of steatosis[25], detect cholelithiasis and its complications, explore the bile ducts and rule out signs of chronic liver disease or portal hypertension; (3) Some alterations in the liver function tests tend to be more specific, and deserve a different approach, such as predominant cholestasis, suggesting PSC, or elevation of aminotransferases more than 10 times the upper normal level, indicative of acute hepatocellular damage, which should bring to mind the possibilities of acute viral or toxic hepatitis; and (4) The alteration of liver tests in a patient with previously normal values, after starting a new therapy (notably thiopurine immunusuppressors) has to be approached and managed as possible liver toxicity[26].

Some causes of altered liver tests deserve a special comment, due to their prevalence or their importance.

The range of lesions collectively known as steatosis (including both uncomplicated fatty liver and steatohepatitis) are more and more frequent in the general population, but also in IBD patients, in which it accounts for the majority of diagnoses when investigating altered liver tests[21]. The usual causes of liver steatosis in the general population will also be present in IBD patients, such as metabolic syndrome, overweight/obesity and alcohol abuse. However, other possible reasons should be considered in our patients, notably glucocorticosteroid exposure, malnutrition and parenteral nutrition[27]. It is

an exclusion diagnosis, and only the presence of a bright liver pattern in the ultrasound examination has been signaled as relatively specific[25]. More specific causes of liver disease have to be ruled out, notoriously those that can be appropriately managed, such as the viral hepatitides, autoimmune liver disease and drug-induced liver injury. A liver biopsy is rarely needed to confirm steatosis, but ultrasound follow-up will detect the potential development of portal hypertension or hepatocarcinoma.

Viral hepatitides B and C are, in older series, somehow more frequent in IBD patients than in the general population[28-31]. However, the current situation is different. In a Spanish national prospective study[32], the presence of markers of hepatitis B virus (HBV) or hepatitis C virus (HCV) infection was prospectively studied in a series of more than 2000 patients. Evidence of current or past infection was present in 9.7% of cases, which is similar to figures observed in the general population: in ulcerative colitis (UC), hepatitis B surface antigen (HBsAg) was present in 0.8%, anti-HBc in 8% and anti-HCV in 1.3%, and in Crohn's disease (CD) HBsAg was present in 0.6%, anti-HBc in 7.1% and anti-HCV in 2.3%. 12% of patients had serological evidence of effective anti-hepatitis B vaccination (anti-HBs without anti-HBc). Multivariate analysis determined that age, family history of hepatitis and moderate to severe IBD were associated with HBV infection or contact, whereas HCV was mainly associated with previous transfusion of blood or blood products, but only if this was performed before 1991, when anti-HCV screening became widespread in local blood banks. Similar data have been communicated by other authors[33]. It is important to remember, that any prevalence of HCV and, especially, HBV markers has to be kept in mind, because the infection can reactivate under immunosuppressive therapy, necessitating prophylactic measures in some cases (antiviral therapy in HbsAg+ patients), and close follow-up in the remaining patients[34].

GASTROINTESTINAL COMORBIDITY

Helicobacter pylori disease

The prevalence of infection by *Helicobacter pylori* (*H. pylori*), as determined by serology, ranges between 15% and 50%. It is always lower than the corresponding prevalence in the general population, and is inversely correlated with sulfasalazine exposure[35-38]. The diminishing use of this drug makes it possible that this situation has

changed lately. The positivity of the urea breath test is also lower then in the general population[39]. However, the prevalence of peptic ulcer in transversal studies can reach 5%[38]. It is important to remember, that about 15% of CD patients will show histologic or even endoscopic lesions in the upper gastrointestinal endoscopy, and that the absence of *H. pylori* in these lesions is an important criterion when identifying them as truly related to IBD.

The indication for gastroprotection in patients exposed to glucocorticoids deserves a mention. The decision to co-prescribing proton pump inhibitors with glucocorticoids is quite usual, at least in our environment, but it is not sustained by medical evidence[40]. Gastroprotection should only be indicated on rare occasions when NSAIDs and glucocorticoids are prescribed jointly. To automatically prescribe proton pump inhibitors in the general patient, will lead to unnecessary higher costs, exposure to yet another set of adverse events and, most importantly, an increased number of tablets taken daily, which generally adversely influences adherence to therapy[41].

Celiac disease /gluten-sensitive enteropathy

Celiac disease and CD share some physiopathological, epidemiological and clinical features[42]. They frequently form part of the differential diagnosis. In older times, it was difficult to rule out celiac disease in a population with IBD, mainly due to the clinical superposition, but also to the possibility of finding very similar histologic changes (duodenal mucosal infiltrate, villous atrophy in Crohn's) and some parallel serologic alterations (positivity of antigliadin antibodies). The higher specificity of both antiendomysium and antitransglutaminase antibodies in the diagnosis of celiac disease, has finally allowed the performance of studies on the prevalence of this condition in patients with an unequivocal diagnosis of IBD.

Following the communication of isolated cases of associated Crohn's and celiac disease[43], an intriguing study was published[44], in which a very high prevalence (15%-20%) of antigliadin or anti endomysium antibodies was detected in a short series of CD patients. The high specificity of these determinations could make it reasonable to deduce that this association is extraordinarily frequent. However, later investigations of better quality have been unable to confirm these results[45-47]. The systematic search for celiac disease in CD patients cannot be recommended, according to the available evidence.

On the other hand, and although data are scarce, it seems that both UC and CD are more frequent in persons with celiac disease than in the general population. This has been described in two clinical series, with an IBD prevalence about 10 times higher than expected[45,48].

Biliary and pancreatic diseases

Cholelithiasis is a very prevalent condition in the general population[49]. Some circumstances explain its increased incidence in IBD patients, mainly the distortion of bile metabolism induced by the functional or anatomical alterations of the gut. Thus, it cannot strictly be considered a comorbid condition. The interest in cholelithiasis as a comorbid condition is mainly due to the possible overlap between its manifestations and those of the IBD or of extraintestinal manifestations, such as PSC. Management does not differ from the approach in the general population.

Pancreatic disease can ensue following the use of medications, the extraintestinal activation of inflammatory phenomena or can appear as an associated autoimmune disease[50]. In any case, it cannot be listed as a comorbid condition.

OBESITY

Presently, obesity is considered an emerging epidemic in Western societies, where it is more prevalent in disadvantaged social classes[51]. It also affects affluent classes in countries with emerging economies. The prevalence of this condition is growing, and some of its causes are sedentary behaviour, changing socioeconomic status and variations in traditional diets[52].

An increasing prevalence of obesity in patients with IBD has been described recently. In the past, this was considered an exception, but today, figures range from 15% to 20% in some series, with a further 40% of patients being overweight[53]. Although there is no evidence that obesity alters the course of the disease, at least in CD[54], obesity is related to unfavorable outcomes such as colonic adenomas, surgical morbimortality, cardiovascular risk and thrombotic disease.

CARDIOVASCULAR COMORBIDITY

Cardiovascular disease (CVD) is the main cause of death in developed countries[55] and its prevalence increases with age. Therefore, IBD patients are very likely to experience these entities throughout their life or, at least, be affected by some of the associated risk factors. The impact of CVD on IBD is the same as for the general population, increasing complications and remaining a common cause of mortality[56], especially when the disease is more severe or surgery is needed[18]. Anecdotally, in the 1950s when Truelove *et al*[57] published the first clinical trial with corticosteroids in UC, which demonstrated a decrease in mortality, the cause of death in 2 of the 5 patients who died was CVD, namely pulmonary thromboembolism. We will discuss IBD as a predisposing factor for CVD in more detail and the possible effects of IBD treatments on cardiovascular morbidity together with the undesired consequences of drugs used in the management of CVD for EII.

Venous thrombosis

Venous thromboembolism (VTE) has been considered a manifestation which is directly related to intestinal inflammatory activity, but in other chronic inflammatory diseases such as rheumatoid arthritis the incidence of VTE is not greater than in the general population[58].

Table 2 Acquired thrombotic risk factors in inflammatory bowel disease

Inflammation
Immobility (surgery or hospitalization)
Surgery
Fluid depletion
Central venous catheters
Drug therapy: Corticosteroids, anti-TNF drugs?
Smoking
Hyperhomocysteinemia (vitamin deficiencies)
Oral contraceptives
Increased levels of lipoprotein A

TNF: Tumor necrosis factor.

Furthermore, IBD patients in remission also have an increased risk of VTE[59], therefore additional factors other than inflammation are involved. This is why we have considered it a manifestation not directly linked with IBD.

In a recent population study[59], the incidence of VTE in IBD was 26 cases/10 000 person-years (PY) with a Hazard ratio of 3.4 (95% CI: 2.7-4.3). These data are similar to those observed in a previous Canadian population study, where the incidence of deep vein thrombosis (DVT) was 31.4/10 000 PY and 10.3/10 000 PY for pulmonary embolism (PE) for CD patients and 30/10 000 PY and 19.8/10 000 PY in patients with UC, respectively[60]. Again, the risk was 3 times higher in IBD compared with controls. There was also a time trend which increased with an annual average of 17% in odds of VTE[61]. There are no major differences between CD and UC, although the incidence in hospitalized patients may be somewhat higher in UC (OR = 1.32), probably because its frequency increases when the colon is involved[61]. IBD activity increases the likelihood of VTE with rates up to 8 times higher than controls[60]. Although VTE episodes are less frequent in outpatients, in this subgroup the differences with controls were even more marked (HR = 15.4) than during hospitalization periods (HR = 3.2)[59]. Similarly, although the majority of thromboembolic events occur in patients over 60 years, differences with controls are greatest in young patients (< 40)[60]. Other aspects that may increase the risk are involvement of the colon in the case of UC (pancolitis in 76% of episodes of VTE *vs* 2% of proctitis) and fistulizing pattern in CD[61].

Causes of thrombosis in IBD are many-fold; in most patients, recognized acquired prothrombotic factors can be identified, such as inflammation, immobilization, surgery, central catheters, corticosteroids, and smoking (Table 2)[62,63]. Nevertheless, in a significant percentage of patients (20%-50%) no obvious cause can be identified[64-66]. This supports the notion, that IBD itself acts as a predisposing factor for thrombosis. Inherited thrombophilias have no role in VTE associated with IBD because VTE is significantly less frequent than in thrombotic non-IBD subjects[67].

The appearance of VTE in a patient with IBD carries a poor prognosis reaching a mortality of 22%-25%[65,66],

significantly higher than the control group (OR = 2.1). Hospital stay also increased by 48% and associated health costs doubled[61].

The most common location of VTE is lower extremity DVT with or without PE[58], which would include three-quarters of all episodes, but many locations have been described such as cerebral sinus[68-71], retinal vein[72-75], portal venous system[76-81] and hepatic or cava veins[82-87]. Portal system thrombosis is particularly important both for its potential complications and for its non-negligible frequency, being reported in up to 6% of patients after restorative proctocolectomy and ileal pouch-anal anastomosis[78,88]. A probable long-term complication is portal hypertension, which can be avoided with early anticoagulant therapy, for which clinical suspicion is fundamental, ordering an abdominal Doppler ultrasound and/or abdominal CT in the case of sudden onset of abdominal pain, fever or prolonged ileus after abdominal surgery[89].

Treatment of thromboembolic episodes of IBD is the same as in the general population and is based on the use of anticoagulation, first with heparin (usually low-molecular-weight heparins, LMWH) and then oral anticoagulants which should be sufficient for most patients[90]. Occasionally other measures may be required, such as thrombolysis or placement of an inferior cava filter that can be used as an effective means of preventing pulmonary embolus when anticoagulant therapy is contraindicated or thromboembolism recurs in spite of anticoagulant therapy. These drugs have proven safe in clinical trials where their effectiveness was evaluated as primary treatment. The optimal duration of anticoagulant therapy is unknown, but in general will vary depending on the severity of thrombosis and bleeding risk. In the first episode, 6 mo provided adequate coverage, but will be extended if the risk factor has not disappeared (surgery, immobilization) opting for lifelong anticoagulation in the setting of an inherited hypercoagulable state[89,91]. Despite treatment, up to 13%-26% of patients have a recurrent thromboembolic event[65,92]. Similar rates were found in patients with prior colectomy, thus surgery does not seem to prevent recurrence[65].

Treatment of thromboembolic episodes is important, but so is prevention. Possible measures include the control of disease activity, correcting vitamin and nutritional deficiencies, cessation of smoking, early mobilization after surgery or the use of intermittent pneumatic compression for patients at high risk of bleeding. Drug prophylaxis with LMWH is recommended in patients hospitalized with severe UC[93] or when planning surgery[94]. Outpatients with moderate flares and restricted mobility (old age, motor deficiencies…) are probably also candidates for pharmacologic prevention.

Atherosclerosis and arterial thromboembolic disease
Early atherosclerosis: Early atherosclerosis is a common phenomenon in several immune-based inflammatory diseases, particularly rheumatoid arthritis and systemic

lupus erythematosus[95], and is one of the most important causes of morbidity and mortality in these diseases, justifying the publication of specific recommendations[96]. The inflammatory process is behind the emergence of this phenomenon with a prominent role for the cytokines IL-6 and TNF that are significantly associated with the severity of subclinical atherosclerosis, independent of Framingham risk score[97]. Both cytokines are implicated in the pathogenesis of IBD, making possible the development of early atherosclerosis in these patients. Few data exist on this entity in IBD, although case reports of arterial occlusions in young patients with CD support this possibility[98]. Furthermore, to assess the presence of subclinical atherosclerosis at an early stage, several methods have been proposed, such as assessment of the intima-media thickness of the common carotid artery wall or the measurement of carotid artery stiffness; these have been shown to predict the occurrence of cardiovascular events[99,100]. Both parameters have been found to be altered in IBD patients compared to controls[101,102], although not uniformly in all studies[103].

Cardiovascular risk factors: There are few data on the prevalence of cardiovascular risk factors in IBD, apart from the known relationship with tobacco use[104]. Only in the cohort study by Ha *et al*[105], where the controls were randomly selected, IBD patients had a higher frequency of hypertension and hyperlipidemia, with similar rates of diabetes mellitus. Plasma lipid levels were inversely correlated with inflammatory activity[106], thus do not appear to have a particularly decisive role in predisposition to atherosclerosis in patients with IBD. As mentioned earlier, inflammatory activity *per se* could promote the development of atherothrombotic complications and in relation to this, C-reactive protein has been identified as a risk factor both in chronic inflammatory diseases[107] and in the general population[108,109]; unfortunately there are no specific data for IBD.

Arterial thrombotic events: Only two studies have evaluated the incidence of arterial events in IBD independently of venous thrombosis. The aforementioned study by Ha *et al*[105] found an overall increased incidence compared to the control group, mainly due to a marked increased in the risk of acute mesenteric ischemia (HR = 11.2, $P < 0.001$). The risk of myocardial infarction, conversely, was only discretely increased (HR = 1.6) in women over 40 years; in contrast, stroke was elevated in women below that age. However, Bernstein *et al*[110], found an overall increase in the prevalence of ischemic heart disease (IRR = 1.26) and cerebrovascular disease (IRR = 1.32) regardless of age group, although the latter only applied to patients with CD. In any case, except for acute mesenteric ischemia, in which local factors are probably involved, the rates found were quite similar to those of the control population, and not necessarily clinically relevant.

IBD therapy and cardiovascular diseases
The deleterious effects of glucocorticoids on the cardio-

vascular system are well known[111,112]: among their adverse effects are hypertension, hyperglycemia, hyperinsulinemia and hyperlipidemia, determining in some contexts increased cardiovascular morbidity, as in renal transplantation[113]. In other diseases, such as rheumatoid arthritis[114], inflammatory activity control can reduce cardiovascular complications. In spite of this, there is no direct evidence that IBD treatments alter the thrombotic tendency of the disease; however, some drugs show a favorable profile on some of the factors involved. For example, aminosalicylates reduce platelet activation and azathioprine inhibits formation of platelet-leukocyte aggregates[62]. There are no specific data for IBD, but methotrexate therapy in rheumatoid arthritis has been shown to decrease the prevalence of metabolic syndrome[115] in this disease and, more particularly, cardiovascular morbidity and mortality[114]. Regarding anti-TNF drugs, the results are somewhat contradictory: initially, endothelial function and insulin resistance transiently improve. On the other hand, infliximab in particular, shows a potential adverse effect on the lipid profile[116]. Likewise, thrombotic events associated with these drugs in patients without other risk factors have been described, although this needs to be confirmed[117].

Finally, it has to be noted, that some of the drugs used in the management of cardiovascular risk factors may be beneficial for IBD. Thus, the anti-diabetes drug rosiglitazone has been proven effective in the treatment of UC in two clinical trials[118,119], atorvastatin could have an antiinflammatory effect in CD[120] and ACE inhibitors have an antifibrogenic effect[121,122], not yet explored in CD.

PSYCHIATRIC COMORBIDITY
Anxiety and mood disorders have been extensively studied in IBD patients, whereas data on other conditions, such as psychoses, are scarce. However, there may be some connection, because some of the drugs used in the management of IBD, such as steroids[123], can precipitate psychotic manifestations and, on the other hand, the treatment of IBD may be followed by improvement of psychiatric illness[124].

As in other chronic diseases, the prevalence of anxiety and depression is higher in patients with IBD than in controls, both in hospital[125-128] and population cohorts[129-132]; their frequency is variable but approaches 24%-27%[129,133], which is two to three times higher than in a control population[129,131]. There are no great differences between UC and CD[130], or with other chronic diseases such as rheumatoid arthritis or diabetes[134].

Psychiatric comorbidity in IBD has been considered a risk factor for the onset of IBD itself, because it can precede its diagnosis[129,132]. However, the relative risks are low, and are limited to the year prior to diagnosis, which could represent the presence of symptoms of an undiagnosed somatic illness[135]. Moreover, the frequency of anxiety and depression increases after diagnosis of IBD,

suggesting that it is a consequence rather than a cause of the disease[132].

The role of daily stress and major life events in the precipitation of flares has also investigated, mainly because patients with higher perceived stress have a greater chance of disease reactivation[136,137]. However, there are several potential factors which may have contributed to this finding. In many studies, the sample size is not enough, and on the other hand, these results may be influenced by the fact that the influence of stress on disease activity is what patients, and probably many physicians, expect to be true[138]. Furthermore, anxiety and depressive symptoms predicted an increased likelihood of functional symptoms[139], and have a decisive influence on variables such as abdominal pain and overall well-being, used in the calculation of indices for most common activity indices. In addition, episodes of recurrence are limited to a relatively restricted period following the initial outbreak[137], which could be attributed to an incomplete improvement of IBD. Finally, several studies did not find such an association[130,140,141] and the results of trials of psychological interventions in IBD have been negative[140]. Thus, although anxiety and depression are more frequent around the periods of IBD activity, they did not seem to be risk factors for flares; also, more importantly, to wrongly assume that stress is responsible for disease exacerbation, may contribute in some way to induce unjustified and harmful feelings of guilt in some patients.

Psychiatric comorbidity has a marked impact on the management of IBD because it is, together with disease activity, the main determinant of quality of life in these patients[142]. Additionally, it is one of the factors associated with poorer adherence to treatment[41] and determines a greater use of health resources[139]. Thus, given the particular importance of these observations, and the frequent association of psychiatric symptoms with IBD, it is essential to identify and properly manage these conditions. In this sense, the use of screening tests with a good balance between sensitivity and specificity, such as the Anxiety and Depression Detector[143,144] or the Goldberg Anxiety and Depression Scale, could be recommended as an initial screening tool[134]. Treatment of psychiatric comorbidity in IBD does not differ from the general approach to these disorders, and the options include different types of psychotherapy[145] or second-generation antidepressants such as selective serotonin reuptake inhibitors or serotonin norepinephrine reuptake inhibitor, with fewer side effects than traditional drugs (tricyclics and MAO inhibitors) and that may be initiated by the gastroenterologist pending evaluation by the appropriate specialist.

CONCLUSION

Throughout the evolution of a patient with IBD, these diseases are frequently associated with other non-related diseases which may change management and prognosis. On the one hand, decision making is complicated because the available evidence does not always apply, as in most clinical trials such patients are excluded. On the other hand, their existence entails taking into account the possible consequences of treatment on other comorbidities, both by the possibility of interactions and by the facilitation of potential adverse effects. Prognosis also changes, especially in the presence of cardiovascular comorbidity, which is associated with a greater overall morbidity and mortality, especially in the surgical context. Finally, the concomitant presence of several diseases requires collaboration and coordination among professionals for joint decision making, and implementation of the proper clinical circuits to facilitate medical attention.

Abstract

Inflammatory bowel disease (IBD) in patients aged > 60 accounts for 10%-15% of cases of the disease. Diganostic methods are the same as for other age groups. Care has to be taken to distinguish an IBD colitis from other forms of colitis that can mimic clinically, endoscopically and even histologically the IBD entity. The clinical pattern in ulcerative colitis (UC) is proctitis and left-sided UC, while granulomatous colitis with an inflammatory pattern is more common in Crohn's disease (CD). The treatment options are those used in younger patients, but a series of considerations related to potential pharmacological interactions and side effects of the drugs must be taken into account. The safety profile of conventional immunomodulators and biological therapy is acceptable but more data are required on the safety of use of these drugs in the elderly population. Biological therapy has risen question on the possibility of increased side effects, however this needs to be confirmed. Adherence to performing all the test prior to biologic treatment administration is very important. The overall response to treatment is similar in the different patient age groups but elderly patients have fewer recurrences. The number of hospitalizations in patients > 65 years is greater than in younger group, accounting for 25% of all admissions for IBD. Mortality is similar in UC and slightly higher in CD, but significantly increased in hospitalized patients. Failure of medical treatment continues to be the most common indication for surgery in patients aged > 60 years. Age is not considered a contraindication for performing restorative proctocolectomy with an ileal pouch-anal anastomosis. However, incontinence evaluation should be taken into account an individualized options should be considered

INTRODUCTION

Old-age colitis refers to patients over 60 years of age who are affected by a group of diseases of the colon, including infections, vasculitis, microscopic colitis, colorectal cancer, ischemic colitis, drug-associated colitis [particularly non-steroid anti-inflammatory drugs (NSAIDs)] and inflammatory bowel disease (IBD)[1]. Diagnosis of IBD in this age group may be difficult because it can be easily confused with other forms of colitis. Of particular relevance is so-called segmental colitis associated with diverticular disease (SCAD), which may simulate IBD both clinically, endoscopically, and histologically[1-3]. SCAD is characterized by the presence of diverticula, most often in the sigmoid colon, and affects middle and old

aged patients. A recent study in a German IBD elderly population showed that 8% of older patients diagnosed as IBD patients were in fact affected by SCAD[4]. Special precautions and attention must be taken in the diagnosis of these patients to avoid errors. New diagnostic tools, such as serological markers or advanced radiological examinations, may be useful in for a correct diagnosis.

FREQUENCY

Approximately 10% of patients at first flare of IBD are > 60 years old, with a similar distribution between ulcerative colitis (UC) and Crohn's disease (CD); 50% of them are diagnosed between 60-70 years of age[4,5]. However, it is difficult to establish the true incidence of IBD in older patients due to problems of case definition, population, and particularly because it may be confused with other clinical conditions, such as NSAID-associated colitis or ischemic colitis[1]. A bimodal age curve for IBD incidence has been suggested in epidemiological studies, with a second peak occurring at 50-70 years[5-7], but this point is currently the subject of debate, and it was not observed in the results of four population studies using strict radiological and endoscopic diagnostic criteria. A clear decrease in incidence occurs from age 40 in patients with CD and then stabilizes from age 60. Although there is a similar trend in patients with UC, the decrease is smaller in this group[8].

Thus, the incidence in patients over 60 years old represents approximately 10% of the cases of IBD; the bimodal distribution is questionable, and care should be taken to avoid including inadequately diagnosed patients.

CLINICAL MANIFESTATIONS

The clinical manifestations of the first flare of disease, both in UC and CD, are similar in the group aged > 60 years and younger age groups. It has been noted that the severity of the symptoms of UC, particularly rectal bleeding and diarrhea, may be lower in patients in this group, but it may also have atypical forms of presentation, such as constipation[9,10]. With regard to disease location, according to the Montreal classification, proctitis and left-sided UC are more common in patients > 60 years old than in younger patients. Severity of recurrence is usually higher in elderly patients (S2-S3 by the Montreal classification), with a longer duration of symptoms, which has influence on the need for steroid treatment[11-14].

In the case of Crohn's disease, the Montreal classification considers three age groups, establishing age > 40 years as the more advanced age group[11]. It has been observed that the form of disease presentation is similar between the different age groups, but that the L2 (colonic) disease location (clinical pattern) is the most common form in the older group (48% colon involvement in > 40 years group versus 28% and 20% in the groups diagnosed between 20-40 years and < 20 years, respectively)[1,15-19]. This frequency rises to 66% in patients aged > 60 years. With regard to the disease behavior, the most common is the inflammatory disease behavior (B1),

the stricturing and penetrating pattern being less common than in the 18-60 years age group[1,5,19].

There are few references on the frequency of presentation of extraintestinal manifestations in this subgroup of patients. In the study by Hadithi[5], 17% of patients over 60 years of age had extraintestinal manifestations, which, in order of frequency, were: peripheral arthritis, uveitis, spondylitis, and erythema nodosum.

DIFFERENTIAL DIAGNOSIS

There are various clinical situations that may hinder diagnosis of IBD in elderly patients. IBD may be complicated by infections or by taking certain medications, such as NSAIDs and antibiotics[1,20-22]. Similarly, certain neoplasms, and specifically small bowel lymphoma, may have similar characteristics to those of IBD or be a complication of the disease itself[23-25]. The most common causes of chronic diarrhea and bowel inflammation in patients aged > 60 years are indicated in Table 1[25-31].

Segmental colitis associated with diverticular disease (SCAD) warrants special consideration[1,25-27]. Diverticulosis affects more than half of the people over 60 years of age. SCAD is clinically manifested by abdominal pain, rectal bleeding, and altered bowel habits, but only 3%-8% of patients have mucosal inflammation around the diverticula. It involves only the sigmoid colon, with sparing of the rectum and proximal colon. Endoscopic examination shows a circumferential distribution of erythema, granularity, and friability, and sparing of the diverticular ostium and cavity with a diffuse periosteal distribution of inflammation confined to the area of the diverticula[24,25]. Histopathologically, inflammation analogous to that seen in the UC and nonspecific chronic inflammation that may contain granulomas has even been reported, leading to misdiagnosis with CD. In general, SCAD may be suspected when colitis is confined to the diverticular segment of the left colon (excluding the rectum), the rectum and proximal colon are endoscopically and histologically normal, and if surgical resection of the affected segment is required, when no recurrence of segmental colitis occurs.

There are no randomized studies specifically assessing treatment of SCAD[1,5]. Overall response to oral (2.4-3 g/d) or topical (enemas 1-2 g/d) mesalazine was good, with a clinical response of 80% at six weeks and a maintenance of response in 90% of patients at six months[5,27]. The addition of fiber and antibiotics (rifaximin) during the acute phase may improve the response. If there is no improvement with this combination treatment, steroids applied topically as enemas may improve the clinical response. Exceptionally, oral prednisone has been evaluated in some cases of non-responders. These are patients who will rarely require surgery with segmental resection for SCAD.

MEDICAL TREATMENT

The principles governing medical management of IBD in patients aged > 60 years are the same as in other age groups. The location, extent, severity, and disease behavior,

Table 1 Differential diagnostic of colitis in patients older than 60 years

Disease	Clinical characteristics	Endoscopic findings
Colitis associated to diverticulosis	Rectal bleeding, abdominal pain, diarrhea	Segmentary distribution, peridiverticular, sigma affected, rectum and proximal colon are normal
Ischemic colitis	Abdominal pain rectorragia acute onset	Segmentary colitis (sigma/left colitis), majority are non-obstructive
Microscopic colitis	Watery diarrhea, no rectal bleeding, no fever, frequent cause of diarrhea in the eldery	Normal endoscopy, multiple biopsies from colon, celiac disease association
Infectious colitis	Disenteriforme diarrhea, different agents, *C.difficile* to be ruled out	Difuse effects on the colon Increased morbidity and mortality in older-aged population
NSAIDs colitis	Recurrent abdominal pain; obstruction, perforation, hemorrhage; chronic anemia	Any part of the intestine, isolated lesions, aggravate previous UC and CD

NSAIDs: Non-steroid anti-inflammatory drugs; UC: Ulcerative colitis; CD: Crohn's disease.

both in UC and CD, will determine the medical treatment options to be used[32-37]. Special precautions and the most generally used treatments in IBD old-aged patients are summarized below. In brief, depending on the kind and severity of IBD suffered by patients, we should choose the best treatment, taking special care of side effects caused by advanced age or by drugs associated with another diseases.

Mesalazine

Oral and/or topical mesalazine is the main option for medical treatment in patients with a mild to moderate flare of UC. The availability of new distal release mesalazine preparations with the MMX formulation may facilitate compliance and, therefore, adherence to treatment. It is similar in terms of efficacy to other oral preparations of mesalazine, regardless of its form of release[38]. However, in Crohn's disease, the efficacy of mesalazine is questionable and it has a limited role in the treatment of mild flares of ileal or colonic location[36,37].

Oral or topic steroids

Beclomethasone combined with mesalazine has been shown to be effective for treating moderate flares of left UC when administered orally as a single 5 mg dose for 2-4 wk, obtaining remissions in about 60% of patients[39]. Although there is no specific study by age subgroups, it remains an option to consider that may avoid the need for systemic steroids[40,41]. Nevertheless, we have to bear in mind that local or systemic steroids administered intrarectally are absorbed and therefore not free from their side effects.

Antibiotics

A detailed case history should be made in the group of patients > 60 years old, looking for symptoms suggestive of sensory neuropathy in the use of metronidazole[42].

Immunomodulators

The prevalence of corticosteroid resistance or dependence in this group of patients has not been specifically evaluated, but it is estimated at about 30%[43]. Although there is little objective data on which to base this practice, treatment was started with conventional immunomodulatory agents (azathioprine, mercaptopurine, and methotrexate)

in this group of patients without evidence of differences in terms of efficacy, metabolism, and toxicity between the patients aged > 60 years and younger patients[35-37].

Biological agents

Their indications remain similar to those for patients aged < 60 years[44-46]. However, one of the most important aspects regarding the use of these agents is the safety profile, particularly that related to the risk of infections. The trend observed in the subgroup of elderly patients with rheumatoid arthritis > 65 years old to develop infections has not been confirmed in any controlled study. It is not uncommon for patients to be treated with combination therapies (corticosteroids, conventional immunomodulators, and biological agents) because of the disease's complexity. In this regard, the higher rate of infection found in the TREAT registry in patients treated with anti-TNF agents (infliximab (IFX) in this case) may have been due to the greater severity of these patients and the greater use of steroids[47]. In fact, the only independent risk factor for infections was the concomitant use of steroids (RR = 2.33, 95% CI = 1.50-3.62). However, the results of series describing the clinical experience in treatment with these drugs will best reflect what we would encounter in our clinical practice, particularly when they report observations collected over years. In this regard, the results of the Leuven group comparing adverse effects in 734 patients treated with IFX versus 664 control patients, with a follow-up of 58 to 144 mo, showed no significant differences in the risk of severe infections, mortality, and malignant conditions. No specific analysis by age subgroups was done[48].

In the Stockholm cohort study[44], it was observed that the use of infliximab in the subgroup of patients aged > 60 years was associated with an increased risk of serious side effects and higher mortality, which was also suggested in the multivariate analysis of the Lichtenstein registry[41]. However, more safety data are required on the use of biological therapies in patients aged > 60 years. In the meantime, it seems logical to use them according to recommended usage guidelines and with strict adherence to performing all tests prior to administration. It should be kept in mind that in this age group, and particularly in countries where the prevalence of tuberculosis is higher, it is more likely that an increased frequency of cases of latent TB will be observed.

Surgical indications

In older patients surgical indications are the same as in younger patients, with failure of medical treatment being the most common cause of surgery[49]. In general, the need for surgery is lower in CD patients with an age at diagnosis > 40 years and colonic disease location, and more common in the elderly. However, it is similar in ileocecal disease[49-51].

In UC, restorative proctocolectomy with ileal pouch-anal anastomosis continues to be the surgical technique of choice[52,53]. In general, results are not as good in older patients compared to younger patients, but they are both reasonably good in terms of efficacy and morbidity. Only an increased frequency of diurnal incontinence and nocturnal leakage has been reported among patients aged > 65 years. Generally, overall quality of life was good, to the extent that in the study by Delaney[52] 89% of patients over 65 years of age were satisfied with surgery and 96% would recommend it. Therefore, age is currently not considered a contraindication for performing an ileal-anal pouch.

MORTALITY

Mortality from UC is similar to that of the general population, with more controversial results in the case of CD[1,5,41,54,55]. In UC, age at diagnosis is not associated with increased mortality, whereas in CD, there appears to be a slight increase in the risk of mortality in older aged patients (> 55 years) with long-standing disease[56-58]. However, we should be cautious, because some of the results may be biased by the type of study, study population, follow-up period, etc.

There are a number of aspects to consider regarding possible factors that may be associated with an increased relative risk of mortality. In this regard, there were more hospitalizations in patients > 65 years than in the younger group, representing 25% of all admissions for IBD occurring in the USA (33% of hospitalizations for UC and 20% for CD)[41]. In general, the disease course of UC is more severe in elderly patients and mortality in hospitalized patients, both with UC and CD, is estimated to be 3-5 times higher than in age subgroups < 65 years. In the study by Ananthakrishnan et al[41], hospital mortality was higher (OR: 3.91; 95% CI: 2.50-6.11) and age was an independent risk factor in the group of IBD patients aged > 65 years; other variables significantly associated with hospital mortality were fistulizing disease, malnutrition, and need for intestinal resection for stenosing disease. Interestingly, in this study, a greater difference was observed in mortality between unoperated and operated patients, possibly because medical salvage therapies, including immunomodulatory and/or biological therapies, may increase morbidity and mortality, suggesting that "early" surgery is associated with lower mortality in older patients. However, hospital stays were longer, particularly in the group of operated patients. Although postoperative complications were similar between this age group and those younger than 60 years, the risk of cardiovascular or pulmonary complications was greater, these being aspects to be taken into account in the

Table 2 Summary of inflammatory bowel disease onset in the elderly

Home messages
10%-15% patients with inflammatory bowel disease > 60 years
12% UC patients
16% CD patients
Differential diagnosis with colitis associated to diverticulosis, ischemic colitis, infectious colitis (C.difficile)
Ulcerative colitis: proctitis/left colitis is more frequent
CD: Granulomatous colitis > frequent than ileocecal
Medical treatment
Same treatment options as younger patients
Increased rate of complications with steroids
Similar response, but recurrence less frequent
Surgery: Equal indications, ileoanal reservoir is secure
More hospitalizations
Similar mortality, increased in hospitalized patients, comorbidity

UC: Ulcerative colitis; CD: Crohn's disease.

postoperative period of patients.

Related to the use of biological agents, there is a study[59] that points out that 3 out of 5 deaths attributable to infliximab treatment were older than 70 years. However, these patients had a longer evolution of disease (15-26 years) and they suffered from severe diseases and comorbidities.

The risk of suffering dysplasia and cancer is higher in extended Crohn's colitis patients > 45[60]. However there is an increased incidence of these complications related to disease duration (increased risk among patients with disease duration longer than 20 years). Therefore, older and long-evolution patients should be under colonoscopic surveillance, however, only being of advanced age when an IBD outcome occurs is not enough to maintain different colonoscopic surveillance compared to naïve younger patients.

Little is known about effects of age on colonoscopy risks. In a large retrospective study of safety, feasibility, and tolerability of ileonoscopy in IBD patients[61], few severe complications where detected (0.3%-0.8%) and none of them were related to the advanced age of patients or disease activity.

CONCLUSION

The main messages regarding IBD in the elderly are summarized in Table 2. The prevalence of IBD in patients aged > 60 years is difficult to determine, but accounts for 10%-15% of cases of the disease. Diagnosis may be difficult because there are a number of clinical conditions that may mimic IBD, particularly ischemic colitis or colitis associated with diverticular disease. Diagnostic methods are the same as for other age groups. The clinical pattern in UC is proctitis and left-sided UC, while granulomatous colitis is more common in CD. Its disease course is similar to that of the younger groups. The treatment options are those used in younger patients, but a series of considerations related to potential pharmacological interactions and side effects of the drugs must be taken into account.
The safety profile of conventional immunomodulators and biological therapy is acceptable, but more data are required on the safety of use of these drugs in the elderly population. The overall response to treatment is similar in the different patient age groups, but elderly patients have fewer recurrences. The number of hospitalizations in patients > 65 years is greater than in younger groups, accounting for 25% of all admissions for IBD. Mortality is similar in UC and slightly higher in CD, but significantly increased in hospitalized patients. Failure of medical treatment continues to be the most common indication for surgery in patients aged > 60 years. Age is not considered a contraindication for performing restorative proctocolectomy with an ileal pouch-anal anastomosis.

Abstract

Smoking is a major environmental factor that interferes in the establishment and clinical course of ulcerative colitis (UC). Firstly, the risk of smoking status impact in the development of UC is reviewed, showing that current smoking has a protective association with UC. Similarly, being a former smoker is associated with an increased risk of UC. The concept that smoking could have a role in determining the inflammatory bowel disease phenotype is also discussed. Gender may also be considered, as current smoking delays disease onset in men but not in women. No clear conclusions can be driven from the studies trying to clarify whether childhood passive smoking or prenatal smoke exposure have an influence on the development of UC, mainly due to methodology flaws. The influence of smoking on disease course is the second aspect analysed. Some studies show a disease course more benign in smokers that in non-smokers, with lower hospitalizations rates, less flare-ups, lower use of oral steroids and even less risk of proximal extension. This is not verified by some other studies. Similarly, the rate of colectomy does not seem to be determined by the smoking status of the patient. The third issue reviewed is the use of nicotine as a therapeutic agent. The place of nicotine in the treatment of UC is unclear, although it could be useful in selected cases, particularly in recent ex-smokers with moderate but refractory attacks of UC. Finally, the effect of smoking cessation in UC patients is summarised. Given that smoking represents a major worldwide cause of death, for inpatients with UC the risks of smoking far outweigh any possible benefit. Thus, physicians should advise, encourage and assist UC patients who smoke to quit.

INTRODUCTION

The development of inflammatory bowel disease (IBD) is the result of an inappropriate inflammatory response to intestinal microbes in a genetically susceptible host. Some environmental factors, such as cigarette smoking and appendectomy, have been shown to play a significant role in the pathogenesis of IBD. Cigarette smoking may cause lung cancer, atherosclerotic vascular disease, other kinds of cancers and chronic obstructive pulmonary disease.

Nowadays, smoking represents a major cause of preventable morbidity and is probably the most important and preventable cause of premature mortality in developed and developing countries.

As smoking is a major environmental factor that interferes in the clinical course of ulcerative colitis (UC), in this article we will review its influence on patients with UC.

RISK OF DEVELOPING UC

It is now fully accepted that UC predominantly affects non-smokers and former smokers, and that smoking exerts a universal protective effect against developing UC[1].

This relationship between smoking and UC has been described for more than 30 years. The first to report this association was Samuelsson[1], who noted a lack of smokers among UC patients compared with matched control subjects. The author attributed this observation to interaction with medication rather than to pathogenesis. In 1982, Harries *et al*[2] confirmed this observation; in a study on 23 UC patients, they found only 8% were current smokers compared with 44% of matched control subjects [patients with Crohn's disease (CD) or a cohort evaluated for fractures]. After the first reports, numerous other studies also confirmed this association. The first meta-analysis, including nine case-control studies, revealed a pooled odds ratio (OR) for non-smoking as the risk factor for acquiring UC of 2.9 (95% CI: 2.6-3.2)[3]. The authors also demonstrated a higher risk for former smokers compared to non-smokers with a pooled OR of 1.64 (95% CI: 1.36-1.98). Additionally, they found a dose-response association with an overall pattern of decreased risk of disease with increased level of smoking. A subsequent meta-analysis[4] that included new information from 11 741 patients with UC in 13 studies confirmed the previous data. When they compared current smoking with never smoking, all studies, with the exception of one, found an OR of less than 1.0, indicating a protective association of current smoking and UC; current smoking decreased the risk for UC (OR: 0.58, 95% CI: 0.45-0.75), suggesting that current smoking is associated with an approximately 42% reduced risk of an UC diagnosis. In contrast to current smoking, when former smokers were compared with never smokers among patients with UC *vs* controls, being a former smoker was associated with an increased risk of UC, with an overall OR of 1.79 (95% CI: 1.37-2.34).

The influence of smoking in genetically predisposed IBD patients has been analyzed in family studies. It is well known that there is high concordance within a family between smoking habits and the IBD phenotype, with UC developing in non-smokers and CD in smokers[5]. Thus, some of the apparent protection that smoking exerts on sporadic UC may be due not only to a therapeutic effect of tobacco usage, but rather that in some instances, it is CD rather than UC which develops as a result of the influence of smoking on the pathogenic pro-

cesses. Bridger *et al*[6] examined 89 sibling pairs with CD or UC discordant for both smoking and IBD phenotype to investigate whether smoking determines the type of IBD that develops in individuals with very similar genetic susceptibility. Of 89 sibling pairs discordant for smoking at diagnosis, 23 were also discordant for disease type. In 21 of these, CD occurred in the smoker and UC in the non-smoker, suggesting that tobacco consumption may act on the IBD genetic predisposition to shift the phenotype from UC towards CD. This role of smoking habits on the IBD phenotype has been confirmed in twins[7]. Among 103 pairs (at least one twin who suffered from IBD), the frequency of smokers was lower among twins with UC. Furthermore, smoking habits were found to be of significance for discordance of disease.

Another issue that should be noted is whether gender may influence the effect of tobacco smoking on UC. Motley *et al*[8] noticed that current smoking delayed disease onset in men but not in women. The effect of gender was also described in the aforementioned article by Bridger *et al*[6], who noted different effects of smoking on the incidence of CD or UC in females and males. This paper showed more pronounced protection from UC (OR 0.18, 95% CI: 0.11-0.3) in females smoking at diagnosis compared with non-smokers (OR 0.47, 95% CI: 0.28-0.79). Later, Cosnes *et al*[9] studied a cohort of 1784 consecutive adult patients (978 with UC). In this study, the beneficial effect of smoking in UC was modulated importantly by gender: they described a more marked increase in disease presentation in men during the few years after smoking cessation.

One important question that should be resolved is whether childhood passive smoking or prenatal smoke exposure has the same influence on the development of UC. This issue was analyzed in a meta-analysis of 13 studies[10]; the results revealed that, in contrast to the inverse association between active smoking and UC development, there was no significant association between childhood passive smoke exposure or prenatal smoke exposure and the development of UC. A dose-response relationship is a possible explanation for the failure of this meta-analysis to show a protective effect of childhood passive smoke exposure on UC; thus it is possible that the level of exposure does not reach a threshold level which is required for the protective effect that has been well documented in active smokers. Moreover, the size of the studies regarding prenatal smoke exposure and the development of IBD were too small to reach a definitive conclusion. After the publication of the meta-analysis, van der Heide *et al*[11] published a new study that addressed this issue; the authors did not find that passive smoking had a beneficial effect. Furthermore, passive smoking UC patients had a higher prevalence of ileal disease (pouchitis and backwash ileitis) than non-passive smoking UC patients.

All the presented data support the view that current smoking is associated with a low risk of UC, but before drawing conclusions we should be aware of the possible

bias that may be present in the studies analyzed, such as differences in study methods, measurement error, or a lack of verification of self-reported smoking status. The lack of uniformity in smoking definitions is probably a serious weakness in many of the published studies. Another important issue that should be noted is that most of the studies are based strictly on the effects of smoking on the non-Jewish white population. Certain races have not demonstrated associations between smoking behaviors and IBD[12,13], suggesting that different races may have varying degrees of susceptibility to IBD, although these differences are probably more important in CD than in UC. In fact, in Israeli Jewish patients, there was no association between smoking and CD patients, although the opposite association exists in UC[14].

INFLUENCE OF SMOKING ON DISEASE COURSE

Active tobacco smoking has a protective effect on the severity of UC; the disease course is more benign in smokers than in non-smokers[15,16]. Flare-up, hospitalization rates, the need for oral steroids and, more importantly, colectomy rate are reported to be lower in smokers compared with non-smokers, though this has not been observed in all studies[17-19].

The link between smoking and colectomy in UC patients is controversial. In a retrospective analysis of a large series of UC patients, current smoking was found to decrease the 10-year cumulative colectomy risk from 0.42 to 0.32[18]. A subsequent meta-analysis with a total of 1489 UC patients found the risk for colectomy to be lower (OR: 0.57, 95% CI: 0.38-0.85) in current smokers compared with non-smokers[20].

In agreement with these results, a population-based cohort study performed in Europe[16] with 771 UC patients prospectively included and followed for 10 years revealed a lower relapse rate (Hazard ratio: 0.8, 95% CI: 0.6-0.9) in smokers compared with non-smokers. Another similar study carried out in the Netherlands by van der Heide *et al*[11] with 295 UC patients identified smoking after diagnosis as a protective factor for colectomy (OR 0.27, 95% CI: 0.11-0.67), whereas pancolitis at diagnosis (OR 3.18, 95% CI: 1.85-5.48) was a risk factor.

On the other hand, a study by Beaugerie *et al*[21], designed to determine the impact of cessation of smoking on the course of UC, analyzed the disease severity in 32 patients with UC who stopped smoking after the diagnosis compared with 32 non-smokers and 32 continuing smokers matched for sex, age, and age at onset. There was no significant difference in colectomy rate among quitters during the 5-year period after smoking cessation and either non-smokers or continuing smokers during the matched periods. Nevertheless, smokers who quit experienced an increase in disease activity, hospital admissions, and the need for major medical therapy (oral steroids, immunosuppressants) within the first years following the cessation of smoking.

As well as the study by Beaugerie *et al*[21], Boyko *et al*[17] reported a lower hospitalization rate in patients who were smoking at the onset of UC, but could not identify a difference in the colectomy rate between smokers and non-smokers.

In agreement with the presented data, improvements in symptoms and a milder course of disease have been reported in ex-smokers who returned to smoking[22,23]. In fact, many patients noted symptom exacerbation when they stopped smoking, followed by symptom relief when they smoked again[8].

Interestingly, some studies reported a gender association; when compared to non-smokers, male UC who smoked ran a more benign disease course as assessed by the decreased need for immunomodulators, whereas this difference was not observed in females[3,9,20]. Additionally, smoking delayed the onset of the disease, although only in males.

Smoking seems to be a protective factor against proximal extension. In patients with distal UC at diagnosis, retrograde extension of the disease process was less frequent in smokers than in non-smokers[24]. A retrospective analysis in France showed that in a subgroup of patients with limited disease at onset of symptoms, the percentage of smokers developing pancolitis was lower than among non-smokers[18]. More recently, Meucci *et al*[25], in a cohort of 273 patients, described proximal extension of the disease in 27.1%. The cumulative rate of proximal extension was higher in non-smokers, in patients with more than three relapses per year and in patients requiring systemic steroid or immunosuppressive treatment.

Not all the studies could identify a protective effect of smoking on the retrograde extension of UC. Pica *et al*[26] retrospectively reviewed 138 patients with ulcerative proctitis; in this series, proximal extension of the disease was seen in 30% of patients. The prevalence of smoking habit was not higher in patients with extended disease.

Finally, it is important to note that many studies failed to identify a beneficial effect of smoking on the course of UC[27-30]. For instance, Roth *et al*[31] included 102 consecutive patients in a survey to assess the natural history of the disease and to determine predictors of future disease severity at the time of diagnosis. Delay from symptoms to diagnosis of UC, gender, family history of IBD, smoking status and disease severity at the time of diagnosis did not significantly predict the disease severity. Similar results were described by Romberg-Camps *et al*[32] in a population-based survey designed to predict the disease course in 630 UC patients. In this study, disease severity, cumulative medication use, and "surgical" and "nonsurgical" recurrence rates were calculated as outcome parameters. A protective effect of smoking on disease recurrence in UC could not be confirmed in this study.

Tobacco smoking also influences other clinical scenarios in patients with UC. Smoking may also prevent the development of primary sclerosing cholangitis (PSC), or pouchitis after colectomy and ileal pouch anal anastomo-

sis[33-36]. PSC is a chronic cholestatic liver disease of unknown etiology that is associated with UC. Loftus *et al*[33] published a case-control study to determine whether the relationship between smoking and PSC is similar to that found between smoking and UC. Like UC, PSC was found to be a disease of non-smokers, as the odds of having PSC in current smokers compared with never-smokers was 0.13. The protective effect was independent of whether or not the PSC patient had underlying IBD; the odds of having disease among former and current users of any tobacco relative to never-users were 0.41 regardless of the presence or absence of IBD. Another study published recently by van der Heide *et al*[11] found that never smoking was a risk factor for the development of PSC in UC patients (OR 4.32, 95% CI: 1.52-12.25). In this article, proctitis (OR 0.09, 95% CI: 0.02-0.39) and left-sided colitis at diagnosis (OR 0.35, 95% CI: 0.13-0.93) were associated with a lower risk for PSC.

NICOTINE AS A THERAPEUTIC AGENT IN UC

Four different formulations of nicotine have been used as a therapeutic agent in patients with UC: nicotine gum, transdermal nicotine, delayed release oral capsule and enema (Table 1).

Chewing polacrilex gum containing up to 4 mg of nicotine results in peak blood nicotine concentrations that are usually observed with cigarette smoking. However, the extraction of nicotine from gum is incomplete and variable (53%-72%) for a variety of reasons, including: variable nicotine extraction because of differences in chewing intensity and duration, variable saliva production (the basic pH of saliva enhances absorption), variability in the amount of nicotine retained in the mouth for buccal absorption *vs* the amount swallowed (which undergoes first pass hepatic metabolism) and inconsistent administration schedules[37,38].

Transdermal nicotine administration provides a steady plasma nicotine concentration that is directly proportional

to the nicotine dose and leads to peak nicotine concentrations of approximately two thirds of those measured during smoking[39]. Nevertheless, compared with smoking cigarettes, no sharp increases in blood nicotine concentrations have been observed using transdermal application.

Topical administration of nicotine directly to the colon *via* enema or delayed release oral capsule formulations decrease the systemic absorption and side effects, and may be clinically beneficial. Nicotine is rapidly and extensively metabolized, primarily in the liver *via* the cytochrome P450 enzyme pathway[40,41]. When nicotine is ingested orally, bioavailability is low (20%-44%) due to the first pass hepatic metabolism[42,43].

A pharmacokinetic study in healthy volunteers demonstrated that nicotine tartrate administered as a liquid enema had low systemic absorption (mean systemic bioavailability for various formulations ranged from 15% to 25%) and was well tolerated after a single dose[42].

Uncontrolled studies reported that nicotine gum 4 mg, 5-7 sticks/d was beneficial in some ex-smokers with active UC[44-46] but, in contrast, nicotine gum had no benefit and was poorly tolerated in those with active UC who had never smoked[45]. Similarly, uncontrolled studies reported that transdermal nicotine 15 mg/24 h and 30 mg/24 h (22 mg delivered) was beneficial in patients with active and steroid-dependent UC[47-49]. As happened with the nicotine gum, patients who had never smoked were reported to tolerate nicotine poorly[47]. Following the uncontrolled studies, six controlled trials have assessed the utility of nicotine therapy in UC patients[50-56].

A study in seven patients with active UC confirmed that nicotine gum 2 mg administered 5-7 times/d was beneficial compared with placebo in three of four ex-smokers and in none of three who had never smoked[50].

Two randomized, placebo-controlled trials of transdermal nicotine for active UC showed that nicotine was useful when compared with placebo[51,52]. Both studies began with lower nicotine doses (15 mg and 11 mg) to improve patient tolerance, followed by dose escalation after 1-2 wk. The first study, conducted by Pullan *et al*[51]

treated 72 patients with active left-sided UC with either transdermal nicotine patches (up to 25 mg/24 h) or placebo over a period of 6 wk. The standard medication, which included mesalamine (all patients) and glucocorticoids (12 patients), continued to be administered during the study. Most patients tolerated the nicotine doses. Patients in both the nicotine and placebo groups improved, although the improvement in clinical and histological grades was greater in the group treated with nicotine. Seventeen of 35 (48.6%) patients in the nicotine group had complete remission, compared with only nine of 37 (24.3%) patients in the placebo group.

Similar results were found by Sandborn *et al*[52], who compared transdermal nicotine (22 mg/24 h) for 4 wk with placebo. Nicotine treatment led to a clinical benefit in 39% of patients compared with 9% receiving placebo. No improvement in histology was observed.

A fourth randomized controlled trial compared transdermal nicotine at the highest tolerated dose (up to 25 mg/16 h) with prednisolone 15 mg/d in active UC[53]. No significant differences were found between the two groups, although the corticosteroid therapy tended to be more efficacious.

A fifth randomized controlled trial compared transdermal nicotine 15 mg/24 h for 5 wk to prednisone 30 mg/d tapered over 5 wk and demonstrated equivalence, although again there was a tendency towards prednisone being more efficacious[54]. After following up 30 patients with remission of distal UC after therapy with either mesalazine plus transdermal nicotine or mesalazine plus oral prednisolone for 12 mo, Guslandi *et al*[56] suggested that nicotine-induced remission of UC lasts longer than that obtained by therapy with oral corticosteroids. With respect to the maintenance of remission in patients with UC, no beneficial effect was noted with a lower dose of transdermal nicotine (up to 15 mg/16 h) compared with placebo over a period of 6 mo in the sixth randomized, placebo-controlled trial[55].

In two studies in which liquid nicotine enemas were used to treat patients with active distal UC, the results suggested a clinical benefit in the absence of detectable serum nicotine concentrations[57,58]. Adverse events were of minimal consequence. Nevertheless, the liquid enemas were difficult to retain. Further controlled trials are needed to determine the therapeutic value of topical nicotine administration.

Finally, in patients with PSC, a pilot study of oral nicotine tartrate capsules delivered to the gastroduodenum did not report a beneficial effect[59].

Adverse events when nicotine is therapeutically administered are common (> 50%), but generally mild. They include contact dermatitis, nausea, lightheadedness, headache, sleep disturbance, central nervous system stimulation, sweating, tremor, and tachycardia. The side effects are more frequent in non-smokers than in ex-smokers. Non-smokers have fewer nicotine-associated adverse events if they are initially administered a low dose patch, subsequently escalating the nicotine dose, presum-

Table 2 Possible mechanisms in the pathogenic interactions of smoking and inflammatory bowel disease[64]

Alteration of mucosal blood flow
Pro-thrombotic effects and promotion of microvascular thrombosis
Alteration of gut permeability
Modification of gut motility

ably because they have not yet developed a tolerance to nicotine side effects[60].

PATHOGENIC MECHANISMS OF SMOKING ON UC PATIENTS

The exact mechanisms of action of nicotine and smoking in UC patients is not well known (Table 2)[61]. Tobacco smoke contains hundreds of different substances including nicotine, free radicals and carbon monoxide. It is suspected that the main metabolite responsible for the impact on the course of UC is nicotine, however there is no absolute proof of nicotine being the sole active moiety. In consequence, probably the mechanisms are diverse and considering that the pathogenesis of UC is only partially understood, any dissertation on their possible mechanisms can only be hypothetical.

Nicotine increases mucin synthesis in UC patients[62]. Patients with UC are shown to have a significantly thinner mucus layer in the left colon and rectum compared with healthy (smoking and nonsmoking) control subjects[63]. Nevertheless, no effect of transdermal nicotine on mucin gene expression in UC patients could be demonstrated by Louvet *et al*[64].

Nicotine also affects the immune system. Heavy smokers may have reduced levels of immunoglobulin A in both saliva and intestinal secretions[65,66]. Heavy smoking also influences cellular immune-defense mechanisms, leading to a state resembling immune suppression with an increased level of suppressor CD8+ T cells and a diminished ratio of CD4/CD8 T cells, which is reversible after the cessation of smoking[67]. Nicotine has been shown to decrease the synthesis of proinflammatory molecules, for instance, interleukin (IL)-1β and tumor necrosis factor (TNF)-α by mouse colonic mucosa as well as the production of mucosal eicosanoids[68] and some proinflammatory cytokines by human mononuclear cells (e.g. IL-2[69], IL-8, and TNF-α[70]).

Smokers with UC have a significant reduction in mucosal cytokine levels, specifically, IL-1b and IL-8[71]. Beneficial effects of nicotine in active UC may be associated with a decrease in IL-8 expression. In rats, DNBS-induced colonic damage was improved in passive-smoking rats involving changes in colonic cytokine levels[72]. The increase

of leukotriene B4, TNF-α, IL-1β, and IL-6 levels was alleviated. In contrast, the deprivation of IL-10 during UC was preserved. The exact meaning of these changes in the cytokine balance still remains poorly understood.

Smoking has a deleterious effect on phagocyte function, decreasing their bactericidal and bacteriostatic activity[73]. Chronic exposure of rats to nicotine inhibits the antibody-forming cell response, impairs the antigen mediated signaling in T-cells and induces T-cell anergy[74].

Smokers have a greater capacity for the generation of free oxygen radicals, with reduced antioxidant capacity[75]. This fact correlates with the harmful effect of smoking on patients with CD but does not offer an explanation for the beneficial effects on UC patients.

Other effects of nicotine or smoking on the intestine include hypoperfusion of the rectum and of acutely damaged colonic tissue[76], the alteration of gut motility, the reduction of smooth muscle tone and contractility (modulated by nitric oxide)[77], altered permeability[78], and alterations in the microcirculation[79]. Patients with IBD have an increased intestinal permeability[80]. Smoking was found to decrease the intestinal permeability in healthy control subjects[81]. However, no such observation could be made in smokers with UC compared with nonsmokers with UC[82], refuting the notion that the protective effect of smoking on UC is due to the moderation of an increased intestinal permeability.

SMOKING CESSATION

Based on all the available data, it is clear that smoking cessation in a patient with UC could exacerbate its symptoms as well the disease activity. For this reason, in order to decide whether we should recommend that UC patients quit smoking, we need to balance the decision with the patient.

First and foremost, the patient has to be aware that active cigarette smoking causes a broad spectrum of diseases; it is a major cause of vascular disease, cancer and chronic obstructive pulmonary disease. In addition to these, cigarette smoking also causes other respiratory symptoms, adversely affects reproductive outcomes and is a cause of diminished health status. Furthermore, exposure to second-hand smoke is an established cause of coronary heart disease and lung cancer, as well as a host of other adverse health effects.

Secondly, patients should be given truthful information; it is important to explain to them that there is the possibility of disease exacerbation (flares, hospitalization or the need for oral steroids) following cessation of smoking. We should also explain that the risk of colectomy in the short term appears not to be increased in the case of quitting smoking.

Additionally, patients should be given other important information about the effects of smoking on the course of UC. Patients with UC had a significantly decreased risk of pulmonary cancer, which may primarily be explained by the smoking habits of the patients with UC[83]. Patients should also be informed about the influence of

smoking on the risk of colon cancer (CRC). It is well accepted that UC is associated with an increased risk of colon cancer. A recent meta-analysis of 36 studies showed that current smokers had a significantly increased risk of CRC incidence[84].

Finally, the patient should be aware that nowadays there is an increasing number of treatments that can be used to control inflammation in the case of disease exacerbation after smoking cessation, such as immunosuppressants, leukocyte apheresis or anti-TNF-α products[85].

Based on all the deleterious health effects combined with the substantial prevalence, cigarette smoking represents a major worldwide cause of death. In patients with UC, the risks of smoking far outweigh any possible benefit, so physicians should advise, encourage and assist UC patients who smoke to quit.

CONCLUSION

(1) Smoking is protective in UC, with a lower incidence of disease in smokers; (2) Current smoking protects against UC and, after onset of the disease, improves its course, reducing the need for colectomy; (3) Ex-smokers have an increased risk of developing an unfavorable clinical course; (4) PSC is observed almost exclusively in non-smokers; (5) Nicotine is efficacious for active UC, but in most studies, side-effects (nausea, headache, dermatitis) were frequent and tended to overcome the clinical benefit; (6) The place of nicotine in the algorithm of treatment of UC patients is unclear, although it may be useful in selected cases, particularly in recent ex-smokers with moderate but refractory attacks of UC; and (7) Since smoking is associated with several additional deleterious effects (e.g. cardiovascular, lung cancer risk), gastroenterologists should encourage both UC and CD patients to quit smoking. Before stopping, UC patients should be informed about the potential risk of an increase in disease activity, without a higher risk for surgery.

Abstract

AIM: To understand which and how different miRNAs are implicated in the process of hepatic stellate cell (HSC) activation.

METHODS: We used microarrays to examine the differential expression of miRNAs during *in vitro* activation of primary HSCs (pHSCs). The transcriptome changes upon stable transfection of rno-miR-146a into an HSC cell line were studied using cDNA microarrays. Selected differentially regulated miRNAs were investigated by quantitative real-time polymerase chain reaction during *in vivo* HSC activation. The effect of miRNA mimics and inhibitor on the *in vitro* activation of pHSCs was also evaluated.

RESULTS: We found that 16 miRNAs were upregulated and 26 were downregulated significantly in 10-d *in vitro* activated pHSCs in comparison to quiescent pHSCs. Overexpression of rno-miR-146a was characterized by marked upregulation of tissue inhibitor of metalloproteinase-3, which is implicated in the regulation of tumor necrosis factor-α activity. Differences in the regulation of selected miRNAs were observed comparing *in vitro* and *in vivo* HSC activation. Treatment with miR-26a and 29a mimics, and miR-214 inhibitor during *in vitro* activation of pHSCs induced significant downregulation of collagen type I transcription.

CONCLUSION: Our results emphasize the different regulation of miRNAs in *in vitro* and *in vivo* activated pHSCs. We also showed that miR-26a, 29a and 214 are involved in the regulation of collagen type I mRNA.

INTRODUCTION

Liver fibrosis, characterized by an overproduction of extracellular matrix (ECM), is a common outcome of

different chronic liver diseases[1]. Hepatic stellate cells (HSCs) are one of the major cell types responsible for the production of ECM molecules like collagens, laminin, proteoglycans and fibronectin[2]. The production of different ECM molecules is increased upon transdifferentiation (activation) of HSCs from a quiescent to an activated myofibroblast-like state[3,4]. Consequently, the regulation of the complex process of HSC activation is of great interest to the research community. Understanding this process should lead to the discovery of therapeutic strategies for liver fibrosis. Due to the complexity of the activation of HSCs, the number of regulatory steps is expected to be overwhelming[5], and requires addressing many different targets at the same time, either with different compounds or with one compound that is able to work on many different targets.

miRNAs are small approximately 23-nt non-coding RNAs, which are able to regulate hundreds of different proteins. The versatility of miRNAs is attributed to the imperfect binding (seed region) to the 3'-UTR of mRNAs, which results in, contrary to siRNA, many binding partners. The regulation by miRNAs is also different to siRNAs because it leads to a translational repression and/or mRNA destabilization[6,7]. That miRNAs fulfil regulatory functions has been established by their involvement in many different processes and diseases[8,9]. Therefore, it is tempting to use these molecules in order to treat liver fibrosis; a condition that is caused by a deregulation of biological processes. To succeed in this attempt, we need to identify the miRNAs, which are differentially regulated in the normal and diseased liver, and more specifically in the HSCs; one cell type that is responsible for the fibrotic process.

The purpose of this study was to identify differentially regulated miRNAs in *in vitro* activated HSCs, in order to study them in an *in vivo* animal model, and finally, to determine their role in the activation process.

MATERIALS AND METHODS

Isolation of rat primary HSCs and cell culture conditions

Wistar rats were used to isolate primary HSCs (pHSCs) according to a published pronase/collagenase *in situ* perfusion protocol[10]. The isolation protocol was approved by the Institutional Animal Care and Use Committee under #080389. For *in vitro* activation, the cells were seeded into 75-cm^2 culture flasks and harvested after 3, 5, 7 or 10 d. Primary cells and the HSC-2 cell line were cultured in high glucose Dulbecco's Modified Eagle's Medium (DMEM) containing 10% fetal bovine serum, 100 U/mL penicillin and 100 μg/mL streptomycin at 37℃ in a 5% CO$_2$ humidified incubator.

HSC-2 is a spontaneous immortalized cell line derived from the pHSCs of a male Wistar rat. The primary cells were passaged several times before clonal selection by limiting dilution[11].

The purity of pHSCs from rats on normal and choline-deficient ethionine supplemented (CDE) diet was

assessed using vitamin A autofluorescence or real-time polymerase chain reaction (PCR), respectively (Figure 1A). All cell culture reagents were purchased from Invitrogen (Carlsbad, CA, USA).

In vivo activation of rat HSCs

Six- to eight-week-old male Wistar rats were fed the CDE diet (CDE model) (MP Biomedicals, Solon, OH, USA, #0296021410) for 4 wk (Figure 2). Livers were isolated, perfused with PBS and fixed in neutralized formalin (paraffin embedding) or *in vivo* activated pHSCs were isolated.
Isolation of miRNA for microarray and analysis

miRNA was extracted from quiescent (freshly isolated) and 10-d *in vitro*-activated pHSCs using the PureLink purification kit (K1570-01; Invitrogen). The miRNA microarray (NCode Multi-Species miRNA microarray V2) was performed according to the manufacturer's manual (MIRLS-20; Invitrogen). For each experiment, a dye swap was performed. The arrays were scanned using a GenePix 4200AL array scanner. The raw datasets were deposited under #GSE19463 at the Gene Expression Omnibus (GEO) repository[12]. For two-color miRNA arrays, averaging of dye-swapped arrays was performed to minimize the dye effects prior to normalization using the Cross-Correlation method[13]. The targets of differentially regulated miRNAs (Table 1) were predicted by three different methods, TargetScan 5.1[14], mirBASE target[15], and miRNA Viewer[16] using default parameters. Targets predicted by at least two tools were selected and grouped into upregulated and downregulated miRNAs, respectively. These two groups of targets were subjected to pathway analysis using Ingenuity Pathway Analysis (Ingenuity Systems, Redwood City, CA, USA). A ratio was calculated whereby the number of predicted targets in a given pathway was divided by the total number of molecules in that pathway. The Fisher's exact test was used by the software to calculate a *P* value. This *P* value represented the probability that the association between the predicted targets and the pathway could not be explained by chance alone. The *P* value cutoff was set at $P \leq 0.001$. The x axis was the negative logarithm of *P* value with a base of 10 (-log$_{10}$ *P* value).

Real-time PCR

The verification of the microarray data and subsequent miRNA assessments were performed for let-7b, let-7c, miR-16, 26a, 29a, 31, 125b, 143, 146a, 150 and 214 by using the respective Taqman MicroRNA assays (P/N 4427975, Applied Biosystems, Foster City, CA, USA). The U6 snRNA assay (ID 001973) served as a normalization control. Total RNA was isolated using the NucleoSpin RNAII kit (Macherey-Nagel, Germany). Total RNA and miRNA were isolated using the same kit but with a small modification. Briefly, the cell lysate was adjusted to contain 35% ethanol and passed through the RNAII column to bind the total RNA. The ethanol concentration of the flow through was then adjusted to > 70% and passed through the same column in order to bind the miRNA.

Figure 1 Primary hepatic stellate cells and over-expression of miR-146a in hepatic stellate cell-2 cell line. A: Bright-field image of 1 d cultivated primary hepatic stellate cells and the corresponding vitamin A autofluorescence image are shown. Scale bar represents 100 μm. Real-time polymerase chain reaction (PCR) for *in vivo* activated hepatic stellate cells from rats on normal (*n* = 2) and choline-deficient ethionine supplemented (CDE) diet (*n* = 4). The mean ± SE for each diet model is shown; B: A representative image for the over-expression of miR-146a as visualized by the reporter GFP is shown. Real-time PCR for three independent clones confirmed the expression of miR-146a. The data represent the mean ± SE of triplicate reactions. SMAA: Smooth muscle α-actin.

The Cells-to-Ct kit (Invitrogen, P/N 4391848) was used for some experiments to quantify the miRNA expression with the respective miRNA assays. The reverse transcription and real-time PCR were performed according to the assays protocol using the ABI 7500 Fast Real Time PCR System (Applied Biosystems). Taqman assays used were smooth muscle α-actin (SMAA) (Rn01759928_g1), Col1a1 (Rn01463849_g1), interleukin (IL)-6 (Rn00561420_m1), cyclooxygenase-2 (Cox-2) (Rn00568225_m1), RelA (Rn01502266_m1), CD31 (Rn01467259_m1), Albumin (Rn01413833_m1), CD68 (Rn01495643_g1) and tissue inhibitor of metalloproteinase (TIMP)-3 (Rn00441826_m1).

Nuclear factor-κB siRNA transfection

HSC-2 cells were seeded at a density of 10^6 per 100 mm cell culture dish and incubated at 37℃. The siRNA was mixed at a final concentration of 10 nmol/L with 1 mL DMEM without serum and 120 μL HiPerfect transfection reagent (Qiagen, Germany) and incubated for 10 min. The mixture was added drop-wise to the cells and incubated for 48 h. For the mock control, only the HiPerfect reagent was used. The ON-Targetplus nuclear factor (NF)-κB siRNAs used were J-080033-11 and J-080033-12 (Dharmacon, Lafayette, CO, USA). These conditions were tested for transfection efficiency using FITC-labeled siRNA and FACS analysis.

Overexpression of miR-146a in an HSC cell line

The vector was constructed by amplification of a 487-bp fragment containing the rno-miR-146a from rat genomic DNA using the following primer pair: sense 5'-*AAGCTT*GCCACCAGTCCCATCCTTCACC-3' (*Hin*dIII), anti-sense 5'-*GGATCC*TTCCTCTGTGCT-GGGATTACAGGGTG-3' (*Bam*HI). After sub-cloning, the rno-miR-146a was excised using *Bam*HI/*Eco*RV and cloned into pcDNA6.2/GW EmGFP-miR (Invitrogen). The HSC-2 cells were stably transfected with the construct using Lipofectamine 2000 (Invitrogen) and selected in cell culture medium supplemented with 10 μg/mL Blasticidin. The clonal selection was achieved using FACS.

Gene expression array and analysis

Total RNA from HSC-2 cells overexpressing miR-146a and control cells (two different passages) were used to study the transcriptome changes using the GeneChip Rat Genome 230 2.0 (Affymetrix, USA). The preparation of the samples was performed according to the technical manual P/N 702232 Rev. 3 (Affymetrix) using one-cycle cDNA and target labeling. The chips were scanned using a Genechip Scanner 3000 (Affymetrix). The raw datasets were deposited under #GSE19463 at the GEO repository[12].

The microarray probe set data was summarized using the Robust Multi-Array Average expression measure method, and pre-processed to correct unreliable (small) intensities for each array. The pre-processed data were then normalized using the Cross-Correlation method[13]. For

Figure 2 Histological and immunohistochemical analysis of livers from rats receiving choline-deficient ethionine supplemented diet for 4 wk. A: HE staining shows the structural changes between control and choline-deficient ethionine supplemented (CDE) diet livers. No severe steatosis is observed; B: The Sirius Red staining depicts the deposition of collagen around the portal area and the whole liver; C: The increase in smooth muscle α-actin (SMAA) staining reflects the increasing number of myofibroblasts seen in patches throughout the liver. Scale bar represents 200 μm; D: The Western blotting data confirm the increase in SMAA and Col Ⅰ .

each gene, a fold change value was calculated for samples *vs* control. Differentially expressed genes (DEGs) were selected based on the criterion of fold change > 2. The *P* values of DEGs were obtained using one-tailed Student's *t* test. Pathway analysis was carried out on the DEGs using Ingenuity Pathway Analysis (Ingenuity Systems).

Transfection of miRNA mimics and hairpin-inhibitor

Cells were seeded at 20 000 per well in 48-well plates 24 h prior to transfection. The miRNA mimics or hairpin-inhibitor were added at the required final concentration (miR-26a, 146a, controls and quadruple transfection: 50 nmol/L each; miR-29a and 214: 200 nmol/L each) to 750 μL DMEM without serum, followed by 10 μL Hi-Perfect transfection reagent. The mixture was incubated for 10 min. The medium from each well was aspirated and replaced by 250 μL of the mixture. The transfection was performed in triplicate. Controls were either Hi-Perfect reagent only (mock) or control miRNAs for the

mimic and/or inhibitor.

SDS-PAGE and Western blotting

Cells were lysed in ProteoJet lysis buffer (#K0301; Fermentas, Glen Burnie, MD, USA) and the protein concentration was estimated using the BCA method (Thermo Scientific, USA). The samples were separated in 4%-12% Bis-Tris NuPage gels (Invitrogen) and transferred onto nitrocellulose membranes. The membranes were blocked for 1 h at room temperature using 5% non-fat milk in TBS-Tween (TBS-T). The primary antibodies were applied in the following dilutions: interleukin receptor associated kinase 1 (IRAK1) (sc-7883; Santa Cruz Biotechnology, Santa Cruz, CA, USA,) 1:400; tumor necrosis factor receptor associated factor 6 (TRAF6) (sc-7221; Santa Cruz Biotechnology) 1:400; IκBα (#4814; Cell Signaling, Danvers, MA, USA) 1:1000; pIκBα (#2859; Cell Signaling) 1:750; Cox-2 (sc-1747; Santa Cruz Biotechnology) 1:5000; and β-actin (ab-8227; Abcam, Cambridge,

[1]Data from two experiments.

UK) 1:5000. After three washes in TBS-T, the appropriate HRP-conjugated secondary antibody was given at 1:2000 dilution in blocking solution. After three washes in TBS-T, the membrane was developed using the chemiluminiscence substrate (Millipore, Billerica, MA, USA). Primary and secondary antibodies were incubated at 4℃ overnight and 1 h at room temperature, respectively.

Electrophoretic mobility shift assay
Nuclear protein extract from rno-miR-146a-overexpressing clones was obtained using the NE-PER Nuclear and Cytoplasmic Extraction kit (Thermo Scientific). The electrophoretic mobility shift assay (EMSA) was performed using the NF-κB(I) EMSA kit according to its protocol

(AY1030; Panomics, USA), as described previously[17]. The samples were separated in a 6% non-denaturing polyacrylamide gel (Invitrogen) and transferred to a nylon membrane.

Immunohistochemistry and staining of liver sections
Slides were de-paraffinized and the antigen retrieved by heat exposure in the Target Retrieval Solution pH 9 (S2367; Dako, Glostrup, DK) using a 2100-Retriever retrieval steamer for 45 min. The endogenous peroxidase was blocked with 3% H_2O_2 in methanol for 15 min. Protein was blocked in 10% normal goat serum in PBS for 20 min. The slides were incubated with mouse anti-human SMAA (M0851; Dako) at 1:100 dilution for 1 h, washed and incubated with an anti-mouse HRP-conjugated antibody (K4001; Dako) for 30 min, and developed with DAB (K3468; Dako). All incubations were carried out at room temperature. Nuclei were counter stained with hematoxylin. Hematoxylin and eosin and Sirius Red staining was performed according to standard protocols on paraffin sections. Bright-field images were taken with the LEICA RMB-DM epifluorescence microscope (LEICA, Germany).

Statistics
All quantitative data were presented as mean ± SE. Experimental data were analyzed using the two-tailed Student's *t* test assuming equal variances. $P \leqslant 0.05$ was considered significant. The time-dependent changes during *in vitro* HSC activation were tested for significance at the 0.05 level using one-way ANOVA and Bonferroni's *post-hoc* test. The array data were normalized and analyzed as described in the respective sections above.

RESULTS

Identification of differentially regulated miRNAs in in vitro activated pHSCs and comparison to in vivo activated pHSCs
In 10-d *in vitro* activated pHSCs, 16 miRNAs were upregulated and 26 were downregulated significantly in comparison to quiescent pHSCs (Table 1). We included miR-29a, although the *P* value was above the threshold of 0.05, for further studies because of its predicted targets, which consisted of a number of collagens. The microarray data were confirmed for a number of chosen miRNAs (let-7b, 7c, miR-16, 26a, 29a, 31, 125b, 143, 146a, 150 and 214) using real-time PCR in three additional experiments (Figure 3A). Using isolated *in vivo* activated pHSCs from rats on CDE diet, we found that only miRNAs let-7b, 7c, miR-31, 143 and 214 showed the same regulation as observed for the *in vitro* activated pHSCs (Figure 3B).

Pathway analysis for differentially regulated miRNAs in in vitro activated pHSCs
We performed a pathway analysis using the predicted targets of the differentially regulated miRNAs. The enrich-

Figure 3 Verification of microarray data by real-time polymerase chain reaction of 11 differentially regulated miRNAs and their regulation upon *in vivo* activation of hepatic stellate cells. A: The graph depicts the changes in the miRNA expression of 11 miRNAs detected by real-time polymerase chain reaction, comparing quiescent with 10-d culture activated primary hepatic stellate cells (pHSCs). The data represent the mean ± SE of three independent experiments ([a]$P \leqslant 0.05$, [b]$P \leqslant 0.005$); B: The graph illustrates the relative expression levels of miRNAs in isolated *in vivo* activated pHSCs ($n = 4$, choline-deficient ethionine supplemented diet) compared to normal diet ($n = 2$) ([a]$P \leqslant 0.05$, [b]$P \leqslant 0.005$).

Figure 4 Predicted targets of all differentially regulated miRNAs during *in vitro* activation of primary hepatic stellate cells (Table 1) were analyzed. The two charts represent the enrichment of molecules in affected pathways for the upregulated (A) and downregulated (B) miRNAs. Only pathways with $P \leqslant 0.001$ are shown. IGF-1: Insulin-like growth factor-1; ERK: Extracellular signal-regulated kinase; MAPK: Mitogen-activated protein kinase; BMP: Bone morphogenetic protein; IL: Interleukin; ROS: Reactive oxygen species; AMPK: AMP activated protein kinase; TGF: Transforming growth factor; PTEN: Phosphatase and tensin homolog; LXR: Liver X receptor; RXR: Retinoid X receptor; PPAR: Peroxisome proliferator-activated receptor; HGF: Hepatocyte growth factor.

ment of genes in single pathways is shown as the -log of the P value ($P \leqslant 0.001$). Signaling pathways which were affected include endothelin-1, cyclin-dependent kinase 5, extracellular signal-regulated kinase (ERK)/mitogen-

activated protein kinase (MAPK), p70[S6K], chemokine, bone morphogenetic protein (BMP) and IL-6 for the upregulated miRNAs, as well as ERK/MAPK, production of NO and reactive oxygen species (ROS), AMP

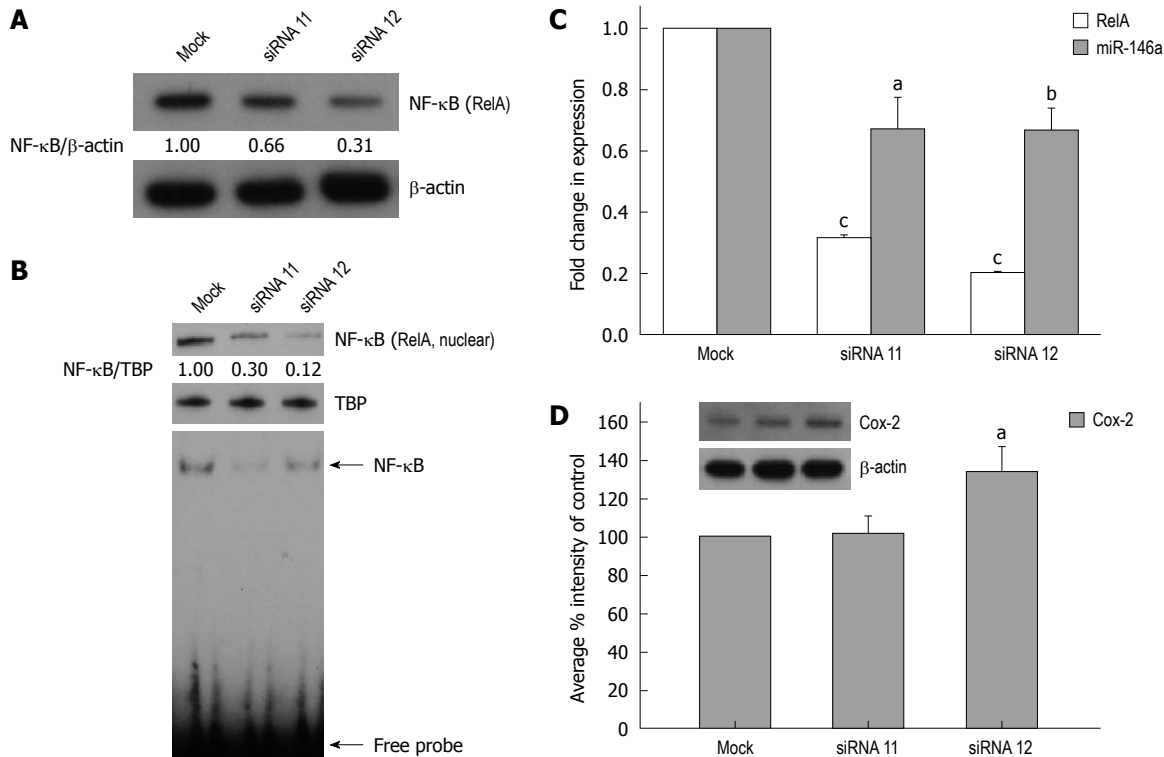
Figure 5 Changes during overexpression of rno-miR-146a in the hepatic stellate cell-2 cell line. A: Depicted are two putative binding sites of miR-146a to the 3'-UTR of rat tumor necrosis factor receptor associated factor 6 (TRAF6) and rat interleukin receptor associated kinase 1 (IRAK1), respectively; B: The Western blotting data show the suppression of TRAF6 and IRAK1, resulting in the decreased phosphorylation of IκB, although the expression of IκB remained unchanged. A representative Western blotting for two independent experiments is shown; C: Electrophoretic mobility shift assay (EMSA) results demonstrated a decrease in nuclear factor (NF)-κB DNA binding activity due to the overexpression of miR-146a. TATA binding protein (TBP) showed equal loading of samples. A representative EMSA experiment is shown out of three independent samples for each clone; D: miR-146a-overexpressing clones showed a reduced level of cyclooxygenase-2 (Cox-2) protein. The Western blotting shown is representative of two independent experiments; E: The relative fold change in mRNA expression between hepatic stellate cell (HSC)-2 and miR-146a-overexpressing HSC-2 cells for five different targets [NF-κB (RelA), Cox-2, smooth muscle α-actin, Col I , interleukin-6] is shown. The data represent the mean ± SE of two independent experiments ($^aP \leqslant 0.005$).

activated protein kinase (AMPK), transforming growth factor (TGF)-β, integrin, cAMP-mediated signaling and phosphatase and tensin homolog (PTEN) for the down-regulated miRNAs (Figure 4A and B).


Overexpression of miR-146a in HSC-2 and transcriptome analysis

Studies have shown that miR-146a is linked to inflammation and the NF-κB pathway through the two known targets IRAK1 and TRAF6[18,19]. In order to study the function of miR-146a in activated HSCs *in vitro*, we over-expressed this miRNA in a HSC cell line HSC-2[11]. The level of miR-146a in this cell line is very low, making it suitable for the overexpression. The expression of the reporter green fluorescent protein and the real-time PCR validation of the miR-146a expression (Figure 1B) provided evidence for the successful overexpression of miR-146a in three different clones (S1, S4 and S5).

IRAK1 and TRAF6 are direct targets of miR-146a with two target sites for each mRNA (Figure 5A). We were able to show downregulation of these proteins in

all three clones (Figure 5B). The functional consequence of this downregulation can be seen by suppression of the phosphorylation of IκB at Ser32 (Figure 5B). The reduced phosphorylation of IκB in turn should lead to the retention of NF-κB in the cytoplasm. Indeed, our EMSA illustrated that there was reduced nuclear binding activity of NF-κB to an NF-κB probe in all clones (Figure 5C). One of the genes regulated by NF-κB is Cox-2, which is functionally related to HSCs due to its pro-apoptotic effect on HSCs[20,21]. Therefore, we investigated the protein level of Cox-2 in the miR-146a-overexpressing clones, and found the expected downregulation (Figure 5D). Surprisingly, further investigation revealed that the mRNAs of NF-κB and Cox-2 were upregulated (Figure 5E). In contrast, we observed a significant downregulation of IL-6 mRNA, another target of NF-κB, in the clones S1, S4 and S5 (Figure 5E). We also found a significant upregulation of SMAA and collagen I (Col I) mRNAs, a HSC activation and a fibrotic marker, respectively (Figure 5E).

In order to establish a link between the regulation of

Figure 6 Regulation of miR-146a by nuclear factor-κB. A: Knock-down experiments using nuclear factor (NF)-κB siRNAs showed a reduced level of cellular NF-κB (RelA) protein; B: The nuclear level of NF-κB (RelA) was decreased and showed a diminished DNA binding activity. Depicted is a representative Western blotting and electrophoretic mobility shift assay from three independent experiments; C: Downregulation of NF-κB (RelA) mRNA due to NF-κB siRNA transfection was accompanied by a decrease in miR-146a after 24 h. The data represent the mean ± SE of two independent experiments ($^aP \leqslant 0.05$, $^bP \leqslant 0.01$, $^cP \leqslant 0.001$); D: Cyclooxygenase-2 (Cox-2) protein was upregulated after NF-κB siRNA transfection. Shown are a representative Western blotting and the densitometric analysis of six independent experiments ($^aP \leqslant 0.05$).

miR-146a and NF-κB activity, as proposed by Taganov *et al*[18], we transfected NF-κB siRNAs into HSC-2 cells. The efficiency of the transfection was shown by the downregulation of NF-κB in total cell lysates and nuclear extracts, which resulted in a decrease in NF-κB DNA binding activity (Figure 6A and B, respectively). We also found downregulation of miR-146a in NF-κB siRNA-transfected cells, thereby confirming a regulation of miR-146a by NF-κB in HSCs (Figure 6C). Surprisingly, we noticed an increase in the Cox-2 protein expression (Figure 6D), which implied a yet unclear involvement of miR-146a in the regulation of this enzyme.

The differences in the NF-κB-dependent regulation of Cox-2 and IL-6 have already hinted at the intricacy of the influence of the miR-146a overexpression has on the gene expression in activated HSCs. In order to get an overview of the transcriptome changes, we performed a gene expression analysis of the three miR-146a-overexpressing clones, and compared them with control cells using a cDNA microarray. The analysis yielded 485 up- and 309 downregulated transcripts (Supplementary Tables 1 and 2), which satisfied a *P* value $\leqslant 0.05$ and at least twofold change. Among the upregulated genes were Lmcd1, CD81, FGF13, Col4a1, Cadherin 11 and BMP-4. The highly downregulated genes included Col15a1, MMP-2, Thy-1, IL-1RL1 and Cadherin 13.

We further analyzed the pathways which were signifi-

cantly enriched, using a *P* value $\leqslant 0.05$ as a threshold. Here, we observed enrichment for signaling pathways like integrin-linked kinase, hepatic fibrosis/HSC activation and caveolar-mediated endocytosis, calcium, cAMP-mediated signaling, integrin, endothelin-1 for the upregulated genes (Figure 7 A), and hepatic fibrosis/HSC activation, lipopolysaccharide (LPS)/IL-1-mediated inhibition of retinoid X receptor (RXR) function and nitrogen metabolism, and liver X receptor/RXR activation for the downregulated genes (Figure 7 B).

The most interesting finding was the robust upregulation of TIMP-3 mRNA (Supplementary Tables 1), verified by real-time PCR (Figure 8 A), which is an inhibitor of the tumor necrosis factor-α converting enzyme[22], and has been proposed as a tumor suppressor. Similarly, pHSCs treated with miR-146a mimic also showed induction of TIMP-3 mRNA (Figure 8 B).

Time-dependent expression of different miRNAs during in vitro activation of pHSCs

The fact that miR-146a was not downregulated in *in vivo* activated pHSCs (CDE diet) prompted us to study the time-dependent expression of this miRNA during the *in vitro* activation of pHSCs, together with miR-26a, 29a and 214. The expression of miR-146a was indeed downregulated at day 3 already, and recovered subsequently until day 10. Although the miR-146a level at day 10 was
Upregulated genes A

Downregulated genes B

Figure 7 Pathway analysis for the differentially expressed genes of miR-146a over-expressing clones. The charts depict the pathways affected by the (A) or (B) of genes upon stable transfection of miR-146a into hepatic stellate cell-2 cells. Only pathways with $P \leqslant 0.05$ are shown. ILK: Integrin-linked kinase; FGF: Fibroblast growth factor; IL: Interleukin; LPS: Lipopolysaccharide; LXR: Liver X receptor; RXR: Retinoid X receptor.

Figure 8 Relative expression of tissue inhibitor of metalloproteinase-3 mRNA in rno-miR-146a-overexpressing hepatic stellate cell-2 cells. A: The graph depicts the relative changes in tissue inhibitor of metalloproteinase (TIMP)-3 mRNA of three rno-miR-146a-overexpressing clones detected by real-time polymerase chain reaction (PCR). The data represent the mean ± SE of two different passages for each clone ($^aP \leqslant 0.005$); B: Primary hepatic stellate cells were treated with 50 nmol/L miR-146a mimic, and the expression of TIMP-3 mRNA was analyzed by real-time PCR and expressed as fold change relative to mock controls. The data represent the mean ± SE of three independent experiments ($^bP \leqslant 0.01$). HSC: Hepatic stellate cell.

Figure 9 Time-dependent changes in the expression of different miRNAs during *in vitro* activation and miRNA mimic and inhibitor transfection of primary hepatic stellate cells. A: The relative changes in the expression level after 3, 5, 7 and 10 d of *in vitro* primary hepatic stellate cells (pHSCs) activation is shown for miR-146a, 26a, 29a and 214 ($^aP \leqslant 0.05$, one-way ANOVA). The data represent one of two independent experiments performed in triplicate; B: pHSCs were transfected with miR-146a, 26a, 29a mimics or miR-214 inhibitor or in combination. The control transfection consisted of control miRNAs for the mimic and/or inhibitor. The smooth muscle α-actin and Col I mRNA expression was analyzed as fold change relative to mock controls. The data represent the mean ± SE of two independent experiments, each performed in triplicate ($^aP \leqslant 0.05$, $^bP \leqslant 0.01$, $^cP \leqslant 0.001$). SMAA: Smooth muscle α-actin.

Figure 10 Transfection of primary hepatic stellate cells with different miRNA mimics and inhibitor. The miRNA expression was analyzed as fold change relative to mock transfected primary hepatic stellate cells (pHSCs). Shown are data for the transfection of miR-146a mimic and miR-214 inhibitor with respective control (A), for the transfection of miR-26a and miR-29a mimic with respective control (B) and for the quadruple transfection of miR-146a, miR-26a, miR-29a mimic and miR-214 inhibitor (C) ($^aP \leq 0.05$, $^bP \leq 0.005$).

still lower than that in quiescent pHSCs at day 0, there was still a 10-fold increase between day 3 and 10 (Figure 9A). In contrast, the expression of miR-26a and 29a did not change as dramatically from day 3 to day 10. We also noticed that miR-214 started to increase only from day 5 onwards (Figure 9A).

Regulation of SMAA and Col I transcripts in pHSCs by different miRNA mimics and inhibitor

In order to study the effect of different miRNA mimics or inhibitor on the *in vitro* activation process, we transfected 3-d *in vitro* activated pHSCs for 3 d with miR-146a, 26a, 29a mimics, miR-214 hairpin inhibitor or all combined. The impact on the HSC activation was followed using real-time PCR to study the changes on the mRNA levels of SMAA and Col I. The high efficiency of transfection was demonstrated by real-time PCR (Figure 10). We found moderate upregulation of the activation marker SMAA by miR-146a (Figure 9B); an observation seen also for the miR-146a-overexpressing clones (Figure 5E and cDNA microarray data). In fact, all cells transfected with the mimics, the inhibitor or combined showed an upwards trend for SMAA mRNA compared to the mock control, although the level did not always change significantly (Figure 9B). For the Col I expression, we noted again an increase caused by miR-146a mimic (not significant) and a decrease by miR-26a, 29a mimic and miR-214 inhibitor. The quadruple transfection led to a suppression of Col I mRNA (Figure 9B).

DISCUSSION

The aim of this study was to gain a deeper insight into the regulation of miRNAs during the activation process of pHSCs, as well as the influence of up- or downregulation of miRNAs on the gene expression and activation of HSCs.

The expression analysis of miRNAs between quiescent and *in vitro* activated pHSCs yielded a number of induced and suppressed miRNAs (Table 1), some of which

(miR-143, 16, 122, 146a, 92b, 126) confirmed the findings of Guo *et al*[23]. On the other hand, there were some differences in the regulation of certain miRNAs (miR-328, 207), which could be attributed to the dynamic nature of miRNA regulation and the different use of quiescent pHSCs (day 0 *vs* day 2).

When evaluating the miRNAs expression profile of the *in vitro* and *in vivo* activated pHSCs, a clear distinction was seen in the expression of miR-16, 26a, 29a, 125b, 146a and 150 (compare Figure 3A and B); a phenomenon which could be explained by the distinct HSC activation process. This has been shown at the gene expression level by De Minicis *et al*[24]. The *in vivo* activation was performed over a period of 4 wk, whereas the *in vitro* activation was monitored over 10 d, which could also account for some differences in the miRNA expression, assuming a dynamic regulation.

On the other hand, we found that certain miRNAs (let-7b, 7c and miR-214) were regulated in the same way during *in vitro* and *in vivo* activation of pHSCs. It also became clear to us that miR-214 could be a potential candidate for a diagnostic approach, because this miRNA always shows robust upregulation.

Pathway analysis of the miRNA microarray data was performed to obtain information on signaling cascades involving predicted targets of the differentially regulated miRNAs in *in vitro* activated pHSCs (Figure 4A and B). NO and ROS are known to play a role in the activation process and apoptosis of HSCs[25,26]. The pathways for AMPK, ERK/MAPK, PTEN and TGF-β are also implicated in HSC activation[27-30]. We noticed that a number of pathways were present in the charts for both up- and downregulated miRNAs, which could denote the complexity of regulated targets by each single miRNA, and possibly a cooperative effect between up- and downregulated miRNAs.

A number of publications have shown that miR-146a is involved in inflammatory diseases, regulation of the immune response and NF-κB[19,31-33]. In the early events of liver fibrosis, the activation of HSCs is in part driven by

the hepatic inflammatory process, during which different cytokines are secreted by various liver cells, like Kupffer cells, endothelial cells and hepatocytes[34,35]. Involvement of NF-κB in HSC activation has also been shown in several research papers[36,37]. Therefore, we overexpressed miR-146a in an HSC cell line and observed changes consistent with the findings from Bhaumik *et al*[19]. The detected increase in the NF-κB transcript (Figure 5E) could be explained by a feedback mechanism to the reduced nuclear activity, which leads to the upregulation of the mRNA.

Cox-2 is inducible in activated HSCs by various stimuli and is thought to regulate proliferation[21]. Others have shown that the inhibition of this enzyme has a beneficial antifibrotic effect[20,38,39]. The seemingly discrepant findings of the protein (lower) and transcript (elevated) level for Cox-2 in the miR-146a-overexpressing HSCs (Figure 5D and E) hint at independent pathways for the regulation of Cox-2. These pathways have been shown for intestinal myofibroblasts[40] and during ischemic injury of ileal mucosa[41]. Lasa *et al*[42] and others have shown that the p38 MAPK signaling cascade is able to stabilize the Cox-2 mRNA[43], which could also explain an elevated transcript level. We also cannot exclude that other mechanisms could be involved in stabilizing the Cox-2 mRNA and/or a regulation of Cox-2 by other miRNAs like miR-26a or 143, which are also present in the cell line HSC-2 and for which Cox-2 is a predicted target.

In contrast, the IL-6 mRNA, another molecule regulated by NF-κB, was downregulated (Figure 5E). This observation implies that IL-6 regulation in HSCs is more tightly associated with NF-κB than that of Cox-2.

We were also interested to know whether downregulation of the NF-κB DNA binding activity triggered by miR-146a overexpression could facilitate a feedback loop in HSCs; a notion supported by the fact that the promoter region of miR-146a contains a number of NF-κB binding sites[18]. As expected, a reduction in the NF-κB DNA binding activity (Figure 6B) leads to a decrease in miR-146a (Figure 6C). The observed upregulation of Cox-2 protein (Figure 6D) was somewhat surprising and again substantiated the speculation that other pathways such as p38 MAPK, C-Jun N-terminal kinase and ERK could participate in the regulation of Cox-2 in HSCs[40,44,45].

The microarray analysis revealed that the transcriptome changes caused by miR-146a overexpression are complex and numerous pathways are affected (Figure 7, Supplementary Tables 1 and 2). We found that several DEGs coincided with data from earlier publications on HSC activation[24,46], suggesting that a number of genes affected by miR-146a overexpression are also involved in the activation process. Pathway analysis of the DEGs (Figure 7) confirms a link between miR-146a and inflammation (LPS/IL-1 mediated inhibition of RXR function, eicosanoid signaling, nitrogen metabolism and NRF2-mediated oxidative stress response pathways). That the miR-146a overexpression in HSC-2 cells leads to changes in the pathway called hepatic fibrosis/HSC activation

emphasizes that these changes are specific for the HSCs. The upregulation of TIMP-3 (Supplementary Table 1 and Figure 8) again emphasizes the involvement of miR-146a in inflammatory processes and immunity, by linking it to the TNFα activity[47].

We noticed a robust downregulation of miR-146a during *in vitro*, but a missing regulation of miR-146a during *in vivo* activation of pHSCs (CDE diet). We hypothesized that there is a dynamic component in the regulation of miR-146a. We effectively found that there is a time-dependent regulation of miR-146a over 10 d of *in vitro* activation of pHSCs. From an *in vivo* perspective, it could be a possibility that miR-146a is decreased following the first insult to the liver, but reaches almost a normal level during the developing fibrosis, as seen for the *in vivo* activated pHSCs (CDE diet). The mechanism behind this miR-146a regulation is not clear, but the involvement of different transcription factors [NF-IL6, interferon regulatory factor (IRF 3/7)] binding to its promoter region is conceivable[18].

The dynamic nature of miRNA regulation during the *in vitro* activation of pHSCs could also partially explain the differences in the expression pattern of the miRNAs *in vitro* and *in vivo*. The dynamic nature of miRNA expression has been shown for the T-cell development[48], and it makes sense if we consider the multitude of effects a single miRNA can have due to the imperfect complementarity to its target sequence.

The *in vivo* targets of a miRNA treatment are pHSCs, therefore, we assessed the effects of several miRNAs mimics (miR-26a, 29a, 146a) and inhibitor (miR-214) on the activation state of pHSCs. The transfection with a combination of all mimics and inhibitor was performed so as to examine possible cooperative effects between different miRNAs, as a first step to understand the co-operativity of miRNA expression changes during HSC activation. The miR-26a, 29a mimics and miR-214 inhibitor showed a significant suppression of the Col I mRNA (Figure 9B). This is somewhat surprising because even though a number of collagens are predicted targets for miR-26a and 29a, none has a perfect binding site, which would explain regulation by mRNA degradation. Therefore, we conclude that the mechanism by which miR-26a, 29a and 214 downregulate the Col I mRNA is indirect, as also suggested by van Rooij *et al*[49] for miR-29a. The downregulation of Col I by the quadruple transfection shows some synergistic effect between the miRNAs.

Our findings showed the differential regulation of miRNAs in *in vitro* and *in vivo* activation of pHSCs, and particularly, the involvement of miR-26a, 29a and 214 in the regulation of Col I mRNA. Moreover, miR-146a overexpression or treatment with miR-146a mimic upregulates TIMP-3 mRNA, which suggests an association between miR-146a, TNFα activity and inflammation. In conclusion, our observations help build a global picture of the miRNA regulation during HSC activation *in vitro* and *in vivo*, and may have important implications when considering a therapeutic approach for treating liver fibrosis using miRNAs.

COMMENTS

Background

miRNAs are a relatively new and exciting tool to control the expression of multiple genes. During liver injury and subsequent wound healing involving hepatic stellate cells (HSCs), complex regulatory processes occur and have to be tightly regulated in this cell type. miRNAs could be one tool to control these processes, and therefore, it is of interest to the research community to gain information about the expression of miRNAs during liver fibrosis in HSCs.

Research frontiers

Liver fibrosis and subsequently cirrhosis are common outcomes of chronic injuries to the liver. HSCs are involved in liver fibrosis and repair. The tools for the treatment of liver fibrosis are limited and are still under development. In this study, the authors aimed to gain information for the possible role of miRNAs in liver fibrosis and whether they could become a future tool to develop a treatment for liver fibrosis by addressing the changes in HSCs.

Innovations and breakthroughs

Different publications have analyzed the miRNA expression in HSCs *in vitro* and studied the effect of various differentially regulated miRNAs in HSCs. The authors analyzed the miRNA expression in an *in vivo* model of hepatic fibrosis, namely choline-deficient ethionine supplemented diet. Furthermore, they studied the transcriptome changes upon overexpression of miR-146a and found that, in particular, tissue inhibitor of metalloproteinase-3 showed robust up-regulation, a hitherto unreported effect, which emphasizes its involvement in inflammation. Another important finding was the dynamics of miRNA regulation during the *in vitro* activation of HSCs.

Applications

miRNAs are becoming a promising tool for the regulation of gene expression. In order to use this tool, it is necessary to understand the role and regulation of the targeted miRNA. In this study, the authors describe the dynamic regulation of specific miRNAs. The results of this study show clearly that the use of miRNAs as target molecules will have to take this dynamic component into consideration. The same is valid for the use of miRNAs as therapeutic agents.

Terminology

miRNAs are small non-coding RNAs that are about 23 nucleotides long. The versatility of miRNAs depends on the imperfect binding (seed region) to the 3'-UTR of mRNAs. This imperfect binding results in many different binding partners. The regulation by miRNAs leads to a translational repression and/or mRNA destabilization.

Peer review

The field of miRNA research as well as HSC activation mechanisms are very up to date and important areas of research, in order to find new strategies against liver fibrosis. The methods used are comprehensive and convincing. In all, the study was fairly well conducted and interesting.

Abstract

AIM: To investigate the influence of chitosan nanofiber scaffold on the production and infectivity of porcine endogenous retrovirus (PERV) expressed by porcine hepatocytes.

METHODS: Freshly isolated porcine hepatocytes were cultured with or without chitosan nanofiber scaffold (defined as Nano group and Hep group) for 7 d. The daily collection of culture medium was used to detect reverse transcriptase (RT) activity with RT activity assay kits and PERV RNA by reverse transcription-polymerase chain reaction (PCR) and real time PCR with the PERV specific primers. And Western blotting was performed with the lysates of daily retrieved cells to determine the PERV protein gag p30. Besides, the *in-vitro* infectivity of the supernatant was tested by incubating the human embryo kidney 293 (HEK293) cells.

RESULTS: The similar changing trends between two groups were observed in real time PCR, RT activity assay and Western blotting. Two peaks of PERV expression at 10H and Day 2 were found and followed by a regular decline. No significant difference was found between two groups except the significantly high level of PERV RNA at Day 6 and PERV protein at Day 5 in Nano group than that in Hep group. And in the *in-vitro* infection experiment, no HEK293 cell was infected by the supernatant.

CONCLUSION: Chitosan nanofiber scaffold might prolong the PERV secreting time in pig hepatocytes but would not obviously influence its productive amount and infectivity, so it could be applied in the bioartificial liver without the increased risk of the virus transmission.

INTRODUCTION

Although liver transplantation is currently recognized as the most effective treatment for acute liver failure and end-stage liver diseases, its application has been seriously limited because of the lack of donor organs[1,2]. Therefore, bioartificial liver (BAL) has been proposed as a temporary liver support for patients awaiting liver transplantation[3-5].

At present, porcine hepatocytes were still a major cell source because of their adequate resources, accessibility and characters similar to human hepatocytes[6-8]. However, the clinical application of BAL based on porcine hepatocytes was not very optimistic[4]. So how to increase the *in-vitro* function of hepatocytes with a suitable scaffold was always an attractive issue and some previous reports showed the enhanced function of procine hepatocytes with their scaffold, including the chitosan nanofiber scaffold developed in our institute[9-11].

Nevertheless, as xenogeneic cells, there were some problems with porcine hepatocytes. The security of the transmission of porcine endogenous retrovirus (PERV) has been one of the most essential concerns that can not be ignored, since PERV infection of human cells *in vitro* was widely reported[12]. Therefore, it raised new questions that whether the production and infectivity of PERV would be influenced and whether the risk of PERV infection in BAL would be increased when the function of porcine hepatocytes was enhanced with certain scaffolds.

Previously, we had proved the chitosan nanofiber scaffold could enhanced hepatocytes adhesion, viability and function *in vitro*[13]. This study was focused on the influence of chitosan nanofiber scaffold on PERV expression and infectivity in pig hepatocytes.

MATERIALS AND METHODS

Animals and reagents

Outbred white pigs with an average weight of 15-20 kg received humane care and all animal procedures were performed according to institutional and national guidelines and approved by the Animal Care Ethics Committee of Nanjing University and Nanjing Drum Tower Hospital. All cell culture-related reagents were purchased from GIBCO (USA). Lactobionic acid (LA) and chitosan (low molecular weight, brookfield viscosity 20 000 cps, 85% deacetylation) were purchased from Sigma-Aldrich (Saint Louis, USA). N-Hydroxysuccinimide was purchased from Thermo-Pierce (Rockford, USA). 1-Ethyl-3-(3-dimethyl aminopropyl) carbodiimide and N,N,N0N0-tetramethylethylenediamine were obtained from TCI (Tokyo, Japan). Poly(ethylenoxide) (PEO, MWz1_106) was supplied by Guoren Chemical Co. (Beijing, China). All other reagents were of analytical reagent grade.

Preparation of chitosan nanofiber scaffold via electrospinning

The chitosan nanofiber scaffold was prepared according to the previous reference[13]. In brief, Chitosan (Sigma) and PEO powders (9:1 w/w) were dissolved in formic acid/ethanol (7:3 v/v) to give 2.6% (w/v) at room temperature. The stock solution was then filled into a 5 mL glass syringe fitted with a 20 G needle and then expressed at 5 mL/h using a syringe pump. The nanofibers were collected on 24 mm diam. coverslips located at a fixed distance of 10-20 mm from the needle tip. A non-coated cover slip was also prepared and tested in the same manner as control.

Hepatocytes isolation, characterization and culture

Primary pig hepatocytes were harvested by a two-step *in situ* collagenase perfusion technique[14,15]. First, the prewarmed (37℃) Ca^2+ and Mg^2+ free Hanks balanced salt solution was perfused into the livers of the anesthetized pigs *in vivo via* the portal vein at a flow rate of 80-100 mL/min for 30-40 min, followed by 0.05% Type IV collagenase (37℃) at a rate of 10 mL/min for 40-50 min. The released cells were filtered through nylon mesh with 100-mm openings and washed *via* three centrifugations (50 g). The viability of the isolated primary hepatocytes determined by trypan blue exclusion was more than 95%. Nonparenchymal cells, as judged by their size (< 10 mm in diameter) and morphology (nonpolygonal or stellate), were less than 1%, which was also verified by immunocytochemical analysis of albumin and cytokeratin 18 (data not shown). Freshly isolated hepatocytes were seeded at a density of 10^6 cells/mL in the substratum of 2 mL RPMI-1640 without serum and incubated in 6-well microtiter plates with or without chitosan nanofiber scaffold (defined as Nano group and Hep group) at 37℃ and 5% CO_2. Culture medium was replenished daily without the growth medium containing low-glucose Dulbecco's modified Eagle's medium (DMEM-LG) supplemented with 10% fetal bovine serum (FBS) for 7 consecutive days. The daily collection of culture medium and cells were deposited at -80℃ for later use.

Reverse transcription-polymerase chain reaction

Total RNA was extracted respectively from the centrifuged supernatant with Trizol (Invitrogen, US) and then treated with DNase I (Invitrogen, US) according to the manufacturer's instructions. For each sample, 60 ng extracted RNA with the value of OD 260/280 among 1.60 and 2.00 was reversed transcribed to cDNA using the reverse transcriptase (RT) kits (Biouniquer, China) in accordance with the instructions. Then polymerase chain reaction (PCR) was completed with the protease-specific primers (forward, 5'-GCTACAACCATTAG-GAAAACTAAAAG-3'; and reverse, 5'-AACCAG-GACTGTATATCTTGATCAG-3'), polymerase-specific primers (forward, 5'-CTACAACCA TTAGGAAAACTA-AAAG-3'; and reverse, 5'-AACCAGGACTGTATATCTT-GATCAG-3'), and porcine glyceraldehyde 3-phosphate dehydrogenase-specific primers (forward, 5'-CATCAC-CATCTTCCAGGAG-3'; and reverse, 5'-TGCCCA-CAGCCTTGGCAGC-3') and its conditions were as follows: 50℃ for 30 min and then 95℃ for 5 min followed

by 35 cycles of 94℃ for 30 s, 55℃ for 45 s, 72℃ for 30 s, and a final extension step of 72℃ for 5 min[16,17]. Amplified production was detected by 2% agarose gel electrophoresis and ethidium bromide (EB) staining.

PERV-specific real time PCR

Quantitative real time PCR was performed with the obtained cDNA, the Roche SuperScript Ⅲ platinum system, the MX3000P thermocycler (Stratagene), and the primers specific for PERV protease gene (GenBank accession number U77599) (forward, 5'-AGTGCTGCTACAAC-CATTAGGAAA-3'; and reverse, 5'-AGGGATGAC-CAGAAACGAGTG-3') and for porcine β-actin gene (GenBank accession number DQ845171) (forward, 5'-GGACTTCGAGCAGGAGATGG-3', and reverse, 5'-AGGAAGGAGGGCTGGAAGAG-3').The conditions were as follows: 95℃ for 10min followed by 40 cycles of 95℃ for 15 s, 60℃ for 1 min and a final cycle of 95℃ for 1 min, 65℃ for 30 s, 95℃ for 30 s. PERV expression was normalized to the amount of the expression of the house-keeping genes β-actin and denoted with the relative value of protease/β-actin.

Western blotting analysis

The lysates of the cultured cells harvested every day were analysed by sodium dodecyl sulfate-10% polyacrylamide gel electrophoresis (SDS-10% PAGE) and Western blotting with polyvinylidene difluoride membranes (Millipore, Eschborn, Germany). The membranes were then incubated with a 1:1500 dilution of mouse anti-FeLV p27 IgG antibody (ABcam, San Francisco, US) which had been proven cross-reactivity with protein gag p30 of PERV[18] overnight at 4℃, followed by a 1:10 000 dilution of goat protein anti-mouse IgG conjugated horseradish peroxidase (KeyGEN, Nanjing, China) for 1 h at 37℃. Immunoreactive proteins on membranes were detected with the enhanced chemiluminescence system and exposured for 15 to 20 s on hyperfilm ECL (Kodak, US) Meanwhile, The protein β-actin was detected as controls. Software ImageJ was used to measure the lightness of each band.

In vitro infection experiments

The *in vitro* infection experiments were performed according to the reference with some modification[19,20]. Human embryo kidney 293 (HEK293) cells (as gifts from Professor Hua, Nanjing University) were passed overnight in 24-well plates and then incubated in the supernatant of the cell culture (0.5 mL/well) for 6 h in the presence of 8 mg/mL of polybrene after the supernatant was centrifuged at a speed of 5000 r/min for 5 min to remove the cells and cell debris. Meanwhile, the supernatant of porcine kidney 15 (PK15) cells and 0.8 g/mL polybrene was inoculated into the culture of HEK293 cells as positive control. After 4 h of exposure at 37℃, the incubating medium was removed and the cell monolayer was washed with phosphate buffered solution for two times. Then the cells were cultured with the DMEM-

HG supplemented with 10% FBS and passed upon confluence for 1 mo before collection.

DNA extraction and PCR

Total DNA was extracted from the treated HEK293 cells with the DNA extracting kits (Axygen, California, US) according to their instructions. PCR was completed with the human β-actin primers (forward, 5'-GCTCGTCGTCGA-CAACGGCTC-3'; and reverse, 5'-CAAACATGATCT-GGGTCATCTTCTC-3'), Sus scrofa cytochrome B (SsCytB) primers (forward, 5'-CATTGGAGTAGTCCTAC-TATTTACCG-3'; and reverse, 5'-GTAGGATTAGTAT-TATAAATAAGGCTCCT-3'), above mentioned protease-specific primers and polymerase-specific primers and its conditions consisted with the proceeding of PCR in reverse transcription-PCR (RT-PCR). Amplified production was detected by 2% agarose gel electrophoresis and EB staining.

RT activity assay

The RT activity of the supernatant from the cultured hepatocytes in both group and the treated HEK293, was detected by the C-type RT activity kits (Cavidi-Tech, Uppsala, Sweden) according to the quantitative and qualitative protocols of the manufacturer's instructions, respectively. The RT activity was examined twice for each collected supernatant sample.

Statistics

Both culture conditions of this study were completed in quintuplicate. All values were expressed as mean ± SD. The two-tailed unpaired Student's *t*-test was used to evaluate the statistical significance of differences which was set with a *P*-value less than 0.05.

RESULTS

PERV RNA in the supernatants

From the results of electrophoresis (shown in Figure 1A and B, representatively), it could be found that the changing trend of the protease sequence and the polymerase sequence was accordant. In real time PCR, the relative value of protease/β-actin was defined as the normalized amount of PERV RNA. Two PERV secreting peaks at 10H and Day 2 was observed, and then the amount of PERV RNA declined gradually after Day 2. No PERV expression was found after Day 6 in Hep group and Day 7 in Nano group, respectively (Figure 1C). There were significant differences at Day 6 between two groups (0.071 ± 0.0348 *vs* 0.014 ± 0.0193, *P* < 0.05).

Western blotting

Figure 2A demonstrated a representative result in Western blotting. In Hep group, positive gag p30 proteins were found at 10H and from Day 2 to Day 4, while in Nano group positive bands were observed at 10H and from Day 2 to Day 5. The lightness of each band was measured by the software ImageJ and the amount of the expressed

[a]*P* < 0.05. PERV: Porcine endogenous retrovirus; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

gag p30 protein was normalized with the relative value of gag/β-actin, which was depicted in Figure 2B. Except for the significant differences found at Day 5 (0.70 ± 0.0929 *vs* 0.11 ± 0.180, *P* < 0.01), there were no remarkable differences between two groups in other days.

Infection of HEK293 cells in vitro

No PERV DNA sequence including protease and polymerase genes and SsCytB sequence were found in the HEK293 DNA (Figure 3). The DNA extracted from PK15 infected HEK293 cells and the pure water was used as positive control and negative control, respectively. And the RT activity in the culture supernatant of the treated HEK293 cells was all negative.

RT activity assay

The RT activity in the supernatants from the cultured hepatocytes was demonstrated in Figure 4. No significant difference was found between two groups in each day.

Figure 2 Western blotting of the porcine endogenous retrovirus gag protein in the cell lysates. A: Representative results of Western blotting with the cell lysates in both groups; B: The normalized protein amount in different days. [a]*P* < 0.05.

And there was no positive RT activity in the supernatant of the HEK293 cells incubated with the supernatant from Hep group or from Nano group.

DISCUSSION

Porcine hepatocytes were still a major cell source for BAL at present[6-8]. How to enhance their function was always an attractive issue and some progress has been made[9-11]. The chitosan nanofiber scaffold fabricated in our previous study had been proved its superior abilities on cell adhesion and biocompatibility, thereby greatly improved the functions of hepatocytes[13]. However, there had been a new and un-ignorable issue that whether the porcine hepatocytes with improved function would secrete more

PERV with enhanced infectivity, which might limit its application in BAL.

PERV was first discovered in 1971 in porcine kidney (PK15) cells[21]. In 1997, Patience *et al*[22] found for the first time that PERV released from PK15 could infect HEK293 cells *in vitro*. And then PERV is known to exist regularly in the porcine genome and various porcine cells can excrete PERV particulates[12]. Meanwhile, it was found that PERV successfully infected a variety of human cells *in vitro*, such as endothelial cells, fibroblasts and bone marrow stromal cells and so on, and virus replication was observed in some of these cells as well[23-28]. Nyberg *et al*[19] reported that freshly isolated porcine hepatocytes secreted the PERV which didn't infect HEK293 cells *in vitro*, at the same time, the production of PERV by cultured pig hepatocytes was unaffected by exposure to growth factors and cytokines present in human FHF sera. Fortunately, there was no evidence of PERV transmission into the patients treated with BAL so far[20,29-32]. However, a recent article[33] claimed PERV released from a BAL infected primary human cells by short-term contact of primary porcine liver cell supernatants with primary human cells, which increased the anxiety about the problem of PERV infection in the application of BAL.

In this study, we sought to find the influence of chitosan nanofiber scaffold on the production and infectivity of PERV expressed by porcine hepatocytes. PERV RNA, RT activity and PERV gag protein was detected for analysis of PERV production by porcine hepatocytes. At present, RT-PCR was the most specific and sensitive method for PERV detection[12]. And it had been identified that the RT activity was related with the retrovirus particles[34], so the result of low RT activity implied a small number of secreted PERV particles. In addition, in previous reports[18,35], sucrose gradient-purified PERV from the culture supernatant was used to qualitatively detect the protein gag p30 by Western blotting, but the condensed PERV was not suitable for hemi-quantitative analysis of the protein. Then we considered the supernatant as the samples directly and attempted to do all the test again. Much to our regret, no positive bands were observed. The possible reason may lay on the microamount of the virus. Therefore, the cell lysate was chosen as samples in Western blotting and the expressing level of the protein in cell lysate was detected to reflect the level of virus replication indirectly.

The results of real time PCR, RT activity assay and Western blotting presented a similar changing trend with some minor differences. Positive PERV RNA but no gag protein at Day 6 might result from less sensitivity of Western blotting. From these results, it could be seen that two peaks of PERV expression at 10H and Day 2 were followed by a regular decline in both groups, and no obviously increased expression level with chitosan nanofiber scaffold was found in first 5 d. The first secreting peak might be regarded as the expression of fresh

isolated hepatocytes with some contents of the ruptured non-adherent cells. In order to reduce the influence of the ruptured non-adherent cells, 10H was chosen as the first time point for detecting. But the second peak should be the real secreting peak and the low PERV level in Day 1 might be attributed to the short supernatant collecting interval between 10H and Day 1. On the other hand, the level of PERV RNA at Day 6 and the amount of PERV protein at Day 5 in Nano group was significantly more than that in Hep group, implying a prolonged expression time, which might be due to the superior activity maintaining of hepatocytes cultured on chitosan nanofiber scaffold[13].

The most important concern was no doubt the effect of chitosan nanofiber scaffold on the infectivity of PERV secreted by hepatocytes. Nyberg *et al*[19] had reported PERV released from hepatocytes didn't infect the HEK293 cells *in vitro* and its infectivity would not influenced by human fulminant hepatic failure sera. Likewise, our *in vitro* infection experiments demonstrated no PERV gene sequence and even no porcine specific SsCytB gene existed in the DNA of HEK293 cells, and no positive RT activity could be detected in the supernatant of treated HEK293 cells either, which implied no PERV transmission into the HEK293 cells and no microchimerism. So it could be concluded that there was no obvious infectivity of the PERV secreted by porcine hepatocytes.

In conclusion, porcine hepatocytes could express PERV for 5 d with normal culture condition, but the secreting time might be prolonged to 6 d when cells were cultured with chitosan nanofiber scaffold. Nevertheless, the productive amount and infectivity of the PERV expressed by porcine hepatocytes would not be obviously influenced by chitosan nanofiber scaffold. Therefore, it could be applied in BAL without enhanced risk of the virus infection.

COMMENTS

Background
Bioartificial liver (BAL) carrying porcine hepatocytes which were still a major cell source at present has been proposed as a temporary liver support for patients waiting for liver transplantation or even as a treatment for liver failure. However, the clinical application of BAL was not very optimistic. As a result of that, much progress had been made on cellular function improvement.

Research frontiers
Some scaffold materials were reported to be capable enhancing the *in vitro* function of hepatocytes. And chitosan nanofiber scaffold fabricated in our previous study had demonstrated superior abilities on cell adhesion and biocompatibility, thereby greatly enhanced the functions of hepatocytes. So it became a potential material which could be applied in BAL and a new bioreactor based on chitosan nanofiber scaffold was developed in our institute.

Innovations and breakthroughs
Although much progress had been made cellular function improvement, there were few researches on the influence of the materials on the expression and infectivity of porcine endogenous retrovirus (PERV) in porcine hepatocytes. So this study was focus on the safety of chitosan nanofiber scaffold, finding probable prolonging of PERV expression within chitosan nanofiber scaffold but no increased productive amount and infectivity.

Applications
The study identified no obvious influence of chitosan nanofiber scaffold on

PERV expression and infectivity in porcine hepatocytes, and concluded that it could be applied in BAL without enhanced risk of the virus infection.

Terminology
PERV was a porcine specific C-type retrovirus which was capable infecting human cells *in vitro*. Chitosan nanofiber scaffold was a scaffold material made with chitosan by nanotechnology, and it was proved to enhance the hepatocyte function *in vitro*.

Peer review
Generally speaking, the paper presents a laboratory-based study in which a number of highly sophisticated procedures took place, especially in terms of the methods utilized to demonstrate the presence and infectivity of retroviral agent. In this sense, efforts made by the authors deserve particular attention, making this manuscript very interesting.

2011 Advances in Inflammatory Bowel Diseases/Crohn's & Colitis Foundation's Clinical & Research Conference, Hollywood, FL 34234, United States

World Journal of Gastroenterology

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclu-

sion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Baishideng Publishing Group Co., Limited

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUC-

TIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/ g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract
There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/ study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words
Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text
For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations
Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520. pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http:// www.wjgnet.com/1007-9327/13/4986.pdf; http://www. wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself.

File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of P values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as ^1F, ^2F, ^3F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the

cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean $\pm$ SD or mean $\pm$ SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 $\pm$ 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Fax: +86-10-85381893

Language evaluation
The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form
Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers
Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support
For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript
WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases
Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee
WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

AIM AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

Cancer treatments are rapidly changing. Curative treatment for oesophageal adenocarcinoma currently involves surgery and cytotoxic chemotherapy or chemoradiotherapy. Outcomes for both regimes are generally poor as a result of tumor recurrence. We have reviewed the key signalling pathways associated with oesophageal adenocarcinomas and discussed the recent trials of novel agents that attempt to target these pathways. There are many trials underway with the aim of improving survival in oesophageal cancer. Currently, phase 2 and 3 trials are focused on MAP kinase inhibition, either through inhibition of growth factor receptors or signal transducer proteins. In order to avoid tumor resistance, it appears to be clear that targeted therapy will be needed to combat the multiple signalling pathways that are in operation in oesophageal adenocarcinomas. This may be achievable in the future with the advent of gene signatures and a combinatorial approach.

INTRODUCTION

Oesophageal adenocarcinoma is the 10th commonest malignancy in the UK yet it is the 5th commonest cause of cancer death[1]. This poor prognosis is partly attributable to a disease afflicting an elderly population. All too often the disease presents with symptoms of dysphagia which usually heralds advanced disease, typically with lymph node or distant metastases[2]. The 5 year survival, despite recent advances in neo-adjuvant chemotherapy, radiotherapy and surgery is approximately 25%. The incidence has been steadily increasing over the past 30 years[3-5]; this is thought to be due to the trend of an aging and increasingly obese population in combination with *Helicobacter pylori* eradication[1,6,7]. Barrett's oesophagus has been established

as a clear risk factor for oesophageal adenocarcinoma[8]. It has been demonstrated that surveillance of patients with Barrett's oesophagus can identify early stage adenocarcinomas[9,10]. If diagnosed at an early stage, with the disease confined to the submucosa, 5 year survival rates are as high as 90%[11]. Unfortunately current strategies for surveillance of Barrett's oesophagus are insufficient to reduce the incidence of oesophageal adenocarcinoma and most cases are diagnosed in patients that are not on Barrett's surveillance programs[10]. This may be accounted for by the fact that a significant proportion of patients with Barrett's oesophagus are asymptomatic. Currently, it is not economically viable to screen the whole population for Barrett's oesophagus[12]. Until this is addressed, there does not seem to be a solution to providing an early diagnosis of oesophageal adenocarcinoma for the majority of patients. This indicates the importance of developing improved treatments for advanced disease.

CURRENT MEDICAL TREATMENTS

The medical therapies in mainstream use for the treatment of oesophageal and junctional adenocarcinomas are cytotoxic and antimetabolite agents. They target rapidly dividing cells in an non cancer cell specific manner[13]. 5-Fluorouracil (5-FU) inhibits DNA synthesis through inhibition of thymidylate synthetase[14]. The platinum agents cisplatin and oxaliplatin form DNA adducts and cross-links which prevents DNA transcription and replication[15]. The anthracyclines epirubicin and doxorubicin induce DNA damage and inhibit DNA transcription through inhibition of topoisomerase Ⅱ and DNA helicase activity[16]. The cytotoxic action of taxanes are predominantly due to disruption of microtubules[17].

Cytotoxic chemotherapy is generally not very effective and side effects are common. The agents are usually contraindicated in severe cardiac and liver disease, a common occurrence in the affected elderly population. Recent advances have been made with the route of administration. A tablet form is now available, capecitabine, which is an effective alternative to infusing 5-FU. This reduces the morbidity associated with central venous catheterisation. Furthermore, oxaliplatin appears to be less toxic and more potent than cisplatin, and it can be infused over a shorter period of time[18,19]. Approximately 30% of patients with oesophageal adenocarcinoma are offered palliative chemotherapy and radiotherapy[1,20]. Prognosis is only 6-11 mo[21,22], with a 5 year survival of 4%[22]. Surgery is beneficial in patients that present with disease localised to the oesophagus or with localised lymph node metastases. Neo-adjuvant chemotherapy modestly improves survival compared to surgery alone; 5 year survival is 23% compared to 36% with neo-adjuvant chemotherapy[23]. On subgroup analysis, patients with tumors at the gastro-oesophageal junction seemed to benefit the most and this regimen is offered in the UK[24]. In the USA, the protocol of neo-adjuvant chemo-radiotherapy is favoured[25]. 5 year survival is 8%-20% in selected patients. Curative chemo-radiation is an alternative strategy to surgery and prognosis is similar[2].

This may be due to the avoidance of postoperative mortality and morbidity. Whatever regimen is used, the poor prognosis for oesophageal adenocarcinoma is largely a result of disease recurrence and the morbidity surrounding major surgery[2]. Treatment failure is thought to be a consequence of the blanket therapy approach due to the nature of the non-specific or non-targeted mechanism of action of the medical agents described earlier. Recent evidence suggests that standard chemotherapy and radiotherapy activate signalling pathways that stimulate growth and resistance of cancer cells[26]. Prognosis may improve with agents that specifically target mitogenic signalling pathways and intense research is currently underway.

The aim of this review is to explore the key signalling pathways that are associated with oesophageal adenocarcinoma and review the clinical trials of novel therapeutic agents that are in progress. We will draw parallels from breast and colon cancer. We will address the question: by targeting key signalling pathways is personalised medicine a reality in oesophageal adenocarcinoma?

DEFINING SIGNALLING PATHWAYS

Signalling pathways are essential components in all cells; they are important to stimulate cell growth, proliferation, differentiation, invasion and apoptosis. Certain pathways are specifically important in embryonic development, inflammation and carcinogenesis. Signalling pathways have common mechanisms of action. They convey extra-cellular stimuli, usually *via* cell surface receptors, onto a chain of signal transducer proteins which subsequently enter the nucleus. In the nucleus the signalling proteins activate transcriptional machinery on gene promoters. Gene expression and cell phenotype are altered. In the context of cancer cells, phenotypic change may include cell growth, cell division, increased cell motility, evasion of apoptosis and sustained angiogenesis. These changes constitute the hallmarks of cancer[27]. Signalling pathways in cancer cells are usually unregulated and resistant to feedback inhibition, and this usually occurs as a consequence of sustained activation from their components. The components are commonly known as oncogenes or tumor suppressor genes[28]. Oncogenes and tumor suppressor genes are usually expressed as a result of genetic mutations. In oesophageal cancer, mutations occur as a consequence of DNA damage from bile or acid reflux, nitric oxide, alcohol and cigarette smoking. Mutations usually involve chromosomal translocations of oncogenes or tumor suppressor genes onto housekeeping genes or other genes undergoing active transcription[29,30]. This culminates in persistent activation or inhibition of specific signalling pathways. Components of signalling pathways can be potentially inhibited at a variety of levels. Inhibitors can target the cell surface receptor, signal transducer proteins or even transcription factors. Unfortunately multiple pathways and receptors are associated with oesophageal cancer and the complexity that exists between different pathways is likened to a computer circuit (Figure 1). Blockade of one pathway or component may not be sufficient.

Figure 1 Signalling pathways in oesophageal adenocarcinoma. The pathways known to be operative in oesophageal adenocarcinoma are A: PI3-Kinase, B: Mitogen activated protein (MAP) Kinase, C: Wnt signalling and D: Nuclear factor-κB (NF-κB). The green arrows indicate activation, the red arrows indicate inhibition. Vascular epidermal growth factor (VEGF), human epidermal growth factor receptor 2 (HER2), epidermal growth factor receptor 1 (EGFR), insulin growth factor receptor (IGFR), hepatocyte growth factor receptor (MET), platelet derived growth factor receptor (PDGFR) and fibroblast growth factor receptor (FGFR) are the known receptor tyrosine kinase (RTK) associated with oesophageal adenocarcinomas. The pathways are complex and inter-connected. For example RTKs can activate all 4 known pathways. The ultimate biological response varies from cell proliferation, development, apoptosis, differentiation, inflammatory response, angiogenesis and invasion depending on which specific pathway or receptor is activated. A: PI3-Kinase pathway. RTK activates PI3-Kinase directly or through RAS. As a consequence of phosphorylation, PI3K recruits AKT. AKT inhibits tuberin, this allows activation of the Raptor/mTOR complex to activate transcriptional machinery. mTOR/raptor activates transcription factors and co-activator proteins cMyc and hypoxia inducible factor (HIF)-1α that drive the biological response of growth, proliferation, glycolysis, angiogenesis and invasion; B: MAP Kinase pathways. The 3 main MAP Kinase pathways are extracellular related kinase (ERK), p38 and JUN kinase (JNK). They are all activated by similar RTKs. The signalling pathways have a common feature of a cascade of phospho-proteins. A MAPKK Kinase (e.g. RAF), a MAPK Kinase [e.g. MAP ERK kinase (MEK)1/2] and a MAP Kinase (eg. ERK) transfer the signal onto multiple transcription factors on gene promoters[31]. ERK signalling for example can alter the gene expression of over 200 genes[32]. The subsequent biological response varies from cell proliferation, development, apoptosis, differentiation and inflammatory response, depending on the specific pathway activated; C: Wnt signalling. Wnt signalling exerts a biological response through release of β catenin into the nucleus with subsequent action on gene promoters. β catenin is released directly from RTK phosphorylation of Axin. Alternatively Wnt ligands bind to Frizzled receptors and form a complex with the LRP5/6 membrane receptor. The membrane receptor complex recruits dishevelled and axin from a cytoplasmic complex of dishevelled, Axin, adenomatous polyposis coli protein (APC) and β catenin. This allows release of β catenin; D: NF-κB pathway. NF-κB (p65p50) activates gene promoters only when released from IκB. Interleukin-8 (IL-8), tumour necrosis factor (TNF)α and radiation activate the pathway. Adding to complexity, ERK MAP Kinase and Wnt, through protein Kinase C, can also potentially activate NF-κB although this link has not been investigated in oesophageal adenocarcinoma.

KEY SIGNALLING PATHWAYS IN OESOPHAGEAL ADENOCARCINOMA

MAP-Kinase and PI3 kinase pathways

MAP-Kinase (MAPK) pathways are the most well described pathways in carcinogenesis. They are made up of three distinct pathways: ERK, SAP/JNK and p38[31] (Figure 1[31,32]). The pathways are normally activated by growth factors, temperature changes, cytokines and hypoxia *via* a variety of cell surface receptors[33]. In oesophageal cancer cells, gastric and bile acid[34,35] and the cytotoxic agent etoposide[36] are known to activate MAPK pathways. Cell surface receptors known to activate MAPK include receptor tyrosine kinase (RTK), G protein linked receptors and integrins[33]. Following activation of cell surface receptors a cascade of phospho-proteins is initiated *via* GTPase signal transducer proteins. RAS and RAF are examples of GTPase signal transducer proteins which act as a hub, receiving signals from many different cell surface receptors[28] (Figure 1). GTPase signal transducer proteins also amplify signals onward through multiple signalling pathways (Figure 1). MAPK pathways are often up-regulated in breast[37,38], ovarian[39] and prostate cancer[40]; however the impact on prognosis of MAPK signalling is sometimes conflicting. ERK MAPK is active in 60% of ERK MAPK oesophageal adenocarcinomas[36]. Tumors with active ERK MAPK signalling frequently have metastases and a worse prognosis. This suggests that blockade of ERK MAPK in oesophageal adenocarcinomas may have an important therapeutic role.

The PI3-Kinase (PI3K) pathway is activated by RTKs and RAS (Figure 1). Following RAS and/or RTK activation, AKT is phosphorylated by PI3K. Activation of the PI3K pathway stimulates cell growth, glycolysis, and proliferation[41] mainly through cMyc and hypoxia inducible factor 1α (HIF-1α) stimulation. Components of the PI3K pathway are up-regulated in oesophageal adenocarcinoma. The expression of phosphorylated AKT is increased in oesophageal adenocarcinoma tissue compared to normal epithelial and Barrett's tissue[34]. PI3K pathway mutations are thought to occur in 6% of oesophageal adenocarcinomas[42]. Crosstalk exists between the MAPK and PI3K pathways at the levels of RAS and ERK (Figure 1). This is likely to play a role in drug resistance seen in therapies that target signal transducer proteins. Crosstalk indicates that inhibition of multiple pathways may be needed for effective anti-cancer therapy.

Mechanisms of sustained MAPK and PI3K activation

RTKs on the cell surface are key activators of MAPK and PI3K pathways. RTKs can be activated constitutively by dimerisation, by ligand activation or by receptor over-expression[43]. Alternatively RAS mutations can render the GTPase in its active form so that the signal is permanently switched on, resistant to the activity of cell surface receptors. RAS mutations occur in only 10% of oesophageal adenocarcinomas. Aberrant expressions of RTK are frequently associated with oesophageal adenocarcinoma and there are many different family members (Figure 1). Receptor over-expression is usually associated with disease recurrence and a poor prognosis. Human epidermal growth factor receptor 1 (EGFR) and human epidermal growth factor receptor 2 (HER2) are over-expressed in 50% of oesophageal adenocarcinomas and positive expression is associated with a poor prognosis and cytotoxic drug resistance[30,44]. High expression of the hepatocyte growth factor receptor (Met) predicts metastases and recurrence in resectable oesophageal adenocarcinoma[45]. Vascular endothelial growth factor receptors (VEGF) are commonly associated with oesophageal adenocarcinoma, VEGF is thought to be important in angiogenesis and correlates with tumor microvessel density, crucial for tumor growth. VEGF A and C expression indicates a poor prognosis[46]. The significance of insulin like growth factor receptors (IGFR) has not been studied in oesophageal adenocarcinoma[47,48], however low IFGR expression correlates with an improved survival in metastatic gastric adenocarcinoma. The platelet derived growth factor receptor (PDGF) has also been shown to be expressed in oesophageal adenocarcinoma[49]. In oesophageal squamous cell carcinoma, fibroblast growth factor receptors[50] and tropomyosin-related kinase receptors[51] are indicators of tissue invasion and chemo-resistance respectively. Each member of an RTK family may have up to 20 subtypes[52] and it has been demonstrated that oesophageal adenocarcinoma cells often co-express the different subtypes of RTKs[49]. Therefore a therapy that targets only one receptor may not be effective. Furthermore cancers are known to be heterogeneous, made up of a population of genetically different cells. Gene expression at the invasive site of a tumor is different from the centre[53] and the gene expression of primary tumors is different to those at metastatic sites[54]. The variety of RTKs and downstream MAPK signalling pathways indicates that complete blockade of such a complex and diverse system may be impossible. Growth inhibition is more pronounced in oesophageal adenocarcinoma cells treated with combined inhibition of the EGFR and IGFR compared to inhibition of either receptor in isolation[55]. Furthermore patients with co-expression of HER-2 and EGFR also have a worse outcome[56]. Even if drug inhibition of both IGFR and EGFR is successful, resistance will prevail if alternative receptors or signal transducer proteins are active. Tumor heterogeneity may explain the modest improvement in response and survival seen with agents directed towards a solitary receptor, discussed in more detail below.

Targeting the epidermal growth factor receptor 1

Gefitinib and Erlotinib: Gefitinib and Erlotinib are small molecular inhibitors of tyrosine kinase phosphorylation of EGFR (Figure 2). Gefitinib therapy has been investigated in metastatic oesophageal adenocarcinoma[57]. Two thirds of patients had prior standard cytotoxic chemotherapy of which half had received surgery. Partial response and stable disease (according to Response Evaluation Criteria of Solid Tumors) was achieved in 37% and the median survival was 4.5 mo[57]. It is difficult to compare small phase 2 clinical trials but results were not significantly different compared to treatment with combined cytotoxic chemotherapy in a similar cohort of patients. Partial response was 12.5% and a median survival of 5 mo was seen in patients treated with irinotecan with docetaxel[58]. Partial response was 29% and median survival was 6.4 mo in patients treated with irinotecan with 5-FU/leucovorin[59]. To understand the poor results seen with gefitinib, ERK MAPK and PI3K pathway activation was determined by immunohistochemistry. Staining for phospho-ERK and phospho-AKT was assessed before and after treatment in 7 patients. No differences in staining patterns were seen in tumors treated with gefitinib, suggesting that the two pathways were not inhibited by the drug. This result is mirrored in a larger study of 70 gastric adenocarcinomas treated with gefitinib[60]. This indicates ERK MAPK and PI3K pathway resistance to EGFR blockade. A further study conducted in 43 metastatic adenocarcinomas at the gastro-oesophageal junction treated with gefitinib[61] also had similar survival and response rates to the study by Ferry *et al*[57]. Trends for favourable outcome were more likely in tumors with expression of EGFR, ERK MAPK and PI3K signalling activation. This was assessed by immunohistochemistry prior to treatment although assessment was not made post treatment. The differences in outcome did not meet statistical significance, but this is likely due to the small sample size. Of the poor responders, 2 (9%) had k-RAS mutations. This study indicates the importance of patient selection with targeted therapy. On the contrary in gastric and oesophageal adenocarcinomas treated with a similar EGFR inhibitor, erlotinib (Figure 2), EGFR expression

Figure 2 Drug inhibition of signalling pathways. Drugs that target signalling pathways can be divided into two groups. Antibodies [Becazutumab, trastuzumab, cetuximab and matuzumab are antibodies that target the receptor tyrosine kinase (RTK), vascular epidermal growth factor receptor (VEGFR), human epidermal growth factor receptor 2 (HER2) and epidermal growth factor receptor 1 (EGFR) respectively] and small molecular inhibitors (The small molecular inhibitors gefitinib and erlotinib target EGFR. Temsirolimus specifically inhibits the PI3-kinase pathway at the level of Raptor/mTOR. CI1040 and PD0325901 inhibits ERK MAP kinase pathway at the level of MEK. Sorafenib is a dual inhibitor of the VEGF receptor and ERK MAP kinase at the level of RAF).

and PI3K signalling activation was not found to influence drug response[62]. The difference may be explained by different receptor specificity between gefitinib and erlotinib or it may indicate the activity of additional RTKs or other cell surface receptors

Matuzumab: Matuzumab is a humanised monoclonal antibody that binds with the EGFR (Figure 2). Phase 1 trials have been conducted in metastatic oesophageal adenocarcinoma treated with conventional therapy with matuzumab[63]. EGFR was evident in 80%-100% of tumor specimens; however MAPK activity was not measured post treatment. This makes it difficult to assess the efficacy of the medication in the absence of survival data from this phase 1 study.

Cetuximab: Cetuximab is a monoclonal antibody directed against the EGFR (Figure 2), utilised in the treatment of advanced colorectal adenocarcinoma[64]. Trials have shown an improvement in average survival to 9 mo. RAS mutations occur commonly in colon cancer and account for resistance seen with cetuximab. When taken into account, colorectal carcinoma patients without k-RAS mutations have a significantly improved response to cetuximab compared to patient with k-RAS mutations which have survival

times comparative to that of supportive care alone[65]. RAS mutations are less commonly seen in oesophageal adenocarcinomas and occur in less than 10% of cases so this is unlikely to account for the poor response seen with tyrosine kinase receptor inhibition[66]. Phase 2 clinical trials with cetuximab in advanced oesophageal adenocarcinoma have shown modest results similar to that seen with gefitinib[67].

Targeting the epidermal growth factor receptor 2

A Phase Ⅱ trial has been conducted with trastuzumab, a monoclonal antibody targeted to targeting the epidermal growth factor receptor 2 (HER2) (Figure 2). Trastuzumab was tested in combination with cisplatin, paclitaxel and radiotherapy in locally advanced oesophageal adenocarcinoma[68]. Patients were selected and included those with HER2 expression on immunohistochemistry. 74% of patients had positive HER2 expression. Median survival was 24 mo and 50% survived for 2 years. The patient population was different to the patients treated with gefitinib and cetuximab. None of the patients had organ metastases and distant lymph node metastases were present in only 37%, which makes it difficult to make direct comparisons.

Targeting the vascular epidermal growth factor receptor

Becazutumab is a monoclonal antibody directed against

the targeting of vascular epidermal growth factor receptor (VEGFR) (Figure 2). A phase 2 trial in metastatic gastric adenocarcinomas with 23 oesophageal junctional adenocarcinomas showed a response rate of 65% and median survival time of 12.3 mo[69]. Most patients were inoperable and the results were an improvement on standard cytotoxic therapies. Although VEGFR is frequently over-expressed in oesophageal adenocarcinomas[49], an assessment of VEGFR expression was not made prior to treatment. This may suggest that an improved outcome could be achieved by selecting tumors with high VEGFR expression.

Taken together, this may indicate that tailored RTK inhibition has a role in the treatment of selected patients with oesophageal adenocarcinomas. Initial trials have yet to make a significant impact and this may be down to poor patient selection and the use of growth factor receptor inhibitors in isolation.

Wnt signalling

Wnt signalling is important in cell growth, motility, angiogenesis, differentiation and other important phenotypic characteristics of cancer cells. Wnt ligands activate the Frizzled cell membrane receptor; Wnt is under feedback control from Wnt ligand inhibitors. Once activated, Frizzled forms a complex with another receptor LRP5/6 and recruits Dishevelled and Axin. The complex of APC, Axin and GSK and β-catenin is disrupted releasing unphosphorylated β-catenin (Figure 1). β-catenin can then enter the nucleus, and activate genes that stimulate growth, angiogenesis, invasion and cell cycle progression (*c-Myc, COX2, MMP7* and *Cyclin D1)*. Alternatively β-catenin can also be released by RTK phosphorylation of E-cadherin or Axin (Figure 1). Furthermore Wnt ligands can also directly activate calmodium kinase II and protein kinase C in turn releasing intracellular calcium or increasing JNK. Components of the pathway are altered in oesophageal adenocarcinoma. APC, Axin and Wnt ligand inhibitors are silenced by loss of heterozygosity or DNA methylation and collectively these events increase β-catenin activity. Although APC mutations are less commonly seen than in colorectal cancer, β-catenin or Wnt ligands are over-expressed in up to 77% of oesophageal adenocarcinomas[70,71]. This makes components of this pathway a potential target for drug inhibition.

Transforming growth factor-β pathway

Transforming growth factor-β (TGF-β) is a tumor suppressor gene and a potent inhibitor of cell growth. TGF-β binds to serine/threonine kinase type 1 and type 2 receptors. Upon binding to receptors, TGF-β forms a complex and phosphorylates intracellular signalling mediators called SMAD2/3. SMAD2/3 dissociates from the receptors and forms a complex with SMAD4 allowing it to enter the nucleus and regulate a large number of target genes. One target is *SMAD7* which targets ubiquitin to the membrane receptor complex resulting in feedback inhibition of the pathway. Down regulation of SMAD4 has been shown in the progression of Barrett's oesophagus to adenocarcinoma. TGF-β is anti-proliferative in some oesophageal

cancer cell lines[72]. In contrast TGF-β expression has been demonstrated at the invasive margin of oesophageal adenocarcinomas and promotes cell invasion[73]. This may be explained by cross talk between the TGF-β pathway with PI3K, Wnt, PKC and the MAP-Kinase pathways. One potential mechanism is *via* SMAD7 inhibition leading to loss/diminished feedback inhibition of the pathway.

Nuclear factor-κB pathways

Nuclear factor-κB (NF-κB) is a proinflammatory transcription factor. It exists as a heterodimer p50/p65, situated in the cytoplasm under inhibitory control by IκB (Figure 1). Numerous activators have been identified including ERK MAPK signalling, cytokines (IL-8, TNF-α) and radiation. Specifically for oesophageal adenocarcinoma, bile salts and gastric acid have been shown to activate NF-κB. Gastrin has been shown to activate NF-κB through PKC signalling in gastric cancer cells[74]. Once activated, NF-κB enters the nucleus and through chromatin re-modelling it becomes a central regulator of many genes including cell cycle regulators (*cyclin D1, cMyc, p53*), inhibitors of apoptosis (*Bcl-2*), cytokines (*interleukins, TNF-α*), angiogenic mediators (*COX2*) and the growth factor receptor *EGFR*. Increased NF-κB expression is seen in Barrett's oesophagus and adenocarcinoma. In oesophageal adenocarcinoma the expression correlates with chemo-radiation resistance[75].

Wnt signalling, TGF-β pathway and NF-κB pathways all activate important mediators in oesophageal adenocarcinoma. However there are no trials investigating the impact of specific inhibitors of these pathways outside the laboratory setting. RTK inhibitors have been investigated in oesophageal adenocarcinoma; however their role in Wnt signalling inhibition of β catenin has not been evaluated. The development of agents that inhibit alternative components of the Wnt, TGF-β and NF-κB signalling pathways are needed to avoid resistance and improve the modest responses seen with current therapies in clinical trials in oesophageal adenocarcinoma that focus on RTKs and MAPK.

POTENTIAL FUTURE TREATMENT TARGETS IN OESOPHAGEAL ADENOCARCINOMA

ERK MAPK inhibition by targeting MEK

An alternative approach is to target signal transducer proteins which may be downstream of many different RTKs. Theoretically this may reduce resistance of RTK co-expression. MEK is a downstream signal transducer protein of the ERK MAP Kinase pathway (Figure 1). No clinical trials have explored the role of MEK inhibition in oesophageal adenocarcinoma but lessons may be learned from trials in other cancers. Phase 2 clinical trials of the MEK inhibitor CI1040 (Figure 2) in advanced pancreatic, breast and non small cell lung cancer failed to make an impact on tumor progression[76]. Parallels can be drawn from colon cancer where RAS mutations reduced the efficacy of ce-

tuximab. Patients treated with MEK inhibition were tested for ERK MAPK and PI3K signalling activation in archived samples, sometimes many months preceding treatment. This did not influence recruitment into the study and patients were enrolled if ERK or PI3K activation was judged to be low. Better patient selection may have resulted in a better response to treatment. ERK MAPK signalling activity was not assessed post treatment which may mean that the dosage was insufficient. More potent MEK inhibitors, such as PD0325901, have been evaluated in hepatocellular carcinomas[77]. Alternatively the poor responses with MEK inhibition may be explained by "cross talk" between different signalling pathways (Figure 2). Resistance to MEK inhibition may be explained by PI3-Kinase activation. The combination of MEK inhibition and PI3-Kinase inhibition is superior to treatments in isolation for inhibiting the growth of breast cancer cells[78]. This suggest that dual therapy is needed to combat both pathways.

ERK MAPK inhibition by targeting RAF and VEGF

A combined targeted approach may be beneficial in oesophageal adenocarcinoma. Sorafenib, a multifunctional kinase inhibitor, which acts on several growth regulatory pathways including VEGF and RAF (Figure 2), has been shown to be of benefit in renal cell carcinoma and hepatocellular carcinomas[78,79]. Sorafenib has been shown to inhibit key signalling pathways in SEG-1 lung adenocarcinoma cells[80]. This method of inhibition of both receptor and signalling protein such as RAF may prove beneficial due the diversity of growth factor receptors displayed by tumors and this approach may have a future role in the treatment of oesophageal adenocarcinoma.

PI3 kinase by targeting mTOR

No inhibitors of the PI3 kinase have been evaluated in oesophageal adenocarcinoma. Cell line studies in oesophageal adenocarcinoma have identified that the PI3 kinase pathway is important for cell growth. Mutations of the PI3 kinase pathway occur infrequently in oesophageal adenocarcinoma. However, activation of the pathway is known to occur from RTK, a common occurrence in oesophageal adenocarcinomas. Indeed in breast cancer, the PI3 kinase pathway has been proposed as a mechanism of drug resistance to MEK inhibition[55]. Inhibition of the PI3 kinase pathway has been used with success in metastatic renal cell carcinoma. Analogues of rapamycin have been developed to target mTOR (Figure 2). The agent temsirolimus has been evaluated in stage 3 clinical trials[81] (Figure 2). In this trial, 626 patients were divided into 3 groups; temsirolimus alone, interferon alone, and interferon in combination with temsirolimus. Overall survival was 10.9, 7.3 and 8.4 mo respectively in favour of temsirolimus. In view of this, a strategy of mTOR inhibition may have a future role in oesophageal adenocarcinoma.

Targeting transcription factors

Targeting an activated transcription factor or central regulator such as NF-κB would theoretically reduce the chance of the development of drug resistance from the activity of multiple surface receptors and multiple signalling pathways. This is not without problems. Firstly transcription factors are difficult to target. Interference RNA technology involves the insertion of an oligonucleotide into the nucleus of a cancer cell, usually using a viral vector. Oligonucleotides can be manufactured to complement the sequence and therefore dimerize with any RNA of interest such as NF-κB. This allows the targeting of transcription factor RNA with the prevention of protein translation. Interference RNA technology may be the answer to transcription factor inhibition but the technology remains in its infancy. The major hurdle appears to be the development of an efficient delivery system of oligonucleotides into cancer cells. Phase 1 trials are currently underway targeting VEGF in macular degeneration using direct ocular injection[82,83]. If this technology is developed in oesophageal cancer then gene expression profiling of tumors would be required to ensure that specific targeted therapy is delivered. The identification of more central regulators of carcinogenesis, such as HIF-1α and PEA3/ETV4 transcription factors, is likely to increase treatment options. The advent of gene expression profiling will certainly increase the number of potential targets.

CONCLUSION

An international effort is underway with the aim of improving survival in oesophageal adenocarcinoma by targeting key signalling pathways. Clinical trials using receptor tyrosine kinase inhibitors in oesophageal adenocarcinomas have so far only recruited patients with advanced or metastatic cancer. Studies utilised agents that inhibit solitary receptor tyrosine kinase, sometimes in an unselected manner. This strategy is problematic. At an advanced stage the heterogeneity within the tumor is extensive, which increases the likelihood of alternative signalling pathways resistant to receptor blockade. Secondly the pathway or receptor of interest may not be active or expressed, culminating in ineffective treatment. Tumor growth is immensely complex and this is emphasised in a study of 75 oesophageal adenocarcinoma specimens. Micro array studies identified 4 genes important in disease progression[84]. The genes independently predicted prognosis independent from traditional radiological methods. Unfortunately a further 115 genes were also indicators of survival. It is not clear what role the genes play in carcinogenesis; however this study indicates the complexity and diversity of the factors implicated in oesophageal adenocarcinoma development. Taken together, this suggests that a tailored combinatorial approach for treatment that inhibits multiple genes may be useful; therapies targeting either receptors, hub signalling proteins or even transcription factors, is likely to be necessary to deliver effective responses. By tailoring therapy to tumors that express specific gene and protein signatures and prescribing a regimen of treatments that act in fundamentally different

mechanisms, then further improvements in survival are likely to be possible in oesophageal adenocarcinoma.

REVIEW

Need for a comprehensive medical approach to the neuro-immuno-gastroenterology of irritable bowel syndrome

Abstract

Irritable bowel syndrome (IBS) is defined by the Rome III criteria as symptoms of recurrent abdominal pain or discomfort with the onset of a marked change in bowel habits with no evidence of an inflammatory, anatomic, metabolic, or neoplastic process. As such, many clinicians regard IBS as a central nervous system problem of altered pain perception. Here, we review the recent literature and discuss the evidence that supports an organic based model, which views IBS as a complex, heterogeneous, inter-dependent, and multi-variable inflammatory process along the neuronal-gut axis. We delineate the organic pathophysiology of IBS, demonstrate the role of inflammation in IBS, review the possible differences between adult and pediatric IBS, discuss the merits of a comprehensive treatment model as taught by the Institute of Functional Medicine, and describe the potential for future research for this syndrome.

INTRODUCTION

Functional abdominal pain (FAP) and irritable bowel syndrome (IBS) are debilitating and common conditions. IBS is defined by the Rome III criteria as, "symptoms of recurrent abdominal pain or discomfort and a marked change in bowel habit for at least six months, with symptoms experienced on at least three days of at least three months, with two of the three following findings: (1) Pain is relieved by a bowel movement; (2) Onset of pain is related to a change in frequency of stool; and (3) Onset of pain is related to a change in the appearance of stool"[1].

FAP occurs in 10%-15% of school-aged children, of which 17%-24% have pain significant enough to disrupt their activity, and 13%-15% awaken from their sleep due to the pain[2,3]. Up to 53% of children with abdominal pain continue to have abdominal pain as adults, and 18% are ultimately diagnosed with IBS[4].

Chronic abdominal pain is associated with significant morbidity, including depression[2], decreased quality of life measures[5], and disability leading to inability to work[6]. Adults with abdominal pain have higher rates of potentially unnecessary surgeries[7-10]. Patients with IBS and FAP are costly to the medical system[11,12]. Both children and adults with IBS frequently visit the offices of primary care physicians and gastroenterologists[13]. Adults with IBS

have significantly more hospitalizations, outpatient visits, diagnostic testing, and overall medication use than well patients[14]. A large percentage of the medical costs associated with IBS are related to hospitalizations and inpatient diagnostic testing, such as endoscopies[15]. Antidepressants and other neuropharmacological agents help the symptoms of IBS[16], but these treatments have their own limitations and potential adverse effects.

IBS is thought to be just a functional problem that is "without demonstrable evidence of a pathological condition such as an anatomic, metabolic, infectious, inflammatory, or neoplastic disorder"[17]. IBS is seen as a non-organic syndrome, primarily involving altered perception and processing of pain. As a result, the majority of current therapies for IBS revolve around stress reduction, alteration of pain pathways, and alleviation of symptoms[16].

In this literature review, we delineate the gastrointestinal-neuro-immune pathophysiology of IBS and discuss the link between inflammation and pain. We believe that more effective treatment models are possible through a patient-centered approach that simultaneously treats the multiple variables that lead to IBS, as addressed in this review. The integration of this IBS treatment model may improve patient outcomes while reducing the medical cost burden of IBS. This paper will also discuss the possible differences between adult and pediatric IBS and present potential areas of future research.

STRESS AND THE GASTROINTESTINAL-NEURO-IMMUNE AXIS

Stress in various forms predisposes individuals to developing IBS[18-20] and increases IBS symptoms in children[21]. Abuse or other significant stressors change the neurobiology of stress and alters the levels of corticotropin-releasing factor (CRF) or hormone (CRH)[22], a hypothalamic stress hormone. CRF activates the pituitary-adrenal axis and mediates behavioral, autonomic, immune, and visceral responses to stress[23]. Patients with IBS have enhanced stress responses and release higher amounts of CRF in response to stress[24].

Stress changes the physiology of the gastrointestinal tract. Maternal separation of rat pups causes CRF-mediated mucosal barrier dysfunction with macromolecular permeability and increased bacterial adherence/penetration of the gastrointestinal mucosa with translocation to the spleen[25]. These animals also have mitochondrial swelling of the gut epithelial cells, immune cell infiltration, mucus depletion, and mast cell degranulation[23,26-29]. Stressed human beings show similar findings[30].

Stress compromises the integrity of the gut and induces inflammation through numerous pathways, as demonstrated by several published papers[22,28,31]. CRF released from the hypothalamus can directly influence human colonic mast cells[32,33], which then induce intestinal epithelial pathophysiology and mucosal barrier defects[34-37]. Substance P (SP) and calcitonin gene-related peptide (CGRP)-containing gastrointestinal efferent neurons can also influence mast

cells[38-41] and result in degranulation[42] and release of TNF-α[43]. These compounds, in turn, result in gut inflammation and intestinal permeability[44].

These stress-induced changes in the gastrointestinal tract "persist after the stressor is removed from the animal"[37]. This is likely to be due to the ability of mast cells to influence their environment. In rats, inflammation results in increased mast cell-neuronal contacts and mucosal nerve cell density that last well beyond the initial insult[43,45]. Gastrointestinal inflammation in humans also results in neuron proliferation[46-48]. Stress and inflammation modulate nerve growth factor (NGF), which then affects mucosal nerve remodeling[49,50], sprouting, and synaptogenesis[51]. Mast cells, in close contact with neurons, synthesize and release NGF, and thus, can alter neuronal density and synaptogenesis[49,52].

Furthermore, inflammation preceding a psychological stress can alter the epithelial response to stress signals and make the gut more susceptible to stress[53]. In addition, inflammation can change the morphology of mast cells and their intracellular contents, further changing the susceptibility of the gut to various future stressors[54-57].

Inflammation can play an important part in the manifestation of IBS symptoms[58]. Once the inflammatory cascade is activated, this immune response can create a vicious cycle of self-perpetuating inflammation. Activated mast cells can directly release CRF[59]. Patients with inflammatory bowel disease (IBD) and IBS have CRF-immunoreactive macrophages, enterochromaffin cells, lymphocytes, neutrophils, and eosinophils, which are present in higher concentrations than in healthy controls[60-63]. CRF induces lymphocyte proliferation[64] and macrophage release of pro-inflammatory cytokines (TNF-α, IL-1, and IL-6)[65]. These activated immune cells, in turn, locally release CRF and other immune peptides[61,66], which then activate mast cells[22]. Mast cell-derived tryptase is another compound that recruits lymphocytes, eosinophils, and macrophages[67], and can further perpetuate inflammation.

INFLAMMATION INDUCED NEUROLOGICAL TONE

Patients with IBS have central processing abnormalities associated with the perception of pain[68-71]. Colonic irritation can lead to visceral hypersensitivity[72]. Patients with IBS have inflammatory changes in their gut mucosa, which can only be identified by quantitative histopathology, immunohistochemistry, and electron microscopy[73]. These patients have increased numbers of mast cells in the mucosa of the colon[30,74,75]. Mast cell concentrations and their distance from mucosal nerve cells are positively associated with various IBS symptoms[75]. The tryptase released from these mast cells can directly activate gastrointestinal neurons in animals and humans, and can cause visceral hypersensitivity[76-78]. Tryptase cleaves and activates transmembrane proteins called proteinase-activated receptor-2 (PAR2), which are found on the primary afferent neurons of the gastrointestinal tract[79]. Activation of PAR2 receptors leads to neuronal activation, which then creates the experience of

chronic pain.

In addition to central nervous system activation, patients with IBS also have sensitization and upregulation of the dorsal horn[70,71,80], which explains the cutaneous hyperalgesia found in the lower extremities, rather than upper extremities, due to viscerosomatic convergence of nociceptive afferent neurons from the colon/rectum and lower extremities[81]. Seybold *et al*[82] review the mechanisms by which gastrointestinal inflammation leads to gastrointestinal primary afferent neuronal activation and spinal cord activation/sensitization and inflammation.

If true, the perpetual mild mast-cell mediated inflammation can trigger the "excessive or prolonged stimulation of extrinsic afferents (that) may also result in the development of neuronal sensitization, at peripheral, spinal, or higher CNS levels, such that perception of sensations from the bowel is heightened, resulting in symptoms of urgency, bloating, and pain"[83]. This subclinical inflammation may also influence gastrointestinal serotonin pathways.

IBS, NEUROLOGICAL TONE, AND SEROTONIN

Serotonin (5-HT) can influence the motor function and sensitivity of the gastrointestinal tract[84-89]. Serotonin exerts a range of effects *via* its seven receptor subtypes (5-HT$_1$ to 5HT$_7$). Serotonin receptor 5HT$_5$, 5HT$_6$, 5HT$_7$ are found in the brain, whereas 5HT$_1$, 5HT$_2$, 5HT$_3$, 5HT$_4$, and 5HT$_7$ are the gastrointestinal serotonin receptors[90]. A large majority of the body's serotonin is stored in gastrointestinal enterochromaffin cells (EC)[85]. Patients with diarrhea predominant IBS have increased EC cells[91-93], which are activated by inflammation to release serotonin and may result in the elevated serotonin levels found in patients with IBS[94,95]. Tegaserod, a partial 5HT$_4$ agonist has been used for constipation dominant IBS and Alosetron, a 5HT$_3$ antagonist, in diarrhea dominant IBS.

Serotonin reuptake transporters (SERT) in the gut epithelial cells terminate the effects of serotonin[96,97] and influence serotonin concentrations and symptoms of IBS[85]. Patients with IBS have genetic polymorphisms that lead to lower expression of transport proteins and less serotonin reuptake[83,98,99]. The noted inflammation may also alter SERT expression and decrease its function in patients with IBS[100]. Further studies on the modulation of the gastrointestinal tract serotonin pathways may help further define and treat IBS.

INTESTINAL PERMEABILITY, CHRONIC INFLAMMATION, AND ANTIGENS

The presence and activity of mast cells, along with other inflammatory cells, alone are not likely result in chronic inflammation. Other intestinal antigens, such as food, bacteria, and fungi, are likely to be needed to perpetuate the inflammation in the presence of an impaired gastrointestinal epithelial barrier.

Healthy individuals have tight junctions that help to form the gastrointestinal epithelial barrier along with mucous, SIgA, and other peptides. This epithelial barrier controls the interaction between luminal bacteria and antigens and the mucosal immune system[22,101]. It also allows immune tolerance of food antigens and bacteria. Activation of PAR2 not only leads to neuronal activation, but also to epithelial barrier defects in patients with IBS[102,103].

Low level PAR2 activation of the myosin light chain kinase (MLCK), causes phosphorylation of the myosin light chain, which then leads to contraction of the actin-myosin ring. Tight junction protein zona occludens-1 (ZO-1) relocalizes into the cytoplasm and disrupts the tight junctions, which increases paracellular permeability. High level PAR2 activation in the rat colon results in localized inflammation and increased production of TNF-α and IFN-γ. INF-γ decreases ZO-1 expression and alters the actin cytoskeleton organization[104]. TNF-α activates MLCK and results in tight junction protein relocation[105,106]. A more detailed discussion of these pathways can be found in articles by Gareau *et al*[23] and Cenac *et al*[103].

Children and adults with IBS have increased intestinal permeability[107,108]. Increased intestinal permeability results in "mucosal barrier defects (that) allow the passage of an increased load of luminal antigens of dietary and bacterial origin which, in turn, elicit the activation of mucosal immune responses"[109].

Various triggers can activate mast cells. Bacteria are powerful antigens for the gastrointestinal immune system[110-115]. Stress can result in increased bacterial adherence and penetration into the gastrointestinal mucosa[23,25-27], which may increase the interaction between the luminal bacteria and local immune response. This may explain why patients with IBS have higher antibody titers to specific bacterial flagella than healthy controls[116]. The DNA of these bacteria can interact with toll-like receptors[117], which then influence the immune system through regulation of tumor necrosis factor alpha and interferon gamma[118].

Escherichia coli, Campylobacter, and other bacteria can negatively influence the GI immune system and result in gastrointestinal inflammation and intestinal permeability[46,91,119-121]. Conversely, commercially available beneficial bacteria, in the form of probiotics, can reduce gastrointestinal inflammation[122-125], reverse or prevent intestinal permeability[120], and stop bacterial adhesion[126] and translocation[27,127]. Probiotics can also reverse visceral hypersensitivity from various causes[128,129], including stress[130]. Probiotics attenuate the upregulation of pain pathways at the spinal and supraspinal levels[131], and induce epithelial cells to express micro-opiate receptor 1 (MOR1) and cannabinoid 2 (CB2) opioid receptors[132]. Probiotics can reduce the symptoms of IBS[133,134].

Adults with IBS have gastrointestinal microflora that are significantly different than those of healthy populations[135]. Children with IBS are also likely to have significant alterations in their gastrointestinal microflora. We speculate that there may be a subset of children who are predisposed to developing IBS through repeated or

prolonged exposure to antibiotics for various reasons (recurrent otitis media, sepsis, meningitis, osteomyelitis, vesicoureteral reflux, acne, *etc*). Various antibiotics, including Augmentin, the macrolides, and amoxicillin significantly alter the composition of the bacteria in the GI tract[136-138]. Antibiotic use has been related to increased rates of IBS and functional abdominal pain[139,140].

Gastrointestinal bacteria are also influenced by the diet. Dietary soluble fiber encourages the growth of beneficial species like lactobacilli and bifidobacteria[141-143]. In mice, a white bread diet significantly prolonged antibiotic induced bacterial perturbations[136]. It is common knowledge that the standard American diet lacks fiber, and thus may predispose human beings to have prolonged antibiotic induced bacterial perturbations.

Prebiotics are short chain carbohydrates that help some of the beneficial bacteria or probiotics in the intestines to grow more effectively[142,143]. Prebiotics may decrease IBS symptoms[144-146]. Prebiotics are fermented by probiotics and metabolized into short chain fatty acids (SCFA). SCFAs can decrease inflammation and are used in maintaining the intestinal epithelial lining[147]. While breast milk naturally contains prebiotics[148], up until a few years ago, most infant formulas did not contain prebiotics. Thus, there may be a population of children who were formula fed and required several courses of antibiotics that now have perturbed gastrointestinal flora, as well as intestinal epithelial barriers. We believe that these children may be at risk of developing IBS.

Food proteins are other significant antigens for the gut immune system. Food antigens induce mast cell activation[149] and degranulation, which can lead to visceral hypersensitivity. In children, certain foods may exacerbate intestinal permeability and the elimination of the foods help resolve the IBS symptoms[150]. Elimination of certain foods may decrease immune activation by removing the allergic antigenic load to the local immune system. In patients with IBS, sodium cromoglycate can eliminate IBS symptoms[151-153] by preventing the degranulation of mast cells and inhibiting the release of inflammatory mediators, following contact with an allergen[154].

Over 60% of patients believe that certain foods worsen their IBS symptoms and that elimination of these foods can reduce their symptoms[155-157]. Some believe that these food reactions are psychological in origin[158-160]. Blinded food challenges have raised many questions about the validity of elimination diets for IBS treatment[161-163]. There is also a growing body of evidence to support the use of elimination diets as part of a treatment protocol for IBS[164-167]. Milk, wheat, and eggs are the most commonly identified food triggers[163].

Another potential antigen for the gastrointestinal immune system is *Candida albicans*. Adult studies have shown that *Candida* does not play a significant role in patients with IBS[168,169]. To our knowledge, the role of candida in pediatric IBS has not been determined. Some children who have received numerous courses of antibiotics, such as amoxicillin, can have disruption of the bacterial balance and have overgrowth of the commensal *Candida*[137,170-173]. *Candida* induces inflammation. It produces alcohols and glycoproteins that stimulate mast cells to produce histamine and prostaglandins[174,175]. *Candida* also produces inflammatory prostaglandins that affect mammalian cells[176], as well as proteases that degrade the gastrointestinal IgA and, thus, allow candida to overcome the local immune defense mechanisms[177]. Candidal proteases can induce a B-cell response and result in increased inflammation[174]. In animals and humans, *Candida* perpetuates intestinal inflammation[169].

SMALL INTESTINAL BACTERIAL OVERGROWTH

Another possible contributing factor to IBS signs and symptoms is small intestinal bacterial overgrowth (SIBO), defined as bacterial counts greater than 10^5 cf/mL from small intestinal aspirates[178]. Controversy exists over the ideal method of assessing SIBO[178-181]. A significant number of patients with IBS complain of bloating and pain. SIBO may explain this bloating and pain, as well as other IBS-like-symptoms[182-184]. Several studies have shown antibiotics to be helpful in reducing the symptoms of IBS[185-188].

Patients with IBS who have delayed gastric emptying have a higher risk of developing SIBO[189-192]. Stress is one cause of delayed gastric emptying[193-196]. Once SIBO is present, it can trigger an inflammatory response. SIBO, through abnormal gastrointestinal flora fermentation, may be another cause of IBS symptoms and must be considered in the evaluation of the patient. Furthermore, proton pump inhibitors can also increase the risk of SIBO by decreasing gastric acidity and further perturbations of the gastrointestinal flora species[170,197-200]. We speculate that SIBO may play a larger role in adults with IBS than in children. Further studies are required to elucidate the various differences between adult and pediatric IBS.

CONCLUSION

The evidence presented in our review suggests that IBS is an organic disease with a complex pathophysiology (Figure 1) that is difficult to identify by standard diagnostic tools. The pathophysiology of IBS varies from person to person and from children to adults. The underlying mast cell mediated inflammation of IBS, along with serotonin signaling, can drive the chronic nociceptive input from the periphery to dynamically maintain the altered central processing defects and perception of pain[70,80,201].

In addition to the pathophysiology, clinicians must focus more attention on the well known and less well characterized risk factors that may predispose individuals to developing IBS (Table 1). It is our belief that clinicians should further use the field of neurogastroenterology to better understand the effects of stress on the gastrointestinal tract. Clinicians and researchers must work to develop and adopt models to help us better predict and prevent this condition in susceptible individuals. For chil-

Table 1 Risk factors for irritable bowel syndrome

Genetics/family history
Stress/high academic performance/parental psychiatric disorders
Recurrent or chronic antibiotic use
Bacterial or viral enteritis
Unrecognized food sensitivities
Low fiber diet/diet high in simple carbohydrates
Formula feeding
Chronic acid suppression

Figure 1 Proposed pathophysiology of irritable bowel syndrome. CRF: Corticotropin-releasing factor; SIBO: Small intestinal bacterial overgrowth; PAR2: Proteinase-activated receptor-2.

dren, these models will require additional studies to evaluate the impact of recurrent antibiotic use and resultant overgrowth of candida on the development of IBS.

Effective treatment models for IBS must reflect the complex physiology of IBS and simultaneously address multiple pathophysiological factors to break the vicious cycle of inflammation and ultimately allow for cessation of symptoms. The Institute of Functional Medicine (IFM)[202] has created such a model of care for IBS. The IFM model has the potential to provide significant improvement in patient care, while reducing healthcare costs and deserves further consideration and evaluation. Please refer to the IFM website and various publications for a more detailed discussion on treatment options.

REVIEW

Adiponectin, a key adipokine in obesity related liver diseases

Christa Buechler, Josef Wanninger, Markus Neumeier

Christa Buechler, Josef Wanninger, Markus Neumeier, Department of Internal Medicine I, University Hospital of Regensburg, D-93042 Regensburg, Germany
Author contributions: Buechler C wrote the review article and Neumeier M and Wanninger J revised the manuscript and participated in the design of the figures.

Abstract

Non-alcoholic fatty liver disease (NAFLD) comprising hepatic steatosis, non-alcoholic steatohepatitis (NASH), and progressive liver fibrosis is considered the most common liver disease in western countries. Fatty liver is more prevalent in overweight than normal-weight people and liver fat positively correlates with hepatic insulin resistance. Hepatic steatosis is regarded as a benign stage of NAFLD but may progress to NASH in a subgroup of patients. Besides liver biopsy no diagnostic tools to identify patients with NASH are available, and no effective treatment has been established. Visceral obesity is a main risk factor for NAFLD and inappropriate storage of triglycerides in adipocytes and higher concentrations of free fatty acids may add to increased hepatic lipid storage, insulin resistance, and progressive liver damage. Most of the adipose tissue-derived proteins are elevated in obesity and may contribute to systemic inflammation and liver damage. Adiponectin is highly abundant in human serum but its levels are reduced in obesity and are even lower in patients with hepatic steatosis or NASH. Adiponectin antagonizes excess lipid storage in the liver and protects from inflammation and fibrosis. This review aims to give a short survey on NAFLD and the hepatoprotective effects of adiponectin.

INTRODUCTION

Obesity is associated with insulin resistance, a common risk factor for type 2 diabetes, cardiovascular disease, hepatic steatosis and non-alcoholic steatohepatitis (NASH)[1,2]. Hypertrophied adipocytes in obesity fail to appropriately store excess triglycerides and excessive ectopic accumulation of lipids in skeletal muscle and liver disturbs insulin signalling[3]. Body fat distribution appears to be even more important than the total amount of adipose tissue, and visceral fat mass is strongly linked to insulin resistance and non-alcoholic fatty liver disease (NAFLD)[4]. Visceral fat released free fatty acids are transported to the liver by the portal vein and may contribute to hepatic steatosis, production of triglyceride rich very low density lipoproteins (VLDL) and elevated β-oxidation[5,6] (Figure 1). Metabolically healthy but obese (MHO) individuals are insulin sensitive and hepatic fat accumulation is significantly lower compared to similarly overweight subjects that develop

insulin resistance[7,8]. Despite comparable fatness between MHO and control cohorts that develop insulin resistance, MHO subjects have 49% less visceral fat which further emphasizes the unfavourable characteristics of this fat depot[9]. Lean body mass may be associated with a higher insulin sensitivity and is significantly lower in MHO subjects[9]. A recent study even describes an independent association of lean body mass with impaired glucose disposal and systemic C-reactive protein (CRP) levels in centrally obese postmenopausal women that may exacerbate the harmful effects of visceral fat mass[10]. These studies further point to the highly complex interplay of various factors associated with metabolic diseases like the metabolic syndrome.

Various epidemiological studies have identified central obesity as an independent risk factor for metabolic diseases and highlight the crucial role of impaired production or activity of adipose tissue released proteins[6,11]. Most of the adipokines identified so far are elevated in obesity and raised chemokine C-C motif ligand 2 (CCL2) contributes to the increasing number of adipose tissue resident macrophages[11,12]. They produce inflammatory proteins like interleukin-6 (IL-6) and tumour necrosis factor (TNF) whose circulating levels are increased in obesity, a state of low-grade, chronic inflammation[13]. TNF impairs insulin signalling and plays a crucial role in non-alcoholic steatohepatitis (NASH) progression[14,15]. Visceral fat released proteins are directly transported to the liver by the portal vein and the anatomical feature of this fat depot may explain the harmful metabolic effects of visceral adiposity[6]. IL-6 is preferentially released from visceral fat and upregulates suppressor of cytokine signalling 3 (SOCS3) in the liver that causes hepatic insulin resistance[16-18]. Furthermore, IL-6 is a well known inducer of CRP, a marker protein for systemic inflammation[19] (Figure 1). Leptin is mainly produced by adipocytes, and obesity is characterized by elevated systemic levels and central and peripheral leptin resistance[6]. Leptin prevents lipid accumulation in non-adipose tissues like the liver. Leptin lowers stearoyl-CoA desaturase that catalyzes the rate-limiting reaction of monounsaturated fatty acid synthesis and thereby may ameliorate hepatic insulin sensitivity[20]. Animal studies have proven that leptin directly promotes fibrogenesis. Leptin induces transforming growth factor β (TGF-β) and connective tissue growth factor (CTGF) production in hepatic stellate cells through indirect effects on Kupffer cells[21]. In humans, a direct association of circulating leptin and liver fibrosis has not been confirmed yet and locally produced leptin and/or leptin resistance may have to be taken into account[22].

The adipokine adiponectin is highly abundant in human serum and is secreted by adipose tissue in inverse proportion to the body mass index[23]. Adiponectin circulates as trimer, hexamer and higher order multimer in serum and isoform-specific effects have been described[24-26]. Adiponectin may also form hetero-oligomers with additional members of the C1q/TNF-related protein (CTRP) family like the recently described CTRP9[27]. Early studies indicate

Figure 1 Crosstalk of visceral adipose tissue and the liver. Free fatty acids and Interleukin (IL)-6 released by visceral adipose tissue (VAT) are transported to the liver by the portal vein. Free fatty acids promote steatosis, enhance β-oxidation and the release of very low density lipoproteins (VLDL) contributing to dyslipidemia. IL-6 induces hepatic C-reactive protein (CRP) synthesis and suppressor of cytokine signalling 3 (SOCS3), and thereby is linked to systemic inflammation and hepatic insulin resistance, respectively (adapted from Schaffler A, Scholmerich J, Buchler C. Mechanisms of disease: adipocytokines and visceral adipose tissue--emerging role in nonalcoholic fatty liver disease. *Nat Clin Pract Gastroenterol Hepatol* 2005; 2: 273-280[6]). ER: Endoplasmatic reticulum; TG: Triglycerides.

that globular adiponectin, the globular C1q domain of this protein generated by proteolysis of the full-length protein, may also exist in serum[28]. However, circulating levels seem to be rather low, questioning the biological significance of this protein[29] that may nevertheless be of therapeutic relevance. Epidemiological studies revealed that low adiponectin levels are associated with NASH independent of insulin resistance and body mass index, and hepatoprotective effects of adiponectin have been identified in animal studies or with isolated liver cells[30-32]. MHO individuals are insulin sensitive and have adiponectin levels similar to normal-weight controls despite excessive weight and body fat, and this association may further underline the protective effects of this adipokine[33].

NAFLD not only compromises the hepatic manifestation of the metabolic syndrome but is linked to a higher risk of develop metabolic disorders like type 2 diabetes or cardiovascular disease[34,35]. Fatty liver is even associated with dyslipidemia, metabolic syndrome and low adiponectin independent of body mass index (BMI), waist to hip ratio and visceral fat mass[36]. NAFLD has been predicted to increase along with the growing epidemic of obesity[37] and understanding of its pathophysiology is a prerequisite to develop non-invasive diagnostic tools and to establishing effective treatment regimes. Rising adiponectin levels may be beneficial in liver disease and its protective effects in hepatic steatosis and NASH[38] are summarized in the current review article.

EPIDEMIOLOGY OF NAFLD

Diagnosis of NAFLD requires a careful anamnesis to exclude other liver diseases or drug-mediated liver damage. Moderate alcohol intake, defined by most physicians as 20 to 40 g/d in men and 20 g/d in women, has to be en-

Figure 2 Epidemiology of non-alcoholic fatty liver disease. Current estimates of the prevalence of fatty liver, non-alcoholic steatohepatitis (NASH) and obesity-related liver cirrhosis in the general population and in obesity defined as body mass index (BMI) above 30 kg/m².

quired about[39]. Liver biopsy is essential for diagnosis and staging but the use of this invasive method is limited to a subgroup of patients[39].

When NAFLD is defined as elevation of aspartate aminotransferase (AST) or alanine aminotransferase (ALT) and transferrin saturation of less than 50% the frequency is 5.4% in the general population of the United States[40]. When elevated gamma-glutamyltranspeptidase (GGT) is included and lower cut-off values are used the prevalence is 24%[41]. Studies performed in gastroenterology units restricted cohorts identified 11% of the patients as having NAFLD[42]. In bariatric surgery patients hepatic steatosis ranges from 65% to 90%[43,44]; NASH has been diagnosed in 15 to 55% and fibrosis in 34% to 47%[41,45].

Current estimates based on different studies in unselected and selected populations indicate that about 20% to 30% of adults in Western countries have excess fat accumulation in the liver, 2% to 3% of adults are thought to meet current diagnostic criteria for NASH and eventually up to one third of those with NASH suffer from progressive fibrosis or even cirrhosis[41,45,46]. In obesity defined as BMI above 30 kg/m² and in morbidly obese patients these values are much higher and patients with NASH are over-represented in these populations[41,45] (Figure 2).

GENETICS OF NAFLD

Visceral adiposity and insulin resistance are clearly related to NAFLD[47] and genetic variations associated with obesity and disproportionate body fat distribution may predispose to development of steatotic liver. Chemerin is a recently identified adipokine and a common genetic variation is associated with increased visceral fat mass in non-obese subjects but epidemiological studies to link chemerin alleles with NAFLD are still lacking[48]. The adiponectin 45T →G variant contributes to overall fatness and abdominal obesity but is not an important determinant of NAFLD at least in Chinese people[49,50].

Gene variations may influence NAFLD stage, progression and even occurrence. NAFLD is much more likely in Hispanic Americans than among whites[51] and African Americans have a lower degree of hepatic steatosis relative to whites[52]. Familial clustering of NAFLD has been dem-

onstrated, and fatty liver is more common in siblings and parents of children with NAFLD indicating that NAFLD, similar to type 2 diabetes, is a multifactorial disease[53]. Environmental and genetic factors define the individual risk of developing NAFLD and may also explain why only a subgroup of patients develop more progressive liver damage.

Studies in small cohorts have identified genetic associations of microsomal triglyceride transfer protein, an enzyme regulating hepatic VLDL release, the antioxidant mitochondrial enzyme superoxide dismutase 2, the inflammatory cytokine TNF and the main profibrotic cytokine TGF-β with NAFLD[54,55]. Genome-wide association studies find that variations of patatin-like phospholipase domain containing 3 (PNPLA3, adiponectin), a protein with close homology to adipose triglyceride lipase but so far unknown function, contributes to ethnic and interindividual differences in hepatic steatosis and susceptibility to NAFLD[56,57].

This association has not been confirmed in a recent study in non-Hispanic, Caucasian, women with liver biopsy proven NAFLD, where an association between NASH activity score and single nucleotide polymorphisms (SNPs) within the squalene synthase (FDFT1) gene, a key regulator of cholesterol biosynthesis, is described. Polymorphisms of the pregnancy zone protein, a proteinase involved in clearance of TGF-β, are linked to systemic AST levels, and variants of platelet-derived growth factor α are linked to liver fibrosis[58].

Genetic variations of adiponectin are found to be associated with NAFLD[50,59], and single nucleotide polymorphisms in adiponectin receptor 1 (AdipoR1) and AdipoR2 contribute to variations in hepatic fat accumulation in humans[60,61].

SYSTEMIC ADIPONECTIN IN NAFLD

Systemic adiponectin concentrations are in the μg/mL-range indicating that adiponectin constitutes a substantial fraction of plasma proteins, and these high levels are remarkably constant. Despite its abundant presence in plasma, adiponectin is cleared rapidly by the liver with a half-life of about 75 min[62].

Visceral adiposity is associated with elevated circulating free fatty acids and higher concentrations of most adipose tissue released proteins[63]. Adiponectin differs from the adipokines described so far because its systemic levels are decreased in obesity[23]. In high fat diet induced obese rodents and in ob/ob mice adiponectin levels are reduced in plasma and clearance is significantly prolonged, indicating markedly impaired adiponectin synthesis in obesity[62,64,65]. Visceral fat accumulation is associated with hypoadiponectinemia and negative associations of visceral fat with systemic adiponectin have been identified[66,67].

Besides adiponectin, circulating levels of omentin predominantly released from the stromovascular cells of visceral fat are found reduced in obesity and serum omentin levels are increased in patients with NAFLD and independently predict hepatocyte ballooning[68].

In healthy Caucasians, BMI and adiponectin, but not insulin resistance, predict serum concentrations of both ALT and GGT[69]. Low adiponectin levels are even found associated with NASH independent of insulin resistance and BMI[30]. Multivariate regression analysis identifies decreased adiponectin as an independent predictor of liver steatosis and elevated ALT and GGT levels in healthy obese individuals[32]. In NAFLD patients low adiponectin levels are closely associated with the degree of hepatic steatosis, necroinflammation and fibrosis[30,52]. Shimada *et al*[70] reported that 90% of patients with early-stage NASH can be predicted by a combined evaluation of the serum adiponectin level, homeostasis assessment model-insulin resistance (HOMA-IR) score, and serum type IV collagen 7S level.

Circulating adiponectin levels in the μg/mL range by far exceed concentrations commonly required for receptor-dependent signalling. This may indicate receptor independent functions of adiponectin and binding to growth factors like platelet derived growth factor (PDGF), extracellular matrix proteins, low density lipoprotein (LDL) and opsonization of apoptotic cells to stimulate phagocytosis have been described[71-74].

Systemic adiponectin is about 20% to 60% lower in NAFLD than healthy controls[75-77] but considering the high levels in the circulation and a half-maximal effective dose of 0.85 μg/mL full-length adiponectin for AdipoR2 stimulated fatty acid oxidation[78] the question arises whether impaired receptor-mediated signalling due to reduced concentrations is a reasonable explanation for metabolic complications associated with hypoadiponectinemia. Therefore, it is likely that adiponectin receptor signal transduction pathways are also impaired in NAFLD.

ADIPONECTIN RECEPTORS IN NAFLD

Two 7-transmembrane proteins, AdipoR1 and AdipoR2, have been identified to function as adiponectin receptors[78]. Although initial studies using rodent tissues reveal preferential expression of AdipoR2 in the liver, in human tissues AdipoR1 and AdipoR2 mRNAs are most abundant in skeletal muscle and both are moderately expressed in the liver[78]. AdipoR1 protein is easily detected in human hepatocytes indicating that both receptors may play a role in liver physiology[79].

Although there is a well documented relationship between low adiponectin and liver disease, an association of NAFLD and reduced expression of hepatic adiponectin receptors is not consistently reported. Furthermore, mainly mRNA expression has been analysed and this may not necessarily predict protein abundance[80,81].

In animal models of obesity, hepatic adiponectin receptor mRNAs are found unchanged or even increased[65,82,83]. In human biopsies, hepatic adiponectin receptor mRNAs are increased in biopsy-proven NASH compared to steatotic livers[84]. Other studies, however, describe similar levels of adiponectin receptor mRNA in normal liver, steatotic liver and NASH[85,86]. There are also reports on reduced AdipoR2 mRNA in NASH compared to simple steatosis or lower AdipoR2 mRNA in fatty liver with no further reduction in NASH[87,88].

Data on AdipoR2 proteins are sparse and one study demonstrates reduced AdipoR2 protein in human NASH compared to steatotic liver[88]. Treatment of hepatocytes with palmitate is used as an in vitro model for hepatocyte steatosis and 200 μmol/L of this fatty acid reduce AdipoR2 protein in Huh7 cells[89]. Activating transcription factor 3 (ATF3) is induced upon endoplasmic reticulum stress and in the liver of ob/ob mice, and suppresses AdipoR2 in HepG2 cells[90]. Therefore, besides low circulating adiponectin, AdipoR2 may be reduced in hepatic steatosis and NASH indicating a possible adiponectin resistant state.

ANTISTEATOTIC EFFECTS OF ADIPONECTIN

Dyslipidemia is characterized by high circulating triglycerides[91] and low high density lipoprotein (HDL) cholesterol levels, and is frequently accompanied by hepatic steatosis[92]. Adiponectin negatively correlates with serum triglycerides and apolipoprotein B (ApoB), the main apolipoprotein of the triglyceride rich VLDL[93,94]. Hepatocyte ApoB and triglycerides are reduced by adiponectin indicating lower hepatic VLDL release[28,95,96]. Furthermore, VLDL catabolism is enhanced by an increased skeletal muscle lipoprotein lipase and VLDL receptor expression[97]. This more favourable lipid profile may be linked to lower hepatic lipid storage.

A choline and L-amino acid deficient diet induces more severe hepatic steatosis in adiponectin deficient mice compared to wild type animals[14]. Adenoviral expression of adiponectin ameliorates lipid deposition in the liver[95]. SREBP-1c is a central regulator of fatty acid synthesis, and is suppressed by adiponectin in hepatocytes and in the liver of db/db mice[95]. AMP-activated protein kinase (AMPK) is physiologically activated by low energy status, and switches on ATP-producing catabolic pathways (such as fatty acid oxidation and glycolysis), and switches off ATP-consuming anabolic pathways (such as lipogenesis)[98]. Adiponectin activates AMPK by binding to AdipoR1[78]. Suppression of SREBP-1c by adiponectin is mediated through AdipoR1/LKB1, an upstream kinase of AMPK, and AMPK pathway[95]. AMPK in addition phosphorylates acetyl-CoA carboxylase (ACC) and this is subsequently associated with a higher activity of carnitine palmitoyl-transferase 1 (CPT-1), a rate limiting enzyme in fatty acid oxidation[98].

Signalling *via* AdipoR2 enhances peroxisome-proliferator activated receptor α (PPARα) activity[78,99]. PPARα upregulates CPT-1, stimulates β-oxidation, reduces lipid synthesis and thereby prevents excess triglyceride storage[100].

ANTIINFLAMMATORY AND ANTIAPOPTOTIC EFFECTS OF ADIPONECTIN

Lipopolysaccharide (LPS) is involved in the pathogenesis

of NAFLD and elevated levels of circulating LPS are found in obesity[101,102]. Increased gut permeability and a higher prevalence of small intestinal bacterial overgrowth correlates with the severity of steatosis but not with NASH[103]. Besides age, inflammation was identified as an independent predictor of progression to advanced fibrosis in NASH patients[104]. Hepatic steatosis may be accompanied by inflammatory cell infiltrates composed of neutrophils and mononuclear cells. In several mouse models of immune mediated hepatitis, adiponectin reduces TNF and induces interleukin-10 (IL-10) release from Kupffer cells[105]. Adiponectin lowers CRP synthesis in cytokine stimulated rat hepatocytes, and an inverse correlation of systemic adiponectin and CRP has been identified in obese patients[106,107]. Adiponectin may exert its anti-inflammatory activity by lowering nuclear factor kappa B (NFκB) action in preactivated cells or by inducing tolerance to inflammatory stimuli by a rapid and transient activation of NFκB that subsequently renders the cells inert to further activation[108-111].

Nevertheless, in patients suffering from chronic inflammatory diseases like inflammatory bowel disease or type 1 diabetes that are not associated with adiposity elevated circulating adiponectin levels that even correlate with inflammatory markers are found[112-114], and an induction of inflammatory proteins and activation of NFκB by recombinant adiponectin is described in several studies[25,108,113,115]. Therefore, adiponectin seems to be regulated in the opposite direction in classic versus obesity-associated chronic inflammatory diseases and may even exert opposite activities in resting compared to activated cells[116].

NFκB promotes cell survival and NEMO-mediated NFκB activation in hepatocytes has an essential physiological function to prevent the spontaneous development of steatohepatitis and hepatocellular carcinoma[117]. Adiponectin activates NFκB in human hepatocytes, and thereby may prevent hepatocyte apoptosis. Adiponectin further upregulates the chemokine interleukin 8 (CXCL8) *via* AdipoR1 and NFκB dependent pathways in primary human hepatocytes[118]. CXCL8 is an antiapoptotic protein[119] and overexpression of the rodent CXCL8 homologous protein protects the liver from galactosamine and endotoxin induced damage[120].

Adiponectin further antagonizes hepatocyte death by blocking fatty acid-induced activation of c-Jun NH2 terminal kinase[121], by reducing TNF levels[105] and by inhibiting fatty acid mediated upregulation of CD95[122].

ANTIOXIDATIVE EFFECTS OF ADIPONECTIN

Fatty liver is thought to represent the first incident towards the subsequent development of liver fibrosis[6]. Accelerated β-oxidation of fatty acids in hepatic steatosis is associated with excess reactive oxygen species (ROS), lipid peroxidation, the release of inflammatory cytokines, death of hepatocytes and activation of hepatic stellate cells[1]. ROS and lipid peroxidation are thought to contribute to the progression of liver injury partly by accelerating inflammation that in turn causes ROS production[1]. Oxidative stress is enhanced in human hypoadiponectinemia and in adiponectin knock-out mice fed a choline-deficient L-amino acid deficient diet[123,124]. Hepatic cytochrome P450 2E1 (CYP2E1) is elevated in these animals and in human NASH and may contribute to higher ROS levels[125,126].

Aldehyde oxidase 1 (AOX1) is a xenobiotic metabolizing protein whose physiological role has not been evaluated in detail so far[127]. AOX1 activity has been identified as an important source of ROS[128] and is reduced in hepatocytes by adiponectin *via* activation of PPARα[31] Adiponectin also increases ROS detoxifying enzymes and AdipoR2 is involved in the induction of superoxide dismutase 1 and catalase[129].

ANTIFIBROTIC EFFECTS OF ADIPONECTIN

Liver injury causes activation of otherwise "quiescent" hepatic stellate cells (HSC) and activated cells proliferate, synthesize CTGF and extracellular matrix proteins[130]. TGF-β is the main profibrotic factor in fibrosis and induces CTGF synthesis. CTGF stimulates binding of TGF-β to its receptor and thereby enhances TGF-β activity[130]. CTGF is induced by TGF-β indicating an autocrine or paracrine loop that mutually enhances synthesis of both proteins[130]. Knock-down of AdipoR2 in mice fed a methionine-choline deficient diet to cause progressive fibrosing steatohepatitis is associated with higher levels of steatosis, inflammation and fibrosis[131]. Overexpression of AdipoR2 is protective, and this mechanistically includes inhibition of TGF-β signaling and stimulation of PPARα activity[131].

Expression of recombinant adiponectin in activated HSC reduces proliferation and lowers α-smooth muscle actin that is induced in activated HSC[132]. Furthermore, apoptotic cell death of activated HSC is augmented[132]. Exogenously added recombinant adiponectin suppresses PDGF-stimulated HSC proliferation by activation of AMPK[133]. Adiponectin may also bind to growth factors like PDGF and thereby inhibits binding to their corresponding receptors[71]. Leptin is a well described profibrotic adipokine and several studies have shown that adiponectin antagonizes leptin bioactivity[134,135]. Adiponectin blocks leptin-induced STAT3 phosphorylation in activated HSC and leptin-mediated upregulation of TIMP-1 release and these in-vitro findings have been confirmed *in-vivo*[134].

DIET, EXERCISE AND PHARMACOLOGICAL INTERVENTIONS

Studies analysing the impact of changes in life style and medications in NAFLD have been performed in small patient groups sometimes even lacking suitable controls. Currently weight loss and exercise are recommended as initial strategies to improve NASH[136]. Diet and diet in conjunction with exercise for 6 mo cause a similar reduction in body weight and intrahepatic fat[137]. In 19 sedentary obese

Figure 3 Hepatoprotective effects of adiponectin. Hepatic insulin resistance correlates with liver fat content, and is currently thought to represent the first incident in metabolic liver diseases. Insulin resistance and steatosis may also promote inflammation and fibrosis although the factors leading to advanced liver damage have not been identified so far. Major pathophysiological alterations of hepatocytes, hepatic stellate cells (HSC) and Kupffer cells in hepatic steatosis and/or non-alcoholic steatohepatitis are indicated. The protective activities of adiponectin are listed and arrows indicate an induction or repression of these pathways/proteins by adiponectin. IL: Interleukin; TGF: Transforming growth factor; TNF: Tumor necrosis factor; ECM: extracellular matrix; ROS: Reactive oxygen species.

men and women four weeks of aerobic exercise improved hepatic steatosis even in the absence of weight loss[138]. In a randomized controlled trial enrolling 31 patients with biopsy-proven NASH intensive changes in life style with the objective of at least 7% weight loss and educational training without weight reduction have been compared[139]. Weight loss significantly correlates with improvement in NASH histological activity score and weight loss of 7% or even more is recommended as a treatment strategy for these patients[139]. Another study also reports improvements of histological and laboratory parameters when body weight is reduced by 10% in NASH patients[140]. Adiponectin concentrations increase by about 36% in type 2 diabetic patients by 13% weight loss[141], and this may partly contribute to the metabolic improvements observed in these patients.

Clinical trials using fibrates have revealed inconsistent results so far. Treatment of sixteen NASH patients with clofibrate did not ameliorate biochemical or histological parameters[142], whereas a second study demonstrated biochemical and ultrasound improvements with fenofibrate[143]. Emerging data on thiazolidinediones have demonstrated improvement in both liver enzymes and histology[144,145]. These drugs activate PPARγ and thereby inhibit growth of HSC and TGF-β mediated induction of CTGF, respectively[146]. PPARγ is the main adipogenic transcription factor and its agonists stimulate adipogenesis[147]. Thiazolidinediones strongly stimulate adiponectin synthesis and elevate systemic adiponectin[147]. Increase of adiponectin by pioglitazone is related to histological improvement of steatosis, inflammation and fibrosis confirming the crucial

role of adiponectin in NAFLD[148]. The PPARγ agonist rosiglitazone even induces AdipoR2 in hepatocytes[146]. A recent study reports that pioglitazone therapy improves adipose tissue insulin sensitivity and this correlates with a reduction in hepatic fat and necroinflammation[149]. Activation of PPARγ primes human monocytes into alternative M2 macrophages with anti-inflammatory properties and patients may also benefit from reduced inflammation[150]. In line with this hypothesis pentoxifylline with multiple pharmacological effects including antioxidant and anti-inflammatory activity[151] has been tested in small clinical trials, and biochemical and histological improvements have been reported[151,152]. Vitamin E therapy decreases AST and ALT levels and hepatic steatosis but does not improve necroinflammation and fibrosis[153]. Antioxidants may even prevent health-promoting effects of physical exercise namely insulin sensitivity and rise of systemic adiponectin in untrained and pre-trained individuals, and therefore, may be more effective in patients with low physical activity[154]. In summary to date no pharmacologic treatment has been reliably shown to be effective for the treatment of NASH patients.

CONCLUSION

Adiponectin has emerged as a protective adipokine in insulin resistance and obesity related liver diseases (Figure 3), and drugs that elevate systemic adiponectin may be useful as therapeutics for NAFLD. Adiponectin receptor signalling pathways and potential hepatic adiponectin resistance in NASH, however, have been poorly investigated so far. Identification of molecules downstream of AdipoR1/2 and strategies to enhance adiponectin receptor activity may constitute promising approaches towards treatment of NAFLD.

Abstract

AIM: To investigate the mechanism behind β-cell regeneration in neonatal rat pancreas treated with streptozotocin (STZ).

METHODS: Neonatal Sprague Dawley rats were intraperitoneally injected with 70 mg/kg STZ. Body weight, pancreas weight and blood glucose were recorded every two days after the treatment. To identify the expression and location of transcription factors in the rat pancreas, double immunofluorescent staining was performed using antibodies to specific cell markers and transcription factors.

RESULTS: Expression of Neurogenin 3 (Ngn3), a marker for endocrine precursor cells, was observed by immunofluorescence in a few β-cells and many α-cells. The expression reached a peak 12 d after treatment. Pax4, a transcription factor that lies downstream of Ngn3 and

plays an important role in β-cell differentiation, was also expressed in the α-cells of STZ-treated rats. We did not observe significant changes in Nkx6.1, which is essential for β-cell maturation in the treated rats.

CONCLUSION: α-cells dedifferentiated into endocrine precursor cells and acquired the ability to dedifferentiate in the neonatal rat pancreas after STZ treatment.

Streptozotocin-induced expression of Ngn3 and Pax4 in neonatal rat pancreatic α-cells. *World J Gastroenterol* 2011; 17(23): 2812-2820 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i23/2812.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i23.2812

INTRODUCTION

The pancreas originates from gut endoderm. During development, the rat pancreas undergoes two transitions in embryonic days[1]. After birth, many major developmental changes occur, including β-cell apoptosis, replication, and exogenesis[2]. This stage is referred to as the remodeling of pancreas. In our previous work, we found alpha-fetoprotein and Mesothelin in embryonic rat pancreases but not in adult rat pancreases, nevertheless, we observed the expression of these two proteins during the remodeling of the rat pancreas[3,4]. These studies indicate that during the remodeling phase, the neonatal pancreas is not fully matured. Furthermore, after treatment with Streptozotocin

(STZ) during this stage, the ontogeny of regeneration can be observed[5]. Conversely, after treatment with STZ during adulthood, little regeneration of β-cells was found[6]. Extensive studies have been reported on the model of STZ-induced depletion of β-cells in the neonatal rat pancreas, which showed that this model can be used to study β-cell replacement therapy for diabetes[5,7,8].

The development of β-cells is regulated by a series of transcription factors[9,10]. However, few studies have focused on the expression of these transcription factors during the regeneration of β-cells in STZ-treated neonatal rats. One of the most important upstream transcription factors is pancreas-duodenal homeobox 1 (Pdx1)[11]. The initial expression of Pdx1 (E8.5-E9.0) marks the pre-pancreatic endoderm before it is visibly thickened[12-14], and corresponds to the classically defined period of pancreatic specification[15]. Following the expression of Pdx1 is the Neurogenin 3 (Ngn3), a basic helix-loop-helix transcription factor[16] that marks endocrine pancreatic precursor cells. Among a series of transcription factors that differentiate endocrine precursors into β-cells, paired domain homeobox gene 4 (Pax4)[17] and NK family member Nkx6.1[18] lie downstream of Ngn3.

Although these factors are essential for the development and maturation of β-cells, it is unknown whether Ngn3, Pax4 and Nkx6.1 participate in the regeneration of β-cells after STZ treatment during the remodeling phase of the pancreas. Especially, there is little information on the differentiation factors that are involved in the remodeling of the rat pancreas. This study was designed to determine the expression and location of these transcription factors in the STZ-treated neonatal rat pancreas.

MATERIAL AND METHODS

Animals

Pregnant Sprague Dawley rats from the Animal Center of Nanjing Medical University, Nanjing, China, were kept under conventional conditions and provided with a 12:12 h light-dark cycle. Litters were reduced to 12 pups at birth. Four days after birth, half of the pups in each litter was intraperitoneally injected with 70 mg/kg STZ freshly dissolved in citrate buffer (0.05 mol/L, pH 4.5). The remaining pups received vehicle only. Blood glucose was measured with a OneTouch Ultra blood glucose meter (LifeScan Inc. Milpitas, CA, USA) in blood obtained by lancing the tail vein. Body weight was recorded every two days. On the day of treatment and days 4, 8, 12, 16 and 20 after treatment, animals were killed by decapitation or by overdose of anesthesia (sodium amobarbital, amytal sodium, Sigma-Aldrich 200 mg/kg body weight). Pancreases were collected immediately and frozen in liquid nitrogen or fixed. Three to five pups from at least three separate litters were studied at each time point. All experiments were conducted in accordance with the Chinese Law for Animal Protection and were approved by Nanjing Medical University Ethics Review Committee (approval No. 200913).

Fluorescence immunohistochemistry

Tissues were fixed in 4% paraformaldehyde for 24-36 h followed by a standard protocol of dehydration and paraffin embedding. Sections (5 μm) were cut and mounted on glass slides (Fisher Scientific, Pittsburgh, PA, USA). The paraffin sections were deparaffinized in xylene and dehydrated in graded ethanol and distilled water. The tissue sections were blocked in 1% bovine serum albumin for 1 h. For double fluorescence immunohistochemical localization of glucagon and insulin, the mouse anti-glucagon (1:100, Sigma-Aldrich, St. Louis, MO, USA) antibody was applied after blocking and revealed using goat anti-mouse IgG-FITC (1:400, Santa Cruz, Santa Cruz, CA, USA). Rabbit anti-insulin polyclonal antibody (1:100, Santa Cruz, Santa Cruz, CA, USA) was then applied and revealed by Cy3-labeled anti-rabbit IgG (1:400, Santa Cruz, Santa Cruz, CA, USA). For dual fluorescence immunohistochemical localization of Ngn3, Pax4 or Nkx6.1 and insulin, rabbit anti-neurogenin 3 (1:100, Santa Cruz, Santa Cruz, CA, USA), goat anti-Pax4 (1:100, Santa Cruz, Santa Cruz, CA, USA) or goat anti-Nkx6.1 (1:100, Santa Cruz, Santa Cruz, CA, USA) antibody were added, respectively, and revealed by rabbit anti-goat IgG-FITC (1:400, Chemicon, Temecula, CA, USA) or mouse anti-rabbit IgG-FITC (1:400, Chemicon, Temecula, CA, USA). Mouse anti-insulin (1:100, Sigma-Aldrich, St. Louis, MO, USA) was applied and revealed by Cy3 conjugated anti-mouse (1:400, Chemicon, Temecula, CA, USA) antibody. For co-localizations of Ngn3, Pax4 or Nkx6.1 and glucagon, rabbit anti-neurogenin 3 (1:100), goat anti-Pax4 (1:100) or goat anti-Nkx6.1 (1:100) antibodies were added and revealed by rabbit anti-goat IgG-FITC (1:400) or mouse anti-rabbit IgG-FITC (1:400). Mouse anti-glucagon (1:100) was applied and revealed by Cy3 conjugated anti-mouse (1:400) antibody. Sections were placed in Gel Mount Aqueous Mounting Medium (G0918, Sigma) with a cover glass, and were examined under an Olympus BX51 microscope (Olympus Optical, Tokyo, Japan) at a magnification of × 200 or × 400.

β-cell mass

β-cell mass was measured by point counting morphometry on the same stained sections as described above. Each section was covered systematically at a magnification of × 400 using a 48-point grid to obtain the number of grid intercepts over β-cells, endocrine non-β-cells, exocrine pancreatic tissues, and non-pancreatic tissues. The relative β-cell area was calculated by dividing the number of intercepts over β-cells by the number of intercepts over total pancreatic tissue; the β-cell mass was then estimated by multiplying the relative β-cell volume by the corrected pancreatic weight. Non-β-cell mass was similarly calculated. A correction factor for pancreas weight was obtained by multiplying the pancreas weight by the ratio of intercepts over non- pancreatic tissues to intercepts over total tissues. Actual pancreas weight was then calculated by subtracting this correction factor from total pancreas weight. A monogram related to the number of points, the

	Days after STZ treatment

volume density and the expected relative standard error of the mean (< 10%) was used to determine the number of intercepts needed for a representative sampling.

Statistical analysis
The experimental data was analyzed by paired Student *t* test using the SPSS 17.0 software. $P < 0.05$ was considered statistically significant. Data were presented as mean ± SD.

RESULTS

Body and pancreatic weight, blood glucose and islets in STZ-treated neonatal rat pancreases
After STZ treatment, body and pancreas weight did not change significantly (Table 1). Blood glucose concentrations significantly increased within 2 d after STZ treatment (Figure 1A). However, on day 20 after treatment, there was no longer a difference in blood glucose concentrations between the two groups.

Histological analysis showed that approximately 60% of insulin immunoreactive cells within the islets were lost 4 d after STZ treatment (Figure 1B). On day 8 after treatment, an increased number of small islets was observed (Figure 1C). On day 20 after treatment, more large islets were found, which may indicate that islet function had also recovered. Similarly, calculation of β-cell mass showed a reduction in β-cell mass from 4 d after STZ treatment onwards (Figure 1D). While β-cell mass was still reduced in STZ-treated rats on day 20 after treatment, blood glucose levels were not significantly different.

Expression and location of Ngn3
We used double immunofluorescence to stain Ngn3 and insulin or glucagon at different time points after STZ treatment. We did not find Ngn3 co-located with insulin in either treated or control rats (Figure 2A). By analyzing the coexpression of Ngn3 and glucagon, we observed abundant expression of Ngn3 in the treated rat islet α-cells (Figure 2B). In the STZ group, expression of Ngn3 could be detected on day 8 and reached a peak on day 12 after treatment (Figure 2C). However, no significant changes were observed in the signal from Ngn3 in α-cells 20 d after treatment compared with the control rats. In contrast,

few α-cells expressed Ngn3 in control rats at each time point.

Expression and location of Nkx6.1
We stained Nkx6.1 and glucagon or insulin by immunofluorescence. Consistent with previous work, we found coexpression of Nkx6.1 and insulin in both the controls and the treated group (Figure 3A), while no Nkx6.1 expression was found in α-cells at any time point (Figure 3B) when we studied the coexpression of glucagon and Nkx6.1.

Expression and location of Pax4
We studied the colocation of Pax4 and insulin or glucagon by dual immunofluorescence. Consistent with previous work, we observed coexpression of insulin and Pax4 in both the control group and the treated group (Figure 4A). We also found enhanced expression of Pax4 in STZ-treated rat pancreases compared with control rats (Figure 4A). Eight days after treatment, we observed expression of Pax4 in α-cells of the treated rats but little expression in the control rats. However, we found coexpression of glucagon and Pax4 in both treated and control rats on day 12 after treatment (Figure 4B). On day 20 after STZ treatment, we could still observe a signal of Pax4 in the α-cells. However, in the control rats, few α-cells expressed Pax4 on day 20.

DISCUSSION

It is established that neonatal β-cells are able to regenerate after subtotal β-cell damage by STZ treatment. Regeneration of neonatal β-cells after destruction mainly relies on replication of pre-existing β-cells and heterogenesis of new cells[19]. In this article, we demonstrated a series of transcription factors expressed in pancreatic α-cells, which suggested that α-cells may be a source of β-cells during the regeneration of the STZ-treated neonatal rat pancreas.

We found that β-cells were damaged 4 d after STZ treatment. On day 8 after treatment, β-cell numbers were recovered in STZ-treated rats. By day 20 after treatment, there was still a reduction in β-cell mass but the blood glucose concentrations had reverted to normal. Although the model resulted in transient hyperglycemia, no difference in the mean body weight or pancreatic weight was seen between the two groups.

The study of pancreatic development has focused on transcription factors and transcription factor hierarchies during development. A central and heavily studied transcription factor in pancreatic development is Pdx1. Although Pdx1 is a key component of pancreatic specification, we found no significant difference in α or β-cells between STZ-treated rats and control animals. This indicates that Pdx1 is not involved in the regeneration of β-cells in STZ-treated animals.

After pancreatic formation, which is mediated by Pdx1, Ngn3 regulates the differentiation of endocrine pancreas. Lack of Ngn3 leads to an absence of islets[20]; and the ectopic expression of Ngn3 in other cells converts these

cells into endocrine cells[21]. We observed Ngn3 expression in the α-cells of treated rats, which reached a peak on day 12 after STZ treatment. It has been reported that Ngn3 is

activated through partial duct ligation in the adult mouse pancreas[22]. However, Ngn3 is absent in the β-cells of mice that underwent partial pancreatectomy[23]. The dif-

ferent results among these three models indicate that the mechanism of β-cell regeneration in different pathological situations can be varied. Interestingly, we observed abundant expression of Ngn3 in STZ-treated rats but not in control rats. The expression of Ngn3 in α-cells after STZ treatment indicated that α-cells dedifferentiated into precursor cells and may be candidates for β-cell formation. It has been suggested that high Ngn3 expression at an inappropriately early time in the developing mouse pancreas may result in a pancreas entirely consisting of small clusters of glucagon-positive cells[21,24]. Furthermore, by overexpression of Ngn3 in human[25] or mouse[26,27] pancreatic duct cells, the pancreatic duct cells could become endocrine cells. Apparently, the expression of Ngn3 is necessary for the transdifferentiation of α-cells to β-cells.

Next to Ngn3 induction, a complex network of transcription factors, including Pax4, progressively and differentially promotes the particular endocrine fates[28,29]. The expression of Pax4 is first observed around E9.5 in dorsal pancreatic buds of mouse embryos and vanishes shortly after birth[29,30]. Pax4 specifies the β-cell lineage into β and δ precursor cells[31]. In mice lacking Pax4, mature pancreatic and δ-cells were absent[29]. Conversely, ectopic expression of Pax4 in the mouse pancreas converted α-cells into β-cells. Moreover, the transgenic adult mice could survive after STZ-induced hyperglycemia[32]. Activation of Pax4 in endocrine progenitor cells may be mediated by Ngn3 since it binds to the Pax4 regulatory region and is necessary for Pax4 expression[33]. Ngn3 is required for ectopic Pax4 expressing α-cells to acquire a β-cell phenotype[34]. Interestingly, we observed expression of Pax4 in α-cells of both control and STZ-treated rats. In the STZ-treated rats, the expression of Pax4 reached a peak on day 16 after the treatment. The expression of Pax4 in the control animals suggests that Pax4 expression is characteristic of the pancreatic remodeling phase. Both cell differentiation and maturation occur during remodeling of the pancreas, which explains the presence of transcription factors in islet cells. After STZ treatment, the expression of Pax4 increased and a Pax4 signal could still be observed in α-cells 20 d after the treatment. This suggests that STZ treatment exaggerates and extends the period of remodeling.

Another transcript factor which lies downstream of Ngn3 is Nkx6.1, and it is associated with the development and maturation of β-cells. Nkx6.1 appears to be a marker for multipotent pancreatic progenitor cells[35]. At later developmental stages and in the adult pancreas, Nkx6.1 becomes completely restricted to insulin-expressing cells. Consistent with previous researches, we observed coexpression of Nkx6.1 and insulin in both STZ-treated and control rats. However, we did not find any Nkx6.1-positive α-cells. Immunoblotting revealed that the expression of Nkx6.1 decreased 4 d after STZ treatment, and reached normal levels on day 12 after treatment. Although Nkx6.1 is critical for the development of β-cells, it does not affect the generation of β-cells from α-cells.

It has been established that regeneration of neonatal rat β-cells after subtotal destruction by STZ occurs by two mechanisms of equal significance. The first mechanism is the replication of surviving β-cells in the islet compartment, the second mechanism is the replication of cells from a β-cell pool outside the islet compartment. In this article, we have demonstrated that α-cells may also be a source for β-cell regeneration. Mature α-cells converted to β-cells after partial duct ligation plus alloxan treatment, and the contribution of α-cells to the emergence of new β-cells was proportional to the degree of β-cell ablation[36]. However, α-cells could only convert to β-cells when the proportion of β-cell loss reached 99%[37].

In conclusion, during the period of pancreatic remodeling, the islets are not completely matured and the dedifferentiation of α-cells into endocrine precursor cells contributes to the recovery of β-cell mass after impairment by STZ.

COMMENTS

Background
Streptozotocin-induced β-cell loss in neonatal rat pancreas can trigger transient hyperglycemia. β-cell mass recovers 20 d after treatment. It is unknown whether Ngn3, Pax4 and Nkx6.1 participate in the regeneration of β-cells after streptozotocin (STZ) treatment during the remodeling phase of the pancreas.

Research frontiers
It has been shown that mature α-cells converted to β-cells after partial duct ligation plus alloxan treatment, and that the contribution of α-cells to the emergence of new β-cells was proportional to the degree of β-cell ablation.

Innovations and breakthroughs
There is little information on the differentiation factors that are involved in the remodeling of the rat pancreas. This study was designed to determine the expression and location of these transcription factors in the STZ-treated neonatal rat pancreas. The authors for the first time found the expression of Ngn3 and Pax4 in α-cells during remodeling of rat pancreas after STZ treatment.

Applications
Insulin deficiency caused by a reduced pancreatic islet β-cell number underlies the progression of both type 1 and type 2 diabetes, prompting efforts to develop β-cell replacement therapies. This study demonstrated the dedifferentiation of α-cells into endocrine precursor cells may contributes to the recovery of β-cell mass after impairment by STZ and this may provide a alternative way for β-cell replacement therapies.

Terminology
After birth, many major developmental changes occur, including β-cell apoptosis, replication, and exogenesis. This stage is referred to as the remodeling of pancreas.

Peer review
The study is well conducted and the results are interesting. This paper puts up the fact that α-cells dedifferentiate to endocrine precursor cells.

Abstract

AIM: To investigate apparent diffusion coefficient (ADC) values as an indication of reconditioning of acute hepatic injury (AHI) after allogeneic mononuclear bone marrow cell (MBMC) transplantation.

METHODS: Three groups were used in our study: a cell transplantation group ($n = 21$), transplantation control group ($n = 21$) and normal control group ($n = 10$). AHI model rabbits in the cell transplantation group were injected with 5 mL of MBMC suspension at multiple sites in the liver and the transplantation controls were injected with 5 mL D-Hanks solution. At the end of the 1st, 2nd and 4th wk, 7 rabbits were randomly selected from the cell transplantation group and transplantation control group for magnetic resonance diffusion-weighted imaging (MR-DWI) and measurement of the mean ADC values of injured livers. After MR-DWI examination, the rabbits were sacrificed and the livers subjected to pathological examination. Ten healthy rabbits from the normal control group were used for MR-DWI examination and measurement of the mean ADC value of normal liver.

RESULTS: At all time points, the liver pathological scores from the cell transplantation group were significantly lower than those in the transplantation control group (27.14 ± 1.46 *vs* 69.29 ± 6.16, 22.29 ± 2.29 *vs* 57.00 ± 1.53, 19.00 ± 2.31 *vs* 51.86 ± 6.04, $P = 0.000$). The mean ADC values of the cell transplantation group were significantly higher than the transplantation control group ((1.07 ± 0.07) $\times 10^{-3}$ mm^2/s *vs* (0.69 ± 0.05) $\times 10^{-3}$ mm^2/s, (1.41 ± 0.04) $\times 10^{-3}$ mm^2/s *vs* (0.84 ± 0.06) $\times 10^{-3}$ mm^2/s, (1.68 ± 0.04) $\times 10^{-3}$ mm^2/s *vs* (0.86 ± 0.04) $\times 10^{-3}$ mm^2/s, $P = 0.000$). The pathological scores of the cell transplantation group and transplantation control group gradually decreased. However, their mean ADC values gradually increased to near that of the normal control. At the end of the 1st wk, the mean ADC values of the cell transplantation group and transplantation control group were significantly lower than those of the normal control group [(1.07 ± 0.07) $\times 10^{-3}$ mm^2/s *vs* (1.76 ± 0.03) $\times 10^{-3}$ mm^2/s, (0.69 ± 0.05) $\times 10^{-3}$ mm^2/s *vs* (1.76 ± 0.03) $\times 10^{-3}$ mm^2/s, $P = 0.000$]. At any 2 time points, the pathological scores and the mean ADC values of the cell transplantation group were significantly different ($P = 0.000$). At the end of the 1st wk, the pathological scores and the mean ADC values of the transplantation control group were significantly different from those at the end of the 2nd and 4th wk ($P = 0.000$). However, there was no significant difference between the 2nd and 4th wk ($P = 0.073$ and 0.473, respectively). The coefficient of correlation between the pathological score and the mean ADC value in the cell transplantation group was -0.883 ($P = 0.000$) and -0.762 ($P = 0.000$) in the transplantation control group.

CONCLUSION: Tracking the longitudinally dynamic

change in the mean ADC value of the AHI liver may reflect hepatic injury reconditioning after allogeneic MBMC transplantation.

INTRODUCTION

Mononuclear bone marrow cells (MBMCs) are adult stem cells that have multi-potential differentiation capabilities and low immunogenicity. Direct allogeneic MBMC transplantation can repair various organ injuries such as hepatic injury without obvious immune rejection[1]. There are many studies evaluating the therapeutic effect of MBMC transplantation therapy for hepatic injury. However, few studies have been undertaken to determine the feasibility of magnetic resonance diffusion-weighted imaging (MR-DWI) to evaluate the therapeutic effect of MBMC transplantation therapy on models of acute hepatic injury (AHI).

MR-DWI is an atraumatic and functional imaging technique that is very sensitive to molecular diffusion from the random and microscopic translational motion of molecules known as Brownian motion[2]. MR-DWI can image the difference in microscopic diffusion movements of water molecules in various tissues. The most noticeable merit of MR-DWI is providing an apparent diffusion coefficient (ADC) value that can distinguish the microscopic diffusion movement of water molecules in different tissues *in vivo* by assigning numerical values[3-7]. When a tissue has a pathological change, the microscopic diffusion movement of water molecules changes and the mean ADC value should also change. It has been generally accepted that MR-DWI is valuable in qualitatively and quantitatively diagnosing cerebral ischemia in the hyper-inchoate period[8]. During recent years, many studies of hepatic pathological changes using MR-DWI have been reported[3-7]. These showed that MR-DWI of the liver seems promising for the characterization of many diseases (especially focal liver lesions) by calculating ADC values.

Similarly, after MBMC transplantation therapy, there should be a dynamic change in the microscopic diffusion movement of water molecules in hepatic tissue during the repair process of AHI. Thus, the aim of our study was to evaluate the contribution of the mean ADC value in reflecting the repair process of AHI after MBMC

transplantation therapy by comparison with the pathological change. The pathological mechanisms behind the dynamic change of the mean ADC value from injured hepatic tissue will be discussed in further detail.

MATERIALS AND METHODS

Material and instruments
Experiments were performed using 57 healthy, male New Zealand White rabbits weighing -2.5 kg with an average age of -2 mo. All animal work was conducted in accordance with the guidelines provided by the Institutional Animal Control and Utilization Committee. Five rabbits were randomly selected and used to isolate MBMCs. Dulbecco's modified Eagle's medium and fetal bovine serum were purchased from Gibco (New York, USA). Mononuclear cell separation medium was purchased from Tianjin Haoyang Company (Tianjin, China). D-Hanks solution, an electronic balance, 3% pentobarbital sodium, sterile surgical instruments, an optical microscope, cell separation tools and 2% trypan blue were supplied by the Second Xiangya Hospital. D-galactosamine (D-GaIN) was purchased from Jiangsu Nantong Tonglu Co. Ltd. (Nantong, China). Imaging was performed using a 1.5-Tesla Signa Twinspeed MR scanner (General Electron Medical Systems, USA) with a small diameter cylindrical brain radiofrequency coil.

Study groups and the establishment of AHI models
Acute hepatic injury was induced by D-galactosamine (D-GalN). D-GalN was dissolved in sterile 0.9% NaCl at a concentration of 10 g/100 mL (w/v). Forty-two rabbits were randomly selected to establish the AHI models. According to the weight of each rabbit, D-GalN solution was injected into the upper abdomen at a dosage of 1.0 g/kg. This amount was determined by preliminary experiments. The rabbits' weight, drug dosage and detailed administration times were recorded. The 42 AHI rabbits were randomly and equally divided into 2 groups: a cell transplantation group and a transplantation control group. Liver function assays were performed 24 h after drug administration and pathological examinations of liver sections taken during cell transplantation were performed to verify the establishment of the AHI model. The remaining 10 healthy rabbits were assigned to the normal control group, and only MR-DWI examination was performed for measurement of the normal liver mean ADC value.

Isolation and transplantation of MBMCs
After being sacrificed by air injection into the ear vein, the bodies of 5 healthy male rabbits were sterilized by incubation in 75% ethanol. Their limb bones were then isolated and bone marrow was repetitively flushed using D-Hanks solution containing heparin. Soft tissue clumps were removed with 100 pore filters. Recovered cell suspensions were aliquoted into multiple centrifuge tubes. MBMCs were then obtained through density gradient centrifugation. Cell number was counted and the viabil-

Table 1 Criteria for the acute injured liver pathological score

Score	Cellular necrosis and liver hyperplasia	Inflammatory cell infiltration in the area of the header and lobule	Injury of vascular endothelium and thrombus
0	Without	Without	Without
1	Spotty liver cell degeneration, necrosis without change of hepatic sinusoid and lobule shape	Infiltration area < 1/3 lobule or low inflammatory cell infiltration in the area of the header	Hyperemia of hepatic sinusoid or thrombus
2	Scattering severe liver cell degeneration, necrosis of whole lobule or unobvious liver cell hyperplasia	Infiltration area: 1/3-2/3 of lobule or comparatively wide-bound inflammatory cell infiltration	Injury of vascular endothelium or inflammatory cell infiltration under vascular endothelium
3	Large sheet liver cell degeneration and necrosis involving multiple lobules	Infiltration area: > 2/3 of lobule or inflammatory cells surround header	Extensive injury of vascular endothelium and thrombus

Obvious liver cell hyperplasia score: -2; Not obvious liver cell hyperplasia score: +2.

ity examined using trypan blue. The percentage of live cells had to be > 95%. The MBMCs were resuspended in D-Hanks solution at a density of 4×10^6/mL. Five milliliters of cell suspension was aliquoted into 10 mL glass syringes and kept in an incubator at 37℃ with 5% CO_2 for a short time before transplantation.

MBMC transplantations were performed between 24 and 48 h after establishing the AHI models. Each AHI rabbit from the cell transplantation group was properly anesthetized and immobilized on an operating table. The skin of the upper abdomen was prepared and sterilized, then the liver was exposed with a 2 cm cut beneath the xiphoid process. After slowly injecting 5 mL of the MBMC suspension at multiple sites in the liver, the needle was withdrawn and the wound sutured to stop bleeding. The wound was treated with penicillin and covered with a sterile dressing. After transplantation, each model rabbit was given intramuscular injections of penicillin in the buttocks over a 3-d period with normal feeding. In addition to 5 mL of D-Hanks solution substituted for the MBMC suspension, manipulations of the rabbits in the transplantation control group were the same as those in the cell transplantation group.

Pathological management of the liver
At the end of the 1st, 2nd and 4th wk after transplantation, 7 rabbits were randomly selected for MR-DWI examination of the liver at each time point in the cell transplantation group and transplantation control group. Then they were sacrificed for histological examination. Rabbit liver tissue blocks were fixed in 4% paraformaldehyde and were processed for paraffin embedding. Microsections were prepared and stained with hematoxylin and eosin, then examined under an optical microscope. The *criteria* for the liver pathological scores were established according to the characteristic of this study, histology activity index and previous studies[9] (Table 1). Six pathological microsections from each model rabbit were randomly selected to count the pathological scores by 2 experienced pathologists using a double-blind method. The sum of the pathological scores from 10 random high power fields (400 ×) from each microsection was regarded as the pathological score of that microsection.

MR-DWI protocol
Rabbits in the normal control group were subjected only to liver MR-DWI examination. At the end of the 1st, 2nd and 4th wk after transplantation, 7 rabbits from the cell transplantation group and from the transplantation control group were randomly selected at each time point for liver MR-DWI examination.

Rabbits were anesthetized and immobilized, then MR-DWI (axial) was carried out with a 1.5-Tesla Signa Twinspeed MR scanner equipped with a small diameter cylindrical brain radiofrequency coil. The scanning parameters of the MR-DWI included a spin echo echoplanar imaging series, b value 0 and 400 s/mm², repetition time 6000 ms, echo time 45 ms, all diffusion directions, frequency coding direction R/L, field of view 20 cm × 15 cm, number of excitations 8, thickness layer 3 mm, 0.5 mm space, and matrix 128 × 128.

ADC values were obtained using Function Software on a GE workstation. Three different regions of interest (ROIs) (-50 mm² each) were chosen in the liver parenchyma in every clear axial slice of each liver and their ADC values were measured. The mean value of the above was considered to be the ADC value of each liver.

Statistical analysis
Based on the mean ADC values from ROIs and the pathological scores, the differences between the various groups and time points, and the correlation between the mean ADC value and pathological score were assessed. The statistical significance was calculated by an independent sample *t*-test, analysis of variance and linear correlation using SPSS 11.0 software. P values < 0.05 were considered to indicate statistical significance.

RESULTS

Mean ADC values from each group and analysis
The mean ADC value of the normal control group was $(1.76 \pm 0.03) \times 10^{-3}$ mm²/s. At all time points after transplantation, the mean liver ADC values from the cell transplantation group were significantly higher than those of the transplantation control group ($P = 0.000$) (Table 2, Figure 1).

The mean liver ADC values from the cell transplantation group and transplantation control group gradually increased to near those of the normal control group over time. At the end of the 1st wk after transplantation,

Figure 1 Diffusion-weighted imaging of hepatic injury at different time point. A: At the end of the 1st wk after transplantation, the mean apparent diffusion coefficient value of the acute hepatic injury liver in the transplantation control was $(0.69 \pm 0.05) \times 10^{-3}$ mm^2/s; B: At the end of the 1st wk after transplantation, the mean apparent diffusion coefficient value of the acute hepatic injury liver in the cell transplantation group was $(1.07 \pm 0.07) \times 10^{-3}$ mm^2/s; C: At the end of the 2nd wk after transplantation, the mean apparent diffusion coefficient value of the acute hepatic injury liver in the transplantation control group was $(0.84 \pm 0.06) \times 10^{-3}$ mm^2/s; D: At the end of the 2nd wk after transplantation, the mean apparent diffusion coefficient value of the acute hepatic injury liver in the cell transplantation group was $(1.41 \pm 0.04) \times 10^{-3}$ mm^2/s; E: At the end of the 4th wk after transplantation, the mean apparent diffusion coefficient value of the acute hepatic injury liver in the transplantation control group was $(0.86 \pm 0.04) \times 10^{-3}$ mm^2/s; F: At the end of the 4th wk after transplantation, the mean apparent diffusion coefficient value of the acute hepatic injury liver in the cell transplantation group was $(1.68 \pm 0.04) \times 10^{-3}$ mm^2/s.

Table 2 Mean apparent diffusion coefficient values from the cell transplantation group and transplantation control group at each time point (mean $\pm$ SD) $\times 10^{-3}$ mm^2/s

Group	1st wk	2nd wk	4th wk

Transplantation control	0.69 ± 0.05	0.84 ± 0.06	0.86 ± 0.04
t		11.452	21.735	37.876
P		0.000	0.000	0.000

they were both significantly lower than those of the normal control group ($t = 23.612$, $P = 0.000$; $t = 52.416$, $P = 0.000$).

Between any 2 time points, the differences in the mean liver ADC values from the cell transplantation group were statistically significant ($P = 0.000$). At the end of the 1st wk after transplantation, the mean ADC values from the transplantation control group were significantly lower than those at the end of the 2nd and 4th wk ($P = 0.000$). However, there was no significant difference between the end of the 2nd and 4th wk ($P = 0.473$).

Pathological scores and analysis

The livers' pathological scores from the cell transplantation group and transplantation control group gradually decreased over time (Table 3, Figure 2). At all time

Figure 2 Pathological change of hepatic injury at different time point (Hematoxylin and eosin × 100). A: At the end of the 1st wk after transplantation, the pathological sections of the cell transplantation group showed extensive hepatic cell degenerations, few binucleate cells, abnormal hepatic cords and local inflammatory cell infiltration; B: At the end of the 1st wk after transplantation, the pathological sections of the transplantation control group showed obvious and extensive edema of hepatic cells, spotty hepatolysis, abnormal hepatic cords, local inflammatory cell infiltration and injured vascular endothelium; C: At the end of the 2nd wk after transplantation, the pathological sections of the cell transplantation group showed extensive edema of hepatic cells, abnormal hepatic cords, imperceptible inflammatory cell infiltration and few scattered binucleate cells. (Hematoxylin and eosin ×100); D: At the end of the 2nd wk after transplantation, the pathological sections of the transplantation control group showed obvious and extensive edema of hepatic cells, an increased number of binucleate cells and obvious inflammatory cell infiltration around the header; E: At the end of the 4th wk after transplantation, the pathological sections of the cell transplantation group showed scattering edema of the hepatic cells, hepatic cords, sinusoid near normal and hyperemia in local sinusoid; F: At the end of the 4th wk after transplantation, the pathological sections of the transplantation control group showed scattering and sheet edema of the hepatic cells, hyperemia in local sinusoids and an increased number of binucleate cells.

Table 3 Pathological scores from the cell transplantation group and transplantation control at each time point (mean ± SD)

Group	1st wk	2nd wk	4th wk
Cell transplantation group	27.14 ± 1.46	22.29 ± 2.29	19.00 ± 2.31
Transplantation control	69.29 ± 6.16	57.00 ± 1.53	51.86 ± 6.04
t		-17.619	-33.379	-13.444
P		0.000	0.000	0.000

points after transplantation, the pathological scores of the livers from the cell transplantation group were significantly lower than those from the transplantation control group ($P = 0.000$) (Table 3, Figure 2).

Between any 2 time points, the differences in pathological scores from the cell transplantation group were statistically significant ($P = 0.000$). At the end of the 1st wk after transplantation, the pathological scores from the transplantation control group were significantly higher than those at the end of the 2nd and 4th wk after transplantation ($P = 0.000$). However, there was no significant difference between the end of 2nd and 4th wk ($P = 0.073$).

Correlation analysis
When the *b* value was 400 s/mm^2, there was a significant negative correlation between the pathological score and

mean ADC value in the cell transplantation group and transplantation control group (r = -0.883, P = 0.000; r = -0.762, P = 0.000).

DISCUSSION

The efficacy of allogeneic MBMC transplantation therapy for AHI has already been proven[10,11]. Our results showed that the pathological changes such as cellular edema and inflammatory cell infiltration in the hepatic tissue of the transplantation control group were more obvious than those in the cell transplantation group at any similar time point. The pathological scores from the cell transplantation group were significantly lower than those of the transplantation control group at all time points. These results imply that allogeneic MBMC transplantation into an acute injury of the liver could improve hepatic injury reconditioning. This trend is similar to that found in other studies[10,11].

Because of the high resolution and sensitivity, recent studies have focused on *in vivo* real-time tracking and detecting the fate of transplanted stem cells with MRI[11,12]. However, there are few studies using MR-DWI to evaluate the therapeutic efficacy of MBMC transplantation for acute hepatic injuries.

When the b value is more than 300 s/mm², physiological factors such as perfusion have little influence on the mean ADC value of hepatic tissue[13-15]. Therefore, in our study we performed the MR-DWI examination of rabbit liver with 400 s/mm² for the b value, as determined by preliminary experiments.

Our study showed that at the end of the 1st wk after transplantation, the mean liver ADC values from the cell transplantation group and transplantation control group were much lower than the normal control group and both gradually increased to near the normal control over time. The correlation between the pathological scores and mean ADC values in the cell transplantation group or transplantation control group was significantly negative. This suggests the possibility of determining the reconditioning of an injured liver after allogeneic MBMC transplantation by tracking the longitudinally dynamic change of the mean ADC value from the AHI liver tissue.

By observing the pathological sections from the cell transplantation group and transplantation control group, we found the main pathological change was varying degrees of cytotoxic edema of the hepatocytes in all pathological sections. Therefore, we hypothesized that the pathological mechanism behind the change of the mean ADC value in hepatic tissue was mainly connected with cytotoxic edema of the hepatocytes in our study. Because the D-GalN injected into the peritoneal cavity was absorbed to injure the hepatic tissue causing Na-K pumps to be dysfunctional, the concentration of intracellular electrolytes increases. This causes water molecules inside cells to increase significantly, while extracellular water molecules decrease significantly. The cytotoxic edema of hepatocytes causes a decrease in gaps between hepatocytes, so that the space where extracellular water molecules can randomly move decreases. Therefore, the mean ADC value of hepatic tissue in the AHI model started to decrease[13-18] and was lower than that of the normal hepatic tissue.

In our study, the mean ADC values from the cell transplantation group and transplantation control group gradually increased over time and their pathological scores gradually decreased. The pathological sections showed their hepatic tissue injury gradually healed. At any similar time point, the mean ADC values from the cell transplantation group were significantly higher than those from the transplantation control group, and the pathological scores of the cell transplantation group were significantly better than those of the transplantation control group. According to previous studies[19-22] and our pathological sections, we hypothesized that there were 2 main hepatic reconditioning mechanisms causing these results. Firstly, the transplanted MBMCs promoted hepatic tissue reconditioning. Secondly, the hepatic injury caused the autologous hepatic reconditioning mechanism to activate. Because of the hepatic reconditioning, the hepatic cells' cytotoxic edema gradually decreased, and the number of extracellular water molecules and the space where extracellular water molecules could move randomly both gradually recovered. Thus, the macroscopic mean ADC values from the cell transplantation group and transplantation control group gradually increased[23,24]. Because of the 2 mentioned hepatic reconditioning mechanisms, the reconditioning in the cell transplantation group was faster than the transplantation control group without transplanted MBMCs. Therefore, at any time point, the mean ADC values from the cell transplantation group were significantly higher than those from the transplantation control group.

Of course, if there were extensive hepatolysis and necrosis, the number of extracellular water molecules and the space where extracellular water molecules randomly move in the AHI model liver would greatly increase. This would cause the mean ADC value of the hepatic tissue in the AHI model to exceed that of the normal hepatic tissue[25,26]. However, we did not observe this phenomenon in our study. Through observing pathological sections from all time points, we found sporadic scattering but no extensive hepatolysis and necrosis. The dominant pathological change in the hepatic tissue was varying degrees of hepatocellular cytotoxic edema. Perhaps the reason was that the dosage of D-GalN used was not high enough to cause extensive hepatolysis in our study. Considering the influence of hepatolysis on the ADC value of hepatic tissue, we chose many ROIs in all clear images from each AHI model's liver to measure ADC values. The mean ADC value was calculated from all ROIs and ADC values from each AHI liver. Thus, we could increase the accuracy of the ADC value of each AHI model's liver to the utmost extent.

In conclusion, when the *b* value is equal to 400 s/mm², tracking the longitudinally dynamic change of the mean ADC value of the AHI liver could determine injured he-

patic tissue reconditioning after allogeneic MBMC transplantation.

COMMENTS

Background
Many studies have proven that allogeneic mononuclear bone marrow cell (MBMC) transplantation therapy is an effective way to repair liver injury. The most notable merit of magnetic resonance diffusion-weighted imaging (MR-DWI) is the provision of an apparent diffusion coefficient (ADC) value that can distinguish the microscopic diffusion movement of water molecules in various tissues in vivo by assigning a numerical value. After MBMC transplantation therapy, there should be a dynamic change in the microscopic diffusion movement of water molecules in the hepatic tissue during the repair process of acute hepatic injury. Thus, the authors attempted to use MR-DWI to evaluate the contribution of the acute injured liver's mean ADC value in reflecting the repair process after MBMC transplantation therapy.

Research frontiers
Allogeneic MBMC transplantation therapy can accelerate the repair of liver injury. Many studies are focusing on the mechanisms behind the transplanted MBMCs repair of the liver injury. Recently, some researchers have been attempting to track and detect the fate of transplanted MBMCs with magnetic resonance imaging.

Innovations and breakthroughs
It has been proven that allogeneic MBMC transplantation can repair liver injury. There are many studies on evaluating the therapeutic effect of MBMC transplantation therapy for hepatic injury, but few studies have determined the feasibility of MR-DWI to evaluate the therapeutic effect of MBMC transplantation therapy on models of acute hepatic injury.

Applications
The results of this study suggest that the dynamic change of the mean ADC value of the acute hepatic injury model's liver can determine the injured liver's reconditioning after allogeneic MBMCs transplantation.

Terminology
MR-DWI is a functional imaging technique that can image the difference in microscopic diffusion movements of water molecules in various tissues. This technique only requires the examinee to lie still on the examining table while the examination is carried out. It is atraumatic and very safe.

Peer review
This article investigates the role of MR diffusion-weighted images for detection of acute liver injury following allogeneic bone marrow cell transplantation in a rabbit model. The conclusion reached confirmed the value and usefulness of this modality. The method is non-traumatic and easily performed. The methodology and design of the study was sound. This study is of significance in the field of bone marrow transplantation.

Abstract

AIM: To assess whether polymorphisms in *NOD2* and *ATG16L1* affect cytokine responses and mycobacterium avium subspecies paratuberculosis (MAP) survival in monocytes from Crohn's disease (CD) patients.

METHODS: Monocytes were isolated from peripheral blood of CD patients of known genotype for common single nucleotide polymorphisms of *NOD2* and *ATG16L1*. Monocytes were challenged with MAP and bacterial persistence assessed at subsequent time-points. Cytokine responses were assayed using a Milliplex multi-analyte profiling assay for 13 cytokines.

RESULTS: Monocytes heterozygous for a *NOD2* polymorphism (R702W, P268S, or 1007fs) were more permissive for growth of MAP ($P = 0.045$) than those without. There was no effect of *NOD2* genotype on subsequent cytokine expression. The T300A polymorphism of *ATG16L1* did not affect growth of MAP in our model ($P = 0.175$), but did increase expression of cytokines interleukin (IL)-10 ($P = 0.047$) and IL-6 ($P = 0.019$).

CONCLUSION: CD-associated polymorphisms affected the elimination of MAP from *ex vivo* monocytes (*NOD2*), or expression of certain cytokines (*ATG16L1*), implying independent but contributory roles in the pathogenesis of CD.

INTRODUCTION

Crohn's disease (CD) has been proposed as being the product of chronic inflammation caused by a dysfunctional interaction between the intestinal immune system and commensal gut microbiota[1]. The inflammation seen in CD is characterized by pronounced Th1 and Th17/23 responses involving the cytokines interleukin (IL)-1, IL-6, tumor necrosis factor (TNF)-α, IFN-γ[1-3], IL-23 and IL-17[4-6].

Although the commensal intestinal microflora appear to play an important role in the etiology of CD, certain bacterial species have also been implicated as putative causal agents of CD. These include Pseudomonas maltophilia[7], Chlamydia trachomatis[8], Bacteroides fragilis[9] Yersinia species[10], adherent invasive *Escherichia coli* (*E. coli*)[11] and Mycobacterium avium subspecies paratuberculosis (MAP)[12]. The role of MAP in the etiology of CD is unclear. However, MAP causes chronic intestinal inflammation in ruminants (Johne's disease) with similar pathophysiology to CD[13] and it has been reported as a causative agent of regional enteritis with similarities to CD in a number of monogastrics, including two primate species[14,15]. MAP has also been cultured from both resected tissue[16] and peripheral blood of CD patients[17], and has been visualized inside macrophages from CD patients[18]. Meta-analyses of epidemiological studies confirm an association of MAP with CD[19,20], although it remains unknown whether MAP is pathogenic in humans, or whether this association reflects a defective host immune system permissive for the survival of MAP.

Twin and family studies have demonstrated a significant genetic component to the development and progression of CD[21-23]. Linkage analysis, candidate gene approaches and, most recently, genome-wide association studies (GWAS) have identified over 30 risk genes for CD[24-26], many of which are involved with bacterial recognition (e.g. *NOD2*) or processing and elimination of bacteria through the autophagy pathway (e.g. *IRGM*[27] and *ATG16L1*[25]).

In this study, we developed an *ex vivo* monocyte model to assess the impact of the CD-associated single nucleotide polymorphisms (SNPs) in *NOD2* (rs2066842, P268S; rs2066844, R702W; and 1007fs, rs2066847) and *ATG16L1* (rs2241880, T300A) on cytokine responses to the putative pathogen MAP. MAP can survive and replicate within phagocytic cells, and consequently we also evaluated the impact of these polymorphisms on the intracellular persistence of MAP. The use of *ex vivo* monocytes allows functional evaluation of SNPs associated with CD, and may provide a more realistic insight into the impact that genotype has on CD compared to studies which involve abrogation of protein expression or whole gene deletion.

MATERIALS AND METHODS

Patient recruitment

Patients for the current study were selected from a New Zealand population-based Caucasian inflammatory bowel disease (IBD) cohort recruited to investigate genetic and environmental factors that contribute to IBD etiology[28-32]. Inclusion criteria for the current study were a confirmed diagnosis of CD and negative MAP status as ascertained by IS900 PCR in peripheral blood[28].

The genotype combinations and patient phenotype information are detailed in Table 1. Briefly, the potential impact of *ATG16L1* and *NOD2* polymorphisms were assessed separately. For analysis of *ATG16L1*, monocytes were collected from CD patients who had a wild-type *NOD2* genotype and were homozygous for either the major (G) allele (*n* = 6) or minor (A) allele (*n* = 6) of *ATG16L1* 1138G > A (rs2241880). Conversely, for experiments evaluating the effect of *NOD2* genotype, monocytes were collected from patients who were *ATG16L1* 1138G homozygotes and were heterozygous for one of the three *NOD2* SNPs previously associated with CD; 2104C > T (R702W, rs2066844), 2722G > C (G908R, rs2066845), or 3020insC (1007fs, rs2066847), and were heterozygous for the background variant 802C > T (P268S, rs2066842). A total of 12 patients were recruited, 6 carried the polymorphisms described, and 6 were homozygous at these *NOD2* loci (Table 1). None of the patients included in this study had the SNPs rs13361189 and rs4958847. These SNPs are in complete linkage disequilibrium with a 20 kb insertion/deletion polymorphism which has been shown to alter expression of the autophagy gene *IRGM*[33].

Preparation of monocytes from peripheral blood

Blood (40 mL) was drawn into heparin tubes (Sigma-Aldrich), divided into 20 mL aliquots, and 15 mL of Phosphate Buffered Saline (PBS) was added to each. Ficoll-Paque™ PREMIUM (10 mL) (GE Healthcare Bio-Sciences Uppsala, Sweden) was layered under each aliquot and the samples centrifuged (1000 × *g*, 20 min). Mononuclear cells collected from the interface were added to 30 mL of PBS, centrifuged (350 × *g*, 10 min) and resuspended in 15 mL of PBS. In order to standardize the number of monocytes used in experiments, mononuclear cells were enumerated using a hemocytometer and a 200 μL aliquot was analyzed on a Beckman Coulter FC500 MPL flow cytometer to determine the percentage of monocytes based on forward and side scatter characteristics. After centrifugation (350 × *g*, 10 min), cells were resuspended in RPMI medium 1640 supplemented with 10% fetal bovine serum (FBS) (Invitrogen, Carlsbad, CA, USA) to a concentration of 4 × 10^5 monocytes/mL. Then 500 μL of this preparation were plated per well in a 24-well tissue culture plate (Nunc, Roskilde, Denmark). Monocytes were left to adhere for 1 h in a humidified incubator at 37℃ with 5% CO₂ and non-adherent cells were removed by washing three times with 1 mL of room temperature (RT) PBS.

[1]SNPs located upstream (5′) to *IRGM*; [2]Non-invasive clinical index used to assess disease activity in patients with Crohn's disease. A score of $\geq$ 7 indicates active disease.

Adherent monocytes were incubated overnight in 500 μL of RPMI 1640/10% FBS.

Culture of MAP

MAP strain Dominic (ATCC 43545) was inoculated into 10 mL volumes of Difco™ Middlebrook 7H9 broth (BD Biosciences, Sparks, MD, USA) supplemented with 10% v/v BBL™ Middlebrook OADC Enrichment (BD Biosciences), 0.05% v/v Tween 80 (Sigma-Aldrich, St Louis, MO, USA) and 2 mg/mL Mycobactin J (Allied Monitor, Fayette, MO, USA) and grown at 37℃. A standard growth curve of MAP was obtained by measuring the optical density at 600 nm (OD_{600}) of an aliquot of bacterial suspension during the log phase, which had been passed repeatedly through a 25-gauge needle, and enumerating the bacteria by plating on the same medium supplemented with 1.5% agar (Invitrogen, Carlsbad, CA, USA).

Monocyte challenge experiments

Bacteria were grown to mid log phase (approximately 1×10^8 cells/mL, with reference to previously obtained growth curve data) and harvested by centrifugation ($13\,000 \times g$, 5 min). Bacteria were resuspended in 500 μL of PBS and passed ten times through a 25-gauge needle to break up clumps of cells. One 500 μL aliquot of MAP was heat-inactivated at 90℃ for 5 min and then both aliquots were diluted to 4×10^6 cells/mL in RPMI 1640/10% FBS. The optimal temperature and incubation time for heat-inactivation had been previously confirmed by plating heat-treated MAP cells onto agar. Growth medium was removed from the monocytes and 500 μL of the MAP suspension was added to each well. Challenge experiments were performed in triplicate for each time-point/genotype combination. After incubation for 4 h at 37℃, 5% CO_2, the supernatant

was removed and stored at -80℃ as a zero time-point sample for cytokine assays. Monolayers were washed three times with 1 mL of PBS to remove extracellular bacteria. A zero time-point lysate to assess bacterial uptake and persistence was removed by incubating 500 μL of a 0.1% sodium deoxycholate (Sigma-Aldrich, St Louis, MO, USA) solution with the monolayer for 5 min at RT. Lysates were centrifuged ($13\,000 \times g$, 5 min) and resuspended in 200 μL of PBS. Serial dilutions of the lysates were made with PBS and 50 μL were spread on to a Middlebrook agar plate. The agar plates were left to incubate for four weeks at 37℃ before counting MAP colonies. Subsequent samples at time-points of 24, 48, 72 and 96 h were similarly processed.

Confirmation of genotypes of study participants

ATG16L1 genotypes were confirmed at recruitment by direct DNA sequencing of PCR products. Briefly, genomic DNA was extracted from fresh peripheral blood using GenElute™ (Sigma-Aldrich, St Louis, MO, USA) spin columns according to manufacturer's protocols. A 480 bp fragment containing the *ATG16L1* 1138G > A SNP was amplified for DNA sequencing from patient genomic DNA using the following primers: 5'-CCACAG-GTTAGTGTGCAGGA-3' (forward primer) and 5'-CA-CAGCTGACAGAGCCAAAA-3' (reverse primer). PCR was carried out in a 20 μL volume containing 1 μL of genomic DNA, 0.3 μmol/L of each primer, 200 μmol/L dNTPs, 0.75 mmol/L $MgCl_2$, 1 × TAQ-Ti reaction buffer (Thermo Fisher Scientific, Pittsburgh, PA, USA) and 0.25 U of TAQ-Ti DNA polymerase (Thermo Fisher Scientific). After an initial denaturation step of 94℃ for 2 min, 35 cycles were performed at 94℃ for 30 s, 60℃ for 30 s and 72℃ for 30 s. Five microlitres of each PCR product was checked on 1% agarose. Another 5 μL aliquot was

Figure 1 Effect of *ATG16L1* T300A variant on mycobacterium avium subspecies paratuberculosis numbers. Time course of mycobacterium avium subspecies paratuberculosis (MAP) growth in the context of the *ATG16L1* 1138 G > A variant. Monocytes were derived from subjects homozygous for either *ATG16L1* allele and carrying *NOD2* wild-type alleles (*n* = 6 for each group). MAP growth is expressed as colony forming units (cfu).

Figure 2 Effect of *NOD2* variants on mycobacterium avium subspecies paratuberculosis numbers. Time course of mycobacterium avium subspecies paratuberculosis (MAP) growth in the context of *NOD2* genetic variation. Monocytes were derived from subjects homozygous for the *ATG16L1* 1138G allele and with/without *NOD2* genetic variants (*n* = 6 for each group). MAP growth is expressed as colony forming units (cfu).

purified with Exo-SAP-IT (USB Corporation, Ohio, USA) and sequenced using BigDye chemistry (Applied Biosystems, California, USA) on an ABI 3730 Genetic Analyzer (Foster City, California, USA). The *NOD2* and *IRGM* genotypes of study participants were established as previously described using allele-specific PCR and pre-designed TaqMan SNP genotyping assays, respectively[34,35].

Multiplex cytokine analysis

Cytokine analysis was performed using a 13-plex MILLIPLEX™ MAP human cytokine kit according to manufacturer's recommendations (Millipore) for the following: IFNγ, IL-10, IL-12p40, IL-12p70, IL-17, IL-1b, IL-2, IL-4, IL-5, IL-6, IL-8, TNFα, TNFβ.

Statistical analysis

Data from the five time-points were analyzed by repeated measures ANOVA, with fixed effects for time (as categorical variable) and random effects for subject i.e. genotype. For cytokine analyses, where readings were below the threshold for detection (3.2 pg/mL) they were included as 3.2 pg/mL. Results were considered significant at $P \leqslant$ 0.05.

Ethical considerations

Informed written consent was obtained from all participants in this study and ethical approval for this work was granted by the Upper South B Regional Ethics Committee of New Zealand.

RESULTS

Bacterial persistence ATG16L1

Numbers of MAP increased from a mean $\log_{10}$ colony forming units (cfu) of 4.24 at 0 h to 5.08 at 96 h for the AA genotype, and from log10 cfu of 4.47 to 5.29 for the GG genotype (Figure 1). There was no evidence (T-testing)

for the effect of the *ATG16L1* T300A polymorphism on MAP numbers at any individual time-point, or overall (pooled time-points ANOVA, *P* = 0.175) (Figure 1).

NOD2

MAP also grew in the monocytes with different *NOD2* genotypes, from a mean $\log_{10}$cfu of 4.30 at 0 h to 5.12 for the cells homozygous for the major alleles of the *NOD2* variants, and from $\log_{10}$cfu of 4.58 to 5.42 for cells heterozygous for any *NOD2* variant (Figure 2). There was no significant effect (*T*-testing) of *NOD2* genotype on MAP numbers at any individual time-point. However, analysis of all time-points indicated that monocytes heterozygous for a *NOD2* polymorphism were more permissive for growth of MAP (ANOVA, *P* = 0.045) (Figure 2).

Multiplex cytokine panels

Thirteen cytokines were evaluated from *ex vivo* monocyte supernatants using a MILLIPLEX™ MAP human cytokine kit. Each time-point/genotype combination was assayed in triplicate. All assays passed quality controls and r^2 values for the standard curves were $\geqslant 0.99$.

Of the thirteen cytokines analyzed in the multiplex format, only four, IL-10, IL-6, IL-8 and TNFα, had measurable responses above the detection threshold (> 3.2 pg/mL) on the multiplex ELISA platform used. Where samples had values of < 3.2 pg/mL, they were considered to be 3.2 pg/mL for statistical purposes.

Effect of ATG16L1 genotype

Cytokine expression results are shown in Figure 3. The AA genotype of *ATG16L1* was associated with greater expression of cytokines IL-10 and IL-6 in response to challenge with MAP (*P* = 0.047 and *P* = 0.019, respectively). No significant difference was seen between *ATG16L1* genotypes AA and GG for expression of either IL-8 or TNFα (*P* = 0.758 and *P* = 0.289, respectively) (Figure 3).

Figure 3 Effect of the *ATG16L1* T300A polymorphism on expression of cytokines following challenge with mycobacterium avium subspecies paratuberculosis. Cytokine concentrations are in pg/mL. Results are the means (and standard error of the mean) of triplicate samples from patients in Table 1. *P*-values are derived from repeated measures ANOVA testing for the effect of genotype on cytokine expression. Fixed effects for time (categorical variable) and *ATG16L1* genotype, random effect for subject. IL: Interleukin; TNF: Tumor necrosis factor.

Effect of NOD2 genotype

Cytokine expression changes for IL-10, IL-6, IL-8 and TNFα by cells of different *NOD2* genotypes are shown in Figure 4. In general, the presence of a *NOD2* polymorphism resulted in a trend of lower expression of these four cytokines throughout the time-course, compared to monocytes without *NOD2* variants.

However, this effect was not significant, with P-values of 0.56, 0.32, 0.41 and 0.97 for cytokines IL-10, IL-6, IL-8 and TNFα, respectively (Figure 4).

DISCUSSION

Numerous genetic association studies have indicated a strong role for *NOD2* and *ATG16L1* in the etiology of CD. However, functional studies have yet to fully elucidate whether, and to what extent, polymorphic variation in these genes affects bacterial clearance and inflammation in CD. Models of gene/environment interaction have mostly used epithelial or monocyte cell lines in vitro with bacterial pathogens such as Salmonella typhimurium that are not generally associated with CD. Also, the use of gene silencing or ablation techniques in these models may assist our understanding of the function of these genes, but may not be representative of the effects of SNPs which have been associated with CD. In this study we developed an *ex vivo* cellular model using monocytes from CD patients and a

putative CD pathogen, MAP, in order to assess the effect of SNPs in *NOD2* and *ATG16L1* on bacterial survival and subsequent inflammatory response.

NOD2 is located in the cytoplasm, and plays an important role in cellular responses to bacterial infection[36] through recognition of muramyl dipeptide (MDP), a subunit of bacterial peptidoglycan (PGN)[37]. Furthermore, the R702W, G908R and 1007fs *NOD2* variants, which confer susceptibility to CD, have been shown to impair responses to the bacterial antigen lipopolysaccharide[38].

We found the effect of *NOD2* polymorphisms appeared to be primarily on bacterial persistence/growth, with heterozygosity at R702W or 1007fs making monocytes from CD patients significantly more permissive to growth of MAP. Indeed, a recent study has observed that these variants are associated with an impairment of monocyte phagocytosis and the development of bacteremia in intensive care unit patients[39]. Despite the increased bacterial load, no differences were seen in subsequent cytokine responses for the different host *NOD2* genotypes. Whilst there has been no prior published research with respect to MAP in this type of model of CD, the functional effects of *NOD2* SNPs have been examined for adherent invasive *E. coli* (AIEC). No differences were found in the persistence or growth of AIEC in monocytes from patients who were heterozygous or homozygous for the minor allele of *NOD2* variants R702W, G908R and 1007fs compared to

Figure 4 Effect of *NOD2* polymorphisms on expression of cytokines following challenge with mycobacterium avium subspecies paratuberculosis. Cytokine concentrations are in pg/mL. Results are the means (and standard error of the mean) of triplicate samples from patients in Table 1. *P*-values are derived from repeated measures ANOVA testing for the effect of genotype on cytokine expression. Fixed effects for time (categorical variable) and *NOD2* genotype, random effect for subject. IL: Interleukin; TNF: Tumor necrosis factor.

NOD2 major allele homozygotes[40]. It has also been shown that in peripheral blood mononuclear cells from CD patients, homozygosity for R702W does not affect the cytokine response to Gram-negative (*Helicobacter pylori*) bacterial peptidoglycan[41], although homozygosity for the 1007 fs mutation did. In our study we recruited no 1007fs homozygotes and only a single 1007 fs heterozygote so were unable to make any direct comparisons with this previous study. Comparative studies for a broader range of bacterial species in *ex vivo* cells from patients who are homozygous for these *NOD2* SNPs will help clarify the role of this genotype in disease pathogenesis.

Both MAP and AIEC are capable of intracellular survival and growth in monocytes and macrophages, and it appears that the presence of *NOD2* polymorphisms may influence their respective intracellular survival and growth in different ways[42].

Autophagy has been identified as a mechanism for clearing intracellular pathogens, and two autophagy genes, *ATG16L1* and *IRGM*, have been associated with CD[25,27]. In our study, we investigated the effect of the *ATG16L1* T300A polymorphism, and controlled for genotypic variation in *IRGM* (Table 1). *ATG16L1* T300A (rs2241880; 1138G > A) is a common non-synonymous SNP where the G major allele confers greater disease risk and results in a threonine-to-alanine substitution at amino acid position 300 of the *ATG16L1* protein (T300A). This SNP appears to account for all of the disease risk conferred by

this locus[43], and functionally, this polymorphism has been proposed to contribute to defective macrophage killing of bacteria[44]. This assertion is supported by the results of two in vitro studies. Kuballa *et al*[45] found that the T300A variant impaired handling and autophagy of Salmonella within human epithelial cells, and Lapaquette *et al*[46] showed that siRNA knockdown of *ATG16L1* led to loss of autophagy of intracellular AIEC bacteria by HeLa cells. Transfection of affected HeLa cells with wild-type *ATG16L1* restored autophagic function, whereas transfection with the T300A polymorphic form did not. In contrast, *ATG16L1* T300A had no effect on the survival of either S. typhimurium or group A Streptococcus in mouse embryonic fibroblasts[47]. Although direct comparison of different model systems is complex and potentially misleading, our results with MAP in *ex vivo* monocytes generate the question as to whether the T300A polymorphism of *ATG16L1* affects autophagic clearance of certain intracellular bacteria as profoundly as indicated by knockdown or silencing models of gene function.

In our study, the T300A polymorphism was associated with significant changes in production of the cytokines IL-6 and IL-10 in response to bacterial challenge with MAP. These two cytokines are components of the Th1 (pro-inflammatory) and Th2 (modulatory) pathways of inflammation, respectively, and it is likely that CD results from an imbalance between these two pathways. It is tempting to speculate that the relative levels of the two

cytokines that were induced are indicative of an imbalance, but extrapolating from a very specific model to describe a complex disease state would be misleading and clearly further comparative work is required in this area in disease-relevant models.

Our study is the first to investigate the effect of *NOD2* and *ATG16L1* genotype on the response of *ex vivo* human monocytes to the putative CD pathogen MAP. Although our results are preliminary and need to be replicated in a larger sample, they provide novel insights into the effect of disease-associated SNPs in innate immunity genes on detection, handling, and elimination of bacteria, and ultimately CD pathogenesis. Our observations indicate that *NOD2* SNPs R702W, P268S, or 1007 fs impair the elimination of MAP yet do not impact on cytokine production. They may, therefore, increase susceptibility to prolonged intracellular bacterial infection. Conversely, the *ATG16L1* T300A polymorphism significantly alters the expression of certain Th1 and Th2 cytokines after MAP challenge, but does not seem to affect the autophagic clearance of this putative CD pathogen.

ACKNOWLEDGMENTS

COMMENTS

Background

Polymorphisms of the genes *NOD2* and *ATG16L1* have been associated with susceptibility to Crohn's disease (CD). These genes are important for an effective innate immune response against potential bacterial pathogens [such as *Mycobacterium avium* subspecies *paratuberculosis* (MAP)] which may trigger or exacerbate inflammation. Monocytes from CD patients of known genotype were used to determine whether polymorphisms in *NOD2* and *ATG16L1* alter cytokine responses and bacterial survival following challenge with MAP.

Research frontiers

Previous research has investigated the role of polymorphisms in *NOD2* and *ATG16L1* in various model systems. In general, these have used gene silencing strategies that may not realistically reflect the biological consequences of single nucleotide changes in these genes, or model bacterial pathogens that have little relevance to CD. None have reported the functional consequences of the naturally occurring single nucleotide polymorphisms using patient-derived cells and bacteria such as MAP that have been implicated in CD etiology.

Innovations and breakthroughs

The authors findings indicate that monocytes heterozygous for a *NOD2* polymorphism were more permissive for the intracellular growth of MAP than those without. However, these polymorphisms did not affect subsequent cytokine expression. The T300A polymorphism of *ATG16L1* did not affect growth of MAP in our monocyte model but did result in increased expression of certain cytokines - interleukin (IL)-10 and IL-6.

Applications

By understanding how naturally occurring disease-related polymorphisms of *NOD2* and *ATG16L1* influence bacterial survival and also the production of inflammatory mediators, the authors may gain insight into the contribution of these genetic changes to the function of the host innate immune system. Development of this model system that utilizes patient cells with known single nucleotide changes in key CD-susceptibility genes will provide another research tool to assist better understanding of disease pathogenesis related to bacterial handling.

Terminology

NOD2 (CARD15) - nucleotide oligomerization domain 2 - is a cytosolic pattern recognition receptor that recognizes muramyl dipeptide, a component of bacterial peptidoglycan. Polymorphisms in *NOD2* have been associated with altered susceptibility to CD in many genetic studies. *ATG16L1* - autophagy-related 16-like 1 - is a key component of the autophagic apparatus that is involved with uptake and digestion of intracellular bacteria. The T300A polymorphism of *ATG16L1* has also been associated with altered susceptibility to CD. MAP is an intracellular bacterium that has been cited in several studies as a putative causal agent of CD.

Peer review

This is a very well-designed and well-written study, with interesting and important scientific merit. Not just simple polymorphism descriptions, but their effect on human monocyte cytokine production and intracellular pathogen survival were examined with a very functional methodology. Their *ex vivo* model is much closer to the real pathogenesis of CD than any earlier one. Using the author's concept, more descriptive polymorphism analysis of CD and other diseases may be placed into functional analysis.

Abstract

AIM: To study, whether the association of Schatzki rings with other esophageal disorders support one of the theories about its etiology.

METHODS: From 1987 until 2007, all patients with newly diagnosed symptomatic Schatzki rings (SRs) were prospectively registered and followed. All of them underwent structured interviews with regards to clinical symptoms, as well as endoscopic and/or radiographic examinations. Endoscopic and radiographic studies determined the presence of an SR and additional morphological abnormalities.

RESULTS: One hundred and sixty-seven patients (125 male, 42 female) with a mean age of 57.1 ± 14.6 years were studied. All patients complained of intermittent dysphagia for solid food and 113 (79.6%) patients had a history of food impaction. Patients experienced symptoms for a mean of 4.7 ± 5.2 years before diagnosis. Only in 23.4% of the 64 patients who had endoscopic and/or radiological examinations before their first presentation to our clinic, was the SR previously diagnosed. At presentation, the mean ring diameter was 13.9 ± 4.97 mm. One hundred and sixty-two (97%) patients showed a sliding hiatal hernia. Erosive reflux esophagitis was found in 47 (28.1%) patients. Twenty-six (15.6%) of 167 patients showed single or multiple esophageal webs; five (3.0%) patients exhibited eosinophilic esophagitis; and four (2.4%) had esophageal diverticula. Four (7%) of 57 patients undergoing esophageal manometry had non-specific esophageal motility disorders.

CONCLUSION: Schatzki rings are frequently associated with additional esophageal disorders, which support the assumption of a multifactorial etiology. Despite typical symptoms, SRs might be overlooked.

INTRODUCTION

Lower esophageal (Schatzki) rings are found in 6%-14% of routine barium radiographs[1-4]. Even though most Schatzki rings (SRs) are considered to be the most common cause of episodic dysphagia for solids and food impaction in adults[5,6]. Since their first

description in 1944[7], the etiology and pathogenesis of the SRs has remained obscure and little is known about their association with other structural and functional abnormalities of the esophagus. Theories about their origin include congenital, anatomical, and inflammatory factors as the most likely events that lead to a circular constriction of the esophagogastric junction[8-12].

Therefore, the aims of this study were: (1) to investigate whether the lower esophageal (Schatzki) ring is associated with other esophageal disorders; (2) to determine whether dysphagia is due to the presence of SRs or additional esophageal disorders; and (3) to determine whether one of the pathogenic theories could be supported.

MATERIALS AND METHODS

From 1987 until 2007, all patients with newly diagnosed symptomatic SRs were prospectively registered and followed. The diagnosis of SRs was based on the results of radiographic and/or endoscopic studies. In 119 patients, radiographic and endoscopic studies showed an SR. Fourteen patients had only radiographic and 34 only endoscopic studies. All patients underwent structured interviews to assess clinical symptoms.

Evaluation of symptoms

At the initial investigation and at each follow-up visit, structured interviews were performed. Questions concentrated on clinical symptoms such as the occurrence of food impaction, and frequency of dysphagia, heartburn and regurgitation (less than once a week, weekly, daily, or several times a day).

Radiographic studies

Radiographic studies ($n = 133$) were performed by senior staff radiologists using the prone-oblique, full-column technique. To distend the lower esophagus maximally, patients were asked to take a deep breath and to perform a Valsalva maneuver during the course of swallowing. Diagnosis of SR (Figure 1A) was based on the presence of a fixed, symmetric, thin (< 4 mm) structure, which intersected the esophagus perpendicular to its long axis, at the squamocolumnar junction[6,13]. The diameter of the lower esophageal ring was measured directly from the radiographic picture in the area of the narrowing. An esophageal web is defined as a thin (< 2 mm) eccentric membrane that can occur anywhere in the esophagus[14]. A sliding hiatal hernia was diagnosed when a pouch was visible between the tubular esophagus and the diaphragmatic narrowing (length of the pouch ≤ 3 cm = small hernia, > 3 cm = large hernia)[15]. Diagnosis of diverticulum was based on the presence of a pouch in the esophagus (Zenker's diverticulum: pouch in the pharyngoesophageal area; midesophageal diverticulum: pouch in the mid esophagus; epiphrenic diverticulum: pouch just proximal to diaphragm)[14].

Endoscopic procedures

Upper gastrointestinal endoscopy ($n = 153$) was performed

Figure 1 Radiographic (A) and endoscopic (B) image of the lower esophageal (Schatzki) ring.

by senior staff gastroenterologists using a variety of upper gastrointestinal endoscopes (Olympus, Hamburg, Germany), which varied in caliber from 8.5 to 9.5 mm. The endoscopic mucosal appearance determined the presence or absence of esophagitis as well as further morphological abnormalities of the upper gastrointestinal tract. SR (Figure 1B) was defined as a thin, symmetric, mucosal structure located at the esophagogastric junction[3]. A sliding hiatal hernia was diagnosed when gastric mucosa extended for > 1.5 cm above the diaphragm[16]. An esophageal web was defined as a thin (no more than 1.5 mm), eccentric membrane, located above the esophagogastric junction[14]. The degree of esophagitis was classified into four stages according to Savary and Miller[17]. If there were mucosal alterations in addition to reflux esophagitis, biopsies were taken from the esophagus. The presence of ≥ 20 eosinophils per high-power field in the histopathological examination was used as the criterion to diagnose eosinophilic esophagitis[18].

Esophageal manometry

To exclude an esophageal motility disorder, 57 patients underwent esophageal manometry. Stationary esophageal manometry was performed with the use of a low-compliance capillary perfusion system (Mui Scientific, Mississauga, ON, Canada), using an eight-channel multi-lumen catheter with a 4.5-mm diameter. The four distal openings were 1 cm apart and the four proximal openings were 5 cm apart. Both sets were radially oriented. The manometric tracings were recorded by a computer polygraph system (Standard Instruments, Karlsruhe, Germany). Manometry was performed using a stationary pull-through method with the catheter introduced transnasally into the stomach. Manometry was carried out and interpreted according to the recommendations of the American Society of Gastroenterology[19]. Non-specific motor disturbance was defined as contractile abnormalities that are insufficient to establish a diagnosis of achalasia, diffuse esophageal spasm or typical scleroderma-like esophageal dysfunction[19,20].

Statistical analysis

Numerical variables are expressed as mean ± SD, counts

Figure 2 Clinical symptoms of 167 patients with Schatzki rings.

Figure 3 Frequency of dysphagia in relation to the ring size.

and ranges. Categorical variables are described using frequencies and percentages. Statistical significance of the differences between groups was assessed by Mann-Whitney U test for metric variables, by the Mantel-Haenszel χ^2 test for trends for ordered categorical variables and by Pearson χ^2 test for binary variables. A two-tailed P value < 0.05 was considered statistically significant. The analysis was performed using SPSS for Windows version 15.0 (SPSS, Chicago, IL, USA).

RESULTS

Demographic data and esophageal imaging at initial investigation

One hundred and sixty-seven patients (124 male, 43 female) with a mean age of 57.1 ± 14.6 years were studied. Patients experienced symptoms for a mean of 4.7± 5.2 years before diagnosis. Sixty-four (38.3%) of the 167 patients had endoscopic and/or radiological examinations before their first presentation to our clinic, but only in 15 (23.4%) of these patients was SR was previously diagnosed. In 35 (87.5%) of the 40 patients who received an endoscopic examination, the SR had not been diagnosed, and in 14 (70%) of the 20 patients who underwent radiological examinations, the diagnosis could not be determined.

One hundred and twelve patients received radiological and endoscopic examinations at their initial presentation to our hospital. Endoscopy or a barium swallow accurately diagnosed the SR in all 112 patients in whom both methods were used. In the 34 patients who were only examined by endoscopy, the correct diagnosis was made in all cases, whereas the diagnosis was only made in 14 (66.7%) of the 21 patients who underwent radiological examinations first. In the seven patients without an initial radiological diagnosis, the SR was identified on subsequent endoscopy.

Clinical findings at initial investigation

Clinical symptoms at initial presentation are shown in Figure 2. All patients complained of intermittent dysphagia for solid food: 66 patients (39.5%) less than once per week, 58 (34.7%) weekly, 14 (8.4%) daily, and 29 (16.4%) with every meal. One hundred and thirteen

[1]In two patients, erosive esophagitis as well as esophageal webs could be diagnosed. SR: Schatzki ring.

(79.6%) of the 167 patients had a history of food impaction. Forty (23.9%) patients described regurgitation and 87 (52.1%) complained of occasional heartburn.

The diameter of the lower esophageal ring was evaluated in 126 patients undergoing radiographic studies, and in 27 patients, endoscopic estimation was used with open biopsy forceps (7 mm) being the reference standard. In 14 patients, no measurement was performed. At initial presentation, the mean ring diameter was 13.9 ± 4.97 mm (range: 5-25 mm). Eighty-three (54.2%) of 153 patients had a ring size ≤ 13 mm, and 15 (9.8%) had a ring size > 20 mm. There was no correlation between ring size and frequency of dysphagia (P = 0.29, Figure 3). Also, sex (P = 1.0) and age ≤ 40 or > 40 years (P = 0.93) had no influence on the frequency of dysphagia. Demographic data, ring size and clinical findings of all patients with Schatzki rings are shown in Table 1.

Additional findings and their influence on symptoms

A sliding hiatal hernia was found in 162 (97%) of 167

Figure 4 Additional structural abnormalities of the esophagus.

patients (*n* = 28 radiographic examinations, *n* = 29 endoscopic examinations, *n* = 105 radiographic and endoscopic examinations). One hundred and nineteen patients exhibited a small hernia and 43 had a large one. data, ring size and clinical findings of patients with Schatzki rings and additional erosive esophagitis, and /or esophageal webs are demonstrated in Table 1.

Further structural and functional abnormalities of the esophagus were diagnosed in 87 (52%) of 167 patients (Figure 4). The most frequent additional endoscopic finding was erosive reflux esophagitis, which was found in 47 (28.1%) patients; 40 (85.1%) of whom had stage I esophagitis, whereas seven (14.9%) presented with stage II and III, and none with stage IV. All but one patient with reflux esophagitis showed a hiatal hernia. Twenty-six (15.6%) of 167 patients showed single (*n* = 15) or multiple ≥ 2 (*n* = 11) esophageal webs, and four (2.4%) patients had esophageal diverticula. Two of the four patients with esophageal diverticula showed a Zenker's diverticulum, and in two patients, midesophageal diverticula were diagnosed. Four patients exhibited erosive reflux esophagitis in addition to esophageal webs. Five (16.6%) of the 30 patients in whom biopsies of the esophagus were taken exhibited histopathological signs of eosinophilic esophagitis. All but one patient complained of food impaction, whereas the frequency of dysphagia varied in this subgroup of patients (two patients, every meal; one patient, daily; and two patients, less than once per week).

Four (7%) of 57 patients undergoing esophageal manometry showed pathological results (two with non-specific motor disturbance, one with low contraction amplitudes, and one with diffuse esophageal spasm). Patients with an additional motility disorder of the esophagus showed a higher frequency of dysphagia than patients without (*P* = 0.03), although there was no difference in ring diameter (patients with motility disorders, 13.53 ± 3.6 mm; patients without, 13.7 ± 4.1 mm; *P* = 0.92).

The mean ring diameter in patients with additional esophageal webs (12.3 ± 3.8 mm) was smaller than in patients without webs (14.2 ± 5.1 mm) (*P* = 0.057). However, there were no differences in the frequency of dysphagia in patients with further structural abnormalities of

the esophagus (sliding hernia, *P* = 0.1; erosive esophagitis, *P* = 0.48; and esophageal webs, *P* = 0.15) in comparison to the patients with an SR alone.

DISCUSSION

The lower esophageal SR is a common clinical finding and the most common cause of intermittent dysphagia, especially after consumption of solid food[6,21]. However, little is known about its etiology, its pathogenesis, or its association with other esophageal disorders. In addition, the clinical importance of associated disorders has not been described.

In our study, we were able to show that symptomatic SRs cannot always be diagnosed with a single imaging technique, and that the SR is not a unique entity. It is frequently associated with other esophageal disorders, such as hiatal hernias, reflux esophagitis and esophageal webs. In addition, ring size and most other structural abnormalities do not predict symptoms. In contrast, dysphagia was more common in patients with an additional motility disorder, and food impaction was the most common presentation in patients with eosinophilic esophagitis. Whether the frequent association with hiatal hernias and inflammatory esophagitis plays a pathogenic role remains unclear, but a multifactorial etiology is suspected.

In the present study, we confirmed previous observations that patients with symptomatic SRs complain about episodic dysphagia for solid food (mean duration 4.7 years prior to diagnosis), and more than two-thirds develop food impaction. Despite the typical clinical presentation, there was a significant diagnostic delay. Prior to presentation to our hospital, diagnosis of an SR was made in less than half of symptomatic patients; a surprisingly low number of patients. One of the difficulties in detecting lower esophageal rings might be related to the fact that the radiographic and endoscopic visualization depends on proper distension of the esophagogastric region beyond the caliber of the ring, which is often not accomplished[22]. This is especially true for wider rings with a luminal diameter > 13 mm[23]. In such instances, the radiographic examination has been shown to be superior to endoscopy in detecting lower esophageal rings[24]. In contrast, the present study could show a better diagnostic yield of endoscopy as compared with a barium swallow. This is most likely related to our special attention to membranous structures. Our findings suggest that a second imaging study should be performed in patients with typical clinical presentation if the first study fails to make the diagnosis of SR.

The current investigation showed that SRs are not a unique entity, but associated with additional esophageal disorders in 57% of symptomatic patients. Besides the nearly unanimous association with a hiatal hernia[2,24], we found a common association with reflux esophagitis and esophageal webs. In addition, esophageal diverticula were occasionally diagnosed. However the presence of additional structural abnormalities of the esophagus did not change the clinical presentation. Dysphagia was not more common in these patients. Even in patients with addition-

al esophageal webs, whose ring diameters were generally smaller, dysphagia was not more common. These findings suggest that the ring diameter alone may not be responsible for the observed symptoms.

In contrast, dysphagia was more frequently observed in patients with non-specific motility disorders, regardless of ring size, which suggests that the motility disorder may be responsible for the symptoms. Therefore, manometry should be considered in patients with wide ring diameters and symptoms of dysphagia. In addition, we found that intermittent bolus obstructions were a very frequent finding in those patients with an additional diagnosis of eosinophilic esophagitis, and clinicians should keep this clinical entity in mind. Therefore, the presence of an SR should not deter the endoscopist from taking esophageal biopsies in a patient in whom eosinophilic esophagitis remains a possibility. In fact, ring-like structures are common in eosinophilic esophagitis, and we became aware of this entity only a decade ago. Although an association of eosinophilic esophagitis and SRs has been previously suggested, it is not known if this is caused by shared clinical and endoscopic findings, or rather a shared pathogenesis[25,26]. Common clinical features might also explain the frequent coexistence of esophageal webs and eosinophilic esophagitis in our study. However, it is not clear if the additional esophageal disorders occur by chance, or if there is a common pathogenesis. The etiology of SRs remains obscure, and several theories about their etiology and pathogenesis exist. One of these is the developmental theory that holds that the presence of a congenital mucosal ridge at the esophagogastric junction is a rather frequent anatomical phenomenon that could fold in a valve-like fashion to create the ring[3,8]. Arguing against this, is the fact that the majority of symptomatic individuals were over the age of 40 years in the present and previous studies[27]. In the so called plication theory, Stiennon has postulated that longitudinal shortening in the presence of a hiatal hernia may lead to folding of redundant esophageal mucosa[11]. Consistent with this theory is the fact that most of the patients in the present study had a sliding hiatal hernia. However, it still remains unclear why some patients with a hernia develop an SR and others do not. Therefore, the plication theory is unlikely to be the only cause for the development of SRs. Currently, the inflammation theory with gastroesophageal reflux as the main cause of inflammation, is the most popular theory[28], and consequently, some authors have recommended an antireflux regimen to prevent symptomatic recurrence[29,30]. Others have pointed out that, if less than two-thirds of patients are found to have pathological gastroesophageal reflux[31,32], it might not be the main pathogenic factor. Similar to the latter findings, even if reflux esophagitis were one of the most frequent associated esophageal disorders in the present study, less than one-third of all investigated patients showed endoscopic signs of erosive esophagitis, and only half complained of occasional heartburn, which suggests that gastroesophageal reflux is not the only cause for the development and narrowing of the SR. Therefore, we assume that the etiology of SR is multifactorial.

In conclusion, SRs might be overlooked in endoscopic and/or radiological examinations. Therefore, in patients with a typical clinical presentation, a second diagnostic imaging should be considered. Other esophageal disorders are frequently observed and should be kept in mind; most of which do not alter clinical presentation. Non-specific motility disorders and eosinophilic esophagitis should be considered, especially when frequent dysphagia or food impaction is present. With regard to the etiology of SRs, the present findings suggest a multifactorial genesis, which supports the inflammation theory as well as the plication theory.

COMMENTS

Background
The Schatzki ring (SR) is the most common cause of episodic dysphagia to solid food. Nevertheless its etiology and pathogenesis remains unknown and little is known about its association with other structural and functional abnormalities of the esophagus. Theories regarding its origin include inflammatory, developmental, and congenital factors as the most likely events leading to a circular constriction of the esophagogastric junction. In addition, the clinical importance of associated disorders has not been described.

Research frontiers
Currently, the 'inflammation theory' with gastroesophageal reflux disease (GERD) as the main cause of inflammation, is the most popular theory. However, prospective studies have documented an association with GERD in less than two thirds of patients, suggesting that additional pathogenic factors might be responsible for the development of the SR.

Innovations and breakthroughs
It is known that SRs are associated with hiatal hernias and reflux esophagitis, whereas this is the first study that could show the frequent association of SRs with additional esophageal disorders, most of which do not alter clinical presentation. Nonspecific motility disorders and eosinophilic esophagitis should be considered, especially when frequent dysphagia or food impactions are present, respectively. In regards to the etiology of SRs the present findings suggest a multifactorial pathogenesis. Furthermore, despite the typical clinical presentation SRs might be overlooked in endoscopic and /or radiological examinations.

Applications
SRs are frequently associated with other esophageal disorders. These should be sought, especially when frequent dysphagia or food impaction is the presenting symptom. SRs might be overlooked on radiographic or endoscopic examinations, therefore, a second diagnostic modality should be used when suspicion remains high.

Terminology
"Stiennon's plication theory", postulated that longitudinal shortening in the presence of an hiatal hernia may lead to folding of a redundant esophageal mucosa, creating the SR.

Peer review
The manuscript reads very well and flows nicely. The conclusions are supported by the data and the limitations are well addressed. In addition, the study is novel and the topic chosen is original.

Abstract

AIM: To study the relationship between upper esophageal sphincter (UES) relaxation, peristaltic pressure and lower esophageal sphincter (LES) relaxation following deglutition in non-dysphagic subjects.

METHODS: Ten non-dysphagic adult subjects had a high-resolution manometry probe passed transnasally and positioned to cover the UES, the esophageal body and the LES. Ten water swallows in each subject were analyzed for time lag between UES relaxation and LES relaxation, LES pressure at time of UES relaxation, duration of LES relaxation, the distance between the transition level (TL) and the LES, time in seconds that the peristaltic wave was before (negative value) or after the TL when the LES became relaxed, and the maximal peristaltic pressure in the body of the esophagus.

RESULTS: Relaxation of the LES occurred on average 3.5 s after the bolus had passed the UES and in most cases when the peristaltic wave front had reached the TL. The LES remained relaxed until the peristaltic wave faded away above the LES.

CONCLUSION: LES relaxation seemed to be caused by the peristaltic wave pushing the bolus from behind against the LES gate.

INTRODUCTION

Swallowing dysfunction with esophageal food retention is a common problem in an adult population with hiatus hernia. Most articles reporting lower esophageal sphincter (LES) studies depict LES relaxation caused by neurogenic mechanisms[1] in gastroesophageal reflux (GER). The ability of the LES to allow esophagogastric transit after deglutition has received little attention. Efforts have been made to prove that LES relaxation is triggered by a neurogenic reflex following deglutition[2], that the LES and the upper esophageal sphincter (UES) relaxations are simultaneous events and that the cervical portion of the vagus nerve mediates inhibitory and excitatory changes in LES pressure[3]. In a recent study, a biodynamic approach was proposed for LES opening when GER takes place in hiatal hernia and the gastric wall tension pulls open the LES[4]. As long ago as 1978[5], LES was suggested to be a biodynamic gate which is forced to open when a bolus is propelled by esophageal peristalsis. We decided to further

challenge the idea of LES as an esophagogastric pressure zone dependent on complex neuro-humoral factors.

The recent development of high-resolution solid-state manometry (HRM) systems with closely spaced circumferential pressure sensors has made it possible to display simultaneous recordings along the entire esophagus in color-coded pressure plots (Figure 1) and has dramatically improved the diagnostic assessment of esophageal function and disease. With conventional esophageal manometry, simultaneous events in the UES and LES have been difficult to display especially since deglutition often will displace the pressure sensors due to shortening of the esophagus. The HRM technique enables, therefore, a unique possibility to study UES and LES pressure during the entire deglutition period and independent of any sphincter dislocation. In order to find out if there is an interplay between pulling forces and LES opening, the aim was therefore to study the relationship between UES relaxation, peristaltic pressure and LES relaxation following deglutition using the HRM technique.

MATERIALS AND METHODS

The HRM system (ManoScan 360 A-100, ManoView analysis software ver. 2.0.1 from Sierra Scientific Instruments Inc., Los Angeles, CA) uses a solid state catheter (Ø 4.2 mm) with closely spaced circumferential pressure sensors with 1 cm intervals over 36 cm. The HRM catheter was passed transnasally and positioned to be recording simultaneously from the hypopharynx, through the body of the esophagus, to the stomach. The catheter was calibrated outside the patient before and immediately after the investigation using the thermal compensation option in the software.

We performed a prospective HRM study in 10 adult patients (median age 45 years, range 38-63 years; 7 women, 3 men) who were admitted to an esophageal laboratory for suspected dyspepsia. It can be claimed that our patients with dyspepsia are not representative for studies of normal LES and UES function. Dyspepsia is a diagnosis without organic lesion and with diffuse symptoms predominantly in the gastric region. The patients did not have any symptoms of dysphagia and reflux, they were free of medication, and the presence of hiatus hernia was excluded at gastroscopy and HRM. It is therefore regarded that confounding factors have been excluded in the study material.

The investigation comprised ten swallows of a 10 mL water bolus in a supine position. The characteristics analyzed were: (1) the time lag between UES relaxation and LES relaxation; (2) the LES pressure at time of UES relaxation; (3) the duration of LES relaxation; (4) the length of the esophagus between UES and LES; (5) the distance between the transition level (TL) and the LES; (6) time in seconds that the peristaltic front wave was before (negative value) the TL or after the TL when the LES pressure dropped to nadir; and (7) the maximal peristaltic pressure in the esophagus. The eight best readable swallow recordings in each subject (a total of 78 swallows) were calculated upon, and the mean values of each individual item are given.

TL is defined as an esophageal zone with striated-to-smooth muscle fiber transition[6] showing as a short loss of peristaltic pressure (Figure 1).

RESULTS

Individual values and the mean of all values are presented in Table 1. The LES relaxed on average 3.5 s after the UES had opened. The mean LES pressure was 26 mmHg at time of UES opening. The mean duration of LES remaining relaxed was 6.7 s. The mean length of the esophagus between UES and LES was 26 cm. The mean distance between the TL and the LES was 18 cm, corresponding to on average 72% of the total length. The mean time that the peristaltic wave was before (negative value) the TL or after the TL when the LES opened was -0.5 s. The mean maximum pressure of the peristaltic wave was 138 mmHg. The time lag between UES and LES relaxation was never over 6.4 s. The individual LES pressure, as well as the maximum peristaltic pressure, varied remarkably from swallow to swallow (Table 1).

DISCUSSION

This study shows quite clearly that the LES becomes relaxed several seconds (on average 3.5 s) after the water bolus has passed the UES. This corresponds with findings by Nguyen *et al*[7] when impedance and manometry techniques were used. They found a mean latency between bolus entry into the esophagus and LES relaxation of 3.6 s. This is also in agreement with the esophageal transit time (3.8 s) as assessed with the biomagnetic technique[8]. The LES pressure did not change in our study at time of UES opening. Therefore, it seems unlikely that LES relaxation is triggered by the start of deglutition.

It seems as if opening of the LES coincides with the peristaltic wave front reaching close to the TL, which is an esophageal level with striated-to-smooth muscle fiber transition. Reasonably, this depends on the premise that the distal end of the water bolus has reached the LES, that the water bolus fills up the esophageal lumen between TL and LES, and that the peristaltic wave pushes the water bolus from behind against the LES gate. Only the combination of manometry and impedance measurement or the combination of HRM and radiography can find out whether LES relaxation and opening take place at the moment when the bolus arrives at the LES. In an impedance study of LES opening and bolus transit, it was found that LES relaxation seemed to be modulated by the bolus transit and occurred predominantly upon arrival of the bolus in the distal esophagus[7]. This discovery clashes with the findings by Pandolfino *et al*[9] who used a combined impedance/manometry technique. They showed that LES relaxation did not necessary coincide with bolus passage or LES opening. The hydrostatic pressure in the esophageal body necessary to open the LES in an upright position, as shown in a combined manometric and radiographic study from 1978[5], was approximately the same as the LES pressure before opening. If no deglutition activ-

Different esophageal events, mean values of ten recordings in ten subjects, and mean values of all ten subjects. A: Time lag between relaxing of UES and LES; B: LES pressure when UES opened; C: Duration of LES remaining relaxed; D: Esophagus length; E: Distance between TL and LES; F: Time in seconds that the peristaltic wave was before (minus value) or after the TL when the LES relaxed; G: maximum pressure of the peristaltic wave. F: Female; M: Male. UES: Upper esophageal sphincter; LES: Lower esophageal sphincter; TL: Transition level defined as the zone when the striated muscle layer transitions into the smooth muscle layer.

ity took place and a contrast medium was instilled into the esophagus, the LES opened when the hydrostatic pressure exceeded the resting LES pressure and closed again when the hydrostatic pressure in an upright position fell short of the LES pressure. Deglutition caused the LES to relax and open when the peristaltic wave reached the upper level of the infused contrast medium. These different findings indicate that the LES is a barrier which is forced to open by the peristaltic pressure. In the clinic, this would explain why, for instance, patients with achalasia cardia or with lack of esophageal peristalsis do not have any LES relaxation after deglutition.

If we look upon the LES as a gate that will be pulled open, it is of interest to compare the pressure of the LES and the maximum pressure of the peristaltic wave in the distal esophagus. In this study, the peristaltic pressure was five times stronger than the LES pressure. HRM and conventional manometry are claimed to be the same in their measurement of LES resting pressure[10]. It has been shown that the longitudinal esophageal muscle is contracted during the peristaltic activity[11] which will decrease esophageal wall compliance. Certainly, the peristaltic force displays an interaction between the longitudinal and circular esophageal muscles[12], and a compliance decrease of the esophageal wall will facilitate bolus transit. The reason for the deglutition-induced pressure overload in the esophageal body is therefore of importance, in order to overcome the stiffness of the esophageal wall. In the study by Babaei *et al*[12], it was

even proposed that the longitudinal esophageal smooth muscle has an important role in the relaxation of LES. In our study, the LES remained relaxed as long as the peristaltic wave was present in the esophagus. This indicates that there is a close interplay between LES function and peristaltic activity. It is reasonable to believe that the LES will be pulled open when the pulling direction is either from the esophagus or from the stomach[12].

In conclusion, LES opening seems to be caused by the peristaltic wave pushing the bolus from behind against the LES gate. Therapeutic attention in patients with dysphagia of non-stricture origin should therefore be focused on esophageal motility function rather than on drugs affecting LES pressure.

COMMENTS

Background
Swallowing problems with food retention in the gullet are present in at least 8% of an adult population. For accurate treatment, it is of importance to know whether transit from the esophagus to the stomach can be treated with drugs aimed at opening the lower esophageal sphincter (LES) or whether transit is due to dynamic properties of gullet muscles. So far, it has been claimed that LES is triggered to open by a neurogenic reflex from the upper esophageal sphincter (UES).

Research frontiers
The newly developed high-resolution manometry (HRM) system is a technical innovation and breakthrough for the understanding of dynamic esophageal events, meaning the interplay between esophageal motility and esophageal sphincter relaxations.

Innovations and breakthroughs
The esophageal HRM probe was used in ten non-dysphagic patients with dyspepsia in order to study the time relationship between UES and LES relaxation and to study where the peristaltic wave front was located when the LES relaxed after deglutition of a 10 mL water bolus in the supine position. These simultaneous activities have previously not been possible to study with conventional esophageal manometry.

Applications
The LES was shown to relax 3.5 s later than the UES after deglutition which is the average time it takes a water bolus front to reach the LES. The LES remained relaxed on average 6.8 s; that is until the propulsive force had faded away. The peristaltic front wave reached a level close to the transition level (TL), either 2 s before or 1 s after the TL.

Terminology
Esophagus-gullet. Dyspepsia-a diagnosis without any specified organic lesion and with diffuse symptoms from the gastric region. Dysphagia-swallowing difficulties. HRM-a pressure catheter with a 36 cm long segment of sensors spaced 1 cm apart giving simultaneous pressure information of sphincter and muscular activity from a total of 432 locations from UES to LES. The pressure can be displayed as a color plot offering visual information of the esophagus and its sphincters very similar to an anatomic picture. LES-lower esophageal sphincter. Manometry-pressure measurement. Smooth muscle-a muscle under autonomic, non-volitional control. Striated muscle-a muscle under volitional control. TL, transition level-the level in the esophagus between the upper striated muscle level and the lower smooth muscle level which is located about 7 cm distal of the UES.

Peer review
More emphasis on why HRM is a great technique and the knowledge it provides compared to conventional esophageal manometry has now been given in the Methods section. The reason why we believe that dyspepsia patients can be regarded as normal people with regard to esophageal transit studies is addressed in the Materials section. The previous conclusion, regarding older theories of a neurogenic reflex causing LES relaxation, has been omitted and basic data for this are given in the discussion.

Abstract

AIM: To observe the effects of sargentgloryvine stem extracts (SSE) on the hepatoma cell line HepG-2 *in vitro* and *in vivo* and determine its mechanisms of action.

METHODS: Cultured HepG-2 cells treated with SSE were analysed by 3-(4,5-Dimethyl-thiazol-2-yl)-2,5-Diphenyltetrazolium bromide and clone formation assay. The cell cycle and apoptosis analysis were conducted by flow cytometric, TdT-Mediated dUTP Nick End Labeling and acridine orange/ethidium bromide staining methods, and protein expression was examined by both reverse transcriptase-polymerase chain reaction and Western blotting. The pathological changes of the tumor cells were observed by haematoxylin and eosin staining. Tumor growth inhibition and side effects were determined in a xenograft mouse model.

RESULTS: SSE treatment could not only inhibit HepG-2 cell proliferation in a dose- and time-dependent manner but also induce apoptosis and cell cycle arrest at the S phase. The number of colonies formed by SSE-treated tumor cells was fewer than that of the controls ($P < 0.05$). SSE induced caspase-dependent apoptosis accompanied by a significant decrease in Bcl-xl and Mcl-1 and elevation of Bak expression ($P < 0.05$). Tumor necrosis factor α in the xenograft tumor tissue and the liver functions of SSE-treated mice showed no significant changes at week 8 compared with the control group ($P > 0.05$). Systemic administration of SSE could inhibit the HepG-2 xenograft tumor growth with no obvious toxic side effects on normal tissues.

CONCLUSION: SSE can induce apoptosis of HepG-2 cells in vitro and in vivo through decreasing expression of Bcl-xl and Mcl-1 and increasing expression of Bax.

INTRODUCTION

Although significant progress has been made over the past decades in cancer prevention and treatment, the development of effective treatment regimens remains one of the greatest challenges in the area of cancer che-

motherapy. Recently, plant-derived natural products are becoming important as anti-cancer derivatives, including vincristine, vinblastine, paclitaxel and camptothecin, which are invaluable contributions of nature to modern medicine[1-4]. However, the quest to find novel therapeutic compounds for cancer treatment is a never-ending venture, and diverse plant species are being studied to identify prospective anti-cancer agents[5,6]. Sargentgloryvine stem of *Sargentodoxa cunneata* (Oliv.) has been widely used as an ingredient in Chinese medicine according to the Chinese herbal medicine principles for thousands of years in the treatment of several kinds of diseases, such as chronic pelvic cavity inflammation, rheumatism and appendicitis. Sargentgloryvine stem extract (SSE) as a chemotherapeutic adjuvant can enhance the efficacy and ameliorate the side effects of cancer chemo- or radio-therapy. Because SSE has been used in Chinese herbal medicine as a bioactive constituent in a complex herbal mixture, an important question is whether its biological activity can be largely or exclusively ascribed to one or more individual compounds present in this herb. To address this question, we prepared SSE and studied its effects. Our previous research showed that SSE possesses potent anticancer activities[7]. However, the molecular mechanisms underlying the anticancer effects of SSE are poorly understood and need to be elucidated. To identify potential anticancer mechanisms of SSE in human hepatocellular carcinoma (HCC), the molecular effects of SSE on HepG-2 cells were examined. Downregulation of the two anti-apoptotic Bcl-2 family proteins Bcl-xl and Mcl-1 may be responsible for antiproliferative and cell apoptotic effects of SSE on HepG-2 cells. Meanwhile, HepG-2 xenograft nude mice treated systemically with SSE were also monitored in tumor growth inhibition and toxicity *in vivo*. The purpose of this study was to observe the effects of SSE on the hepatoma cell line HepG-2 *in vitro* and *in vivo*, and preliminarily analyse its mechanisms of action.

MATERIALS AND METHODS

Materials

SSE was extracted from 10 g dried powder of *Sargentgloryvine* stem in a rotary shaker with 200 mL of 50 mL/L ethanol at 60℃ for 24 h. The extract was then filtered, concentrated using a rotary evaporator to remove the solvent, and finally lyophilised in a freeze-dryer to obtain crude freeze-dried powder. The same batch of SSE was used in all studies in order to keep the results reliable. The powder was dissolved in DMEM culture medium at a stock solution of 5 g/L for further use. The hepatoma cell line HepG-2 was preserved in our laboratory. Specific pathogen-free male athymic BALB/c nude mice of 6-7 wk of age with a body mass of 20-30 g were purchased from the Animal Experimental Centre of the Fourth Military Medical University. HepG-2 cells were cultured in DMEM supplemented with 100 mL/L foetal calf serum, 100 kU/L penicillin, 0.1 g/L streptomycin and 250 μg/L amphotericin B, incubated at 37℃ in a humified atmosphere of

50 mL/L carbon dioxide. The primers for PT-PCR detection of transcript are described in Table 1.

Methods

Cell viability and clone formation assay: HepG-2 and ECV304 cells (control cells) were cultured in 96-well plates at a density of 3×10^8 cells/L with 100 μL per well in DMEM. Cells were treated with 1.5, 15, 45, 60 and 90 mg/L SSE for 6, 12, 24, 36 and 48 h or medium only as a control (DMEM-treated) group. After incubation, cell proliferation was detected by 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, and cytotoxicity was studied with a commercial assay kit (Beyotime Biotechnology, China) following the manufacturer's instructions. Absorbance was measured at 570 nm using the Bio-Rad 550 microplate reader. The protracted cell growth curves and the inhibition of cell growth were calculated based on the absorbance (A) value as follows: inhibitory rate = $(1-A_{treated}/A_{control group}) \times 100\%$. For the colony formation assay, a total of 3×10^2 HepG-2 and control cells, and ECV304 tumor cells were plated in 75 mm culture dishes and treated with SSE at a concentration of 30 mg/L. After incubation for an additional 10-14 d, the cells were fixed with methanol and stained with 1 g/L crystal violet (Sigma, USA), and colonies of > 50 cells were manually counted. All experiments were performed in independent triplicates.

Cell apoptosis and cycle analysis: For apoptosis, HepG-2 cells and ECV304 cells were treated with SSE at concentrations of 15, 30 or 60 mg/L, or no drug as a control for 24 h. The cells were harvested and washed twice with cold PBS and resuspended in binding buffer. FITC-labelled annexin V and propidium iodide (PI) were added and incubated for 10 min at room temperature, and the cell suspensions were immediately analysed by flow cytometry. For cell cycle detection, the cells treated with 45 mg/L SSE for 24 h were fixed with 700 mL/L cold ethanol and resuspended in phosphate-buffered saline containing 20 mg/L PI and then analysed for PI fluorescence intensity by flow cytometry to measure the cellular DNA content. The HepG-2 cells were suspended in 75 mm plates and treated with SSE at a concentration of 45 mg/L for 24 h or an equal volume of culture medium as the control. The total volume of each well was one mL. The cells were collected, and a TdT-Mediated dUTP Nick End Labeling assay (Keygen Biotech Co., Ltd., Nanjing, China) was performed as suggested by the manufacturer to detect the incorporation of labelled nucleotides into DNA. At least 300 cells were counted under a light microscope, and apoptotic cells were identified. All experiments were performed in triplicate. The negative control cells were set up with no TdT enzyme added, and positive control cells were pretreated with DNase during the staining process.

Apoptosis quantification and Δψm detection: HepG-2 cells were cultured in 6-well plates and treated with SSE at a concentration of 45 mg/L for 24 h. Acridine orange/ ethidium bromide staining was performed following the

Table 1 The primers for detection of transcript

Gene	Sense sequence 5'-3'	Antisense sequence 5'-3'

Blf-1	ATGAGTGATCCAGAAACCAG	TTAATCCTCTTCTGAACTTTCA

manufacturer's instructions (Keygen Biotech Co., Ltd., Nanjing, China). Acridine orange is a vital dye and can stain both live and dead cells. Ethidium bromide can only stain the cells that have lost membrane integrity. Live cells appear uniformly green, while early apoptotic cells stain green but contain bright green dots in the nuclei as a consequence of chromatin condensation and nuclear fragmentation. Late apoptotic cells incorporate more ethidium bromides and therefore stain orange and show condensed and often fragmented nuclei. At least 300 cells were counted under a fluorescence microscope to quantify apoptosis. All experiments were performed independently in triplicate. Additionally, HepG-2 cells were harvested following treatment with SSE at 45 mg/L for 12 and 24 h. After washing twice with PBS, 1×10^6 cells were incubated with 10 mg/L of Rh123 (Sigma, USA), a cationic lipophilic fluorochrome that is taken up by mitochondria in proportion to the $\Delta\psi m$, for 30 min at 37℃. Fluorescence intensities were determined by flow cytometry (Becton Dickinson Inc., USA).

Gene expression study: Total RNA from 1×10^6 SSE-treated (45 mg/L for 24 h) HepG-2 cells and control cells were extracted by Trizol™ reagent (Invitrogen, USA), and 1 μg total RNA was used to synthesise cDNA with the superscript first-strand synthesis kit (Takara BioTechnology, Dalian, China) following the manufacturer's instructions. One microliter cDNA was used to amplify the specific genes by reverse transcriptase-polymerase chain reaction (RT-PCR). To normalize cDNA loading, the *β-actin* gene was also amplified from each sample. RT-PCR was performed with the primers listed above. HepG-2 cells treated with SSE (45 mg/L for 24 h) and control cells were harvested by suspension in lysis buffer. The cell extracts were clarified by centrifugation, and the protein concentrations were determined using the Bio-Rad protein assay kit. Each protein extract (25 μg) was electrophoresed on a 100 g/L SDS-polyacrylamide gel, transferred to a membrane and blocked in 50 g/L skimmed milk in tris buffered saline-Tween 20 for 1 h at room temperature. Membranes were probed with anti-Bax, -Bak, -Bcl-xl, -Mcl-1, -caspase-8, -caspase-9, -cytochrome C and -β-actin antibodies overnight at 4℃. Primary antibodies were removed, and the blots were extensively washed with TBS-T three times. Blots were then incubated for 1 h at 37℃ with the secondary antibodies in 10 g/L skimmed milk dissolved in TBS-T. After removal of the secondary antibody, blots were extensively washed and developed using the enhanced chemiluminescence kit in the dark (Santa Cruz Biotechnology). The primary antibodies used in this experiment were monoclonal mouse anti-human Bax, Bcl-xl, Mcl-1, cytochrome C, caspase-8 and-9 (latter two from Abcam, UK) and β-actin and polyclonal goat anti-human Bak (Santa Cruz). Goat anti-mouse and rabbit anti-goat IgG coupled to horseradish peroxidase (Santa Cruz Biotechnology) were used as secondary antibodies for detection of protein expression.

Solid tumor growth assay: Athymic BALB/c nude mice were housed in laminar flow cabinets under specific pathogen-free conditions. All animal studies were performed in compliance with the Institutional Guidelines of the Fourth Military Medical University. Aliquots of 1.0×10^6 HepG-2 cells were suspended 1:1 in PBS and subcutaneously inoculated into the right flank of each mouse. When 300 mm^3 tumors were observed, the mice were randomly assigned to two groups ($n = 5$). The mice of the treatment group received 18 mg/kg SSE suspended in 50 μL DMEM, and the mice of the control group were treated with an equal volume of DMEM *via* vena caudalis injection every 2 d for 14 d. The tumor volume was measured each time before SSE administration with callipers using a standard formula as follows: width^2 × length × 0.5. An average tumor volume per mouse was used to calculate the group mean tumor volume ± SD ($n = 5$). Mice were sacrificed 24 h after the last administration of SSE to harvest the tissues of tumors and the heart, liver, spleen, kidneys and lungs. All tissues were then fixed in 40 g/L paraformaldehyde overnight and sectioned, and haematoxylin and eosin staining was performed to identify the toxicity of SSE *in vivo*. The supernatants of nude mice xenografts were preserved at -70℃. After protein concentration determination, tumor necrosis factor α (TNFα) levels were detected by ELISA in tumor tissues from nude mice according to the manufacturer's instructions. Liver function (aspartate aminotransferase and alanine aminotransferase) and kidney function (creatinine) were also detected.

Statistical analysis

All statistical analyses were performed using SPSS13.0. Data were expressed as mean ± SD. Comparisons among all groups were performed with the one-way ANOVA analysis of variance test. Differences were considered significant at $P < 0.05$.

Figure 1 Effects of sargentgloryvine stem extract on HepG-2 viability *in vitro* (MTT assay). HepG-2 and ECV304 cells were treated with sargentglo-ryvine stem extract (SSE) at five concentrations in five different time points. MTT assay showed that cell proliferation inhibition rates were enhanced with increased SSE concentration and treatment time in HepG-2 cells but not in ECV304 cells. Experiments were repeated in triplicate.

RESULTS

Proliferation and colony formation

SSE-treatment at concentrations of 1.5 and 15 mg/L showed no significant growth inhibition of HepG-2 cells, but higher SSE concentrations of 30, 60 and 90 mg/L significantly inhibited the proliferation of the HepG-2 cells (Figure 1). At an SSE concentration of 30 mg/L, the inhibition rate (mean ± SD) increased with treatment time; the rates were 5.0 ± 1.4, 13.7 ± 2.7, 23.3 ± 6.0, 34.2 ± 5.3 h and 53.7 ± 3 at 6, 12, 24, 36 and 48 h, respectively ($P < 0.05$). All concentrations showed no obvious growth inhibition on ECV304 cells. Additionally, the number of colonies of SSE treated HepG-2 cells was lower than that of the control cells (261 ± 16 *vs* 492 ± 21, Student's *t* test, $P < 0.05$), but no difference was observed on the plates of ECV304 cells. Finally, SSE treatment at 45 mg/L for 24 h significantly increased the proportion of S phase HepG-2 cells from 17.8 ± 1.9 to 63.3 ± 3.3 ($P < 0.05$), but decreased the proportion of G_0/G_1 phase and G_2/M phase cells.

SSE-induced apoptosis

SSE treatment of HepG-2 cells increased the apoptosis rates in a dose-dependent manner (0.2%, 4.7%, 9.5%, 28.7%, as analysed by flow cytometry) (Figure 2). Western

blotting analysis showed that SSE treatment (45 mg/L) for 24 h significantly increased caspase-9 but not caspase-8 cleavage (Figure 3), indicating that SSE induces apoptosis through the intrinsic pathway. Additionally, SSE-treated HepG-2 cells lost $\Delta\psi$m, as indicated by a decrease in Rh-123 fluorescence (Figure 4), which was significantly weaker than that of the control cells. Consistent with the results of fluorescence microscopy above, Western blotting analysis demonstrated that the expression of cytochrome C in plasmosin was also altered in SSE-treated HepG-2 cells (Figure 3).

Gene expression

In SSE-treated (45 mg/L) HepG-2 cells, the expression of Bak but not Bax was significantly increased, while the expression levels of Bcl-xl and Mcl-1 were significantly down-regulated compared with the control cells (Figure 5A). Western blotting analysis further confirmed the up-regulation of Bax and down-regulation of Bcl-xl and Mcl-1 (Figure 5B).

Xenograft growth in mice

Compared with DMEM-treated mice, i.v. administration of 18 mg/kg SSE every 2 d for 14 d led to an inhibition of HepG-2 cell growth (Figure 6). No lesions were found in the heart, liver, spleen, lungs or kidneys in SSE-treated xenograft mice, and their functions were also normal. Compared with the control group, the TNFα levels in SSE-treated tumor tissue showed no significant difference at week 8 (9.9 ± 6.8 mg/L *vs* 9.1 ± 5.7 mg/L, $P > 0.05$). In addition, the food intake, mental status and activities were similar in the two groups during the treatment.

DISCUSSION

Recently, the discovery of active compounds from natural products has gained considerable attention as a new source of anticancer drugs[6-10]. The quest to find novel therapeutic compounds for cancer treatment is a never-ending venture. Sargentgloryvine stem, a traditional Chinese medicine, has been used for thousands of years in the treatment of several inflammatory diseases. Recently, we have successfully developed a novel extract from sargent-gloryvine stem SSE that has a potent anticancer activity on HCC cells[1]. However, the molecular mechanisms underlying the anticancer effects of SSE have not been elucidated.

Our research shows that SSE can induce apoptosis of the hepatoma cell line HepG-2 *in vitro* and *in vivo*, and its mechanism of action may be through decreasing expression of Bcl-xl and Mcl-1 and increasing expression of Bax. Compared with the control group, TNFα in the tumor tissue and liver function in SSE-treated mice had no significant changes at 8 wk ($P > 0.05$). In addition, this study provides evidence that SSE may be a potent therapeutic agent in the treatment of HCC without obvious toxic side effects.

In this study, the inhibitory effect of SSE on HepG-2 cells was tested, and ECV304 cells as the control were also studied. It was demonstrated that SSE profoundly

Figure 2 Apoptosis of sargentgloryvine stem extract-treated HepG-2 cells (× 400). HepG-2 and ECV304 cells were treated with sargentgloryvine stem extract (SSE) at a concentration of 45 mg/mL for 24 h. Flow cytometry showed that apoptosis rate was increased obviously compared with the non-treated control cells, $P < 0.05$; while ECV304 cells did not show obvious diversity, $P > 0.05$. Positive signals in nucleus were observed obviously in SSE-treated HepG-2 cells by TdT-Mediated dUTP Nick End Labeling (TUNEL) and acridine orange/ethidium bromide (AO/EB) assays.

Figure 3 Caspase-8, caspase-9 and cytochrome C in sargentgloryvine stem extract-treated HepG-2 cells. Significantly up-regulated cleavage was found in caspase 9 but not in caspase 8 in HepG-2 cells treated with 45 mg/L sargentgloryvine stem extract (SSE) for 24 h. Cytochrome C in plasmosin was notably increased. $P < 0.05$.

inhibited the growth of HepG-2 cells in a concentration- and time-dependent manner but not in ECV304 cells.

MTT and colony formation assays indicate that SSE possesses specific anti-HCC cell activity rather than general cytotoxicity. Additionally, the study suggested that SSE may be safe for normal cells, thus, SSE may have advantages for clinical application.

To reveal the mechanisms of the inhibitory effect of SSE on HepG-2 cells, changes in the cell cycle were analysed. It was demonstrated that the cell cycle of HepG-2 cells was blocked at S phase after 45 mg/L SSE treatment for 24 h, which indicated that the growth inhibition by SSE might be, in part, due to cell cycle arrest. Because cell cycle arrest is always accompanied with cell apoptosis, we analysed apoptosis in the SSE-treated cells. The data showed that SSE treatment induced cell apoptosis, and the apoptosis rates increased with increasing SSE concentrations[11]. More significantly, the induction of apoptosis by SSE in HepG-2 cells was observed at an initial concentration of 30 mg/L within 24 h, further suggesting the safety of SSE for systemic use in the treatment of HCC. It is known that apoptosis is regulated by two main pathways: the extrinsic pathway, which is initiated by the binding of ligands to specific death receptors on the cell surface, and the intrinsic pathway, which is initiated in mitochondria[12,13]. To understand the major *in vivo* pathway through which SSE induces HepG-2 cell growth suppression and apoptosis, the expression of caspase-8 and caspase-9, which play important roles in apoptosis triggered by various proapoptotic signals,

Figure 4 Rh-123 fluorescence in sargentgloryvine stem extract-treated HepG-2 cells (× 400). Flow cytometry showed that fluorescent intensities in sargentgloryvine stem extract (SSE)-treated (45 mg/L) cells for 12 h maintained their $\Delta\psi$m and only displayed minor changes in Rh-123 fluorescence. In contrast, SSE-treated (45 mg/L) cells for 24 h, fluorescent intensities were significantly weaker than control cells.

Figure 5 Gene expression in sargentgloryvine stem extract-treated HepG-2 cells. A: Semi-quantitative reverse transcription polymerase chain reaction (RT-PCR) showed that the expression of Bak but not Bax was significantly increased in HepG-2 cells treated with 45 mg/L sargentgloryvine stem extract (SSE) for 24 h, and the expression of Bcl-xl and Mcl-1 was significantly down-regulated; B: Western-blotting confirmed the SSE induced gene expression changes with up-regulated Bak and down-regulated Bcl-xl and Mcl-1 in HepG-2 cells.

Figure 6 Tumor growth inhibition by systemic sargentgloryvine stem extract-treatment *in vivo*. HepG-2 xenograft tumor (approximately 300 mm^3) growth in Athymic BALB/c nude mice injected with 50 μL of 18 mg/kg sargentgloryvine stem extract (SSE) or DMEM-control every 2 d for 14 d. The tumor size was measured and the tumor volume was calculated as: width^2 × length × 0.5. [a]*P* < 0.05, [b]*P* < 0.01 *vs* DMEM control.

were studied[14]. The results showed that 45 mg/L SSE treatment for 24 h significantly increased caspase-9 but not caspase-8 expression, indicating that SSE-induced apoptosis may be through the intrinsic pathway.

The intrinsic pathway for apoptosis involves several steps including mitochondrial membrane permeabilization and release of cytochrome C, followed by caspase-9 activation[15,16]. Our results showed that treatment with SSE at 45 mg/L for 24 h led to loss of $\Delta\psi$m as indicated by a decrease in Rh-123 fluorescence. SSE also induced cytochrome C release from the mitochondria to cytosol in HepG-2 cells. Taken together, these results further confirmed that SSE may directly trigger the intrinsic pathway to induce the mitochondrial pathway for apoptosis in HCC cells.

Previous studies have shown that in apoptotic cells, anti-apoptotic *bcl-2* members are often inactivated whereas pro-apoptotic members, such as *bax* and *bak,* are activated

and oligomerized in the mitochondria outer membrane. This triggers mitochondrial membrane permeabilization and release of soluble apoptogenic factors such as cytochrome C into the cytosol, which results in caspase activation[17,18]. Further studies revealed that 45 mg/L SSE treatment significantly decreased Bcl-xl and Mcl-1 expression and increased Bak expression and led to mitochondria endomembrane action. Finally, it was confirmed that SSE-induced HepG-2 cell apoptosis is mediated through the *bcl-2* pathway. These results demonstrated that SSE-induced apoptosis is mediated primarily by down-regulated expression of Bcl-xl and Mcl-1, which led to the release of Bak and ultimately activated the intrinsic apoptosis pathway.

In addition to inducing tumor cell apoptosis, systemic injection of SSE into HepG-2 xenografted mice inhibited tumor growth and significantly minimised tumor size but caused no obvious pathological changes in the heart, lungs, liver, spleen or kidneys. The levels of TNFα in the tumor tissue and liver function tests suggest that SEE treatment is relatively safe for the mice.

In conclusion, our research shows that the extract of the Chinese herb sargentgloryvine stem has *in vitro* anti-cancer effects including inhibition of proliferation and induction of apoptosis in the hepatoma cell line HepG-2 by mechanisms involving expression of Bcl-2 family proteins activating the intrinsic mitochondria apoptosis pathway. Moreover, an *in vivo* solid tumor growth assay further confirmed that systemic administration of the extract could inhibit tumor growth with little cytotoxicity to normal tissues. These *in vitro* and *in vivo* studies provide evidence urging the development of SSE as a novel regimen for human HCC.

ACKNOWLEDGMENTS

COMMENTS

Background
Plant-derived natural products have become available such as anticancer derivatives of vincristine, vinblastine, paclitaxel and camptothecin.

Research frontiers
Sargentgloryvine stem extract (SSE) as a chemotherapeutic adjuvant can enhance the efficacy and ameliorate the side effects of cancer chemo- or radiotherapy. However, the effect of SSE on the human hepatocellular carcinoma (HCC) cells remains unknown.

Innovations and breakthroughs
This study showed that SSE treatment was not only able to inhibit the proliferation of human HCC cell HepG-2 cells in a dose and time dependent manner, but also induce apoptosis and cell cycle arrest at S phase.

Applications
SEE is able to inhibit proliferation of human HCC cells and is relatively safe for the mice, and therefore it has a great potential to be a therapeutic agent in the treatment of HCC.

Terminology
SSE: Sargentgloryvine stem is the dried vine stem of *Sargentodoxa cuneata* (Oliv.) and has been widely used as an ingredient in formulated Chinese medicine for thousands of years in the treatment of diseases such as chronic pelvic cavity inflammation, rheumatism and appendicitis.

Peer review
The paper by Wang *et al* addresses an important issue, i.e. novel options for systemic therapy of HCC. In general, the paper is well written, the methods used are sound and the described approach is of potential interest.

Abstract

AIM: To investigate the sonographic features and diagnostic value of endoscopic ultrasonography (EUS) for duodenal lipomas (DLs).

METHODS: A total of eight consecutive patients with DL diagnosed pathologically were included in the study. One EUS expert reviewed the ultrasonic images for all lesions, including the original layer of the duodenal wall, the echo intensity and the echo homogeneity. The size of the lesions and the perifocal structures were also investigated. The diagnosis by EUS was compared with the histological results.

RESULTS: Using routine endoscopy, only one case was correctly diagnosed as DL. Four cases were classified as submucosal tumors, and three cases were mistaken for stromal tumors. All tumors appeared as round or oval intensive hyperechoic lesions with distinct anterior borders that originated from the submucosal layer on EUS. Tumors ranged from 8 to 36 mm in size, with an average size of 16 mm. Homogeneous echogenicity was seen in all cases except one that had a tubular structure inside the tumor. Echo attenuation was observed only in the area behind the tumors in five cases, and it was observed both inside and behind the tumors in three cases in which the posterior border was obscure or invisible. Seven (87.5%) cases were correctly diagnosed as DL, and one (12.5%) was mistaken as Brunner's gland adenoma by EUS. Pathologically, all tumors originated from the submucosal layer and consisted of mature fat cells without heteromorphism. Among the fat cells, there was a small amount of thick-wall vessels infiltrating the lymphocytes, and abundant fibrous connective tissues.

CONCLUSION: On EUS, DL is featured as an intensive homogeneous hyperechoic submucosal lesion with marked echo attenuation and without involvement of the mucosa.

Sonographic features of duodenal lipomas in eight clinicopathologically diagnosed patients. *World J Gastroenterol* 2011; 17(23): 2855-2859 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i23/2855.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i23.2855

INTRODUCTION

Gastrointestinal lipomas are uncommon benign tumors that occur anywhere along the gut. The most common location for these lesions is the colon, followed by the il-

eum and the jejunum[1]. Lipomas found in the duodenum are rare and the literature regarding duodenal lipomas (DLs) is only limited to case reports[2-8], and no systematic study of diagnostic means for DLs has been reported. Since preoperative diagnosis of DLs is difficult, and large DLs can mimic malignant tumors on endoscopy, patients could be subjected to extensive surgical procedures that are sometimes destructive. Endoscopic ultrasonography (EUS) is an optimal method for detecting gastrointestinal submucosal tumors (SMTs) such as stromal tumors and leiomyomas; however, the features and diagnostic value of EUS for examining DLs have not been well established because of the rareness of this disease. In this study, we studied the sonographic features and diagnostic value of EUS for identifying DLs.

MATERIALS AND METHODS

Patients
A total of eight consecutive patients with DL were included. The diagnosis of DL for all patients was pathologically established after surgical excision in five patients and endoscopic resection in three patients during the period from June 2000 to December 2010 in the First Affiliated Hospital, School of Medicine, Zhejiang University, China. The patient group was composed of five males and three females, and aged from 42 to 78 years, with a mean of 60 years. Except for one patient who was asymptomatic, DLs presented as bleeding in four patients, dyspepsia in two patients, and epigastric pain in one patient (Table 1). Laboratory examinations, including liver function tests, serum lipids, and tumor markers (carcinoembryonic antigen, carbohydrate antigen 19-9, carbohydrate antigen 125, and alpha-fetoprotein), showed no obvious abnormalities except for anemia in five patients.

Instrument
The EUS system included Olympus EU-M2000 sonogram processing equipment, an Olympus GIF-2T-240 double-cavity electronic gastroscope, Olympus MAJ drive systems with a high-frequency echo probe, UM-DP12-25R miniature ultrasonic probes with a frequency spectrum of 12-15 MHz, and a Daker WP-800 water pump (Olympus Medical System Corp., Tokyo Japan).
Methods
One EUS expert reviewed the ultrasonic image of all lesions, including the original layer of the duodenal wall, the echo intensity, and the echoic homogeneity. The size of the lesions and the perifocal structures were also investigated. The EUS diagnosis was compared with the histological results.

RESULTS

Endoscopic studies
The tumors were located at the bulb in one case and in the

Figure 1 Endoscopic and endoscopic ultrasonography findings in Case 7. A: A submucosal tumors of the descendant duodenum with an intact surface; B: Endoscopic ultrasonography showed a hyperechoic lesion with a distinct anterior border originating from the submucosal layer. There was marked echo attenuation both inside and behind the lesion, and the posterior border was obscure.

descending part of the duodenum in seven cases. The lesions, with a hemispherical or oval shape, were sessile in six cases and had a stalk in two. The surface of the lesions was intact in three cases (Figure 1A) and had an ulcer (Figure 2A) or an erosion in five cases. Prior to EUS, only one case was correctly diagnosed as DL by routine endoscopy because of the yellowish and soft appearance (Figure 3A). Four cases were classified as SMTs, and three cases were mistaken for stromal tumors.

Endoscopic ultrasonography
The endoscopic ultrasonography (EUS) findings in all cases are shown in Table 1. All tumors appeared as intensive hyperechoic lesions with a distinct anterior border that originated from the third EUS layer without involvement of the overlying first and second layers (Figures 1B, 2B, 3B and 4). Tumors ranged from 8 to 36 mm in size, with an average size of 16 mm. The margins of the tumors were clear in five cases (Figures 3B and 4), and the posterior borders of three lesions were obscure or invisible because of marked echo attenuation (Figures 1B and 2B). Homogeneous echogenicity was seen in all cases except for one that had a tubular structure inside the tumor (Figure 2B). Echo attenuation was observed only in the area behind the tumors in five cases (Figures 3B and 4) and both inside and behind the tumors in three cases (Figures 1B and 2B). With EUS, seven patients were correctly diagnosed as having DLs, but one

Table 1 Clinical settings and endoscopic ultrasonography observations

Case	Sex	Age	Symptoms	Location	Treatment	EUS features					
						Layer	Size (mm)	Echogenicity	Homogeneity	Border	Echo attenuation
1	M	50	None	Bulb	Endoscopic resection	3rd	12	Hyperecho	Homogenous	Distinct	Behind
2	F	64	Melena	2nd portion	Surgery	3rd	10	Hyperecho	Homogenous	Distinct	Behind

EUS: Endoscopic ultrasonography; M: Male; F: Female.

**Figure 2 Endoscopic and endoscopic ultrasonography findings in Case 8.** A: A lobulated submucosal tumor in the descendant duodenum with an ulcer on its surface; B: Endoscopic ultrasonography showed an intensive hyperechoic lesion with a distinct anterior border originating from the submucosal layer without involvement of the overlying mucosal layer. The posterior border of the tumor was invisible because of the marked echo-attenuation.

Figure 3 Endoscopic and endoscopic ultrasonography findings in Case 2. A: A submucosal tumor located in the descendant duodenum with a yellowish and soft appearance; B: Endoscopic ultrasonography showed an oval intensive hyperechoic lesion with homogeneous parenchymal echogenicity and a clear margin originating from the third layer without involvement of the overlying mucosal layers. Echo attenuation was seen at the area behind the focus.

patient with DL was mistaken as having Brunner's gland adenoma (BGA) due to the appearance of a tubular structure.

Pathology

The pathological diagnosis after routine endoscopic biopsy was chronic inflammation of the mucosa, whereas the postoperative diagnosis after surgical excision or endoscopic resection was DL. The tumors presented by gross appearance as a node or finger in six cases and as a sub-lobe or cauliflower in two cases. All tumors originated from the submucosal layer, sometimes involving the muscularis propria, with a fully or partially coated fiber peplos. Microscopically, the tumors were composed of mature fat cells without heteromorphism. Among the fat cells, there were small amounts of thick-wall vessels, infiltrating lymphocytes, and abundant fibrous connective tissues (Figures 5-7).

DISCUSSION

Lipomas of the duodenum are rare, with fewer than 230 cases reported in the literature, and most of the described cases are from autopsy records rather than clinical experience[9]. DLs were mostly detected after bleeding or obstruction occurred. Among the patients in
Figure 4 Endoscopic and endoscopic ultrasonography findings in Case 4. A submucosal tumor located in the descendant duodenum. Endoscopic ultrasonography showed a submucosal hyperechoic lesion with marked echo-attenuation behind the focus.

Figure 5 Pathological findings in Case 3. Microscopically, the tumor was located in the submucosa without involvement of the mucosa (HE, × 40).

Figure 6 Pathological findings in Cases 2 and 4. A, B: The tumors consisted of mature fat cells. Abundant fibrous connective tissues were found among the fat cells (HE, × 100).

Figure 7 Pathological findings in Case 7. Massive fiber ropes were inside the tumor parenchyma (HE, × 100).

this study, four (50%) experienced bleeding, two (25%) experienced dyspepsia, one (12.5%) had epigastric pain, and one (12.5%) was asymptomatic. The symptoms of DL are nonspecific, however, and they are not useful for differential diagnosis.

Endoscopy is the preferred means for detecting upper gastrointestinal diseases. However, it can only suggest the presence of submucosal protruding lesions, but cannot provide additional details even though lesions have been detected[10,11]. In this study, four patients were diagnosed as having SMTs by endoscopy, and three patients were mistaken as having stromal tumors. Only one patient was correctly diagnosed with lipoma by routine endoscopy due to the yellowish and soft appearance of the lesion (Figure 2B).

EUS has been reported to be an effective modality for assessing gastrointestinal tumors and evaluating the original layer of the submucosal tumor, the homogeneity of the internal parenchymal echo, and the echogenicity of the lesions[10]. The typical EUS observations of DLs are intensive homogeneous hyperechoic lesions originating from the submucosa, with echo attenuation behind and/ or inside the rear area. Thus, the signs of DLs are similar to the ultrasonic features of a fatty liver.

Intensive hyperecho is the most noticeable EUS fea-

ture of DLs. A newly-devised echogenicity classification system for SMTs by Okanobu[10] demonstrated the highest echo level of lipomas (levels 5-6). The marked echo-attenuation is another EUS feature of DLs. In our series, there was a more apparent echo decline in the area behind the focus than anywhere else in all cases regardless of the size of the lesions, suggesting a greater attenuation coefficient for DLs than for normal intestinal wall tissues. Furthermore, visible echo decline was seen inside the lesion when the size of the focus was larger than 15 mm. The anterior border was as distinct as the overlying first and second layers of the DLs; however, the appearance of the posterior border depended on the related echo de-

cline. The latter portion and the posterior border of DLs larger than 25 mm are often invisible with the 12-MHz probe. The internal parenchymal echo of DLs is generally homogenous[11]. Occasionally, blood vessels may present as tubular structures inside the focus.

According to two ultrasonic characteristics, we could distinguish DLs from the majority of other SMTs such as leiomyomas, stromal tumors, or cysts. It is noteworthy that Brunner's gland adenomas (BGAs) also show hyperechoic lesions originating from the submucosa, and therefore, DLs may be mistaken for BGAs[11,12]. In our study, one patient was misdiagnosed with duodenal BGA. BGAs appear primarily in the bulb portion or at the junction of the bulb and the descending duodenum, whereas DLs are located primarily in the descending portion of the duodenum. In addition, the echogenicity of BGAs is not as intensive or homogeneous as that of lipomas. Although the second EUS layer often becomes blurry or invisible in BGAs because of involvement of the lamina propria, it is always readable in DLs.

The reason why all gastrointestinal lipomas appeared as hyperechoic is not clear. Interestingly, normal subcutaneous fat tissues appeared as a hypoechoic zone with a small amount of hyperechoic fiber ropes. An earlier report showed that 29% of superficial soft tissue lipomas were hypoechoic, 22% were isoechoic, 29% were hyperechoic, and 20% were of a mixed pattern[13]. Thus, the echo types of lipomas mostly depend on the quantity of the boundary in relation to the mixture of fat and other connective tissues. We found abundant fibrous connective tissues among the fat cells of DLs. The heterogeneous mixture generated innumerable acoustic boundaries that appeared hyperechoic because of the marked acoustic impedance difference between the fat and fibrous tissues.

In summary, EUS has significant value for the differential diagnosis of DLs. The appearance of a round or oval lesion originating from the submucosal layer with intensive homogenous hyperecho and marked echo-attenuation, without involvement of the mucosal layers, suggests a diagnosis of DL. Abundant fibrous connective tissues among the fat cells may be the acoustic basis of this appearance.

COMMENTS

Background
Lipomas located in the duodenum are rare. Because the preoperative diagnosis for duodenal lipomas is difficult to establish and some large lipomas can mimic malignant tumors on endoscopy, patients could be subjected to extensive surgical procedures that sometimes were destructive. Endoscopic ultrasonography (EUS) is the optimal method for the diagnosis of gastrointestinal stromal tumors, but its diagnostic value for duodenal lipomas has not been well established because of its rareness.

Research frontiers
Up to date, less than 230 cases of lipomas have been reported in the literature, but most of them are from autopsy records rather than clinical experience. Clinically, duodenal lipomas are mostly revealed by bleeding or obstruction. Endoscopy can only detect the submucosal lesion but fail to judge its nature. EUS is an effective modality in the assessment of gastrointestinal submucosal tumors and evaluation of the original layer, homogeneity of internal parenchymal echo and echogenicity of the lesions.

Innovations and breakthroughs
EUS is of significant value in the diagnosis and differential diagnosis of duodenal lipomas. The sonographic features were round or oval lesions originated from submucosal layer with intensive homogenous hyperecho and marked echo-attenuation, without involvement of the mucosal layers.

Applications
According to this study, duodenal lipomas can be defined by EUS, thus needless surgery can be avoided. By EUS, they can differentiate duodenal lipomas from other submucosal tumors. The sonographic features of duodenal lipomas can be used for the diagnosis of lipomas in esophagus, stomach and colon.

Peer review
This is an original report on the correlations of the sonographic findings and clinicopathological features of duodenal lipomas. The material is characterized by small case series but the conclusive suggestions are appropriate and interesting. Duodenal lipoma is a rare clinicopathological entity. Therefore, it is interesting to get an eight consecutive duodenal lipoma cases. The EUS is probably the best option to diagnose this pathology.

Li Yang, Department of General Surgery, First Affiliated Hospital of Nanjing Medical University, Nanjing 210029, Jiangsu Province, China

Abstract

AIM: To evaluate the impact of the *ITGA2* gene polymorphism on gastric cancer risk.

METHODS: A hospital-based case-control study was conducted, including 307 gastric cancer patients and 307 age- and gender-matched control subjects. The genotypes were identified by polymerase chain reaction-restriction fragment length polymorphism assay.

RESULTS: The frequencies of the wild and variant genotypes in cases were significantly different from those of controls ($P = 0.019$). Compared with individuals with the wild genotype CC, subjects with the variant genotypes (CT + TT) had a significantly higher risk of gastric cancer (adjusted odds ratio = 1.57, 95% CI = 1.13-2.17, $P = 0.007$). In stratified analyses, the elevated gastric cancer risk was especially evident in older individuals aged > 58 years, nonsmokers and rural subjects. Further analyses revealed that the variant genotypes were associated with poor tumor differentiation and adjacent organ invasion in the sub-analysis of gastric cancer patients.

CONCLUSION: The *ITGA2* gene C807T polymorphism may be associated with an increased risk of gastric cancer, differentiation and invasion of gastric cancer.

Association between *ITGA2* C807T polymorphism and gastric cancer risk. *World J Gastroenterol* 2011; 17(23): 2860-2866 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i23/2860.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i23.2860

INTRODUCTION

Gastric cancer remains a major public health issue as the fourth most common cancer type and the second leading cause of cancer death worldwide[1,2]. Nearly half of the gastric cancer cases occur in China[3]. Although the

cause of gastric cancer is largely unknown, it has been shown that diet, tobacco smoking, alcohol, gastroesophageal reflux and *Helicobacter pylori* (*H. pylori*) infection are associated with the risk of this cancer[4-7]. As genetic polymorphisms are responsible for the inter-individual variation and diversity, they have been recently considered as the main genetic elements involved in the development of common and complex diseases, including various cancers. Like many malignancies, it is believed that gastric cancer is the result of interactions between environmental factors and genetic factors[8]. Our previous epidemiological studies also provided the evidence that genetic polymorphisms were associated with the risk of gastric cancer[9-12].

Integrins are members of a family of cell-surface heterodimeric proteins that mediate cell-matrix and cell-cell interactions. The 18 α-subunits and 8 β-subunits form together at least 25 different integrins, each pair being specific for a unique set of ligands. It has been demonstrated that integrins may play a crucial role in carcinogenesis, tumor behavior and metastasis[13,14]. Several integrins such as α2β1, α Ⅱ bβ3 and αvβ3 are considered as key factors for cancer development and progression. Integrin α2β1, also known as platelet glycoprotein I a- Ⅱ a, is expressed by epithelial cells, and its level of expression in tumor cells is associated with motility, invasiveness and cellular differentiation[15-17]. Several studies have shown that integrin α2β1 expression is closely associated with invasion and metastasis of gastric cancer[18-21].

The integrin, α2 gene (*ITGA2*) is located on chromosome 5q23-31. A silent change in the coding region at nucleotide 807 (TTT/TTC at codon Phe253) has been identified. The C807T single nucleotide polymorphism (NCBI SNP ID: rs1126643) of the *ITGA2* gene was associated with the integrin α2β1 density. The genotype 807 TT was associated with a higher receptor density and the genotype 807 CC with a lower density, whereas heterozygous individuals expressed intermediate receptor levels[22,23].

Recent studies indicated that the *ITGA2* gene C807T polymorphism was associated with various diseases, including stroke, retinal vein occlusion, acute coronary syndrome, colorectal cancer, and breast cancer[24-29]. To the best of our knowledge, there has been no study that assessed the association between the polymorphism and gastric cancer risk.

Given that the roles of *ITGA2* in the progression of gastric cancer as well as the effect of the polymorphism in *ITGA2* gene on the receptor function, it is plausible that the polymorphism may be associated with the risk of gastric cancer. To test the hypothesis, we performed a hospital-based case-control study in a Chinese population.

MATERIALS AND METHODS

Subjects
This hospital-based case-control study consisted of 307 consecutive inpatients with histologically confirmed gas-

tric cancers without synchronous and/or metachronous secondary malignancy and a population-based and sex- and age-matched 307 cancer-free inpatients as controls. All subjects were recruited between March 2005 and November 2009 from the patients who were admitted to the First Affiliated Hospital of Nanjing Medical University. The most common causes for hospitalization in the control subjects were hernias, appendicitis, hydrocele, cholecystitis and cataract. All subjects were of unrelated Han nationality from Jiangsu Province or its surrounding regions. Information on age, gender, smoking status, residence (urban or rural), body weight and personal medical history was collected by questionnaire. Individuals who formerly or currently smoked ≥ 10 cigarettes per day for at least 2 years were defined as smokers. Depth of tumor invasion and local lymph node status were classified according to the TNM classification criteria of International Union Against Cancer[30]. Differentiation was graded according to World Health Organization classification. The study was approved by the Ethics Committee of Nanjing Medical University First Affiliated Hospital and informed consent was obtained from all the participating subjects.

Genotyping
The protocol for genomic DNA extraction was described in our previous study[9]. The polymerase chain reaction (PCR)-restriction fragment length polymorphism assay was used to identify the *ITGA2* C807T genotypes. The PCR was performed in a total volume of 20 μL reaction mixtures containing 2 μL 10 × PCR buffer (MBI Fermentas), 1.75 mmol/L MgCl$_2$, 0.25 μmol/L each primer (forward 5'-GTGTTTAACTTGAACACATAT-3', reverse 5'-ACCTTGCATATTGAATTGCTT-3'), 0.15 mmol/L dNTP, 1 unit *Taq* polymerase (MBI fermentas) and 150 ng genomic DNA. The amplification protocol is as follows: primary denaturation at 95℃ for 5 min, followed by 35 cycles of denaturation at 94℃ for 30 s, annealing at 55℃ for 30 s, and extension at 72℃ for 1 min, then a final elongation at 72℃ for 5 min. The 115 bp PCR products including the polymorphic site were digested at 65℃ for 12 h, using restriction enzyme *Taq* I (MBI Fermentas) and then separated on a 3% ethidium bromide-stained agarose gel. The wild-type homozygotes (CC) produced two bands at 92 and 23 bp, while the variant homozygotes (TT) produced one band at 115 bp, and the heterozygous (CT) produced three bands at 115, 92 and 23 bp (Figure 1). To control the quality of genotyping, all assays were conducted by two researchers separately in a blind fashion. In addition, a 10% masked samples were randomly selected and retested, and the reproducibility was 100%.

Statistical analysis
Statistical analyses were conducted using SPSS 16.0 software (SPSS Inc., Chicago, IL, USA). All statistical tests were two-tailed and $P < 0.05$ was considered statistically significant. Quantitative variables departing from the normal distribution including age and weight were summarized as median and analyzed by Mann-Whitney rank

Table 1 Demographic information *n* (%)

sum test. Pearson's χ^2 test was used to compare the difference in the distribution of categorical variables and genotype frequencies between cases and controls. The Hardy-Weinberg equilibrium of the *ITGA2* genotypes was estimated for cases and controls by a goodness-of-fit χ^2 test. Odds ratio (OR) and 95% CI were calculated to evaluate the association between the polymorphism and the risk of gastric cancer. Carriers of the wild genotype CC were used as the reference. The crude OR was obtained using the Woolf approximation method and the adjusted OR was calculated by unconditional logistic regression method, with adjustment for age, sex, smoking status, residence, hypertension and diabetes.

RESULTS

Demographic information
A total of 614 subjects (307 cases and 307 controls) were analyzed. Baseline demographic characteristics of the study groups are shown in Table 1. The age distribution and proportion of males were quite similar due to the fact that we selected the age- and gender-matched subjects. The two groups were similar with respect to residence, history of hypertension and diabetes. Nevertheless, compared with controls, gastric cancer patients had a lower body-weight (*P* = 0.001) and more smokers were found among gastric cancer cases than among the controls (26.71% *vs* 17.26%, *P* = 0.005).

Distribution of ITGA2 genotype in cases and controls and risk estimates
Table 2 shows the frequency distributions of the genotypes and their association with gastric cancer risk by unadjusted OR, adjusted OR and 95% CI. The genotype distributions in cases and controls were consistent with those from the Hardy-Weinberg equilibrium model (*P* = 0.988, *P* = 0.675, respectively). The frequencies of the *ITGA2* genotype were significantly different between gastric cancer cases and controls (*P* = 0.019). Compared with the control group, T allele frequency was significantly higher in the case group (*P* = 0.024). With the wild genotype CC as reference, we found that the CT genotype was associated with an increased risk of gastric cancer (adjusted OR = 1.54, 95% CI = 1.10-2.18, *P* = 0.013).

Figure 1 *ITGA2* C807T polymorphism in gastric cancer patients and controls. Amplified polymerase chain reaction products were digested with restriction enzyme *Taq* I and analyzed on a 3% agarose gel. Lane 1: The TT homozygous; Lanes 2-5, 8: The CC homozygous; Lanes 6, 7: The CT homozygous.

Individuals with the variant genotypes (CT + TT) had a 1.57-fold increased risk of developing gastric cancer (adjusted OR = 1.57, 95% CI = 1.13-2.17, *P* = 0.007).

Stratified analysis of polymorphism and gastric cancer risk
As shown in Table 3, stratified analyses were performed by the median age of controls (58 years), sex, smoking status, and residence. The elevated risk of gastric cancer associated with the variant genotypes was noteworthy in subjects aged > 58 years (adjusted OR = 1.88, 95% CI = 1.17-3.03, *P* = 0.010), but not in subjects aged ≤ 58 years. In non-smoking subjects, the variant genotypes were associated with a 51% increased risk of gastric cancer (adjusted OR = 1.51, 95% CI = 1.05-2.18, *P* = 0.028), whereas the correlation was not statistically significant in smoking subjects. When stratified by residence, the elevated risk was evident in rural subjects (adjusted OR = 2.35, 95% CI = 1.42-3.90, *P* = 0.001), but not in urban subjects. No statistically significant difference was observed in the association of the polymorphism and susceptibility to gastric cancer between males and females.

Variant genotypes and clinicopathological characteristics of gastric cancer
We also observed the correlations between the *ITGA2* variant genotypes and clinicopathologic features of gastric cancer patients in this study (Table 4). A significantly increased risk was found in individuals with the variant genotypes in both poorly differentiated tumors (adjusted OR = 2.21, 95% CI = 1.12-4.38, *P* = 0.022) and adjacent invaded organs (adjusted OR = 2.12, 95% CI = 1.10-4.07, *P* = 0.024) of gastric cancer. However, no significant association was observed between the polymorphism and lymph node metastasis or tumor location.

DISCUSSION

In the present study, we investigated the role of *ITGA2* gene C807T polymorphism in gastric cancer susceptibil-

ity in a Chinese population. We found that the polymorphism may be associated with an increased risk of gastric cancer, differentiation and invasion of gastric cancer.

It has been reported that integrin α2β1 is one of the key factors accelerating tumor progression and metastasis in various types of cancers[15-21,31]. Koike *et al*[20] found that the α2 integrin was expressed in the intestinal-type and

diffuse-type gastric carcinoma cells, and invasion through basement membrane and type I collagen gel was inhibited by anti-α2 integrin monoclonal antibody, indicating that the α2 integrin plays an important role in invasion of gastric carcinoma cells. Another study conducted by Lee *et al*[32] elucidated the potential mechanisms underlying the spreading and invasiveness of gastric carcinoma

cells, the integrin transduces signaling directly *via* engagements with extracellular matrix proteins, thereby leading to the regulation of downstream intracellular signaling molecules. It also functions in collaborative (indirect) signaling, in which integrins cosignal with other membrane receptor-mediated signal pathways, e.g. growth factor receptors, G-protein coupled receptors or the transforming growth factor β1 signaling pathway.

The *ITGA2* gene C807T polymorphism is associated with integrin density, but the precise molecular mechanism remains unclear. It is a silent polymorphism in codon 253 (Phe253Phe) and does not cause an altered structure of the integrin molecule, but in linkage disequilibrium with a yet unknown functional polymorphism affecting *ITGA2* expression. Another explanation could be a direct effect on the stability of the *ITGA2* mRNA, which resulted in a change of the amount of integrin protein being expressed.

Limited studies have reported the association between the polymorphism in *ITGA2* gene and cancer risks, although the results remain inconsistent[27-29]. Gerger *et al*[27] found that the *ITGA2* gene C807T polymorphism was associated with reduced colorectal cancer risk (OR = 0.77, 95% CI = 0.64-0.94, *P* = 0.011). In their another case-control study, they found that carriers of the most common *ITGA2* haplotype (807C_1648G) had a decreased risk for breast cancer (OR = 0.72, 95% CI = 0.53-0.98)[28]. Nevertheless, Ayala *et al*[29] reported that no association was observed between the *ITGA2* gene C807T polymorphism and breast cancer risk.

Based on these studies, we conducted this hospital-based case-control study to investigate the association between the *ITGA2* gene C807T polymorphism and the risk of gastric cancer in a Chinese population. The frequency of the variant T allele in our control group was 26.22%, which was similar to that in another study in a Chinese Taiwanese population (27.1%)[33] and HapMap database (26.7% for Han Chinese). Our results showed that the variant genotypes had a 57% increased risk of developing gastric cancer.

In the subgroup analyses, we found that the polymorphism was associated with the increased risk of gastric cancer in the subgroup of the subjects aged > 58 years, but not in the subjects aged ≤ 58 years. Milne *et al*[34] indicated that carcinogenesis is considered as accumulation of genetic events, and gastric cancer has a steep slope for age-specific increase in incidence. The increased risk observed in older subjects implies that the *ITGA2* genotype effects tend to be age specific. The polymorphism may contribute to elevated integrin α2β1 levels beyond the age of 58, thus representing a significant risk factor in this age group. However, this is just a hypothesis to interpret the results of our study, and further research is warranted to clarify the mechanism underlying the interaction between the polymorphism and age.

Similarly, in statistical analyses stratified by smoking status, a significant association was observed in non-smokers, but not in smokers. Tobacco smoking has been undoubtedly accepted as a independent risk factor for gastric cancer[3,5,6]. The association between the polymorphism and gastric cancer risk could be masked by the overwhelming accumulated exposure to tobacco carcinogens in smokers so that the association is more evident in nonsmokers.

We also noted that increased risk of gastric cancer associated with the polymorphism was pronounced in rural subjects, but not in urban subjects. It has been suggested that the genetic differences have their strongest effects under conditions of low environmental pollution[9,35]. Our results plausibly agree with the hypothesis that the genetic effects might be more prominent in the better environments of rural areas[9]. However, this result may be found accidentally, further studies are needed to verify it.

In addition, in the stratified analyses by clinicopathological characteristics of gastric cancer, we observed a significant correlation of the variant genotypes with poorly differentiated tumors. Similarly, Langsenlehner *et al*[28] suggested that a histological grade of 3 or 4 was found more often in breast cancer subjects with TT genotype. The result is consistent with our findings. In contrast, Yasoshima *et al*[21] found no correlation between the expression of integrin α2β1 and histopathological features such as the histological grade, stromal type, and infiltrating growth pattern. We also observed the significant association of the variant genotypes with adjacent organ invasions. Several studies have suggested that integrin α2β1 was closely associated with invasion and metastasis in gastric cancer or tumor cells[18-21,31]. These studies might explain the result we observed. However, no correlation between the polymorphism and lymph node metastasis or location of gastric cancer was found in the stratified analyses. Because the number of cases in the subgroups was relatively small and clinicopathological variables were obtained at the time of diagnosis, our findings should be interpreted with caution before being confirmed in further studies. Thus, large-sized studies which prospectively follow up the clinical outcome, especially the survival rate, may be required to elucidate the association between the polymorphism and gastric cancer progression as well as prognosis.

Some limitations may exist in the present study. First, our study is a hospital-based case-control study, so we can not rule out the selection and recall bias. Nevertheless, the T allele frequency in control subjects is quite similar to that reported in HapMap database for Han Chinese in Beijing (0.262 in our study *vs* 0.267 in HapMap database) and the genotype distributions of cases and controls were in Hardy-Weinberg equilibrium. The second limitation is our relatively small sample size, with 307 cases and 307 controls. So gene-environment interactions may have been underpowered in stratified analyses. However, our preliminary data certainly provides some interesting information and valuable guidance for the future studies in this area. Finally, no enough information on *H. pylori* status was available in cases and controls, because of the ethical reasons.

In conclusion, the present study provides evidence that the *ITGA2* gene C807T polymorphism is associated with an increased risk of gastric cancer in a Chinese population. The association is especially evident in older individuals, non-smokers and rural subjects, and the variant genotypes may also play a role in the differentiation and invasion of gastric cancer, indicating that the polymorphism may be a useful diagnostic marker for genetic susceptibility to gastric cancer. Further studies with larger samples and functional studies are needed to elucidate the role of genetic variations in *ITGA2* and the pathogenesis of gastric cancer.

COMMENTS

Background

Integrin α2β1 has been considered as a key factor for cancer development and progression, especially in gastric cancer. Polymorphisms in *ITGA2* gene is responsible for the expression of integrin α2β1. Recent studies indicated that the *ITGA2* gene C807T polymorphism was associated with cancer risk.

Research frontiers

Using polymerase chain reaction-restriction fragment length polymorphism method, this study explored the relationship between *ITGA2* C807T polymorphism and gastric cancer risk.

Innovations and breakthroughs

The results suggest that the polymorphism is associated with the elevated risk of gastric cancer in a Chinese population, especially in older individuals aged > 58 years, nonsmokers, and rural subjects. Further analyses revealed that the polymorphism may play a role in differentiation and invasion of gastric cancer.

Applications

The results of this study could help further understand the genetic determinants of gastric cancer. The polymorphism may be a useful diagnostic marker for genetic susceptibility to gastric cancer.

Terminology

Integrins are members of a family of cell-surface heterodimeric proteins that mediate cell-matrix and cell-cell interactions. Single nucleotide polymorphisms represent a natural genetic variability at a high density in the human genome, which are responsible for the inter-individual variation and diversity. They have been recently considered as the main genetic elements involved in the development of common and complex diseases, including various cancers.

Peer review

The current study was designed, processed and concluded well, deserving publication.

Abstract

AIM: To investigate the efficiency of Cox proportional hazard model in detecting prognostic factors for gastric cancer.

METHODS: We used the log-normal regression model to evaluate prognostic factors in gastric cancer and compared it with the Cox model. Three thousand and eighteen gastric cancer patients who received a gastrectomy between 1980 and 2004 were retrospectively evaluated. Clinic-pathological factors were included in a log-normal model as well as Cox model. The akaike information criterion (AIC) was employed to compare the efficiency of both models. Univariate analysis indicated that age at diagnosis, past history, cancer location, distant metastasis status, surgical curative degree, combined other organ resection, Borrmann type, Lauren's classification, pT stage, total dissected nodes and pN stage were prognostic factors in both log-normal and Cox models.

RESULTS: In the final multivariate model, age at diagnosis, past history, surgical curative degree, Borrmann type, Lauren's classification, pT stage, and pN stage were significant prognostic factors in both log-normal and Cox models. However, cancer location, distant metastasis status, and histology types were found to be significant prognostic factors in log-normal results alone. According to AIC, the log-normal model performed better than the Cox proportional hazard model (AIC value: 2534.72 *vs* 1693.56).

CONCLUSION: It is suggested that the log-normal regression model can be a useful statistical model to evaluate prognostic factors instead of the Cox proportional hazard model.

Key words: Gastric cancer; Log normal regression model; Cox proportional hazard model; Prognostic factors

INTRODUCTION

The survival of patients with gastric cancer has recently been improved because of early detection, rational lymphadenectomy and several therapeutic modalities[1,2]. However, gastric cancer still remains the second leading cause

of cancer mortality in the world. It is acknowledged that surgery and systemic chemotherapy can clearly improve the survival of patients with gastric cancer[3,4]. However, a sensible treatment option must be fundamentally based on the current evaluation of prognostic factors, so a rational method to evaluate the prognostic factors is very important in establishing therapeutic strategies and evaluate prognosis.

Survival analysis is a branch of statistics which deals with death in biological organisms and failure in mechanical systems. The Cox model is the standard tool for assessing the effect of prognostic factors; however, there may be substantive differences in the estimated prognosis obtained by the Cox model rather than a log-normal model[5]. The Cox model is semiparametric, in that the baseline hazard takes on no particular form[6]. In contrast to Cox, a link to parametric survival models comes through alternative functions for the baseline hazard. In this case, one can let the baseline hazard be a parametric form such as log-normal. It is acknowledged that most of studies used the Cox proportional hazard model to find the relation between survival time and covariates of patients with gastric cancer[7-9]. On the other hand, some studies reported that log-normal regression could estimate the parameter more efficiently than the Cox model[5]. However, the efficiency of log-normal regression was still controversial.

The aim of this retrospective study was to elucidate the factors affecting the survival of patients with GC using log-normal regression, and to compare these results with the Cox model.

MATERIALS AND METHODS

Patients

In this study, three thousand and eighteen cases with gastric cancer were selected on whom an operation was performed at the China Medical University between 1980 and 2004. The selection criteria for inclusion were as follows: (1) an operation was performed; (2) lymph nodes were dissected and then pathologically examined; and (3) the patient medical records were available. All patients were periodically followed up through post letters, and/or telephone interviews with patients and their relatives. Clinical, surgical and pathological findings, and all follow-up information were collected and recorded in a database, and 5-year survival rate was calculated. The study protocol was approved by the Ethics Committee of China Medical University.

Reference standard

Lymph nodes were meticulously dissected from the en bloc specimens, and the classification of the dissected lymph nodes was determined by surgeons who reviewed the excised specimens after surgery based on the Japanese Classification of Gastric Carcinoma[10]. Accordingly, lymphadenectomy was classified as D1, dissection of all the Group 1 lymph nodes; D2, dissection of all Group 1 and Group 2 lymph nodes; and D3, dissection of all the Group 1, Group 2 and Group 3 lymph nodes. pN

category was defined as pN0 (no metastatic lymph node), pN1 (1-6 metastatic lymph nodes), pN2 (7-15 metastatic lymph nodes) and pN3 (> 15 metastatic lymph nodes), according to the 5th Edition of UICC[11]. The location of tumors was defined as upper, middle and lower third gastric cancer, according to JCGC[10] and the histological grade was defined as poorly differentiated, moderately differentiated and well differentiated, according to the latest World Health Organization (WHO) classification[12]. The Borrmann type was defined as Borrmann Ⅰ, Borrmann Ⅱ, Borrmann Ⅲ and Borrmann Ⅳ, according to JCGC[10]. The histological type was determined according to Lauren's classification.

Statistical analysis

All data were analyzed using STAT statistics software (Version 10.0, Stata Corp LP). Clinic-pathologic factors were entered to a log-normal censored regression, as well as a Cox proportional hazard model in univariate and multivariate analysis in order to find the prognostic factors. The term of relative risk (RR) was used to interpret the risk of death in parametric results and the term of Akaike Information Criterion (AIC) was employed to compare the efficiency of models. Disease-specific survival was analyzed using the Kaplan-Meier method. The log-rank test was used to analyze survival differences. Lower AIC indicates better likelihood. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

Clinic-pathological characteristics of patients with gastric cancer

The male-to-female ratio among the 3018 patients enrolled was 2.74:1 and the mean age was 57.54 years (range: 19 to 90 years) at operation. 269, 1362 and 608 cases received D1, D2 and more than D2 lymph node dissection respectively. In addition, six hundred and fifty seven cases received palliative surgery. From 3018 cases, a total of 46081 lymph nodes were removed and examined, and the mean number of examined lymph nodes was 15.27. One thousand six hundred and forty three cases were observed lymph node metastasis. Thus, the incidence of lymph node metastasis was 54.44%. The last follow-up was Jan 1, 2009, with a total follow-up rate of 70.68%. More clinicpathologic factors are shown in Table 1.

Multivariate analysis of prognostic factors in gastric cancer

Univariate analysis indicated that age at diagnosis, past history, cancer location, distant metastasis status, surgical curative degree, combined other organ resection, Borrmann type, Lauren's classification, pT stage, total dissected nodes and pN stage were prognostic factors in both log-normal and Cox models. In the final multivariate model, age at diagnosis, past history, surgical curative degree, Borrmann type, Lauren's classification pT stage, and pN stage were significant prognostic factors in both

log-normal and Cox models. However, cancer location, distant metastasis status and histology types were found as significant prognostic factors in log-normal results alone (Table 2). According to AIC, the log-normal model performed better than the Cox proportional hazard model (AIC value: 2534.72 *vs* 1693.56) (Table 3).

Survival outcomes

Overall, the 5-year disease-specific survival rate was 29.57%. The survival was observed significantly different in patients with different cancer locations (5-year disease-specific survival rate, L tumor *vs* M tumor *vs* U tumor *vs* T tumor: 33.11% *vs* 30.46% *vs* 25.66% *vs* 7.59%, $\chi^2 =$ 190.27, *P* = 0.000) (Figure 1). In addition, the cases with distant metastasis received a poorer prognosis than those without distant metastasis (5-year disease-specific survival

DISCUSSION

There were several studies that have investigated the factors influencing prognosis[13,14]. The conclusions of the reports were controversial, though most of them used the Cox proportional hazard model to find the relation between survival time and patient characteristics, and clinical and pathological factors in patients with gastric cancer.

After evaluating the clinic-pathological factors of 738 patients, Kulig *et al*[7] reported that patient age, depth of tumor infiltration, tumor location, and metastatic node ratio were identified as independent prognostic factors in a Cox proportional hazards model. In addition, Shiraishi *et al*[15] reported that independent prognostic factors of gastric cancer were serosal invasion, extragastric lymph node metastasis and liver metastasis, but survival was not significantly associated with any of the patient factors or operation factors, including the extent of lymph node dissection. In our study, age at diagnosis, past history, surgical curative degree, Borrmann type, Lauren's classification, pT stage, and pN stage were significant prognostic factors in Cox mod-

els. There was a small difference between our study and other reports. In the final model of log-normal analysis, we investigated that cancer location, distant metastasis and histologic types were significantly related to the survival. The outcomes were also verified by disease-specific survival analysis. However, the association between above factors and survival were not observed. In log-normal analysis, Pourhoseingholi *et al*[5] observed that distant metastasis, histology type and pT stage were significant prognostic factors after retrospectively studying 746 Iranian patients. Moreover, distant metastasis was a significant prognostic factor only in log-normal analysis, not in the Cox model.

Compared to the Cox model, the evaluation criteria in our study indicated log-normal regression was more powerful not only in the full model, but also in the final one. In the final model, the selected prognostic factors in the log-normal model were different compared to those in the Cox model. Furthermore, the data strongly supported the log-normal regression in the full and final models, and might lead to more precise results as an alternative for Cox.

In conclusion, according to the results of our study, age at diagnosis, past history, cancer location, distant metastasis status, surgical curative degree, combined other organ resection, histology types, Borrmann type, Lauren's classification, pT stage, total dissected nodes and pN stage were significant prognostic factors of gastric cancer. It is suggested that log-normal regression model can be a useful statistical model to evaluate prognostic factors instead of the Cox proportional hazard model.

ACKNOWLEDGMENTS

COMMENTS

Background

Most of studies used the Cox proportional hazard model to find the relation between survival time and covariates of patients with gastric cancer (GC). On the other hand, some studies reported that log-normal regression could estimate

the parameter more efficiently than the Cox model. However, the efficiency of log-normal regression was still controversial.

Research frontiers

In this retrospective study, the authors elucidated the factors affecting the survival of patients with GC using log-normal regression, and to compare these results with the Cox model.

Applications

It is suggested that log-normal regression model can be a useful statistical model to evaluate prognostic factors instead of the Cox proportional hazard model.

Peer review

Overall the study was well designed, performed, and analyzed. The very minor, but important parameters should be added in analysis.

Abstract

As the use of drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs) increases, so too do gastrointestinal ulcers, bleeding, perforation and obstruction. Diaphragm disease of the small intestine is formed by submucosal fibrosis and destruction of lamina muscularis due to chronic ulceration, which corresponds to the most severe stage of NSAID enteropathy. It may lead to stricture of the small intestine. If such ulcerations and strictures in the small intestine are multiple, differential diagnosis is between diaphragm disease and cryptogenic multifocal ulcerous stenosing enteritis (CMUSE), because the gross findings of diaphragm disease are similar to those of CMUSE. We report a rare case of diaphragm disease caused by NSAID. It has been finally confirmed by capsule endoscopy and the origin of chronic obscure gastrointestinal bleeding was found to be multiple ulcers and strictures in the small intestine. After operation, we diagnosed the patient with diaphragm disease rather than CMUSE.

INTRODUCTION

The complications of non-steroidal anti-inflammatory drugs (NSAIDs), aspirin, antiplatelet agents, and antithrombotic agents are known to include gastrointestinal ulceration, bleeding, perforation and obstruction[1]. NSAID-induced mucosal injury can occur to the upper and lower gastrointestinal tract. The incidence of NSAID-induced enteropathy is not less than that of gastropathy. Diaphragm disease is the most severe stage of NSAID enteropathy. In ambulatory patients who took NSAIDs for > 3 mo because of arthritis, 70% had small intestinal ulcers and erosions by capsule endoscopy[2]. The diaphragm is formed by chronic fibrosis and destruction of lamina muscularis with chronic ulceration, and causes obstruction of the lumen in the small bowel[3]. However, diaphragm disease is a rare diagnosis.

Cryptogenic multifocal ulcerous stenosing enteritis (CMUSE) has multiple ulcerations and strictures in the small intestine; it is similar to diaphragm disease in terms of gross findings, and it is characterized by a chronic and

relapsing clinical course, and is more common in middle-aged patients.

We report a case of diaphragm disease in the small bowel that presented with obscure overt bleeding due to NSAID use, which was detected by capsule endoscopy. We review the differential diagnosis with CMUSE through histological findings and clinical course after surgery.
CASE REPORT

A 79-year-old woman was hospitalized for a low level of hematochezia. At admission, her hemoglobin level was 8.9 g/dL. She had also taken 20 mg piroxicam, 275 mg naproxen and 25 mg diclofenac daily for 4 years because of degenerative joint diseases. She had been hospitalized for iron deficiency anemia 5 years ago and there was no active bleeding focus upon esophagogatroduodenoscopy (EGD) and colonoscopy at that time. It was recommended that she undergo capsule endoscopy, however, she refused and was discharged.

After hospitalization, she had EGD and abdominal computed tomography (CT) to find the focus of her bleeding. No bleeding foci were revealed by EGD and abdominal CT. She had no more hematochezia after hospitalization. On day 3 of hospitalization, capsule endoscopy was performed. There were multiple, concentric circular ulcerations, with luminal narrowing in the jejunum and ileum, with many variable-sized erosions and bleeding stigmata in the ulcerations (Figure 1). The capsule in the small bowel was not excreted until 8 d after capsule endoscopy, even though she could have a meal. According to the results of capsule endoscopy, we need to diagnose differentially between NSAID-induced enteropathy and CMUSE, because of the gross similarities, such as multiple ulcerations and strictures in the small intestine. Even though the patient was an elderly woman and took NSAIDs, she was not diagnosed with NSAID-induced enteropathy because of the similar endoscopic findings to CMUSE. To confirm the diagnosis, histological examination was needed. She complained of chronic abdominal pain for 2 years, therefore, we could diagnose by capsule endoscopy that she had symptomatic multiple strictures.

To relieve the chronic abdominal pain caused by the multiple strictures in the small bowel, and to remove the retained capsule and evaluate the exact cause of the multiple ulcerations and strictures, we performed segmental resection of the ileum (Figure 2) instead of double balloon enteroscopy. Histological findings in the ileum (Figure 3) revealed typical multiple, circular ulcerations and a mucosal diaphragm, which suggested the most severe complications of chronic NSAID use. These mucosal diaphragms indicate chronic ulcers, submucosal fibrosis, reactive epithelial change, and chronic inflammation. After discharge, she had no more gastrointestinal bleeding and abdominal pain and took misoprostol at the outpatient clinic with close observation for > 1 year.

DISCUSSION

Diaphragm disease is the pathognomic characteristic of NSAID enteropathy, and was named by Bjarnason *et al*[4].
Figure 1 Capsule endoscopic findings. A: There were concentric ulcerations with luminal narrowing; B: There were many variable-sized erosions and bleeding stigmata in the ulcerations; C: There was a totally obstructed lesion in which the capsule was suspected to be retained.

They described the clinicopathological features of NSAID-induced stricture as diaphragm disease. The histopathological characteristics of diaphragm disease are: superficial ulceration at the apex of the villi; circumferential ring-like stricture; multiple, short segment annular strictures; transmural inflammation; and submucosal fibrosis[5].
Several other authors have reported diaphragm disease in patients taking NSAIDs, by enteroscopy[6] and after laparotomy[5,7]. The first diagnosis of small intestinal diaphragm disease after use of NSAID through capsule endoscopy was reported by Yousfi *et al*[3]. In their study with capsule endoscopy, there were multiple small-intestinal strictures where the capsule was retained. Thus, exploratory laparoscopy was required to remove the retained capsule, as in our case.

After long-term use of NSAIDs for > 20 years, the small intestine shows fibrotic constriction and thickened

Figure 2 Specimen from segmental resection of the ileum. A: A capsule was located at 60 cm up from the terminal ileum. Forceps and hand point out the location in the ileum where the capsule was retained. There were multiple strictures in the ileum (black arrows); B: In longitudinal section, there were multiple thin, web-like mucosal septa that caused abrupt luminal narrowing in the small intestine (black arrows).

Figure 3 Histological findings of the ileum. The mucosal diaphragm reveals surface erosion or ulceration, submucosal fibrosis, reactive epithelial change, and chronic inflammation (hematoxylin and eosin stain, 40 ×).

hyperemic mucosa that lead to obstruction through local damage and healing process[8].

In NSAID-induced enteropathy, capsule endoscopy shows circumferential ulcerations, erosions and multifocal strictures[3,9]. Capsule endoscopy is a useful option to establish the etiology of obscure overt gastrointestinal bleeding, especially in elderly patients. Diagnostic yield of capsule endoscopy for finding the focus of obscure gastrointestinal bleeding is reported to be 38%-93%[10]. Diagnostic yield of capsule endoscopy for obscure gastrointestinal

Table 1 Differences between non-steroidal anti-inflammatory drug-induced enteropathy and cryptogenic multifocal ulcerous stenosing enteritis

	NSAID-induced enteropathy	CMUSE
Definition	Ulceration and stricture of small intestine induced by NSAIDs[19,20]	Unexplained small intestinal multiple stricture and ulceration[17,18]
Causes	NSAIDs	Unknown
Age	Old-aged people[26]	Middle-aged people[18]
Treatment	Stop NSAIDs, Prostaglandin (misoprostol)[21], Sulfasalazine[22], Metronidazole[23], Glutamine[24], Glucose/citrate[25]	Steroids[17]

NSAID: Non-steroidal anti-inflammatory drug; CMUSE: Cryptogenic multifocal ulcerous stenosing enteritis.

bleeding is not different for overt and occult bleeding[11,12]. Diagnostic yields of CT angiography and double balloon enteroscopy in finding the focus of obscure gastrointestinal bleeding were 24% and 75.7%, respectively[13,14].

The origin of gastrointestinal bleeding can be detected in a higher percentage of patients by capsule endoscopy than by CT angiography and double balloon enteroscopy[10]. In our case, we performed capsule endoscopy to find overt obscure bleeding foci after abdominal CT scanning. There was no definite stricture or sign of significant obstruction by abdominal CT. However, the capsule became trapped in the bowel unexpectedly. The important complication of capsule endoscopy is capsule retention, for which the incidence is < 2%[15]. Intestinal stricture might be suspected, especially in patients with chronic NSAID use, ischemic bowel disease, abdominal radiotherapy, and Crohn's disease. For these patients, capsule endoscopy can be performed after abdominal CT or small bowel series to find strictures[10]. Stricture cannot be found completely by abdominal CT or small bowel series, therefore, an M2A patency capsule can be considered, which is biodegradable in the gastrointestinal tract in patients with suspected intestinal stricture[16].

Our patient had multiple ulcerations and strictures in the small intestine, therefore, diaphragm disease was needed to be differentiated from CMUSE, even though the patient was an elderly woman who was taking NSAIDs. The characteristics of NSAID-induced enteropathy and CMUSE using previously published data are summarized in Table 1. CMUSE is defined as unexplained small intestinal multiple strictures and ulcerations of unknown origin. It is characterized as an atypical type of vasculitis[17]. Its clinical features include unexplained stricture and ulceration of the small bowel, without systemic inflammation, which are found in young and middle-aged patients. CMUSE can relapse chronically or after surgery. The symptoms of CMUSE can be improved by steroid treatment[17,18].
In conclusion, NSAID-induced diaphragm disease in the small bowel can be diagnosed efficiently by capsule endoscopy, and the gross endoscopic features of diaphragm disease are similar to those of CMUSE. We

also suggest that NSAID-induced enteropathy, such as diaphragm disease, should be suspected in NSAID users, especially in elderly patients.

Abstract

Percutaneous endoscopic gastrostomy (PEG) is a proven feeding tube, just as the nasogastric tube is proven to be able to deliver enteral nutrition. For long-term use, both patient and caregiver want neither. What is desired is the LOOPPEG® 3G tube, more secure than the PEG, and less risky to change than the nasogastric tube. Future clinical research should focus on this high-comfort low-risk tube.

TO THE EDITOR

I found "Survival of geriatric patients after percutaneous endoscopic gastrostomy in Japan" by Yutaka Suzuki *et al*[1] to be an interesting and timely article.

With an aged population and several centers working together, they were able to recruit a large sample and, consequently, produce robust results. The first lesson to be learnt is that collaboration can produce better results. The second lesson is that, for the Japanese population at least, the percutaneous endoscopic gastrostomy in geriatrics is proven. To the co-authors and their institutions, I offer my heartiest congratulations. My country, Singapore, is ageing rapidly and their experiences can offer valuable lessons.

I emphasize that my subsequent suggestion for future research should not be taken as criticisms of their work, which is an unqualified success. By way of introducing my comments, I pose two questions.

First, since elderly patients in other countries might react differently from Japanese patients, should we not do a similar study of the PEG in Singapore? My answer is no, for the following reason. The difference in year (or mo) is unlikely to be important to the geriatric patient, in whom compassion is more valued than cure.

Second, since the nasogastric tube might give a better survival than the PEG, should we not do a similar study on this feeding tube? Again, my answer is no, for the following reasons. Feeding tube and survival of the elderly have a correlation but not a cause-effect relationship. Both nasogastric tube and PEG can deliver the enteral nutrition, and the choice is determined more by the risk/comfort profile of the tube. Statistical significance does not mean clinical significance. Conversely, lack of the former does not mean that the PEG is not a clinically better tube. The relationship between nasogastric tube and PEG is predictable, independent of age and race, and unlikely to be affected by the study findings, however robust.

This relationship is illustrated in Figure 1. There are enough published data to show that the nasogastric tube is low in risk and low in comfort, whereas the PEG is very comfortable but also high in risk[2]. For long-term use, both patients and caregivers want neither option! What

Figure 1 Risk/Comfort Chart. The desired tube is the high-comfort low-risk option (√). PEG: Percutaneous endoscopic gastrostomy.

they need is a very comfortable but low in risk option.

In my opinion, there is only one feeding tube which meets this profile. The LOOPPEG® 3G tube is comfortable because it bypasses the nose and low in risk because it cannot be dislodged[3]. Also, it is less risky to change than the nasogastric tube. Consequently, the 3G tube can be made 15 Fr or smaller because tube blockage is a non-issue, having been negated by easy tube change. Thus, the trauma of changing the tube - physical, psychological and financial - is minimized.

However, no case series has been published. It may take forever for a sizeable sample and robust results to come out from my part of the world. Hence, I hope our Japanese colleagues, having published a solid study, will take up the challenge to move beyond the PEG, research the 3G tube, and report their findings in this fine Journal.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT
All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statisital review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including t-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (n). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the P value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

　　Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

　　Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS
Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

　　Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions
Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +,

country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract
There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words
Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text
For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations
Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data
Write as mean ± SD or mean ± SE.

Statistical expression
Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units
Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations
Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics
Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc*.
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc*.
Biology: *H. pylori*, *E coli*, *etc*.

RESUBMISSION OF THE REVISED MANUSCRIPTS
Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office
World Journal of Gastroenterology
Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-8538-1893

Language evaluation
The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form
Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers
Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support
For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript
WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases
Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee
WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

World Journal of

Gastroenterology

World Journal of Gastroenterology

A peer-reviewed, online, open-access journal of gastroenterology and hepatology

Editorial Board

2010-2013

The *World Journal of Gastroenterology* Editorial Board consists of 1144 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 60 countries, including Albania (1), Argentina (8), Australia (29), Austria (14), Belgium (12), Brazil (10), Brunei Darussalam (1), Bulgaria (2), Canada (20), Chile (3), China (69), Colombia (1), Croatia (2), Cuba (1), Czech (4), Denmark (8), Ecuador (1), Egypt (2), Estonia (2), Finland (8), France (24), Germany (75), Greece (14), Hungary (10), India (26), Iran (6), Ireland (7), Israel (12), Italy (101), Japan (112), Jordan (1), Kuwait (1), Lebanon (3), Lithuania (2), Malaysia (1), Mexico (10), Moldova (1), Netherlands (29), New Zealand (2), Norway (11), Pakistan (2), Poland (11), Portugal (4), Romania (3), Russia (1), Saudi Arabia (3), Serbia (3), Singapore (10), South Africa (2), South Korea (32), Spain (38), Sweden (18), Switzerland (11), Thailand (1), Trinidad and Tobago (1), Turkey (24), United Arab Emirates (2), United Kingdom (82), United States (249), and Uruguay (1).

Abstract

Organ preservation and ischemia reperfusion injury associated with liver transplantation play an important role in the induction of graft injury. One of the earliest events associated with the reperfusion injury is endothelial cell dysfunction. It is generally accepted that endothelial nitric oxide synthase (e-NOS) is cell-protective by mediating vasodilatation, whereas inducible nitric oxide synthase mediates liver graft injury after transplantation. We conducted a critical review of the literature evaluating the potential applications of regulating and promoting e-NOS activity in liver preservation and transplantation, showing the most current evidence to support the concept that enhanced bioavailability of NO derived from e-NOS is detrimental to ameliorate graft liver preservation, as well as preventing subsequent graft reperfusion injury. This review deals mainly with the beneficial effects of promoting "endogenous" pathways for NO generation, *via* e-NOS inducer drugs in cold preservation solution, surgical strategies such as ischemic preconditioning, and alternative "exogenous" pathways that focus on the enrichment of cold storage liquid with NO donors. Finally, we also provide a basic bench-to-bed side summary of the liver physiology and cell signalling mechanisms that account for explaining the e-NOS protective effects in liver preservation and transplantation.

INTRODUCTION

Ischemia-reperfusion (IR) injury during liver transplantation (LT) is a complex, multi-factorial process in which numerous mediators and a variety of cells interact, leading to tissue damage. It is one of the major cause of both initial poor function and primary non-function of liver allograft, and is responsible for 81% of re-transplantations during the first week after surgery. An intricate network of hepatic and extra-hepatic mechanisms is involved in the genesis of hepatic IR[1-3].

Cold storage and warm reperfusion are unavoidable steps in transplantation and all grafts undergo some degree of IR injury. The cascade of events involves microvasculature (sinusoidal endothelial cells or SEC), Kupffer cells, Ito cells, parenchyma (hepatocytes) and bile ducts. Cold ischemia during organ storage, which is intentionally applied to reduce the metabolic activity of cells in order to preserve the graft before its transplantation, has a substantial effect on graft function. Also, warm ischemia that begins at implantation has an additional negative impact on graft function and outcome. Whatever the type of attack, liver graft damage initiated during the ischemic phases is exacerbated after reperfusion with oxygen and the reintroduction of blood elements.

Although our understanding of the pathophysiology of IR injury is only partial, many response elements indicate that vascular endothelium disruption, the immune response, oxidative mediators, and several cell-death pathways all play important roles. A variety of mediators have been implicated, including reactive oxygen species (ROS) and inflammatory mediators tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-1, transforming growth factor-β, interferon-γ and endotheline (ET)-1. Furthermore, complement and chemokines are also released, which leads to leukocyte recruitment and activation. Upregulated adhesion molecules, including intercellular adhesion molecule 1 and E-selectin, enhance endothelial-immune cell interactions. ROS directly injure many cytoskeletal and functional cellular components, causing cell damage. After IR, direct endothelial damage and abnormal vascular tone occurs as a result of an imbalanced sensitivity to mediators of vasoconstriction and vasodilation, such as ET-1/nitric oxide (NO). Endothelial injury also causes cell swelling and narrowing of the vascular lumen, further reducing blood flow. Finally, key regulators of apoptosis, such as caspases, are upregulated resulting in increased cell death.

It is now largely appreciated that IR associated with LT leads to a rapid endothelial dysfunction characterized by a marked decrease in NO production[4-6]. The decrease in NO bioavailability occurs within the first few minutes after reperfusion, and appears to be due to decreased synthesis of NO by NO synthase (NOS), enhanced inactivation of NO by the overproduction of superoxide anion (O_2-), or both. Experimental studies emphasize that it is essential to minimize the deregulation of hepatic microcirculation during LT[7].

NO is a free-radical diatomic gas of low molecular weight with an unpaired electron[8]. It is highly lipophilic, allowing it to permeate quickly across the cell membranes. Its half-life *in vivo* is a few seconds, and it is rapidly converted to stable nitrites (NO_2-) and nitrates (NO_3-)[8]. Endogenous NO is synthesized from the amino acid precursor L-arginine in an oxidation reaction, catalyzed by the NOS enzymes. This complex reaction requires the presence of co-substrates O_2 and NAD(P)H (nicotinamide adenine dinucleotide phosphate reduced), as well as many cofactors such as flavin adenine dinucleotide, flavin

mononucleotide and BH4 (tetrahydrobiopterin)[8,9]. There are three isoforms of NOS expressed in the liver in different cells and in different conditions, namely endothelial NOS (e-NOS), neuronal NOS (n-NOS) and inducible NOS (i-NOS). Both e-NOS and n-NOS are constitutively present in liver. The exact role of n-NOS in the pathophysiology of IR injury during LT remains to be established[10]. n-NOS has been observed within neurons innervating the portal tracts by histochemical methods, and several authors believe that this protein is scarcely expressed in the liver[11,12]. In contrast to inducible NOS, constitutive NOS activation requires Ca^{2+}.

Like any important signaling molecule, NO diffuses freely across cell membranes. Under physiological conditions, NO binds to soluble guanylate cyclase inside cells and then induces the production of large quantities of cGMP (guanosine 5'-monophosphate), which then triggers the signal (Figure 1)[13]. *In vivo,* NO is inactivated mainly by superoxide anion, but other pathways could be involved. The first pathway involves the autoxidation of NO to NO_2- and then to NO_3-. Other pathways may be mediated by metal-catalyzed oxidation reactions. The copper-containing protein ceruloplasmin (P-Cu^{2+}) has been shown to rapidly oxidize NO to NO_2- in physiological conditions[14,15]. In addition to the P-Cu^{2+}-mediated reaction, ferrous deoxygenated hemoglobin (Hb-$Fe^{2+}O_2$; oxyhemoglobin) rapidly converts NO to NO_3-.

e-NOS ACTIVITY AND e-NOS-DERIVED NO PRODUCTION IN LT: PATHOPHYSIOLOGICAL ASPECTS

e-NOS is constitutively expressed in venous and arterial endothelial cells and it produces small quantities of NO (at picomolar levels)[16]. It is the main source of NO in endothelial cells under physiologic conditions[9]. e-NOS is also induced in response to specific extracellular stimuli, such as shear stress[17] and metabolic stress (Figure 1)[18]. e-NOS is localized to the caveolae[19,20], which are microdomains of the plasma membrane that have been implicated in a variety of cellular functions, including signal transduction. Caveolin proteins are the major coat proteins of caveolae, and in endothelial cells e-NOS binds to caveolin-1. Caveolin-1 and other peptides from the caveola region directly inhibit e-NOS activity[21,22]. This complex membrane structure is sensitive to the fluid pressure on the membrane.

The e-NOS activation can also be triggered through the signalling pathway involving serine/threonine kinase Akt [or protein kinase B (PKB)], which in turn is stimulated by the phosphoinositide 3-kinase (PI3K)[23,24]. e-NOS is one of the targets of Akt. An important step in this activation is the phosphorylation by Akt of the serine residue in position 1179 (bovine sequence) or serine 1177 (human sequence) of the e-NOS enzyme[25,26]. Therefore, Akt-dependent e-NOS phosphorylation may be an important mechanism in the attenuation of IR injury after

Figure 1 Endothelial nitric oxide synthase-derived nitric oxide synthesis. Shear stress leads to endothelial nitric oxide synthase (e-NOS) phosphorylation and through pathway involving phosphoinositide 3-kinase (PI3K) and Akt. Metabolic stress also phosphorylates e-NOS through the adenosine monophosphate kinase (AMPK) route. The coordination of signalling through these converging pathways allows for e-NOS activation. L-arginine is converted in the endothelium monolayer by the constitutive e-NOS to nitric oxide (NO) and L-citrulline. NO diffuses into both the vessel lumen and the vessel wall, thereby activating soluble guanylate cyclase (sGC) to produce cyclic guanosine monophosphate (cGMP) from guanosine 5'-triphosphate (GTP). NO in concert with cGMP involve tissue protection.

LT. Treatment of liver grafts with adenovirus encoding for myr-Akt improves biochemical and cytoprotective parameters after orthotopic LT in pigs, in comparison to uninfected groups[27].

Recent reports demonstrate that metabolic stress can elicit adenosine monophosphate protein kinase (AMPK), which stimulates phosphorylation of e-NOS protein and increases NO bioavailability in endothelial cells[18,28,29]. The e-NOS-derived NO, in turn, decreases hepatic levels of ET-1, improves hepatic microcirculation and significantly attenuates TNF-α hepatic expression and, remarkably, reduces the activation of caspase-8 and caspase-3 after OLT[30].

In addition to its key role in vascular tone regulation, studies have shown that NO is involved in several other protective routes (Figure 2). Animal studies have shown that early in the reperfusion period, tissue damage appears to be associated with decreased NO availability related to e-NOS down-regulation[27,31]. Similarly, the use of NOS inhibitors leads to IR damage[32]. It has been demonstrated that e-NOS-derived NO inhibits the production and release of several endothelial vasoconstrictor factors, including ET-1[33,34]. NO also interferes with the adhesion and aggregation of platelets, adhesion of leukocytes and monocytes to endothelial cells in vessel walls[35,36]. It also modulates the expression of pro-inflammatory molecules, such as vascular cell adhesion molecule-1 and monocyte chemoattractant protein 1. Furthermore, NO is emerging as an endogenous inhibitor of TNF-α. NO decreases endothelial permeability and also exerts anti-mitogenic effects in vascular smooth muscle cells by inhibiting their growth and proliferation.

However, other lines of evidence suggest that ROS production after LT reduces e-NOS activation, which becomes uncoupled and perturbs e-NOS-derived NO homeostasis[37] (Figure 3). In parallel, i-NOS is transcription-

ally up-regulated in all liver cells, leading to the production of large amounts of NO for persistent periods[37]. Excessive NO generation can be detrimental, because it may alter systemic vascular tone and reactivity, leading to hypotension and circulatory shock[38]. In addition, the generation of peroxynitrite (ONOO-), a potent oxidant formed by reacting NO with O_2-[39], could also cause cell injury through lipid peroxidation, direct inhibition of the mitochondrial respiratory chain[40,41], inhibition of membrane Na^+/K^+ ATPase activity, or oxidative protein modification such as the formation of nitrotyrosine[4,38]. Thus, NO acts as a double-edged sword since it has neither harmful or beneficial effects, depending on its source and the experimental conditions.

The importance of e-NOS for hepatic injury after cold storage/warm reperfusion in transplanted liver grafts has been investigated. The functions of mouse liver grafts retrieved from e-NOS-deficient donors and those from wild-type donors were compared after orthotopic transplantation[31]. e-NOS-deficient liver grafts intensified IR injury, as shown by increased ALT, necrosis and apoptosis, and elevated graft infiltration of monocytes/macrophages. In addition, both flow rate and sinusoidal diameter were diminished after transplantation of e-NOS-deficient grafts. All these alterations are detected from 4 h after LT. In another study, decreased hepatic bioavailability of NO was detected as early as 1 h after reperfusion of human liver transplants[4]. This decline was attributed to a reduction of e-NOS protein levels after reperfusion, rather than to a change in e-NOS mRNA transcription. The concerned mechanism would be a rapid turnover/degradation of the e-NOS enzyme[42]. The extent of the alteration of e-NOS protein expression depended on the duration of preservation, because the loss of e-NOS was exacerbated after 6 h of cold ischemia[43]. The stimulus for the rapid decrease in e-NOS expression is not known.

LT depletes serum arginine due to a massive release of arginase I from cold-injured liver parenchymal cells[44,45]. The depletion of arginine decreases tissue arginine availability, with subsequent down regulation of e-NOS[46,47]. In contrast, enhancement of arginine availability through arginase blockade can protect against hepatic IR injury. The results demonstrate that inhibition of arginase with nor-NOHA can partially reverse the arginine depletion seen in IR injury and improve the histopathological damage following transplantation[48].

MODULATION OF e-NOS-DERIVED NO PRODUCTION FOR LT

The quality of cold preservation is a major detriment of initial graft function and survival. While cold ischemia is considered necessary to slow tissue metabolism, it causes well-documented lesions in the SEC[49]. The SEC is the main target cell of reperfusion injury, at least during the early phase[50]. Endothelial dysfunction leads to NO deficiency, which has been implicated in many disorders.

Figure 2 Protective effects of endothelial nitric oxide synthase-derived nitric oxide. The multifactorial consequences are derived from the nitric oxide (NO) generation on oxidative stress (reactive oxygen species), proinflammatory [interleukins (ILs), tumor necrosis factor (TNF)] and vasoconstrictor (endothelins) mediators. e-NOS: Endothelial nitric oxide synthase; ROS: Reactive oxygen species.

Figure 3 Tissue damage after unbalanced nitric oxide production. Cold ischemia reperfusion involves uncoupled endothelial nitric oxide synthase (e-NOS) and inducible nitric oxide synthase (i-NOS) expression. Large amounts of nitric oxide (NO) are produced under these pathological conditions. NO, in association with increased mitochondrial dysfunction and oxidative stress, reacts with superoxide anion (O_2-), to produce peroxynitrite (ONOO-). Peroxynitrite, in concert with other oxidants, induces tissue damage.

Figure 4 Modulation of the decline in endothelial nitric oxide synthase-derived nitric oxide production. endothelial nitric oxide synthase (e-NOS)-derived nitric oxide (NO) bioavailability can be compromised either by a reduced L-arginine and cofactor (tetrahydrobiopterin, BH4) availability, or by a decreased e-NOS protein activity and level. Two ways seem to be able to overcome these obstacles: the use of exogenous sources of NO (NO donors or NO inhalation) and the induction of the endogenous downstream effectors of e-NOS (pharmacological treatment or ischemic preconditioning) or transfection by an adenovirus containing e-NOS enzyme. SNP: Sodium nitroprusside; GSNO: S-nitroso-L-glutathione; AICAR: 5-amino-4-imidazole carboxamide riboside; TMZ: Trimetazidine; APC: Activated protein C; AMPK: Adenosine monophosphate protein kinase; PI3K: Phosphoinositide 3-kinase.

The morphological changes in these cells interfere with the hepatic microcirculation during reperfusion (adhesion and activation of platelets and leukocytes, and thromboses)[51]. So, improving quality of graft preservation is a means to promote its immediate function, to optimize the allocation of grafts and also to reduce the shortage of organs. Various strategies have been developed to promote immediate recovery of graft function and also to increase access to the marginal donor pool.

Many strategies could be developed to compensate for the decline in NO production during LT. We can distinguish two ways to promote NO production *in vivo*: the endogenous and the exogenous routes (Figure 4). The endogenous way consists of the use of arginine[52]

to compensate for the deficiency of this NO precursor. Other methods consist of directly influencing the activity of the e-NOS enzyme by adding to the preservation solution one of its cofactors (BH4)[53], or one of its inducers, to increase downstream effectors of e-NOS such as Akt and AMPK[54-56]. Transfection of donor liver by an adenovirus containing the e-NOS enzyme could also be envisaged before graft extraction[57,58]. Ischemic preconditioning (IP) could be an endogenous source of NO[59]. The exogenous route requires the use of an exogenous source of NO, which may be given directly by inhalation or indirectly by an NO donor such as sodium nitroprusside (SNP) or S-nitroso-L-glutathione (GSNO)[60-63].

These strategies have shown their effectiveness experimentally, but are not always applicable in human clinical contexts. NO can react with superoxide anions to form ONOO-, a highly reactive oxidant, which can induce apoptosis and cause structural and functional disorders of the graft. This explains why some authors claim that the contribution of NO during cold ischemia may be unnecessarily risky, especially if given at a high dose[64], and the use of NO in humans is controversial at present.

NO GENERATION INDUCED BY THE ENDOGENOUS PATHWAY

Pharmacological e-NOS induction during cold preservation

The potentially protective role of endogenous NO in IR-induced injury to the liver is supported by recently published studies demonstrating enhanced hepatocellular injury in post-ischemic animals that had been rendered deficient in e-NOS[65]. In addition, researchers have demonstrated that over-expression of liver e-NOS protects mice from IR-induced liver injury[27,66-68].

Endogenous e-NOS activation and e-NOS-derived NO might be a promising approach to limiting organ injury. Several pro-survival pathways such as PI3K/Akt and AMPK, which are activated following hepatic injury, are involved in the regulation of e-NOS. Pharmacological up-regulation of these pro-survival kinase cascades may provide an approach to limiting cold ischemic insult. In this regard, 5-amino-4-imidazole carboxamide riboside (AICAR), carvedilol (CVD), trimetazidine (TMZ), activated protein C (APC) and insulin-like growth factor (IGF)-1 could be promising additives in preservation solutions to improve the outcome of liver grafts after cold storage and reperfusion.

Recent studies have shown that the enrichment of University of Wisconsin (UW) with AICAR, an activator of AMPK, ameliorated long-term liver preservation[55]. The protective effect of AICAR on liver injury and function seems to be mediated by enhanced e-NOS activation and NO generation following AMPK phosphorylation, which induces vasodilatation in liver grafts[55]. The relevance of AMPK as an e-NOS upstream regulator was evidenced by the administration of AraA, a phospho-AMPK inhibitor, previous to liver graft preservation,

demonstrating that AMPK inhibition reduces e-NOS activation and NO production[55]. In line with these results, Ben Mosbah *et al*[54] demonstrated that the use of CVD, a β- and α-adrenergic blocking drug, when added to UW preservation solution, protected livers through the same mechanism[54]. Livers preserved in this solution show decreased transaminases levels, improved vascular resistance, reduced mitochondrial damage and enhanced ATP levels after reperfusion.

However, the AMPK pathway is not the only e-NOS modulator. Other authors have attempted to improve the histidine-tryptophan-ketoglutarate (HTK) preservation solution by supplementation with an anticoagulant and anti-inflammatory agent, such as APC[30]. They found that the modified HTK preservation solution decreased portal pressure and improved hepatic microcirculation through increased NO hepatic levels *via* up-regulated e-NOS. In addition, the solution attenuated TNF-α expression and markedly reduced the activation of caspase-3 and caspase-8[30]. Although the exact mechanism by which APC activated e-NOS remains unclear, other *in vitro* reports postulated that APC activated e-NOS *via* phosphatidylinositol 3-kinase-dependent phosphorylation, followed by activation of PKB[69].

Recently, Institut Georges Lopez-1 (IGL-1) solution has been proposed as an effective alternative to UW liquid in clinical kidney transplantation, and in experimental orthotopic LT models[70,71]. In addition, we recently demonstrated that IGL-1 is more suitable than UW solution for fatty liver preservation and that the benefits from IGL-1 were linked to an increment of NO synthesis through e-NOS activation which, in turn, reduced oxidative stress and liver injury[72].

TMZ, which has been used as an anti-ischemic drug in the heart for over 35 years, reduced liver injury and improved liver regeneration and survival rate in an experimental model of partial hepatectomy under hepatic blood inflow occlusion[56]. Studies examining the underlying protective mechanisms of TMZ as an additive to UW solution for liver preservation suggest that AMPK up-regulation is the mechanism by which TMZ activates e-NOS and exerts its cytoprotective effect[55]. Another study demonstrated that TMZ attenuated myocardial IR injury *via* PI-3K/AKT kinase pathway activation[73]. We recently found that the addition of TMZ to IGL-1 solution has a synergistic effect on e-NOS-derived NO generation that favours HIF-1α accumulation during normothermic reperfusion[32]. Preserved HIF-1α levels contribute to the increase in the over-expression of cytoprotective proteins such as HO-1 in fatty liver grafts.

It has been established that IGF-1 up-regulates e-NOS activity by interacting with a tyrosine kinase membrane receptor which activates the AKT signalling pathway[74,75]. Furthermore, trophic factors, including IGF-1, have been added to UW solution in an attempt to improve the survival of pig orthotopic liver allografts after cold storage[76]. To this end, we explored the effects of the addition of IGF-1 to IGL-1 solution on fatty liver preservation during cold IRI. We examined the mechanisms

responsible for such effects, including AKT phosphorylation and NO generation. We have demonstrated that the beneficial action of IGF-1 as an additive to IGL-1 is mediated by AKT activation and NO generation, with concomitant prevention of pro-inflammatory cytokines, such as TNF-α[77].

Surgical e-NOS induction by IP

IP is a technique described firstly in the heart by Murry *et al*[78] in 1986, which consists of the application of short and repetitive periods of I/R before a sustained one. The protective effect of IP is not specific to the myocardial muscle, since it is observed in other organs such as skeletal muscle[79], brain[80], intestines[81], lungs[82], kidneys[83] and liver[34]. In any case, the protection induced by IP against IR injury seems to be specific to each organ and animal species, depending on the number of IR cycles applied before the sustained IR. For example, 3-4 cycles are needed for the protection of myocardium[78], whereas in the liver just one cycle of 10 min of ischemia and 10 min of reperfusion is sufficient for maximal protection[59].

In the heart, IP offers an initial protection of 2-3 h after reperfusion, and a remote protection after 12-24 h that lasts for 2 to 3 d. A similar pattern was observed in the liver, although remote protection is not yet well established. Moreover, a differential IP protection was observed in the liver, also depending on the animal species.

Molecular mechanisms responsible for hepatoprotection

The molecular basis of IP is a sequence of episodes triggered by a rapid signal, which leads to an intracellular message and to the amplification of the effector mechanisms of protection[84]. The benefits of IP are caused by the release of several inflammatory mediators such as adenosine and NO, which is followed by the activation of multiple cellular signals. NO is generated by the adenosine released (activation of adenosine A2 receptors), which in turn activates the endothelial constitutive form of the e-NOS enzyme[34,85], a few minutes after IP. The window of liver protection induced by IP is defined by two factors: (1) the concentration of adenosine must be high enough to induce NO; and (2) the concentration of xanthine must be low enough to avoid its prejudicial effects. It is well established that a high concentration of xanthine would support significant increases in superoxide anion. This would react with NO to generate peroxynitrite[86], which would cancel the beneficial effects of IP. Vasodilator effects of NO release improved liver oxygenation and microcirculation[87], and also inhibited the generation of ET, powerful vasoconstrictors generated during liver reperfusion[34].

In addition, IP preserves energy metabolism during sustained ischemia[88,89]. This is confirmed by the maintenance of ATP levels, as well as the depletion of lactate accumulated during the ischemic period. This beneficial effect is mediated by the increase of AMPK, whose activation can be mediated by NO[89].

The activation of the G protein-bound A2 receptor by adenosine stimulates the activity of many intracellular kinases, such as protein-kinase C (PKC) and p38 MAPK[90,91]. In addiction, recent studies implicate PKC in some of the beneficial effects of IP in liver. They show that PKC activation depends on the phosphorylation of different effector molecules, such as the tyrosine kinases[92] and MAPK (including p38 and MAPK[93]), and increases the tolerance of hepatocytes and endothelial cells to the ischemic insult.

Many transcription factors are involved in PKC activation, such as nuclear factor (NF)-κB, which is responsible for the protective effects of PI[94,95]. These transcription factors modulate the expression of particular genes, resulting in the synthesis of proteins such as heat shock proteins (HSP), which are understood to be effectors for the benefits of IP[96]. In the liver, IP is associated with the synthesis of many inducible forms of HSP: HSP70, HSP2 and HSP73 and heme oxygenase (HO-1/HSP32). The induction of HSP depletes the binding between pro-inflammatory transcriptional factors and improves the oxidant capacity of the cells[96-98]. Both effects could contribute to the decrease in TNF-α and to the attenuation of the inflammatory response of preconditioned livers[99,100]. It was also suggested that IP could reduce the transcription of genes, such as *c-fos* and *c-jun*, implicated in the development of the hepatic IRI, and that NFκB activation could induce the activation of signal translator and transcription activator 3, implicated in hepatoprotection and cell proliferation[89,94,96,101,102].

The beneficial role of NFκB in IP is controversial. Whereas Funaki *et al*[103] demonstrate that the protective role of IP is associated with the inhibition of NFκB activation, other authors suggest the opposite, showing that these effects are due to NFκB activation[94,95]. These differences could be attributed to differences in the models used. Besides these cellular signalization pathways, recent studies show that IP could induce the release of small quantities of ROSs[104] and TNF-α, contributing to the protective mechanisms.

Applications to LT

Several studies in animal models have demonstrated the usefulness of IP, but its application to clinical transplantation needs to be clarified. The first clinical application was carried out by Koneru *et al*[105], who used IP in deceased donor LT. They showed that deceased donor liver tolerated 5 min of hilar clamping, but IP did not decrease graft injury. More recently, Azoulay *et al*[106] demonstrated that the effects of 10 min of IP of the liver graft in the donor are associated with better tolerance to ischemia, as well as a worsened early liver function. These studies are consistent with those by Jassem *et al*[107], who demonstrated the protection of cadaver donor livers subjected to IP prior to retrieval by clamping of the hepatic pedicle for 10 min at 24 h after transplantation. This was evidenced by a significant decrease in transaminase levels, and a concomitant reduction of the non-specific inflammatory response.

Similar results were obtained by Cescon *et al*[108], in a prospective randomized study on cadaver donors, by the use of 10 min of IP followed by 15 min of reperfusion. These authors also demonstrated a significant reduction in AST, ALT and i-NOS expression levels after transplantation.

Taking all this into account, new research work is needed to establish the *"effective protection"* window in human LT and confirm the usefulness of IP in clinical transplantation, including the marginal graft donors, which at present are discarded for clinical transplantation purposes.

NO GENERATION INDUCED BY THE "EXOGENOUS PATHWAY" DURING COLD PRESERVATION

Some considerations

Many teams have sought to improve the performance of storage solutions by supplementation with cytoprotective agents. The bulk of the work on these specific modifications was performed on cellular models in rodents. Unfortunately, the benefits observed were not always confirmed in humans and these changes have often led to inconclusive results in clinical practice. Several NO donors have been tested experimentally for their protective effects on cold IR injury. However, due to the numerous possible reactions and related biological consequences, inappropriate NO levels can cause a series of disease states. On the other hand, insufficient NO production also has serious medical consequences. NO donor therapy should aim to achieve the production of the correct quantity of NO in the correct place for the correct length of time. The exogenous NO should acts primarily as a local mediator to respond to specific stimuli, and then it should simply dissipate through diffusion and oxidation to NO_2- and NO_3-, without the need for complex catabolism. The chemical versatility of NO has led to the synthesis of a wide range of NO donors, each with different modes and rates of NO release. NO donors are pharmacologically active substances that spontaneously release NO (direct donors) or are metabolized to NO (donors requiring metabolism)[109].

The selection of one among these NO donors for therapeutic uses is not easy, since it must meet certain requirements. The compound must be highly soluble in aqueous solutions and diffuse easily into cells, where it produces NO. It must be a proven NO donor, remain in a subtoxic range, have a prolonged half-life and mimic the effect of the endogenous NO. Several authors have amply evaluated the consequences of the use of NO donors in liver under warm ischemia conditions, but little work has been done on the effects on cold ischemia and graft preservation. In our opinion the use of such donors as additive to preservation solution is limited by their short half-life.

Kuroki *et al*[110] studied the effects of SNP on liver warm IR injury. They reported improvement of liver microcirculation and hepatocyte injury in the early period of reperfusion. In another study supporting this finding, SNP infusion after a short period of liver ischemia also decreased liver IR injury[111]. Interestingly, deleterious effects observed during cold storage conditions (like vacuolated hepatocytes, increase in intrahepatic resistance and diminution of bile production) were significantly removed after addition of 500 mmol/L SNP to the UW preservation solution[60]. The authors assumed that beneficial effects of SNP were mediated by NO release[63].

In addition, GSNO has been evaluated in the liver. GSNO may serve as an endogenous long-lived adduct or carrier of NO[112]. GSNO possesses significant antiplatelet action at doses that cause mild hemodynamic effects[113]. Thus, one possible mechanism by which the NO-donor can protect the graft against IR-induced damage could be based on its ability to block platelet aggregation, thus avoiding the intravascular coagulation that can occur during reperfusion. Quintana *et al*[60,61] evaluated the benefit of the addition in UW solution of GSNO as a NO donor. After assaying four GSNO concentrations (50, 100, 250 and 500 mmol/L), they reported an improvement in the properties of UW solution when it contained 100 mmol/L GSNO. It preserved the morphology of hepatocytes and endothelial cells and prevented the alteration of the hemodynamics and function of livers after cold preservation/reperfusion.

Some authors conclude that nitrite (NO_2-) therapy might prove beneficial in protecting organ function and integrity during periods of IR such as those encountered in organ transplantation[114-116]. Under physiological conditions of pH and oxygen pressure, NO_2- has been shown to be a non-active metabolic end product of NO oxidation with limited intrinsic biological activity[117]. However, under ischemic conditions, when e-NOS activity is strongly decreased as a result of its essential dependence on oxygen and the depletion on arginine, an increasing body of evidence indicates alternative NO production by NOS-independent routes. For instance, nitrite may be reduced back to NO by the nitrite reductase action of deoxygenated hemoglobin[118], acidic disproportionation[119], or xanthine oxidoreductase (XOR)[120,121]. In summary, the use of NO_2- in the field of cold preservation could be considered for the following reasons: (1) it is a highly stable substance with no potentially toxic effect; (2) it selectively releases NO under conditions that subsist in stored tissue, namely ischemia, hypoxia, or low pH; (3) it increases XOR activity, which may compensate for compromised constitutive e-NOS activity in terms of NO production, during hypoxia and acidosis; and (4) sodium nitrite is an FDA-approved compound. However, the use of nitrite in preservation solutions that contain allopurinol (such as UW or IGL-1 solutions) would be ineffective, since this latter inhibits XOR.

NEW DIRECTIONS FOR THE FUTURE

Along these lines we have evidenced the relevance of e-NOS system as a useful tool for liver preservation

against cold ischemia reperfusion injury. However, new potential strategies should be established in the future to increase e-NOS activity and modulate the NO availability, as well as to define the appropriate "therapeutic window" to provide the most suitable graft protection during cold storage and further during LT. A better knowledge of understanding the molecular pathways involved may lead to more efficient protective strategies to prevent early cold reperfusion injury during transplantation based on multifactorial activation of the endogenous cytoprotective e-NOS existing in preserved liver grafts.

Abstract

The paper provides a basic review of intestinal microflora and its importance in liver diseases. The intestinal microflora has many important functions, above all to maintain the microbial barrier against established as well as potential pathogens. Furthermore, it influences the motility and perfusion of the intestinal wall, stimulates the intestinal immune system and therefore also the so-called common mucosal immune system, reducing bacterial translocation and producing vitamins. Immune homeostasis at mucosal level results from a controlled response to intestinal luminal antigens. In liver cirrhosis, there are many changes in its function, mostly an increase in bacterial overgrowth and translocation. In this review, probiotics and their indications in hepatology are generally discussed. According to recent knowledge, these preparations are indicated in clinical practice only for cases of hepatic encephalopathy. Probiotics are able to decrease the permeability of the intestinal wall, and decrease bacterial translocation and endotoxemia in animal models as well as in clinical studies, which is extremely important in the prevention of complications of liver cirrhosis and infection after liver transplantation. Probiotics could limit oxidative and inflammatory liver damage and, in some situations, improve the histological state, and thus non-alcoholic steatohepatitis could be considered as another possible indication.

INTRODUCTION

In recent years, probiotics have become a promising alternative for the treatment of gastrointestinal and various other diseases. Despite their initially described negative influence on the course of disease, as in the case of acute pancreatitis[1], these medicines are considered safe and their beneficial effects have also been intensively studied and described in hepatology[2].

INTESTINAL MICROFLORA

The average length of an average human adult intestine

is approximately 10 m and its irregular surface is covered with one layer of epithelial cells that represent a surface area of approximately 200 m². The intestinal microflora above all plays a very important role in the immune reactions of the body. During fetal development, the intestine is sterile and becomes colonized with the first microorganisms after the passage of the fetus through the birth canal. After birth, the intestine is very quickly colonized with various microorganisms, the composition of which is highly variable during the first few days of life. After the first week, the intestinal microflora achieves a stable composition that depends on the method of birth, environment and type of nutrition. In breast-fed infants, there is a predominance of bifidobacteria, while in infants on milk formula, the number of bifidobacteria can be several times lower. Breast-fed infants are therefore colonized sooner with bacterial strains whose composition resembles that of the intestinal microflora of an adult[3]. The initial colonization of the intestine also plays a very important role in further development of the individual, as the bacteria present may modulate gene expression of epithelial cells and thus create a favorable environment for themselves[4]. The primary colonizers are permanently settled in the intestine and determine intestinal colonization with further bacterial strains later in life, which are important for the final composition of intestinal microflora in adulthood.

Major changes in the features of the intestinal ecosystem occur after weaning[5]. During this period, anaerobic bacteria such as *Bacteroides spp.* and *Clostridium spp.* achieve a strong position and the intestinal ecosystem evolves into its stable form. The intestinal microflora contains a large amount of microbes that weigh more than 1 kg; this quantity exceeds the number of cells in the human body 10-fold. The microbial community of the intestine consists of more than 500 species, most of which have not been cultivated, and many that have not been identified so far. The intestinal microflora contains both bacteria that are fixed in the intestine (autochthonous, resident) and bacteria that only pass through the intestine (transient allochthonous)[6]. Most of the bacteria in the intestine form an anaerobic bioreactor that helps to digest difficult polysaccharides and synthesizes micronutrients including vitamins and short-chain fatty acids. The fermentation products of these bacteria can provide up to 10% of the daily energy needed by an individual[7]. The composition of human gastrointestinal microflora is given in Table 1.

The relationships between the host and their microflora bacteria also play an important role in postnatal development, maturation of the intestine and development of the mucosal immune system.

The intestinal microflora has many important functions, in particular to maintain the microbial barrier against established as well as potential pathogens, and furthermore, it influences the motility and perfusion of the intestinal wall, stimulates the intestinal immune system, and therefore also the so-called common mucosal immune system, reducing bacterial translocation and producing vitamins.

The digestive tract microflora is continuously influenced by numerous physical, chemical and biological factors that can affect its balance, and therefore it represents a constant potential source of digestive tract and whole-body disease. Changes in the total amount, localization, strain or species structure and in the metabolic activity of microorganisms may occur. Impairment of digestive tract microflora physiology can lead to disease or act as its cofactor (infectious, medication-associated, post-antibiotic and post-radiation diarrhea and colitis, functional diseases of the digestive tract-chronic constipation, irritable bowel syndrome, inflammatory bowel diseases, immunodeficiencies, colorectal carcinoma, some extraintestinal diseases and last, but not least, also liver diseases)[8]. In patients with liver cirrhosis, abnormal colonization of the small intestine with colonic bacteria has been reported, while the amount of these bacteria in the small intestine of healthy individuals is small. There is a reciprocal regulatory activity between intestinal microflora and the motility of the small intestine, where the motility is regulated by the presence of intestinal bacteria. Inhibition of gastric acid production induces bacterial overgrowth in the small intestine, whereas the overgrowth of its proximal part correlates with bacterial translocation into the extraintestinal space, such as the mesenteric lymph nodes, liver and spleen.

CHANGES IN INTESTINAL MICROFLORA IN PATIENTS WITH CHRONIC LIVER DISEASES

Intestinal bacterial overgrowth was described in approximately one-third of patients with alcoholic cirrhosis, ascites or advanced liver dysfunction. The main causes are considered to be anchylosis and hypochlorhydrosis, a decrease in IgA secretion and malnutrition caused by liver dysfunction, and possibly alcoholism. Also, the decrease in intestinal motility associated with cirrhotic liver damage facilitates bacterial overgrowth in the small intestine. The impaired immune mechanisms of the mucous membrane of the small intestine facilitating bacterial overgrowth can be one explanation of the repeated and common infections in patients with liver cirrhosis. In particular, the spontaneous infection of ascites-spontaneous bacterial peritonitis (SBP)-is a frequent and severe condition[9,10]. In contrast, suppression or eradication of intestinal facultative anaerobic gram-negative bacteria prevents their translocation and SBP, both in cirrhotic rats and in liver cirrhosis patients.

As a result of bacterial overgrowth, bacterial translocation may occur, and portal hypertension also plays an important role. It leads to vasodilation of the intestinal mucous membrane, edema of the lamina propria, fibromuscular proliferation and hypertrophy of the muscularis mucosae. Furthermore, the integrity of the intestinal mucous membrane is compromised; toxic influences of alcohol, disturbances in biliary secretion, malnutrition, decrease in growth factor secretion (insulin-like growth factor I),

Table 1 Composition of the human gastrointestinal tract microflora (from Nord and Kager, 1984)

Microorganisms	Numbers of microorganisms (CFU/mL or CFU/g)			
	Stomach	Jejunum	Ileum	Colon
Total bacterial count	$0-10^3$	$0-10^5$	10^3-10^9	$10^{10}-10^{12}$
Aerobically growing agents				
Family *enterobacteriaceae*	$0-10^2$	$0-10^3$	10^2-10^7	10^4-10^{10}
Streptococci	$0-10^3$	$0-10^4$	10^2-10^6	10^5-10^{10}
Staphylococci	$0-10^2$	$0-10^3$	10^2-10^5	10^4-10^9
Lactobacilli	$0-10^3$	$0-10^4$	10^2-10^3	10^6-10^{10}
Yeasts	$0-10^3$	$0-10^2$	10^2-10^4	10^4-10^6
Anaerobic bacteria				
Bacteroides	Rare	$0-10^3$	10^3-10^7	$10^{10}-10^{12}$
Bifidobacteria	Rare	$0-10^4$	10^3-10^9	10^4-10^{11}
Peptostreptococci	Rare	$0-10^3$	10^2-10^6	$10^{10}-10^{12}$
Clostridia	Rare	Rare	10^2-10^4	10^6-10^{11}
Eubacteria	Rare	Rare	Rare	$10^{10}-10^{12}$

changes in bile composition and flow or increased levels of nitric oxide may be present, as well as portal hypertension. The increase in intestinal permeability is conspicuously proportionate to the degree of portal hypertension, but it is independent of severity and etiology of liver impairment[11]. In patients with liver cirrhosis and portal hypertension, vascular resistance decreases and splanchnic flow increases. These changes lead to hypoperfusion and hypoxia of the mucous membrane further compromising the vascular wall. As a consequence of this, translocation of intestinal bacteria occurs easily[12].

The term bacterial translocation was used for the first time in 1979[13]. Bacterial translocation is defined as active or passive penetration of live microorganisms and their toxic products across the epithelial layer of the mucous membrane to the lamina propria mucosae. Microorganisms then migrate to the lymph nodes and/or into extraintestinal locations. Under normal conditions, this refers to the small amount of bacteria that are destroyed by the immune system of the lamina propria. Translocation is only possible when there are a high number of bacteria; the literature reports up to 10^8 bacteria in 1 g of stool[14].

Bacteria that escape phagocytes, as well as destruction by complement, can reach the circulation. *Enterobacteria, staphylococci* and *enterococci* are able to translocate, i.e. pass alive across the intestinal epithelium into the mesenteric lymph nodes, blood and other organs, while most other anaerobic microorganisms lack this ability. Bacterial translocation can be verified by positive cultivation from mesenteric lymph nodes. The main mechanisms leading to translocation include a deficit in the local immune response of the mucous membrane, a decrease in phagocytic activity of macrophages as well as neutrophils, an increase in the permeability of the intestinal barrier, and intestinal bacterial overgrowth[15].

Factors that influence bacterial translocation can be divided into 3 groups. These are the bacterial factor, comprising the nature of the translocating agent and the status of the surrounding physiological microflora, the morphological and functional state of the intestinal wall, and not least the so-called defensive factors, i.e. local and systemic antibacterial activities of the organism[16,17]. All of these systems are impaired in patients with liver cirrhosis[18].

PROBIOTICS

The history of probiotics started at the beginning of the last century with Metchnikoff[19]; however, German authors often report a study by Döderlein as the first description of a possible probiotic 16 years before Metchnikoff proposed the use of vaginal lactate-producing bacteria for the inhibition of pathogenic bacteria growth, and attributed the higher average age of certain ethnic groups to the increased intake of fermented milk products and recommended their use.

Probiotics were originally defined as "microorganisms causing growth of other microorganisms", and later on as "live microorganisms that cause or support the beneficial balance of autochthonous microbial population of the gastrointestinal tract (GIT)". These microorganisms do not have to be an essential permanent component of the GIT, but should have a "beneficial influence on the general and health status of an individual". Currently, probiotics are defined more precisely as "monocultures or mixed cultures of live microorganisms that, if administered to a person, positively influence the host by improving the properties of his/her own microflora"[20].

UTILIZATION OF PROBIOTICS IN HEPATOLOGY

In the Cochrane Library Review, there is currently no unambiguous recommendation for administration of probiotics in any indication in hepatology. According to the World Gastroenterology Organisation Practice Guideline "Probiotics and prebiotics" are probiotics in hepatology indicated only for hepatic encephalopathy[21], and in clinical practice, probiotics are now administered in principle only in the above-mentioned treatment of hepatic encephalopathy, with the disadvantage of a higher price compared to the standard treatment. The use of

probiotics in the treatment of non-alcoholic steatohepatitis and in prophylaxis of infections, or some complications in patients with liver cirrhosis, can be expected in the future.

Liver encephalopathy

It is believed that gut-produced ammonia plays a key role in the pathogenesis of hepatic encephalopathy because of the failure of the diseased liver to clear toxic products. Small intestinal overgrowth and delayed gastrointestinal transit time in cirrhotic patients plays an important role[22].

Lactulose and non-absorbable antibiotics currently hold a dominant position in the treatment of liver encephalopathy. One of the effects of lactulose may be a probiotic effect on lactobacilli that reduce the activity of bacterial ureases, resulting in a decrease in hyperammonemia. Probiotics can also have a similar effect and are already included in some recommendations for the treatment of minimal liver encephalopathy[23].

As early as the 1960s, the beneficial effect of *Lactobacillus acidophilus* was described on the course of liver encephalopathy in patients with liver cirrhosis[24]. In a more recent study on 97 patients, the beneficial effect of a synbiotic (mixture of a probiotic and prebiotic) on minimal liver encephalopathy was observed, with a decrease in ammonium levels as well as the improvement of symptoms of encephalopathy[25]. Minimal liver encephalopathy is described as an otherwise inexplicable impairment of cognitive functions such as prolonged psychomotor tempo, lack of attention, impairment of fine motor functions and the perception of visual sensations that can only be detected using special neurophysiological tests, and is present in 30%-70% of patients with liver cirrhosis without liver encephalopathy. In the treatment of advanced liver encephalopathy, a beneficial effect of *Enterococcus faecium* was observed, the administration of which led to an improvement in clinical status, electroencephalogram findings and a reduction of ammonium levels[26]; the treatment of the *Enterococcus* strain SF69[27] also had a similar effect. A mixture of probiotics[28] may have an even better effect. A combination of *Bifidobacterium* + fructo-oligosaccharides also demonstrated a significant reduction in the Trail Making Test B, a significant increase in the Symbol Digit Modalities Test and Block Design Test and improvement in some laboratory findings[29].

A study confirming improvement of liver encephalopathy during long-term administration of probiotic yogurts with the advantage of excellent adherence with potential for long-term adherence[30] is also of interest.

So far, there are only very few experimental studies, however, the studies comparing the efficacy of probiotic preparation *Golden Bifid* and lactulose on an experimental rat model of minimal hepatic encephalopathy induced by thioactamide showed excellent effects in lowering the level of ammonemia and endotoxemia, improving hepatic histopathology of rats, and decreasing the incidence of minimal hepatic encephalopathy[31].

The use of probiotics in common clinical practice as well as evaluation of the economic effect of the treatment will, however, require further studies. At the moment, a study titled "Probiotic *Lactobacillus* GG (LGG) in Patients with Minimal Hepatic Encephalopathy" is being conducted at Virginia Commonwealth University and we can only hope it will bring novel, positive results.

Effects on bacterial intestinal translocation, reduction in infections or prophylaxis of liver cirrhosis complications

Infectious complications are very frequently caused by bacterial strains that originate from the digestive tract. Bacterial overgrowth, as well as the associated translocation of microbes across the dysfunctional mucous membrane barrier, occurs for the above-mentioned reasons, especially in liver cirrhosis. The small gut of cirrhotic rats is contaminated by colonic microflora, which translocate to mesenteric lymph nodes, and is the most important cause of infection of ascites and spontaneous bacterial peritonitis. The identity of microbial strains in the gut, mesenteric lymph nodes and ascites was demonstrated by analysis of macrorestricted fragments DNA[32].

In 50%-70% of patients with liver cirrhosis, bacterial overgrowth occurs in the small intestine as a result of gram-negative colon microflora contamination. As a result, an impairment of the intestinal barrier with increased bacterial translocation occurs. Apparently, it is the most important point of entry of infection in cirrhotic patients; generally, infections are very common in liver cirrhosis and can be involved in many complications associated with the disease. In the first animal studies with short term application of *Lactobacillus* GG, the treatment did not prevent translocation of colonic microflora, although it was able to colonize the cecum in 90% of cirrhotic rats[33]. In later studies, preventive treatment with *Lactobacillus plantarum* inhibited an increase in permeability after subsequent application of *E. coli*[34], and *Lactobacillus johnsonii* La1 with antioxidants were able to decrease endotoxemia and prevent bacterial translocation in cirrhotic rats[35].

In clinical studies, administration of a symbiotic reduced the endotoxemia, which is an indicator of the degree of translocation[11]. In our study, a reduction in endotoxemia was achieved through administration of *E. coli* Nissle for 42 d[36]. The clinical significance of this has yet to be verified, but the beneficial influence on the prophylaxis of severe infectious complications, such as spontaneous bacterial peritonitis, can be expected.

In both the above-mentioned papers, an improvement in functional liver capabilities was observed, evaluated according to the Child-Pugh classification. It can be presumed that the recovery of physiological microflora in the digestive tract will reduce the liver load of toxic metabolites, above all endotoxin, which might potentially be absorbed. It stimulates secretion of cytokines. The cytokines, such as tumor necrosis factor-α (TNF-α), interleukin-1 and interleukin-6 can influence the formation and degradation of the extracellular matrix, which is important for the development of liver fibrosis as well as during cirrhotic rearrangement[37]. Apart from the above-

mentioned decrease in endotoxin levels, a direct decrease in cytokine levels after administration of VSL#3 probiotic has also been reported[38]. There are some data showing, that Se-enriched *Lactobacillus* can intervene in carbon tetrachloride-induced liver injury in mice by enhancing macrophage function to maintain normal and beneficial effects, elevating antioxidant-enzyme activities, reducing lipid peroxidation reaction and inhibiting excessive release of TNF-α[39]. However, this extremely important finding will have to be confirmed. Another study with VSL#3, presenting a trend of a reduction in plasma endotoxin, on the other hand showed no change in the hepatic venous pressure gradient or intestinal permeability[40].

In liver cirrhosis of alcoholic etiology, the alcohol itself may play a role, such as increased gut permeability, endotoxemia, and TNF-α production[41]. In rats, *Lactobacillus* GG has been shown to reduce alcohol induced gut leakiness and steatohepatitis[42]. The same group also found that the mucosa-associated microflora was altered in rats on a high alcohol diet, and this dysbiosis could be counteracted by *Lactobacillus* GG or oat supplementation[43]. In a rat model of acute pancreatitis, synbiotic (*Lactobacillus acidophilus*, *Lactobacillus helveticus* and *Bifidobacterium* in an enriched medium) and metronidazole were able to effectively protect against endotoxin/bacterial translocation, as well as liver damage in the course of acute pancreatitis and concomitant heavy alcohol consumption. The beneficial effect of synbiotics on liver histology seems to be correlated with endotoxemia. Metronidazole did not produce such a beneficial effect; in fact, it further worsened liver damage when alcohol was added to the background of ongoing acute pancreatic inflammation[44].

However, no large randomization study has been carried out as yet which would be relevant for clinical practice, although a recent study again confirmed the theoretic presumptions for beneficial action in this field[45]. The "Probiotics for the Prevention of Major Complications of Cirrhosis" study, carried out in the Meir Medical Center in Israel, was finished last year but its results have not yet been published.

Non-alcoholic steatohepatitis

Fatty liver disease that develops in the absence of alcohol abuse is increasingly recognized as a major health burden. Non-alcoholic steatohepatitis (NASH) was first described by Ludwig in 1980 as a disease that histologically mimicked alcoholic hepatitis and that also may progress to cirrhosis[46]. The diagnostic criteria for NASH continue to evolve and rely on the histologic findings of steatosis, hepatocellular injury (ballooning, Mallory bodies), and the pattern of fibrosis in patients with minimal intake of ethanol (< 20 g ethanol/d)[47]. Recently, NASH has been studied extensively as it is relatively frequent, and may lead to the development of liver cirrhosis. So far, treatment has not been established and probiotics may play an important role, as the bacterial overgrowth and associated increase of proinflammatory cytokines are important etiopathogenic mechanisms of NASH[48]. Clinical studies so far

have been missing in this field, but the positive effect of probiotics has already been described in some laboratory studies. In mice with non-alcoholic liver steatosis, treatment with probiotics or anti-TNF antibodies improved the histological picture of the degree of damage to the liver parenchyma, led to a decrease in the alkaline phosphatase level, improved insulin resistance, and the content of total fatty acids in the liver also dropped. In another study on a model of non-alcoholic liver steatosis, treatment with the probiotic VSL#3 or TNF-α antibodies had a positive influence on histological findings, the fatty acids in hepatocytes were reduced, the ALT level decreased and the expression of TNF-α[49,50] was reduced. Similar data suggesting that VSL#3 administration could limit oxidative and inflammatory liver damage were published in a more recent study[51]. Some previous studies showed that a high fat diet caused obesity, hepatic steatosis and natural killer T-cell (NKT cell) depletion[52]. The VSL#3 was also shown to increase hepatic NKT cell number and reduce inflammatory signaling[53]. Another study indicated that VSL#3 modulates liver fibrosis but does not protect from inflammation and steatosis in NASH. It means, that VSL#3 effects on fibrosis may occur even in the absence of significant changes in markers of inflammation and fat in the liver[54].

In the Cochrane Library Review, there is currently no unambiguous recommendation for administration of probiotics in NASH, even if the results from pilot studies seem promising. Randomized clinical trials are necessary to assess the clinical implication of probiotic therapy in non-alcoholic fatty liver disease and non-alcoholic steatohepatitis[55]. Two clinical studies on the effects of probiotics on NASH are currently being conducted in Hong Kong and in Israel. Hopefully their conclusions will be encouraging.

Prophylaxis of infections after liver transplantation

In the past, several papers were published that confirmed the positive influence of probiotic administration on postoperative course after large abdominal surgery. The studies are mostly of small sample size and exhibit design flaws, but they showed statistically significant differences in infectious complications in favor of synbiotics[56-58], and the synbiotic group did require significantly less days of antibiotic therapy[59].

Patients in the postoperative period after a liver transplant are mainly at risk of infection by organisms, coming in most cases from the digestive tract. As already discussed in the theoretical part of our paper, the translocation of bacteria or their parts across the intestinal wall into the circulation occurs as a result of disturbances in barrier function of the intestine and disturbance of the immune system. Bacteria that translocated from the intestinal tract can be carried through the circulation into more distant systems and cause colonization or infection in extraintestinal locations. A prospective, randomized, double-blind study was published on 66 patients after liver transplantation, whereas half of the patients received a combination of 4 *Lactobacillus spp.* together with the standard enteral

nutrition. In the probiotic group, a significant reduction in postoperative bacterial infection (3% against 48%) was observed and the length of the antibiotic therapy was substantially reduced[60]. In our study on patients after liver transplantation, we demonstrated a correlation between an increase in endotoxin and the subsequent presence of phenotypically as well as genotypically identical strains (originally cultivated from the gastrointestinal tract) in an extraintestinal location[61]. Monitoring serum endotoxin levels can probably confirm bacterial translocation with an increased risk of infectious complications and this result further confirms the positive effect of probiotics in patients after liver transplantation. However, the conclusion is similar from the perspective of evidence-based medicine-use of prebiotics and probiotics in prevention of bacterial sepsis after liver transplantation is promising. Further randomized clinical trials are necessary.

CONCLUSION

Probiotics are becoming part of numerous therapeutic modalities in hepatology, as their effect on intestinal microflora can positively influence many liver diseases. However, verification of the efficiency of this treatment from the perspective of evidence-based medicine will be difficult, as different probiotics can be expected to have different effects in different diseases. With respect to the increasing number of studies on probiotics, the future prospects in this field are optimistic.

Abstract

In spite of continuous research efforts directed at early detection and treatment of pancreatic cancer, the outlook for patients affected by the disease remains dismal. With most cases still being diagnosed at advanced stages, no improvement in survival prognosis is achieved with current diagnostic imaging approaches. In the absence of a dominant precancerous condition, several risk factors have been identified including family history, chronic pancreatitis, smoking, diabetes mellitus, as well as certain genetic disorders such as hereditary pancreatitis, cystic fibrosis, familial atypical multiple mole melanoma, and Peutz–Jeghers and Lynch syndromes. Most pancreatic carcinomas, however, remain sporadic. Current progress in experimental molecular techniques has enabled detailed understanding of the molecular processes of pancreatic cancer development. According to the latest information, malignant pancreatic transformation involves multiple oncogenes and tumor-suppressor genes that are involved in a variety of signaling pathways. The most characteristic aberrations (somatic point mutations and allelic losses) affect oncogenes and tumor-suppressor genes within RAS, AKT and Wnt signaling, and have a key role in transcription and proliferation, as well as systems that regulate the cell cycle (SMAD/DPC, CDKN2A/p16) and apoptosis (TP53). Understanding of the underlying molecular mechanisms should promote development of new methodology for early diagnosis and facilitate improvement in current approaches for pancreatic cancer treatment.

INTRODUCTION

Pancreatic cancer is a fatal illness that is characterized by late diagnosis in the absence of early symptoms, which results in identification of the illness at an advanced stage. Despite all therapeutic efforts, the mortality of pancreatic cancer remains high, with the number of newly diagnosed patients nearly equaling that of deceased patients[1].

The incidence of pancreatic cancer is constantly on the rise, especially in regions of North America, Europe and Japan. In the United States, pancreatic cancer represents the fourth most frequent cause of death from cancer. In Europe it ranks fifth. In 2009, 42 470 new cases of this disease were diagnosed, and in the same year, 35 240 patients died of this disease[2]. One of the highest incidence and mortality rates among EU countries is observed in the Czech Republic, which, according to GLOBOSCAN 2008 data, ranks second in incidence (Figure 1A) and first in mortality (Figure 1B), followed by Hungary and Finland. In the Czech Republic, pancreatic cancer is the 10th most frequent malignancy, and accounts for 2.6% of all newly diagnosed neoplasms. In 2005, the absolute number of newly diagnosed pancreatic cancer cases was 901 in men and 876 in women. In that same year, the absolute number of deceased persons from the disease reached 1580 (819 men and 761 women)[3].

Five-year survival for pancreatic cancer is < 5%, mainly due to its late diagnosis, when it is already at an advanced stage[4]. At the time of diagnosis, < 5% of tumors are resectable. Median survival following surgical resection ranges from 13 to 21 mo. Without surgery, median survival is a mere 2.5-8 mo[2].

RISK FACTORS

Due to the relative rarity of pancreatic cancer, which is characterized by a complexity of underlying carcinogenesis, it is likely that a combination of multiple factors contributes to the initiation of the disease. Some factors, such as smoking or alcohol intake, can be controlled, while others such as age or family history cannot. Although most risk factors do not directly cause the disease, level of exposure often influences cancer development. As the treatment options are still limited and the survival prognosis remains poor, identification and evasion of the controllable risk factors becomes particularly important for individuals at high risk[5]. The most prominent pancreatic cancer risk factors are summarized in Table 1.

Smoking and alcohol

Cigarette smoking represents one of the most significant and most widely studied risk factors for pancreatic cancer. The carcinogenic effect of tobacco smoke on pancreatic tissue is explained as the direct action of N-nitrosamines or their secretion into bile and their subsequent reflux into the pancreatic duct. Active smoking

Figure 1 Standardized incidence (A) and mortality (B) rates for the 20 European countries with the highest occurrence of pancreatic cancer (Adapted from GLOBOCAN 2008).

Table 1 Pancreatic cancer risk factors

Factor	Type	Group	Maximum risk to average ratio
Smoking	Exogenous	Behavioral	3
Alcohol	Exogenous	Behavioral	Non-significant
Diet/obesity	Exogenous	Behavioral	1.72
Occupational hazard	Exogenous	Environmental	
Radiation	Exogenous	Environmental	Inconclusive
Age	Endogenous	Biological	-
Race	Endogenous	Biological/ behavioral/ environmental	1.4
Family history	Endogenous	Genetic	32
Peutz-Jeghers syndrome	Endogenous	Genetic	132
FAMMM syndrome	Endogenous	Genetic	13.1
HNPCC	Endogenous	Genetic	7
Hereditary pancreatitis	Endogenous	Genetic	60
Chronic pancreatitis	Endogenous	Behavioral	26.3
Diabetes mellitus	Endogenous	Biological/ environmental	2.0
Hormonal	Endogenous	Biological	Inconclusive
Allergy	Endogenous	Biological	Non-significant

FAMMM: Familial atypical multiple mole melanoma; HNPCC: Hereditary non-polyposis colorectal carcinoma syndrome.

increases the relative risk of pancreatic cancer 1.5-3-fold, depending on the number of cigarettes smoked and the duration of this habit. Passive smoking has not been shown to be a risk factor[6].

A number of epidemiological studies have focused on the relationship between alcohol consumption and development of pancreatic cancer. An analysis of 14 prospective studies has not confirmed any association between alcohol consumption and a higher risk of pancreatic cancer[3]. Only a very weak association has been demonstrated in the case of alcohol consumption at a dose of $\geq$ 30 g/d, regardless of the alcohol source of beer, wine or spirits. There is also a significant association with body mass index (BMI), whereby a slight increase in cancer risk has been described in persons with an alcohol consumption of $\geq$ 30 g/d and a BMI of $\leq$ 25 kg/m^2. From the aforementioned, it is possible to infer that the association between alcohol consumption and development of pancreatic cancer is only implied.

This association is apparently conditional on the development of chronic pancreatitis, for which alcohol is a known inducer, and chronic pancreatitis is an independent risk factor for this cancer. It thus appears that alcohol consumption at lower doses that do not damage pancreatic tissue does not carry a higher risk for developing pancreatic cancer.

Diet and obesity
Based on a number of relevant studies, it is possible to observe an association with a diet rich in animal fats and higher consumption of meat (roasted, grilled or fried). The results of studies that focus on the effect of cholesterol, eggs, milk and dairy product consumption on increased risk of pancreatic cancer are inconsistent[7]. In contrast, a diet rich in fiber, fruit, vegetables

and vitamins, especially vitamin C, is considered to be a protective factor[8]. Omega-3 unsaturated fatty acids that are contained mainly in fish oil also act protectively. A similar protective effect has been shown for substances that influence DNA methylation and synthesis, such as folates. As demonstrated in an analysis of 14 prospective studies, a positive association between alcohol consumption and cancer has been discovered for alcoholics with a low daily folate intake. Similar results have also been observed in the case of methionine. No association with coffee or tea consumption has been demonstrated[3].

Obesity is a generally recognized risk factor for pancreatic cancer in men and women[9]. In cases in which prospective studies have evaluated BMI, men with BMI $\geq$ 30 kg/m^2 had a higher relative risk compared to women with the same BMI[10]. One particularly interesting fact is that physical activity did not reduce the risk in persons with BMI < 25 kg/m^2, but it was indirectly proportional to the risk in persons with BMI $\geq$ 25 kg/m^2. Physical activity, which in its final effect leads to increased insulin resistance, decreases the degree of risk in obese patients.

Occupational hazards
The possible influence of aromatic and heterocyclic amines as well as exposure to chlorinated solvents in the carcinogenesis of pancreatic cancer remains unclear. The groups most at risk from this aspect include workers in the petrochemical and rubber industry, as well as barbers and hairdressers in whom exposure to these substances is higher compared to the general population[11]. In contrast, the influence of heavy metals and especially cadmium, in view of its accumulation in pancreatic tissue, has demonstrated an accentuation of neoplastic processes. Another element that is suspected of a carcinogenic effect on pancreatic tissue is chromium. Nonetheless, occupational exposure leads only to an imperceptible increase in the relative risk, in view of the minimal doses involved.

Radiation
A study published in 1990 has stated that ionizing radiation does not increase the risk of pancreatic cancer[9]. These findings are based predominantly on research in people who survived an atomic bomb explosion. The notion that the pancreas is relatively non-sensitive to ionizing radiation has been partially revised by a study of the increased incidence of pancreatic cancer among employees of nuclear research centers in the United States and other countries[12]. Nonetheless, this report[9] has stressed the significance of other concurrent risk factors such as smoking, diabetes, positive family history, or any other pancreatic disease.

Age and race
Age and race are the most prominent confounding factors of pancreatic cancer risk. During the first three decades, pancreatic cancer is a rarity, but from the age of 30 years onwards, its incidence increases significantly, peaking in the seventh to eighth decades, when 80% of adenocarcinomas are diagnosed. The mean age at diagnosis is 65

years. Pancreatic cancer is diagnosed before the age of 50 years only in 10% of patients[13].

With regard to racial differences, pancreatic cancer demonstrates the highest incidence in Afro-Americans in the United States, inhabitants of Northern Europe, in Polynesians in Hawaii, and Maoris in New Zealand. In the United States, the mortality of the Afro-American population is 1.4 times higher than that of the Caucasian population. This fact may be explained by a higher proportion of smokers and patients with diabetes, and at the same time, a positive family history of pancreatic cancer[14].

Hormonal factors and allergy

Pancreatic cancer demonstrates a different incidence in men and women. The cumulative risk in men is 0.2% and 0.1% in women. The lower incidence of pancreatic cancer in women may point to a link between hormonal factors and the development of cancer. The results of studies dealing with the relationship between female hormones and the development of cancer conducted to date have been inconclusive. As studies conducted to date confirm, this malignancy demonstrates minimal estrogen dependency. Parity and duration of hormonal exposure are negatively associated with the degree of risk of pancreatic cancer[15,16]. In the case of postmenopausal women, this risk is not influenced by hormonal substitution. In a number of studies, pancreatic cancer is associated with a higher number of deliveries, with earlier menarche and late menopause, higher age during the first delivery, or hormonal contraception. On the other hand, there exist studies in which the aforementioned factors were associated with a decrease in the risk of pancreatic cancer. An analysis of 10 case-control studies and five cohort studies did not demonstrate any link between hormonal factors and pancreatic cancer in women[17]. Indeed, additional factors, such as differences in life habits, may also contribute to the different cumulative risks between men and women.

Studies published to date have demonstrated a decrease in the risk of pancreatic cancer in individuals with allergies, especially respiratory allergy[18]. Longer survival has been described in allergic patients who have undergone resection procedures compared to resected patients with no allergies. The decrease in risk is most often associated with respiratory forms of allergy such as hay fever, and allergy to pollen and grass. The mechanisms of the possible protective effect of allergy in patients with a tumor is not exactly known[19].

CHRONIC PANCREATITIS

At present, acute and chronic pancreatitis are considered two pathogenically different disease entities; their relation to the genesis of pancreatic cancer is likewise quite different. Although acute pancreatitis is not considered a risk factor in terms of the index diagnosis, the concept of a causal association between alcoholic, hypercalcemic, trophic and hereditary forms of chronic pancreatitis and increased predisposition to developing pancreatic cancer is generally recognized. The obstructive type of chronic

pancreatitis has been questioned as a risk factor by some authors[20].

Although no more than 5% of diagnosed cases of pancreatic cancer can be explained by recurrent attacks of chronic pancreatitis, the same genetic changes have been detected in individuals with chronic inflammation of the pancreas and pancreatic cancer. Chronic inflammation is thought to induce genetic alterations in tissue, while the ongoing healing process exposes defective cells to growth factors; the result is a pathological microenvironment in which stromal elements facilitate the neoplastic process in epithelial cells (the so-called feeder theory)[21]. According to this theory, the effector cells of the inflammatory response include active macrophages whose products, particularly the cytokines tumor-necrosis factor (TNF)-α, interleukin (IL)-1, IL-6, IL-8, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and transforming growth factor (TGF) α and β induce cell proliferation, angiogenesis and desmoplastic reaction, that is, processes that form part of the pathogenesis of chronic pancreatitis and pancreatic cancer. IL-6 promotes the maturation of myeloid precursors into macrophages, and TGF-α inhibits processes leading to apoptosis and stimulates progressive fibrosis. Additionally, the same cytokine activates the transcription factor nuclear factor (NF)-κB, a mediator of inhibition of programmed cell death. Its expression has been reported in cases of chronic inflammation of the pancreas and pancreatic cancer. In addition, NF-κB upregulation promotes the production of reactive nitrogen oxide and cyclooxygenase (COX)-2 and induces IL-8 expression. There have been reports of an autocrine growth promoting effect of IL-8, which is produced at increased rates in response to hypoxia; particularly in the center of tumor foci, thus having a pro-carcinogenic and pro-metastatic effect. COX-2 responds to increased prostaglandin production in cases of inflammation and cancer, facilitates cell proliferation and angiogenesis, and is a potent inhibitor of apoptosis. Additionally, COX-2 is involved in the transformation of chemical carcinogens into their mutagenic derivatives. This particular ability of COX-2 increases the risk of pancreatic cancer in smokers. Immunohistochemical investigations have shown that COX-2 expression is bound to pancreatic islet Langerhan's cells; as a result, increased expression of the enzyme heralds islet inflammation.

One of the hypotheses of pancreatic cancer development is based on the key relations between islet of Langerhan's inflammation, insulin resistance, growth promotion, and diabetes. Additional products of activated macrophages and neutrophil granulocytes in pancreatitis and pancreatic cancer include reactive forms of oxygen and nitric oxide, whose presence is causally related to DNA structural defects[22]. The risk for developing a malignancy in individuals with chronic pancreatitis is 16 times that of the healthy population. One study has reported in patients with chronic pancreatitis, an increased incidence of both extrapancreatic tumors (relative risk, 1.5) and pancreatic malignancy (relative risk, 18.5). When one considers relevant only conditions that develop during 4 years of chronic inflammation, then the relative

risk increased by a factor of 15.6 for smokers, whereas there was no increase in non-smokers[23]. A prospective study of the French Cancer Registry, including 85% of cases of chronic pancreatitis of alcoholic etiology, has reported a relative risk of 19.0[24]. In a Czech study of 213 patients, 11 of whom had cancer, the prevalence of pancreatic cancer was 5.1%. The interval from establishing the diagnoses of chronic pancreatitis and pancreatic cancer was 6-13 years. The cumulative risk for malignancy in patients with chronic pancreatitis was shown to increase in a linear manner, and was 1.8 and as high as 4.0 after 10 and 20 years, respectively[25]. The priority of current clinical research is to identify patients with sporadic chronic pancreatitis who are at increased risk of developing pancreatic cancer.

GENETIC SUSCEPTIBILITY

Family history of pancreatic cancer
Familial pancreatic cancer (FPC) is defined as two or more first-degree relatives with pancreatic cancer. As an independent nosological unit, FPC represents only 3%-10% of the total number of pancreatic cancers. Nonetheless, the relative risk in such cases is 4.6-32 times higher, depending on the number of afflicted persons within the family[26]. Only 20% of FPC patients demonstrate a genetic abnormality. Nonetheless, individuals from families with FPC should undergo genetic testing for the presence of hereditary breast and ovarian syndrome (BRCA1, BRCA2). These mutations are most often identified in FPC. The relative risk of pancreatic cancer in carriers of the BRCA1 mutation increases to 2.26 and in the case of the BRCA2 mutation to 3.5-8[27].

Pancreatic cancer forms a component of a whole range of hereditary diseases and syndromes.

Cystic fibrosis is an autosomal recessive disease that is caused by mutations in the *CFTR* gene, and is characterized by the production of viscous mucus, which apart from blocking the airways, also leads to obstruction of the pancreatic duct, which increases the risk of inflammation. Patients with CF are at increased risk of chronic pancreatitis and of pancreatic tumors[28].

Familial atypical multiple mole melanoma (FAMMM) is an autosomal dominant disease that is characterized by the occurrence of > 50 atypical nevi and malignant melanoma in two or more first or second-degree relatives. Approximately 10% of melanomas have a familial incidence and the mutation of the *CDKN2A* gene is identified in -40% of these families[29].

Peutz-Jeghers syndrome is an autosomally dominant hereditary disease with characteristic hamartoma polyps of the gastrointestinal tract, and mucocutaneous melanin pigmentation. Almost half of these patients are carriers of a germinal *STK11/LKB1* gene mutation. Thus, afflicted individuals have a 36% risk (cumulative lifetime risk) of developing pancreatic cancer[30].

Hereditary non-polyposis colorectal carcinoma syndrome (HNPCC) is another hereditary cancer syndrome, for which the incidence of pancreatic cancer is typical.

This syndrome is caused by mutations in mismatch repair (MMR) genes *MSH2*, *MLH1*, *MSH6* and *PMS2*. The average risk in carriers of MMR gene mutations is 5%-10%. Pancreatic cancer is approximately seven times more frequent in carriers of *MMR* gene mutations, and in these individuals, it is 15 times more often diagnosed before the age of 60 years[31]. Apart from the aforementioned, pancreatic cancer can occur in association with other diseases such as Li-Fraumeni syndrome, ataxia-teleangiectasia syndrome, multiple endocrine neoplasia type I syndrome (MENI) or Von Hippel-Lindau syndrome.

Hereditary pancreatitis
Hereditary pancreatitis is currently considered to be an independent nosological unit. This is an autosomally dominant disease with 80% penetrance. In patients with hereditary pancreatitis, trypsin becomes activated while still in the pancreas. This accounts for partial digestion of the pancreatic tissue, which causes irritation and inflammation. A strong genetic association exists with mutations found in the *PRSS1*, *SPINK1* and *CFTR* genes[32]. Patients with this hereditary pancreatitis have a 40-60-fold higher risk of developing pancreatic cancer. If such predisposed individuals are smokers, then the development of pancreatic cancer, or rather its diagnosis, shifts to younger age categories, in which it occurs up to two decades earlier than in non-smokers. Similarly, alcohol consumption also leads to earlier diagnosis of cancer, also 20 years earlier[2].

DIABETES MELLITUS

A mutual association between pancreatic cancer and diabetes mellitus has long been monitored. However, the issue of mutual linkage is complicated by the fact that, while long-term diabetes is considered to be an etiological factor of the cancer, newly developed diabetes is an early manifestation of the cancer[33].

The pathogenesis of diabetes associated with cancer and the biochemical mediators involved have not been completely elucidated. Its development due to the mere destruction of pancreatic tissue by the tumor or as a consequence of chronic pancreatitis is less probable. The high prevalence of diabetes and disorders of glucose tolerance in small, early carcinomas (< 20 mm), and primary detection of diabetes nearly 2 years before the diagnosis of carcinoma, points to the influence of humoral markers rather than to local effects of the tumor. Further research is necessary to clarify the pathogenesis of carcinoma-associated diabetes, and to uncover new markers that can differentiate it from type 2 diabetes[33]. Newly developed diabetes during a period of < 2 years prior to the diagnosis of carcinoma is a promising sign of the presence of a completely asymptomatic carcinoma. This is why screening of sporadic, early pancreatic cancer in persons with newly diagnosed diabetes is being considered. The interval between primary detection of diabetes and the diagnosis of carcinoma ranges between 5 and 29 mo[34].

Primary detection of hyperglycemia and diabetes represent a reference point for the timely diagnosis of sporadic pancreatic carcinoma before symptoms develop. It is well known that the symptoms of pancreatic cancer occur only weeks or months before diagnosis, which usually means that an advanced, non-resectable tumor is present and expected survival is only 4-6 mo. If we monitor glycemia in patients with small, resectable carcinomas (< 20 mm), then most suffer from disorders of glucose tolerance. Studies have demonstrated in 55%-65% of patients with resectable carcinoma, a disorder of glucose tolerance or newly developed diabetes during a period of < 2 years prior to the diagnosis of carcinoma[34,35]. Approximately half of patients with sporadic carcinoma suffer from diabetes, and in almost 50%, diabetes is diagnosed at the time of carcinoma diagnosis. It is highly probable that diabetes precedes the diagnosis of the malignancy by several months or even years. The aforementioned facts indicate the application of pancreatic cancer screening in asymptomatic individuals with newly diagnosed diabetes[33].

Studies conducted to date have shown that the prevalence of diabetes (determined on the basis of the oral glucose test, fasting blood glucose, and meeting American Diabetes Association criteria) in patients with pancreatic cancer is 45%-65%. In the original study, diabetes was newly diagnosed concurrently with carcinoma in 40% of cases[34]. In other studies, the percentage of newly diagnosed diabetes was as high as 74%-88%. In summary, it could be concluded that the majority of diabetes associated with pancreatic cancer represents *de novo* diabetes, that is, diagnosed during a period of 2 years preceding pancreatic cancer, and almost half of patients with early carcinoma have diabetes. Moreover, diabetes that develops in this way usually improves following pancreatic resection.

MOLECULAR MECHANISMS

Model of pancreatic neoplasia
Molecular mechanisms of solid cancer are very complex with different mechanisms taking place and affecting the tissue at different stages of the disease. Detailed molecular mechanisms of initiation, development and progression of pancreatic cancer have been thoroughly studied since the basic principles of the disease were revealed in the 1970s and 1980s[36-40]. The classic model of pancreatic cancer development describes morphological as well as molecular transformation from precursor lesions into invasive carcinoma[41]. The standard nomenclature and diagnostic criteria for classification of duct lesions has primarily been based on grades of pancreatic intraepithelial neoplasia (PanIN)[42]. The grades 1A, 1B, 2 and 3 represent growing cytological atypia characterized by loss of polarity, nuclear crowding, enlarged nuclei, pseudo-stratification and hyperchromatism. Each PanIN stage is characterized by a distinct pattern of molecular processes that are characterized by genetic irregularities that affect specific genes and genetic pathways.

Proto-oncogenes and tumor suppressors
In the PanIN model, genetic alterations have a fundamental role affecting key guardians of cellular signaling, which induces instability of entire molecular systems such as cell growth, division, apoptosis and migration. Proto-oncogenes code for proteins that act as positive regulators for these systems, such as growth factors, signal transducers, transcription factors or apoptotic inhibitors. Their mutated forms, oncogenes, are often present in cancer cells. The mutation causes the protein products of oncogenes to be permanently activated, which results in uncontrolled cell proliferation. Oncogenic mutations have a dominant character; therefore, deficiency of one allele (i.e. heterozygous mutation) is sufficient for a fatal outcome. There are several key proto-oncogenes involved in pancreatic cancerogenesis, including KRAS, CTNNB1 (β-catenin), PIK3CA or AKT1. The most common oncogenic mutation types are point mutation, deletion, gene amplification, and gene rearrangement.

Tumor suppressor genes code for proteins that act against cell proliferation, such as signaling inhibitors, negative transcription factors, activators of apoptosis, or members of DNA repair systems. As a result of genetic alteration, their normal function may be reduced or eliminated completely. Mutations in tumor suppressor genes have a recessive character; hence, the cell looses their function only when both alleles are affected. In the most common case, described as a double hit model, one allele is initially mutated while the other is subsequently mutated or lost completely[43]. A separate mechanism of tumor suppressor deactivation is by hypermethylation[44]. In pancreatic cancer, the frequently affected tumor suppressors include TP53, APC, SMAD4 and TP16. The genes most frequently mutated in pancreatic cancer are listed in Table 2[45,46].

Signaling pathways in pancreatic cancer c-MET/HGF signaling pathway
The c-MET/HGF (hepatocyte growth factor) signaling pathway is a key factor in early progression of pancreatic cancer. The pathway is responsible for invasive growth through activation of key oncogenes, angiogenesis and scattering (cell dissociation and metastasis). c-MET is a proto-oncogene that encodes an HGF receptor that has a primary function in embryonic development and wound healing[47]. Although c-MET mRNA is present at very low levels in normal human exocrine pancreas, it is upregulated in a majority of pancreatic cancers[48-50], as well as in pancreatitis-affected epithelial cells[51]. Overexpression of c-MET is also observed in regenerating tissue affected by acute pancreatitis[52], and it is seen as an early event in pancreatic cancerogenesis[51]. HGF is a primary ligand of c-MET. Upon c-MET/HGF interaction, several different signaling pathways are activated, including the Ras, phosphoinositide 3-kinase (PI3K), Janus kinase (JAK)/signal transducer and activator of transcription (STAT) and β-catenin (Wnt) pathways.

Ras/Raf/MAPK pathway
The Ras/Raf/mitogen-activated protein kinase (MAPK) pathway is one of the most studied and best described signaling pathways in cancer[53]. The role of Ras/Raf/

Table 2 Genes most frequently mutated in pancreatic cancer[45,46]

Gene symbols	Protein name	Mutation frequency (%)	Type	Main signaling or system
KRAS	K-ras	58	Proto-oncogene	*Ras/Raf/MAPK*
TP53	Tumor protein p53	37	Tumor suppressor	*Apoptosis Cell cycle control*
CDKN2A	Tumor protein p16 (INK4A)	29	Tumor suppressor	*Cell cycle control*
CTNNB1	β-catenin	24	Proto-oncogene	*Wnt*
SMAD4 DPC4	Smad Dpc4	22	Tumor suppressor	*TNFbeta/SMAD*
APC	Apc	16	Tumor suppressor	*Wnt*
PIK3CA	Phosphoinositide 3-kinase	5	Proto-oncogene	*PTEN/PI3K/AKT*

DPC: Deleted in pancreatic cancer; APC: Adenomatous polyposis coli; MAPK: Mitogen-activated protein kinase.

Figure 2 Ras/Raf/mitogen-activated protein kinase pathway.

MAPK signaling is critical for many cancerogenic processes, including cell growth and division, cell differentiation and migration, tissue healing and repair, and angiogenesis. The central regulator of the signal transduction from extracellular to intracellular environment is Ras protein, which is localized at the inner wall of the cellular membrane. Under normal physiological conditions, the hydrophobic Ras protein is inactive and bound to GDP. An extracellular signal coming through growth factor transmembrane receptors (such as growth factor receptors or cytokine receptors) promotes release of a guanidine exchange factor SOS, which initiates removal of GDP from Ras protein and its subsequent activation upon binding to GTP. Activated GTP-Ras complex triggers a kinase activity of Raf kinase, which ultimately results in activation of an MAPK, an important regulator of DNA transcription and mRNA translation. Mutations that affect any of the Ras/Raf/MAPK members produce an increase in tumorigenicity. Aside from Raf and MAPK, there are other downstream effectors of Ras protein, including PI3K, thus providing crosstalk between multiple pathways (Figure 2).

PTEN/PI3K/AKT pathway

PTEN/PI3K/AKT is a significant signaling pathway that is fundamentally based on regulated activation of AKT oncogene through its localization at the cell membrane[54]. The two important protein families involved in the membrane localization of AKT are PI3K and PTEN phosphatases.

PI3K is able to phosphorylate certain membrane-bound lipids known as phosphoinositides. The PI3K-mediated phosphorylation may progress in three stages, which produces phosphatidylinositol 3-phosphate (PIP), phosphatidylinositol (3,4)-bisphosphate (PIP$_2$), and phosphatidylinositol (3,4,5)-trisphosphate (PIP$_3$). The phosphorylated forms, PIP$_3$ and, to a lesser extent, PIP$_2$, attract important protein kinases to the cell membrane. The most prominent is AKT, a family of serine/threonine protein kinases that trigger a number of key cellular processes, including glucose metabolism, cell proliferation, apoptosis, transcription, and cell migration. AKT activity is strongly dependent on its proper localization on the cell membrane. The positioning of AKT at the membrane is achieved through its strong binding to PIP$_3$. In pancreatic carcinogenesis, AKT1 acts as an oncogene that upholds cell survival by overcoming cell cycle arrest[55-57], blocking apoptosis[58-60], and promoting angiogenesis[61]. PTEN is a phosphatase that acts in opposition to PI3K. It has tumor suppression ability by converting PIP$_3$ back to PIP$_2$ and to PIP, hence disrupting membrane localization and reducing activity of AKT[62]. In most cancers, expression levels of PI3Ks and AKT are high, while PTEN is often deactivated by mutation, or deleted completely. Through its key role in pancreatic carcinogenesis, PI3K/AKT/PTEN signaling is an important target for anticancer therapy.

JAK/STAT pathway

The JAK/STAT signaling pathway has an important role in regulation of DNA transcription by transmission of chemical signals from cytokine receptors into the cell nucleus. The signal is passed upon phosphorylation of receptor tyrosine residues by JAK prompting activation and dimerization in a family of STAT proteins. Activated STAT dimers initiate DNA transcription inside the nucleus. It is known that inhibition of JAK/STAT signaling induces apoptosis in various human cancers, and is there-

fore, a primary focus for potential new drug candidates[63]. A recent study has reported reduced growth of pancreatic cancer cells *in vitro* when exposed to benzyl isothiocyanate (BITC), due to its suppression of STAT3 signaling and subsequent induction of apoptosis. This is suggested as a possible explanation of the anticarcinogenic effect of cruciferous vegetables (such as broccoli, cauliflower, cabbage or horseradish) that are rich in BITC[64].

TGF-β/SMAD signaling

TGF-β is a ligand that binds to type II cytokine receptor dimer, which then binds and activates type I cytokine receptor dimer, which triggers phosphorylation of receptor-regulated SMADs (R-SMADs), mainly SMAD2 and SMAD3. In phosphorylated form, the R-SMADs form a complex with SMAD4, which accumulates in the nucleus and interacts with other factors to stimulate transcription of genes that are important for cell cycle arrest and migration. SMAD4 is therefore a key mediator for TGF-β signals. Due to its frequent absence in proliferating pancreatic cancer tissue, it is also known as DPC or "deleted in pancreatic cancer"[65]. Relatively high frequency of SMAD4 mutations and loss of heterozygosity at the DPC4 locus (18q21.1) strongly suggest that the protein is a primary tumor suppressor that is involved in pancreatic cancerogenesis. However, reinstating SMAD4 expression results in tumor growth suppression only *in vivo* and not *in vitro*. It has also been found that SMAD4-independent pathways may be responsible for tumorigenic effect of TGF-β signaling[66].

Wnt signaling

Wnt signaling is crucial to formation and maintenance of endocrine pancreas[67]. During pancreatic carcinogenesis, Wnt triggers transcription of a number of genes that have a direct impact on cell proliferation, differentiation and migration[68]. Activation of Wnt signaling is by interaction of a family of membrane-bound receptors known as Frizzleds with Wnt ligands. Once activated, the downstream signals may proceed through separate pathways. In a canonical pathway, signal transduction is mediated by stabilization and translocation of β-catenin from the cytosol into the nucleus followed by its interaction with T-cell factor (HMG box) which activates transcription of target genes. The localization of high expression levels of β-catenin at the nucleus has been experimentally confirmed for various high grade PanIN lesions, as well as in advanced pancreatic cancer[69]. In a non-canonical, β-catenin-independent pathway, other signal mediators are involved, which block the β-catenin-assisted transcription. The nuclear localization of β-catenin and high expression levels of WNT5a, a gene involved in non-canonical Wnt pathways, suggests involvement of both pathways in pancreatic cancer progression[68].

CDKN2A and cell cycle control

The cell cycle control genes have profound importance in cancer and CDKN2A is one of key factors in its negative control. The CDKN2A has two promoters and alterna-

tive splicing sites that result in two alternative protein products: cyclin-dependent kinase inhibitor p16INK4a and p53-activator p14ARF. Although both proteins are active in negative control of the cell cycle, only the function of p16INK4a is frequently lost in pancreatic tumors due to point mutations, deletions or hypermethylation[70]. p16INK4a protein (also known as p16) inhibits key elements of cell cycle progression at the G1 checkpoint. p16 inactivation is an early event in pancreatic carcinogenesis, and low levels of p16 expression are associated with larger tumors, risk of early metastases and poor survival[71].

MOLECULAR DIAGNOSTICS

A whole range of findings regarding the molecular biological basis of malignant transformation in pancreatic cancer has been published in recent years, and certain progress has been achieved also in the diagnosis, staging and treatment of localized tumors. In the fields of prevention, early diagnosis, screening and treatment of advanced tumors, which represent the majority of newly diagnosed cases, research has failed to provide any fundamental discoveries that would significantly affect the prognosis of patients with pancreatic cancer. Better understanding of the mechanisms of molecular genetics involved in pancreatic carcinogenesis has enabled the identification of a number of hereditary syndromes that in probands represent an increased risk of cancer. An overview is shown in Table 3[72].

Carbohydrate antigen (Ca) 19-9 retains its dominant role among tumor markers. It is the only marker to have been applied in clinical practice, where it is used to detect early recurrence in patients with an already known diagnosis and those undergoing treatment[73]. Use of Ca 19-9 as a screening test has yielded unsatisfactory results. This marker is not specific for pancreatic cancer and may be elevated in various cholestatic syndromes, and not necessarily a tumor. Moreover, the levels of secreted Ca 19-9 are affected by positivity of the Lewis antigen a and b[74]. Table 4 presents an overview of other biomarkers being studied as potentially useful in the diagnosis of pancreatic cancer[75].

Currently, none of the listed biomarkers meets the criteria of utility for the detection of early carcinoma. Even the promising marker PAM4 has demonstrated a sensitivity of 54% in early stage 1a carcinoma and 75% in stage 1b carcinoma[75]. The common denominator of the failure of all biomarkers in early detection lies in their low sensitivity; in some cases, associated with difficult or an invasive collection of biological material.

Detection of early pancreatic cancer in the general population using currently available means is impossible. Interest is now focusing on at-risk groups; especially those in whom the risk of developing this cancer is at least 10-fold higher compared to the general population. This risk may be stratified into low, intermediate and high[76]. Table 5 summarizes this risk stratification.

Several studies published recently have attempted to detect early and resectable carcinoma in high-risk groups with the aid of imaging methods[72,76]. Screening exami-

Table 3 Overview of hereditary syndromes predisposing to pancreatic cancer

Syndrome	Gene	Life-time risk	Relative risk
FAMMM	CDKN2A	10%-15%	20-34
HBOC	BRCA2	5%	10
HBOC	BRCA1	Not known	2
Hereditary pancreatitis	PRSS1/TRY1	30%-50%	50
Lynch syndrome	MLH1/MSH2	Not known	Not known
Peutz–Jeghers syndrome	STK11/LKB1	36%	136
FAP	APC	Not known	4
Li–Faumeni syndrome	p53	Not known	Not known
FPC	Not known	Up to 50%	18-57

APC: Adenomatous polyposis coli; FAMMM: Familial atypical multiple mole melanoma; FAP: Familial adenomatous polyposis; FPC: Familial pancreatic cancer; HBOC: Hereditary breast and ovarian syndrome. Adapted from[72].

Table 4 Overview of biomarkers in pancreatic cancer

Biomarker	Sensitivity (%)	Specificity (%)
CEA	45	75
Carcinoembryonic antigen-related cell adhesion molecule-1	85	98
Ca 19-9	80	73
SPan-1	81-94	75
DUPAN-2	48-80	75-85
Macrophage inhibitory cytokine 1	90	62
Alpha4GnT	76	83
PAM4	77	95
Pancreatic juice DNA methylation	82	100
Fecal K-ras	77	81

CEA: Carcinoembryonic antigen; CA19-9: Carbohydrate antigen 19-9; DUPAN-2: Pancreatic cancer-associated antigen 2; PAM4: Peptidylglycine alpha-amidating monooxygenase 4.

Table 5 Level of risk according to cumulative risk factors

Factors	Risk level
Race/sex: Male; black; Ashkenazi Jewish descent. Exposures: obesity; smoking; diabetes mellitus; *Helicobacter pylori* infection. Family history: Cancer history in a first-degree relative; history of pancreatic cancer in one first-degree relative. Inherited conditions: Hereditary non-polyposis colorectal cancer; familial adenomatous polyposis; *BRCA1* mutation carrier	Low (less than 5-fold)
Family history: History of pancreatic cancer in two first-degree relatives. Inherited conditions: cystic fibrosis; *BRCA2* mutation carrier. Comorbidity: Chronic pancreatitis	Moderate (5- to 10-fold)
Inherited conditions: FAMMM kindreds with p16 germline mutation and at least one case of pancreatic cancer in a first-degree or second-degree relative; hereditary pancreatitis; Peutz–Jeghers syndrome; *BRCA2* or *BRCA1* mutation carrier with at least one case of pancreatic cancer in a first-degree or second-degree relative. Family history: Three or more first-degree; second-degree or third-degree relatives with pancreatic cancer	High (greater than 10-fold)

FAMMM: Familial atypical multiple mole melanoma.

nations usually include some type of imaging method, such as endoscopic ultrasound, magnetic resonance imaging, computer tomography, or genetic tests. Successful identification of small tumors or precursor lesions, cystic tumors and intraductal papillary mucinous neoplasia is now possible in the at-risk population to a higher degree than in the general population. In cases in which solid ductal adenocarcinoma is uncovered, these lesions are usually resectable. Nonetheless, according to the available literature, recurrence has been demonstrated in all such patients over a period of several months.

In recent years, clinical research has focused on identifying patients with chronic pancreatitis with a high risk of developing pancreatic cancer. As discussed above, the following risk factors have been identified to date: smoking[23], duration of chronic pancreatitis[25], status after surgery for chronic pancreatitis in symptomatic individuals (recurrent pain, jaundice, weight loss, loss of appetite)[77], presence of a mutated form of the K-ras oncogene in a sample obtained using fine-needle aspiration biopsy or pancreatic duct brush cytology[78], loss of suppressor gene p16 expression[79], and polymorphism of the uridine diphosphate glucuronyltransferase gene (presence of the UGT1A7 allele causing low detoxification activity of the enzyme)[80].

In view of the completely different pathogenesis of acute and chronic pancreatitis and thus the different

relationship to the development of pancreatic cancer, acute pancreatitis currently is not considered to be a risk factor for the development of pancreatic cancer. On the contrary, the association between alcoholic, hypercalcemic, tropical and hereditary chronic pancreatitis and the increased risk of pancreatic cancer is generally valid. The risk of developing pancreatic cancer in patients with chronic pancreatitis is up to 16-fold higher compared to the healthy population. K-ras mutations are detectable in nearly 80% of patients with carcinoma. Detection of K-ras mutations in patients with chronic pancreatitis may thus be used in combination with other methods as a screening test for the detection of early carcinoma[81].

As described above, much attention is also being paid currently to the relationship between newly diagnosed type 2 diabetes mellitus and pancreatic cancer, whereby diabetes is considered to be an early manifestation of pancreatic cancer, preceding the usual clinical manifestations of this malignancy. Patients with newly diagnosed diabetes will probably be considered to be at higher risk than they are today and will be screened. However, patients with diabetes who are suitable for screening will need to undergo multilevel selection, and the diagnosis of diabetes itself will represent the first filter of such a process. The second level should be the presence of one of the current biomarkers, or preferably the identification of a new marker with a higher predictive value. No

such marker is currently available, therefore, predictive computer models are also being envisaged.

Recent studies have demonstrated in pancreatogenic diabetes mellitus a protective effect of metformin for decreasing the risk of developing pancreatic cancer in patients with chronic pancreatitis. In contrast, treatment with insulin or its secretagogues increases the risk of carcinoma in these patients[82].

CONCLUSION

Uncovering the importance of basic risk factors such as chronic pancreatitis and diabetes mellitus, along with a detailed knowledge of fundamental molecular processes is expected to assist in reducing mortality of pancreatic cancer through development of new approaches for detection of early stages of the disease. This will mainly be applied to evaluation of the survival prognosis and rational selection of therapy; most importantly, with respect to options for radical surgical treatment. In addition, identification of specific genetic aberrations may serve as key molecular markers as predictors of response for targeted therapies. The response prediction should not only prolong survival, but also improve the quality of life for most advanced stages of the disease.

Abstract

AIM: To identify molecular markers shared across South African esophageal squamous cell carcinoma (ESCC) cell lines using cytogenetics, fluorescence *in situ* hybridization (FISH) and single nucleotide polymorphism (SNP) array copy number analysis.

METHODS: We used conventional cytogenetics, FISH, and multicolor FISH to characterize the chromosomal rearrangements of five ESCC cell lines established in South Africa. The whole genome copy number profile was established from 250K SNP arrays, and data was analyzed with the CNAT 4.0 and GISTIC software.

RESULTS: We detected common translocation breakpoints involving chromosomes 1p11-12 and 3p11.2, the latter correlated with the deletion, or interruption of the *EPHA3* gene. The most significant amplifica-
tions involved the following chromosomal regions and genes: 11q13.3 (*CCND1*, *FGF3*, *FGF4*, *FGF19*, *MYEOV*), 8q24.21(*C-MYC*, *FAM84B*), 11q22.1-q22.3 (*BIRC2*, *BIRC3*), 5p15.2 (*CTNND2*), 3q11.2-q12.2 (*MINA*) and 18p11.32 (*TYMS*, *YES1*). The significant deletions included 1p31.2-p31.1 (*CTH*, *GADD45α*, *DIRAS3*), 2q22.1 (*LRP1B*), 3p12.1-p14.2 (*FHIT*), 4q22.1-q32.1 (*CASP6*, *SMAD1*), 8p23.2-q11.1 (*BNIP3L*) and 18q21.1-q21.2 (*SMAD4*, *DCC*). The 3p11.2 translocation breakpoint was shared across four cell lines, supporting a role for genes involved at this site, in particular, the *EPHA3* gene which has previously been reported to be deleted in ESCC.

CONCLUSION: The finding that a significant number of genes that were amplified (*FGF3*, *FGF4*, *FGF19*, *CCND1* and *C-MYC*) or deleted (*SFRP2* gene) are involved in the Wnt and fibroblast growth factor signaling pathways, suggests that these pathways may be activated in these cell lines.

INTRODUCTION

Esophageal squamous cell carcinoma (ESCC) is a major cause of cancer-related death in the world and it is char-

acterized by a peculiar epidemiology with worldwide geographic pockets of high incidence. In South Africa, the region of the Eastern Cape shows the highest incidence and ESCC represents the leading cancer affecting men and the second most common cancer in woman with a prevalence of 31.3 and 18 per 100 000 individuals, respectively[1]. The Gauteng (Johannesburg) and the Western Cape regions are also affected but to a lesser extent[2,3]. The tumors are diagnosed at advanced stages of the disease and patients have a poor survival rate. The etiology of this cancer is unresolved and while the most common risk factors associated with ESCC include smoking and alcohol consumption, these factors are surprisingly lacking in some parts of the world that have a high incidence such as in Iran and northern parts of China[4]. Additional risk factors have been proposed to play a role in some regions. In particular, exposure to fumonisin, a Fusarium fungi toxin that grows on maize, was reported in South Africa and China[5,6] as well as human papillomavirus (HPV) infection[7]. Poor nutrition is associated with ESCC in most parts of the world[4], and chronic inflammation was described in endemic parts of South Africa[8]. The respective part played by environmental risk factors and potential genetic susceptibility remains unclear and it is possible that different combinations of factors may be at play in different parts of the world.

It is widely accepted that recurrent chromosomal breakpoints in malignancies often pinpoint genes involved in the initiation or progression of cancer[9]. A major limitation in assessment of the chromosome complement in ESCC specimens is the difficulty in obtaining metaphases from fresh tumors, and established cell lines provide a unique resource for such investigations. The number of ESCC cell lines that have been reported to date remains limited and were all established in China[10-12] and Japan[13]. These cell lines have been investigated with one or several low resolution molecular cytogenetic techniques including cytogenetics, fluorescence *in situ* hybridization (FISH), multicolor FISH (M-FISH) or SKY and conventional comparative genomic hybridization (CGH). Various clonal aberrations have been identified and the most common abnormalities across studies involved over representation of chromosomes 1q, 3q, 11q and 8q as well as breakpoints in the centromeric or near centromeric regions of chromosomes 1, 3 and 8[10-12,14].

Five cell lines have previously been established from South African ESCC patients[15,16] but apart from cell line SNO, which was karyotyped, these cell lines were never characterized for their genetic constitution. We used conventional cytogenetics, FISH, and M-FISH to identify common chromosome structural abnormalities across these cell lines. Affymetrix 250K single nucleotide polymorphism (SNP) arrays were performed to investigate DNA copy number changes and the common aberrations detected by M-FISH and conventional cytogenetics. Here we describe clonal aberrations shared by these cell lines and highlight preferential targets for chromosomal rearrangements and copy number changes. These are the first ESCC cell lines from Africa to be genetically characterized to our knowledge.

MATERIALS AND METHODS

Cell lines
The five esophageal carcinoma cell lines used in this study were previously isolated from male patients with moderately differentiated ESCCs[16]. These cell lines were previously described and are designated as WHCO1, WHCO3, WHCO5, WHCO6 and SNO cell lines[15,16].

Cytogenetics
Cell lines were cultured at 37℃, 5% CO_2 in Dulbecco's Modified Eagles medium: HAMS F12 (3:1) (GIBCO®, Invitrogen Corporation, USA) containing 10% fetal calf serum, 100 μg/mL streptomycin (ICN, Costa Mesa, CA, USA) and 100 IU/mL of penicillin (ICN, Costa Mesa, CA, USA). When the cultures were half confluent, the cells were incubated with a final concentration of 0.44 μg/mL of Karyomax® Colcemid® (Invitrogen Corporation, USA) for 4 h. Cells were then harvested by standard cytogenetic procedure. Slides were either prepared for metaphase analysis using GTG banding by standard procedures or for FISH preparations.

M-FISH
M-FISH was performed using the SpectraVysion™ Assay (Vysis®, Abbott Molecular Inc, IL, USA) according to the manufacturer's protocol. The slides were analyzed on an Olympus BX41 fluorescent microscope with six single band pass filters for visualization of the six fluorophores. Genus™ CytoVision 3.0 software (Applied Imaging Corporation, San Jose, California, USA) was used for image acquisition and analysis. Ten metaphases were analyzed per cell line.

FISH
FISH was performed on metaphase chromosomes from all cell lines in order to confirm or refine translocation derivative breakpoints and clarify their composition. Probes specific for the short and long arms of chromosome 3, the short arm of chromosome 1 and the long arm of chromosome 22 (Qbiogene, Strasbourg, France) as well as the Vysis® Cep 3 Alpha and Cep 1 Alpha SpectrumOrange probes (Abbott Molecular Inc., IL, USA) were hybridized to further map the breakpoints. The Vysis® LSI IGH and Vysis® LSI RARA, both dual color break apart rearrangement probes (Abbott Molecular Inc., IL, USA) were used to confirm the involvement of chromosomes 14 and 15 in translocation derivatives seen in cell lines WHCO1 and WHCO3 respectively. In order to establish if the *EGFR* (epidermal growth factor receptor) gene was involved in a marker chromosome 7 the Vysis® LSI EGFR SO/CEP 7 SG probe (Abbott Molecular Inc., IL, USA) was hybridized to metaphase chromosomes.

FISH was also performed on interphase nuclei from all cell lines using the Vysis® LSI C-MYC SpectrumOrange

probe and the Vysis® LSI t(11;14) dual color probe (Abbott Molecular Inc., IL, USA). These probes target the *C-MYC* gene (Spectrum Orange) on 8q24 and the *CCND1* gene (Spectrum Orange) on chromosome 11q respectively and were used to confirm SNP array copy number results. A hundred interphase nuclei were analyzed in each cell line. All FISH experiments were performed according to the manufacturer's instructions and analyzed on an Olympus BX41 fluorescent microscope equipped with appropriate fluorescence filters. The Genus™ CytoVision 3.0 software was used for image acquisition and analysis.

DNA isolation
DNA was extracted from the cell lines and from six blood specimens obtained from healthy and population-matched volunteers using standard phenol-chloroform extraction methods. DNA was quantified on the ND-1000 Spectrophotometer (Nanodrop® Technologies, Rockland, DE) and quality assessed by gel electrophoresis.

SNP arrays and data analysis
Cell lines and control DNA were hybridized to the Affymetrix® GeneChip® Human Mapping 250 K Nsp Arrays (Santa Clara, CA). The GeneChip® mapping 500 K protocols were used. The control group used as a reference for analysis was DNA samples extracted from whole blood from black male volunteers.

Data analysis was performed using the Affymetrix®, Genotyping Console™ 2.0 and the copy number analysis tool (CNAT 4.0) software (Affymetrix®, Santa Clara, USA). Subsequently data were analyzed with third party software, Genepattern[17]. The signal intensities from the CEL files were normalized by the PM-MM (perfect match minus mismatch) probe intensity and quantile normalization against the median intensity of the controls. The raw copy number was then estimated as a ratio against the signal intensities of the normal reference samples. The log2ratios were smoothed using GLAD (Gain and Loss analysis of DNA)[18].

To determine the significant common regions of amplification and deletion (i.e. driver aberrations as opposed to random passenger aberrations) across the five cell lines, the GISTIC (Genomic Identification of Significant Targets in Cancer) algorithm[19] was applied to the smoothed data. The algorithm first scores the regions of copy number change according to their frequency and amplitude, which indicates the likelihood of these regions to represent a driver aberration (G-score). The statistical significance of each G-score is calculated by comparison of these scores against a null model of random aberrations. This significance is represented as a q-value (False discovery rate), which is the likelihood that the data was generated by chance. The most probable locations for oncogenes or tumor suppressor genes are identified by calculating the minimal common regions of aberration, which are most significantly altered i.e. high amplitude change. The regions of aberrations with high G-scores and minimal q-values (less than 0.25) are therefore more

Figure 1 G-banded and multicolor fluorescence *in situ* hybridization representative karyotypes of cell line WHCO1. A: G-banded karyotype; B: Multicolor fluorescence *in situ* hybridization (M-FISH) karyotype, the arrows indicate the marker chromosomes, der(1) t(1;14)(p11;q11) and del(7)(q21).

likely to contain target genes that have a significant role in carcinogenesis. The chromosomal regions are then classified as high or low level where low level amplification is considered for a log2ratio greater than 0.1 but smaller than 0.9 and high level amplification is considered for a log2ratio > 0.9 (0.9 corresponds to at least 3.7 copies per diploid cell). Similarly low level deletions (hemizygous) were considered for a log2ratio of -0.1 and homozygous deletions were considered for a log2ratio < -1. The GISTIC algorithm has been used for copy number analysis in previous studies[20,21].

RESULTS

Cytogenetics and M-FISH
Cytogenetic analysis revealed complex numerical and structural chromosome aberrations in all cell lines with a high variability observed between cells from the same cell line (Figures 1 and 2). The G-banded karyotype of cell line WHCO1 and a corresponding M-FISH karyotype that illustrates the degree of variation from one metaphase to another are shown in Figure 1. The M-FISH data confirmed the complexity of the karyotypes and revealed

Figure 2 Multicolor fluorescence *in situ* hybridization representative karyotypes showing complex rearrangements in four cell lines. A: Cell line WHCO3, the white arrow indicates the der(15)t(1;15)(q11;p11); B: Cell line WHCO5, the white arrow points to the der(3)t(1;3)(p11-12;q11); C: Cell line WHCO6; D: Cell line SNO, the white arrow points to the der(3)t(1;3)(p11-12;p11) and the yellow arrow indicates the marker chromosome 7, mar(7), which involves the *EGFR* (epidermal growth factor receptor) locus (Figure 6).

the genetic composition of recurrent chromosome markers that could not be identified on G-banded metaphases (Figure 2); some of these markers are further discussed below. The detailed composite karyotypes obtained from twenty metaphases in each cell line are summarized in Table 1. All cell lines were near diploid except for cell line WHCO5 which was near tetraploid (Figure 2). Across the five cell lines a total of 97 translocations, 19 trisomies and 11 monosomies were detected. The breakpoints amounted to 203, with 78 of these clustering around the centromeric regions of chromosomes. The chromosomes involving the highest number of abnormalities were chromosomes 1, 3, 5, 7, 8, 9, 10, 11, 13, 14, 15, 18, 19, 20 and 22. G-banded metaphases also revealed the presence of isochromosomes involving the D group acrocentric chromosomes in all the cell lines. In particular isochromosome 13q, i(13)(p10) was common to cell lines WHCO3, WHCO5 and WHCO6, isochromosome 14q, i(14)(p10) was common to cell lines WHCO1, WHCO5 and WHCO6, and isochromosome 15q, i(15)(p10) was seen in cell lines WHCO3 and WHCO5.

The combined results of cytogenetics, FISH and M-FISH revealed a common translocation derivative, der (3)t(1;3)(p11;q11) that combined chromosome 3 and chromosome 1 short arms in cell lines WHCO5 and SNO (Figures 2-4). The SNP array copy number data did not bring further information on these breakpoints, possibly due to a lack of SNP probes in this region.

Figure 3 Partial G-banded karyotypes of the five cell lines showing shared chromosomal aberrations across cell lines. Chromosome derivatives from unbalanced translocations involving (A) chromosome 1p11-12 breakpoints in four cell lines, 1q11 in cell line WHCO3, (B) deletions of chromosome 7q in four cell lines, and (C) deletions of chromosome 20q in three cell lines.

[1]Only structural rearrangements are listed due to the complexity of this cell line.

Figure 4 DAPI stained metaphasic chromosomes showing the der(3)t(1;3)(p11-12;q11) in cell lines SNO and WHCO5. A, B: Arm-specific paint for chromosomes 1p (green) and 3p (red) in cell lines SNO and WHCO5 respectively showing the derivatives der(3)t(1;3)(p11-12;q11) arrowed; C, D: Arm specific paint for chromosome 1p (green) and Cep 3 α probe (red) in cell lines SNO and WHCO5 respectively showing that the centromere of chromosome 3 is retained on the derivatives der(3)t(1;3)(p11-12;q11).

Figure 6 DAPI stained metaphase from cell line SNO showing fluorescence *in situ* hybridization results with the locus specific EGFR probe (red) and Cep7 α (green). The arrow indicates the chromosome 7 marker with a homogeneously stained region that contains the *EGFR* locus.

Figure 5 CNAT plot of single nucleotide polymorphism hybridization results showing the map of the region of deletion on chromosome 3p11.2-12.1 in cell lines WHCO1, WHCO3, WHCO5, WHCO6 and SNO. The red bars indicate the segment of deletion as determined by CNAT 4.0. The dotted lines indicate the copy number status for each single nucleotide polymorphism probe for each cell line. The blue block indicates the minimal common region of deletion and the red arrow indicates the two genes in this region, *c3orf38* and *CGGBP1*.

Interestingly, the 1p11 breakpoint was also involved in cell lines WHCO1 and WHCO6 in differing unbalanced translocations (Figure 3). The M-FISH and FISH results with probes for the respective partner chromosomes and centromeric Cep1, confirmed the interpretation of these derivatives as der(1)t(1;14)(p11;q11) in cell line WHCO1 and der(1)t(1;8)(p11;p11) in cell line WHCO6 (results not shown). In contrast, a translocation derivative also involving the chromosome 1 pericentromeric region in cell line WHCO3 (Figure 3) was shown not to involve 1p11 but 1q11, and was interpreted as der(15)t(1;15)(q11-12;p11) (result not shown).

Translocation derivatives involving chromosomes 3 and 22 were seen in cell lines WHCO3 and WHCO5 and were interpreted as der(16)t(3;16;22)(p11;?;q?11) and t(3;22)(p11;q11) respectively (Table 1). The array data showed corresponding hemizygous deletions at 3p11.2, in cell line WHCO3. Interestingly deletions at 3p11.2 were also observed in cell lines WHCO1, SNO and WHCO6. The minimal region of overlap was 343 kb (88 184 220-88 527 215 bp) in size and involved *c3orf38* and CGG triplet repeat binding protein (*CGGBP1*) genes. In addition the *EPHA3* gene was deleted in cell lines WHCO6 and SNO (Figure 5). The *EPHA3* gene encodes a tyrosine kinase, which is mutated in lung and breast cancers[22-24].

Cell lines WHCO1, WHCO3, WHCO5 and WHCO6 all showed a deletion of chromosome 7 long arm with varying breakpoints, q21 to q31, on G-banded metaphases (Figure 3). However GISTIC analysis of the SNP array data identified a significant common focal deletion (q-value of 0.09) of approximately 5.16 Mb at 7q33-q34 (133 721 542-138 880 555 bp) in only three of these cell lines. This region contained 26 genes including the potential target gene homeodomain-interacting protein kinase-2 (*HIPK2*) the product of which activates p53 expression and is pro apoptotic[25].

Although deletions at 20q11.2 were detected in cell lines WHCO5, WHCO6 and at 20q12 in cell line SNO on G-banded metaphases (Figure 3), copy number analysis (CNAT) revealed that there was in fact amplification of 20q sequences in all cell lines implying that complex rearrangement occurred for these sequences to be relocated elsewhere in the genome. Two minimal regions of amplification were identified, the 20q11.21-q11.22, of approximately 1.12 Mb in size (31 799 867-32 906 584 bp), which contained 14 genes and a smaller region at 20q13.12 of 149.48 kb which contained five genes. Both these regions were amplified in all cell lines, yet these amplifications were not found to be significant on GISTIC analysis.

Cell line SNO showed a large marker chromosome 7 on metaphases analyzed by M-FISH. This marker was interpreted as a possible inverted duplication of chromosome 7p sequences (Figure 2D). FISH with an *EGFR* probe, revealed a high amplification of the *EGFR* gene in 14% of the cells (Figure 6). A high level amplification at 7p13-7p11.2 (genomic location of *EGFR*) was confirmed by GISTIC (q-value 0.14) on array analysis in this cell line, while low level amplification was observed in the remaining four cell lines in agreement with the presence of 4 to 7 copies on FISH analysis.

Copy number changes

In view of the high cell to cell heterogeneity in each cell line, and in order to separate the potential driver aberrations out of the background of aberrations that may have occurred by chance, we used the software GISTIC specifically designed for this purpose. Target genes, defined as genes whose alteration confers a cell growth advantage, are likely to reside in the regions amplified or deleted to the highest degree in a majority of cells and within a common region of overlap amongst all cell lines. Fourteen common regions of amplification and 20 regions of deletion were

Table 2 Amplification peaks as detected by the GISTIC algorithm

[1]The mean log2ratio for the samples with a log2ratio > 0.9 (equivalent to 3.7 copies per diploid cell); [2]The selected genes from the peak region.

Figure 7 Plots of recurrent genomic amplifications (A) and deletions (B) detected in the esophageal squamous cell carcinoma cell lines from GISTIC analysis of single nucleotide polymorphism array data. The x-axis shows the G-score (top) and false discovery rate (q value; bottom). The green line indicates the false discovery rate cut off of 0.25. The circles indicate the peaks of the most significantly aberrant chromosomal regions.

identified (Figure 7, Tables 2 and 3). The most significant chromosomal regions of amplification were, in descending order of significance: 11q13.3 and 8q24.21, in four and five cell lines respectively, 11q22.1-q22.3 and 5p15.2 both detected in two cell lines. Chromosomal regions

of less significant amplification were 10p12.33-q21.3, 18p11.32, 20p11.1-p11.22, 22q11.21-q11.22, 22q12.3, 9q31.1, 22q11.21, 3q11.2-q12.2 and 1p34.2 (Figure 7). Similarly, chromosomal regions of deletion were seen in the following order of significance: 1p31.1-p31.2, 2q22.1,

3p12.1-p14.2, 4q22.1-q32.1, 8q11.1-p23.2, 14q21.2, 18q21.1-q21.2 and 21p13-q21.3 detected in all or four cell lines. Other regions of less significant deletion, and only seen in one or two cell lines, included: 10p12.31-p14, 14p13-q32.33, 3p26.3-q29, 9p24.2-p24.3, 6q24.3-q27, 12p13.33-q24.33, 7q33-q34, 8p23.3-q24.3, 10q11.23-q22.1, 11p11.12-q12.2 and 13q21.33-q34 (Figure 7). Together the regions of amplification and deletion encompassed a total of 4595 genes.

Significant gains

We selectively describe below the five regions of amplification that were the most significant on GISTIC analysis (q-value < 0.25) (Figure 7). Chromosomes 11q13.3 (68 753 086-69 985 447 bp) and 8q24.21 (127 445 828-

129 661 846 bp) were the two most amplified and most significant regions with a q-value of 5.76E[-05] and 0.0007 respectively. The 11q13.3 region was 1.23 Mb in size and was highly amplified in cell lines WHCO3, WHCO5, WHCO6 and SNO while amplified to a lesser degree in cell line WHCO1. This region harbors seven candidate genes including the cyclin D1 (*CCND1*), the cortactin (*CTTN*), the protein tyrosine phosphatase, receptor type, polypeptide, interacting protein α 1 (*PPFIA1*), *FGF3*, *FGF4* and *FGF19* and the myeloma overexpressed (*MYEOV*) genes, which could all play a role in ESCC oncogenesis. FISH validated these findings and confirmed the amplification of *CCND1* (Table 4, Figure 8). The common amplicon of 2.22 Mb at 8q24.21 was highly amplified in cell lines WHCO1 and WHCO3 and moderately amplified in cell lines WHCO5, WHCO6 and SNO. This amplicon involved the oncogene v-myc myelocytomatosis viral oncogene homolog (*C-MYC*) and the family with sequence similarity 84, member B (*FAM84B*) gene. Locus specific FISH confirmed the amplification of *C-MYC* in cell lines WHCO1, WHCO3, WHCO5, WHCO6 and SNO (Table 4, Figure 8).

A second focal region of high amplification on chromosome 11 was observed at 11q22.1-q22.3 (2.23 Mb in size) in cell lines WHCO5 and SNO. This region included the regulators of apoptosis *BIRC2* (*cIAP1*) and *BIRC3* (*cIAP2*), the matrix metalloproteinases (*MMP*) and the Yes associated protein (*YAP-1*) genes all potential target genes. The *BIRC2* gene was previously described as a target of amplification /increased expression in cervical cancers[26] and the *YAP-1* gene product is a cellular adaptor protein, which can induce *BIRC2* expression. *YAP-1* was reported to be over expressed in hepatic and mammary cancers[27]. In turn, the MMP genes, which include

Figure 8 DAPI stained interphase nuclei hybridized with locus specific probes for C-MYC Spectrum Orange (red) (A-D) and *CCND1* (red)/*IGH* (green) (E-H). C-*MYC* amplification can be seen in cell lines WHCO1 (A), WHCO3 (B), WHCO5 (C) and SNO (D). *CCND1* amplification was detected in cell lines WHCO3 (E), WHCO5 (F), WHCO6 (G) and SNO (H).

MMP1, *MMP7*, and *MMP13*, have been shown to be co-expressed in early stage ESCC correlating with a poorer prognosis[28].

A 1.75 Mb region on chromosome 5p15.2 (10 051 329-11 800 765 bp) was highly amplified in cell lines WHCO6 and WHCO5 and moderately amplified in cell lines WHCO1 and SNO. This region hosts the potential target gene, delta catenin (*CTNND2*), overexpressed in prostate cancer[29].

Four cell lines, WHCO6, WHCO3, WHCO5 and SNO, had focal gain on chromosome 3q. The minimal common region of amplification mapped at 3q11.2-12.2, and was 6.02 Mb in size (95 917 505-101 945 216 bp) (q-value = 0.17). This region is commonly amplified in a variety of cancers[20,30] including esophageal squamous carcinoma[31] and it involved the potential oncogene, MYC induced nuclear antigen (*MINA*).

The 18p11.32 sub-band was highly amplified in cell lines WHCO3 and WHCO6 and moderately amplified in the remaining 3 cell lines. This region of 1.12 Mb in size (1-1 118 244 bp) has previously been described in ESCC[32] and involves the potential oncogenes *TYMS* and *YES-1*. Both genes have been implicated in gastro intestinal cancer. The *TYMS* gene codes for a thymidylate synthase involved in DNA synthesis and targeted by the chemotherapy agent fluorouracil (5FU). *TYMS* overexpression leads to 5FU treatment resistance[32] and affects colorectal cancer treatment[33]. *YES-1* is a homologue of the Yamaguchi sarcoma virus v-*yes* amplified and overexpressed in gastric cancers and ESCC[32].

Significant losses

The most significantly deleted chromosomal regions were 1p31.1-p31.2, 2q22.1, 3p12.1-p14.2, 4q22.1-q32.1, 8p23.2-q11.1, 14q21.2 and 18q21.1-q21.2 (in descending or-der of significance) in all or four of the cell lines (Figure 7). Less significant regions detected in less than four cell lines are depicted in Table 3. Three small regions of deletions involved chromosomes 1p, 2q and 18q. The 4.5 Mb deletion on chromosome 1 short arm, 1p31.2-p31.1 (66 691 991-71 187 083 bp) was seen in four cell lines (homozygous deletion in cell line SNO and hemizygous in cell lines WHCO1, WHCO5, WHCO6) with a high significant q-value of 0.02. Three genes with a reported tumor suppressor activity were involved in this deletion, the cystathionine γ-lyase (*CTH*), the growth arrest and DNA damage-45 α (*GADD45α*) and the DIRAS family, GTP-binding RAS-like 3 (*DIRAS3*) genes. The *DIRAS3* gene was shown to be down regulated in hepatocellular carcinoma and breast cancers[34,35] and is postulated to have a tumor suppressive activity. Both the *CTH* and *GADD45* genes were shown to negatively control cell growth[36,37].

Chromosome 2, sub-band q22.1 (141 590 067-141 951 947 bp) was lost in all cell lines (homozygous deletion in cell lines WHCO3 and WHCO5 and hemizygous in the other 3 cell lines) (q-value = 0.019). The low density lipoprotein 1B (*LRP1B*) tumor suppressor gene, deleted in lung cancer[38,39] maps in this region.

A chromosome 18q sub-band, q21.1-q21.2 (46 081 464-51 919 972 bp) (5.8 Mb) was hemizygously deleted in all five cell lines, involving both the *SMAD4* and deleted in colorectal carcinoma (*DCC*) genes.

Three large regions of deletion involved chromosomes 3p, 4q and 8p. First, the 24.7 Mb region of deletion at 3p12.1-p14.2 (60 424 050-85 108 679 bp) was significant (q-value of 0.02) in all cell lines (homozygous deletion in cell line SNO). This region houses the FRA3B associated gene, Fragile Histidine triad (*FHIT*), whose deletions were previously detected by MLPA analysis in these cell lines[40]. The potential tumor suppressor *ADAMTS9* gene, a me-

talloproteinase family member involved in inhibition of angiogenesis[41] was also involved in this deletion.

Second, the 4q22.1-q32.1 (91 972 774-162 358 674 bp) (75 Mb) region was homozygously deleted in cell lines WHCO3 and WHCO5 and hemizygously deleted in the three other cell lines with a q-value of 0.02. This region encompasses many genes but of interest are the Bone morphogenetic protein receptor 1B (*BMPR1B*), the caspase 6 (*CASP6*), the secreted frizzled-related protein 2 (*SFRP2*) and the SMAD protein 1 (*SMAD1*) genes, all potential tumor suppressor genes.

Lastly, a chromosome 8p23.2-q11.1 (4 078 057-47 043 375 bp) (43 Mb) deletion was seen in all cell lines (homozygous in cell line WHCO3 and hemizygous in the other 4 cell lines) (q value of 0.02), including five potential target genes, the BCL2/adenovirus E1B 19kDa interacting protein 3-like (*BNIP3L*), the leucine zipper tumor suppressor 1 (*LZTS1*) and the three tumor necrosis factor related superfamily genes *TNFRSF10A, TNFRSF10B* and *TNFRSF10C*.

DISCUSSION

We have characterized the karyotype and genomic constitution of five ESCC cell lines established in SA using a combination of traditional cytogenetics, M-FISH, FISH and SNP arrays. The number of ESCC cell lines genetically described worldwide is limited. Only eight ESCC cell lines have been investigated previously with traditional cytogenetics to our knowledge[10,12,42] and 10 with M-FISH[11,43,44], these are the only two techniques that can detect recurrent translocation breakpoints. In this study the five cell lines had complex karyotypes and were hyperploid with WHCO5 being near tetraploid. There was a high level of intra cell-line heterogeneity. The chromosomes most frequently involved in translocations were chromosomes 1, 3, 5, 7, 8, 9, 10, 11, 13, 14, 15, 18, 19, 20 and 22. These features were comparable to ESCC cell lines previously characterized[10-12,42,43] and across all studies that involved karyotyping, including the karyotyping of fresh ESCC tumor samples[14], chromosomes 1, 3 and 8 were the most commonly affected by translocation breakpoints[10-12,43].

Forty percent of translocation breakpoints occurred in near centromeric regions (Table 1). These were represented by unbalanced whole arm chromosome translocations, frequently involving chromosomes 1 and 3, and by isochromosomes for the D group acrocentric chromosomes 13, 14 and 15. Indeed, frequent centromeric breakpoints have been described in squamous carcinoma including ESCC[10,12] with up to 60% of all breakpoints being in centromeric regions[43] supporting the idea that centromeric disruption is a frequent event in epithelial cancers. It has been suggested that environmental factors may preferentially interact with centromeric sequences[45], and clastogenic compounds, such as mitomycin C, induce breaks in centromeric of chromosomes 1, 9 and 16[46]. Smoking is a major risk factor associated with ESCC and

nicotine is known to induce single strand DNA breaks[47]. Although active smokers exhibit an increased number of breaks at fragile sites[48], it is not known if centromeric regions are also targeted.

Two chromosomal breakpoints were shared across cell lines. First, chromosome 1p11 was involved in a translocation in four cell lines, translocation t(1;3)(p11.2-12; q11) in cell lines SNO and WHCO5 and translocations with differing partners in cell lines WHCO1 and WHCO6. Second, chromosome 3p11-12 was involved in translocations in two cell lines and deletions in, or near the *EPHA3* locus was seen in four cell lines.

This gene codes for a receptor tyrosine kinase, with a tumor suppressor activity[49]. It was found to be mutated in lung and breast cancers[22-24] and interestingly, found to be deleted in 18.2% of ESCC patients in a previous study[31].

Breakpoints in, or near the centromeric regions of chromosomes 1 and 3 have previously been reported in several ESCC cell lines[10-12], as well as in fresh ESCC tumor samples that were karyotyped[14], and in ESCC cell lines obtained by *in vitro* transformation with HPV[50]. This strongly points to 1p11 and 3p11 translocation hotspots in ESCC that may affect genes and/or regulatory sequences not identified by SNP array. Deletions affecting or near the *EPHA3* gene may point to a role for this gene which was previously found to be deleted in 18.2% of ESCC patients[31].

We knew from previous studies that these ESCC cell lines, all overexpress the *EGFR* gene[16]. *EGFR* DNA amplification observed in cell line SNO is likely to contribute to *EGFR* overexpression whilst other factors are likely to be involved in the other four cell lines where low levels of *EGFR* amplification were observed.

In view of the high clonal heterogeneity observed in each cell line, we used the GISTIC software in addition to CNAT to analyze SNP array data and evidence the significant targets of amplification and deletions. The most stable genetic rearrangements are thought to reflect a proliferative cell growth advantage. In this context, the GISTIC algorithm allowed us to prioritize amplicons and regions of deletions in term of their likelihood to host driver genes. The five most interesting significant regions of amplification included chromosomal regions: 11q13.3, 8q24.21, 11q22.1-q22.3, 5p15.2 and 3q11.2-q12.2 in decreasing order of significance.

The 8q24.21, 11q13.3 and 3q11.2-q12.2 regions have all previously been reported in a variety of carcinomas[51-53] and they often co-exist with one another. Genomic amplification at 8q24 occurs in a large variety of cancers[51,53-56], and most amplicons described in the literature involve both the *C-MYC* and *FAM84B* genes, as was observed in this study in four ESCC cell lines. In previous reports the target of amplification has been attributed to either both genes[54], or to one or the other[55,56] based on their respective increased transcription.

The 11q13.3 amplicon covered a large region containing a number of potential target genes. The *CCND1* and *MYEOV* genes (11q13.3) were co-amplified in four cell

lines. Co-amplification of these genes has been reported in multiple myeloma, breast cancer and ESCC[14]. *CCND1* is a downstream effector in the Wnt2/β-catenin pathway and the most frequent target of amplification in several ESCC studies[14,53,57]. While the *MYEOV* gene has been associated with cell proliferation in colon cancer[58], its amplification in ESCC is not always matched by increased transcription due to its silencing by epigenetic mechanisms[59]. The cortactin gene, *CTTN,* involved in cell motility[60], was previously shown to be over expressed in ESCC pre-cancerous lesions, as well as in carcinogen induced murine ESCC supporting a role for this gene in ESCC carcinogenesis[61]. The three fibroblast growth factor (FGF) genes, *FGF3, FGF4* and *FGF19* were part of the 11q13.3 amplicon. FGF and Wnt signaling pathways cross talk in a number of carcinogenesis scenarios[62]. Activated FGF receptors activate the FRS-GR2-GAB1-PI3K-AKT signaling cascade, and downregulate GSK-3β protein activity, thus hampering β-catenin phosphorylation and degradation[62]. In particular, FGF19 ligand downregulates GSK-3β activity, which results in the release and nuclear accumulation of β-catenin. Nuclear β-catenin activates the transcription of downstream genes including *C-MYC* and *CCND1*[63].

In addition to the amplification of Wnt pathway activators, the *SFRP2* tumor suppressor gene locus was deleted at chromosome 4q22.1-q32.1 (Figure 7). The *SFRP2* gene encodes a frizzled-related protein and is part of the SFRP family of Wnt inhibitors. Loss of *SFRP2* is detected in medulloblastoma and is suggested to contribute to carcinogenesis through loss of inhibition of the Wnt pathway[64].

The copy number data therefore suggests that the Wnt signaling pathway may be at work in these ESCC cell lines through one or the combined effects of genes activating the β-catenin transcriptional activity and/or the FGF signaling pathways as well as deletions of genes, at 4q22.1-q32.1, inhibiting this pathway. Amplicons at both 8q24 and 11q13.3-13.4 have been described in a variety of squamous cell carcinoma[54,65-67] suggesting that the activation of pathways through the combined effects of genes at 8q24 and 11q13.3-13.4 contributes to the development and aggressiveness of SCC.

In addition to the *SFRP2* gene, the three tumor suppressor genes *BMR1B, SMAD1* and *CASP6* were also targets of deletion at 4q22.1-q32.1. Both *BMR1B* and *SMAD1* genes have previously been reported to have decreased expression in gliomas correlating with poor survival[68], and *BMPR1B* decreased expression in breast cancer is associated with increased cell proliferation and poor prognosis[69]. The *CASP6* gene encodes the pro-apoptotic caspase-6 protein[70].

Although large 3q amplicons are commonly observed in squamous carcinoma[71,72] in this study the 6 Mb, 3q11.2-12.2 amplicon was focal and involved the *MINA* gene. This gene has previously been reported to be overexpressed in 83% of ESCC in one study and its inhibition was shown to suppress ESCC cell proliferation[73].

A 43 Mb region of deletion at 8p23.2-q11.1 (4 078 057-47 043 375 bp) was observed in the five cell lines and involved five potential target genes. These included the *BNIP3L* gene deleted or downregulated in prostate cancer and malignant melanomas, respectively[65,74], the *LZTS1* gene, deleted in oral squamous cell carcinomas and downregulated in breast carcinomas[75,76]; and the three *TNFR* genes, *TNFRSF10A, TNFRSF10B* and *TNFRSF10C,* whose epigenetic inactivation was reported in gastric cancers[77]. An 8p loss, was previously detected by conventional CGH in a study performed on 29 South African black and colored ESCC patients[78]. Chromosome 8p22 loss has also been reported in prostate, breast, lymphoma, hepatocellular and colorectal cancers[79-83].

Active smoking is linked to increased fragile site expression[84] and is also one of the primary risk factors associated with ESCC in South Africa[85]. We previously hypothesized that deletions affecting anti-oncogenes located at fragile sites may contribute to the etiology of ESCC in South Africa and reported *FHIT* intragenic deletions in these cell lines and a small cohort of patients[40]. *FHIT* gene deletions were confirmed here supporting its role in ESCC carcinogenesis.

Deletion at 18q23 involved the *SMAD4* and *DCC* genes in all cell lines. Both genes have previously been reported to be down regulated in ESCC either by deletion, mutation or methylation[86]. Decreased expression of the *SMAD4* gene, a tumor suppressor of the transforming growth factor β family signaling pathway, has been associated with ESCC tumor invasion[87]. The *DCC* gene was shown to be frequently methylated in ESCC tumor specimens[88].

In summary, breakpoints at 1p11 and 3p11 were recurrent in the five ESCC cell lines and may point to genes such as *EPHA3* that may be involved in ESCC carcinogenesis. Copy number alterations involved both amplicons previously reported in squamous cell carcinoma (8q24, 11q13 and 3q11) as well as novel regions of significant amplification (11q22.1-q22.3, 5p15.2 and 18p11.32). The finding that a significant number of genes that were amplified (*FGF3, FGF4, FGF19, CCND* and *C-MYC)* or deleted (*SFRP2* gene) are involved in the Wnt and FGF signaling pathways suggest that these pathways may be activated in these ESCC cell lines. These results warrant expression studies of these genes in both cell lines and patients' specimens. Of interest, should *FGF* gene expression be increased, ESCC patients may benefit from the respective FGF targeted therapies recently developed[89,90].

COMMENTS

Background

Esophageal squamous cell carcinoma (ESCC) is a major cause of cancer death in the world and has a peculiar epidemiology with worldwide geographic

pockets of high incidence particularly in Asia and Africa. In South Africa, in the Eastern Cape region, ESCC represents the leading cancer affecting men and the second most common cancer in woman. There is a need to identify biomarkers to better understand the pathophysiology of this cancer and inform future diagnostic and therapeutic strategies for these patients. Established cell lines provide a unique resource to investigate both the presence of chromosomes translocations and copy number imbalances.

Research frontiers

A limited number of ESCC cell lines, all established in Asia, were reported to date. These have been investigated with molecular cytogenetic techniques of limited resolution and no key pathways have been reported previously.

Innovations and breakthroughs

This is the first comprehensive molecular cytogenetic study of five ESCC cell lines established in South Africa. The authors combined high-resolution whole genome array copy number analysis with conventional cytogenetics and multi-color fluorescence *in situ* hybridization to assess common chromosomal imbalances. Interestingly, a significant number of genes that were amplified (*FGF3*, *FGF4*, *FGF19*, *CCND1* and *C-MYC*) or deleted (*SFRP2* gene) are involved in the Wnt and FGF signaling pathways. In addition, a deletion within or near the *EPHA3* gene was present in 4 of these cell lines, corresponding to a translocation breakpoint at 3p11.2 shared in some cell lines.

Applications

These results suggest that the Wnt and FGF pathways may be involved in the initiation or progression of ESCC. They also point to the *EPHA3* gene as an added potential key gene. Further study on patients' specimens and functional studies will determine the significance of these genes in ESCC pathogenesis.

Terminology

High-resolution 250K single nucleotide polymorphism (SNP) arrays cover at least one SNP per 100 kb of DNA, using an average of 24 probes per SNP. The copy number data are derived from the summary of non-polymorphic SNPs and examined as a ratio to a reference genome. Changes in intensity ratios are indicative of amplification/deletions. The Wnt and fibroblast growth factor (FGF) signaling pathways are involved in tissue homeostasis as well as in cell proliferation and differentiation. Although their mechanisms differ, these two pathways cross talk through GSK3β inhibition.

Peer review

The manuscript by Brown and coworkers demonstrates that a significant number of genes that were amplified or deleted are involved in the Wnt and FGF signaling pathways in five cell lines established from South African ESCC patients. They suggest that these pathways are activated in these cell lines. The overall goal of the paper is relevant. The data presented are solid and credible. The results are interesting and clinically important.

Abstract

AIM: To characterize a culture model of rat CCA cells, which were derived from a transplantable TTA-induced CCA and designated as Chang Gung CCA (CGCCA).

METHODS: The CGCCA cells were cultured at *in vitro* passage 12 times on a culture dish in DMEM medium. To measure the doubling time, 10^3 cells were plated in a 96-well plate containing the growth medium. The cells were harvested 4 to 10 d after seeding, and a standard MTT assay was used to measure the growth. The phenotype of CACCA cell and xenograft was determined by immunohistochemical study. We also determine the chromosomal alterations of CGCCA, G-banding and spectral karyotyping studies were performed. The CGCCA cell line was transplanted into the nude mice for examining its tumorigenicity. 2-Deoxy-2-(^{18}F)fluoro-D-glucose (FDG) autoradiography was also performed to evaluate the FDG uptake of the tumor xenograft.

RESULTS: The doubling time for the CGCCA cell line was 32 h. After transplantation into nude mice, FDG autoradiography showed that the tumors formed at the cell transplantation site had a latency period of 4-6 wk with high FDG uptake excluding necrosis tissue. Moreover, immunohistochemical staining revealed prominent cytoplasmic expression of c-erb-B2, CK19, c-Met, COX-Ⅱ, EGFR, MUC4, and a negative expression of K-ras. All data confirmed the phenotypic features of the CGCCA cell line coincide with the xenograft mice tumors, indicating cells containing the tumorigenicity of CCA originated from CCA. In addition, karyotypic banding analysis showed that the diploid (2n) cell status combines with ring and giant rod marker chromosomes in these clones; either both types simultaneously appeared or only one type of marker chromosome in a pair appeared in a cell. The major materials contained in the marker chromosome were primarily identified from chromosome 4.

CONCLUSION: The current CGCCA cell line may be used as a non-K-ras effect CCA model and to obtain information and reveal novel pathways for CCA. Further applications regarding tumor markers or therapeutic targeting of CCA should be addressed accordingly.

INTRODUCTION

Cholangiocarcinoma is a malignant neoplasm derived from bile duct epithelium (i.e. cholangiocytes). It is characterized by a great diversity of symptoms commonly occurring in the late course of the disease, and therefore making treatment puzzling. The biological behavior of the tumor and early intrahepatic and/or extrahepatic spread limit the efficacy of surgical management to perform a curative resection; although liver transplantation may provide an alternative option for CCA treatment, high rates of recurrence still limit liver transplantation for most CCA patients[1] and usually lead to a poor prognosis. Three- to five-year survival rates, even with resection, remain dismal[2-7]; in addition, neither radiation therapy nor chemotherapy significantly improves long-term survival rates. This cancer is related to a wide range of risk factors, such as infestation with liver flukes, primary sclerosing cholangitis, and hepatolithiasis, that cause the incidence rates of CCA to vary greatly among different areas of the world[8]. However, many data have shown that the incidence and mortality rates of CCA have been rising worldwide over the past several decades, particularly the intrahepatic CCA[9-11].

Therefore, our goal is to identify potential possible diagnostic biomarkers as the investigation of the molecular pathophysiology associated with this disease becomes more and more important and necessary. In our previous study, a thioacetamide (TAA)-induced CCA rat model was successfully established, and serves as a powerful pre-clinical platform for therapeutic and chemoprevention strategies for human CCA[12]. Herein, we further developed the rat CCA tumor cells as a cell line designated as Chang Gung CCA (CGCCA), and then transplanted the cells into a xenograft of nude mice to further confirm the characteristics of this cell line. A series of IHC studies, including CK19, c-Met, COX-Ⅱ, and MUC4, were performed to determine the phenotype of the cell line. The genotype was examined by cytogenetic studies, and the 2-Deoxy-2-(^{18}F)fluoro-D-glucose (FDG)-avid character of the CGCCA xenograft of the nude mice was demonstrated by animal PET. All of the evidence proved that the CGCCA cell line rat was derived from the original primary tumor formed by the TAA carcinogen. Our current work supports the view that the systematic cell cultures may provide a relevant CCA model to study the complex mechanisms involved in CCA by revealing the potential pathogenesis of this disease. In addition, we may be able to determine the possible diagnostic markers for the early detection and diagnosis of this disease.

MATERIALS AND METHODS

Animal study

This study was approved by the experimental animal ethics committee at the Chang Gung Memorial Hospital, Taiwan. The investigation conformed to the US National Institute of Health (NIH) guidelines for the care and use of laboratory animals (Publication No. 85-23, revised 1996). Male Sprague-Dawley (SD) rats weighing 319 ± 14 g were used in the experiments. The rats were housed in an animal room with a 12:12 hour light-dark cycle (light from 08:00 AM to 08:00 PM) at an ambient temperature of 22 ± 1℃. Food and water were available *ad libitum*.

Establishment of TAA-treated rats CGCCA cell line

The cell isolation procedure as described by Lai *et al*[13] was applied with minor modifications in this study. In brief, hyperplastic bile ductular epithelial cells were obtained from the liver of the male Sprague-Dawley (SD) rats treated with TAA 300 mg/L daily after 25 wk of exposure. The isolation of the CGCCA cell line was established from the nest of cholangiocarcinoma by employing differential cell harvesting with 0.05% trypsin and 0.53 mmol/L EDTA (Life Technologies), and then combined with subsequent serial propagation suspended in a cell culture medium composed of DMEM with 100 U/mL penicillin and 100 U/mL streptomycin (basal medium) plus 10% fetal bovine serum[13].

Estimating growth kinetics of cells in vitro

The CGCCA cells were cultured at *in vitro* passage 12 times on a culture dish in DMEM medium containing 10% fetal bovine serum. To measure the doubling time, 10^3 cells were plated in a 96-well plate containing the growth medium as described above. The cells were harvested 4 to 10 d after seeding, and a standard MTT assay was used to measure the growth according to the instruction manual (MTT Cell Growth Assay Kit; #CT01; Chemicon). The doubling time of the cell population was estimated based on the slope angle of the linear regression model for the four time points.

Determine phenotype of CACCA cells and xenograft by immunohistochemical study

CGCCA rat cells were grown on a miniature cell culture vessel chamber, which permits cells to be grown, fixed, stained, and analyzed all on the same slide (#154461 Lab-Tek II Chamber Slide System; Nalge Nunc International, USA). A total of 2000 cells per well were grown over night, rinsed with PBS twice, fixed with 4% PFA for 1 min, and perforated with 1% Tween 20 for 1 min. In addition, we further compared the cells with the xenograft mice tumors. The mice tissues were obtained for the immunoreactivities study once the mice tumors reached a

diameter of 1.0 cm. The slides were then stained according to the routine IHC staining as described previously[14]. In brief, the primary antibodies CK19 (MAB-1675; Millipore; Temecula, CA), K-ras (clone sc-30; Santa Cruz Biotechnology Vision Corporation; Fremont, CA), c-erb-B2, COX-Ⅱ, EGFR, MET, and MUC4 were diluted at 1:200 and 1:400, respectively (clone sc-284; Santa Cruz Biotechnologies; Santa Cruz, CA; M-3563; Dako Cytomation; RB-9072-9; Lab Vision Corporation; Fremont, CA; clone sc-161; Santa Cruz Biotechnology Vision Corporation; Fremont, CA; and 35-4900; Zymed S; San Francisco, CA) and incubated overnight at 4℃. The slides were then washed three times with TBST, mounted, and analyzed under microscope by authors blindly before visualization with the DAKO LSAB2 System (Peroxidase; DAKO A/S; No. K0675). Control slides were incubated with the secondary antibody only.

Cytogenetic study of the CGCCA cell line

To determine the chromosomal alterations of CGCCA, G-banding and spectral karyotyping (SKY) studies were performed. The CGCCA cells were grown under the conditions as described above. After the cells were harvested, a metaphase chromosome spread was prepared for G-banding and SKY analysis[15]. At least ten metaphases were analyzed after G-banding (data not shown). For SKY analysis, 22 differentially labeled chromosome-specific painting probes and Cot-1 DNA were denatured and hybridized to the tumor metaphase chromosomes according to the protocol recommended by the manufacturer (Applied Spectral Imaging; Migdal Haemek, Israel) with some modifications as previously described[15]. Image acquisitions were performed using a SD200 Spectracube system (Applied Spectral Imaging) mounted on a Leica DM2500 microscope with a custom-designed optical filter (SKY-1; Chroma Technology; Brattleboro, VT). The clonality criteria and the karyotype description followed the recommendations of the International System for Human Cytogenetic Nomenclature (ISCN 2005)[16].

Heterotransplantation of CGCCA cells in nude mice

Seven male nude mice (BALB/cA Jcl nu/nu) (6 to 8 wk old; 20 to 22 g body weight) were purchased from Clea Japan (Ohita, Japan). The CGCCA cell line was transplanted into the nude mice for examining its tumorigenicity. Each of the 7 mice received a 50 μL subcutaneous inoculation that contained ten million CGCCA cells suspended in the thigh area. Tumor size was measured with a digimatic caliper, and tumor volume was calculated according to the subcutaneous tissue on the flank of each mouse using the formula V = 1/6πabc (a, b, and c indicate the diameter in each axis). The xenograft developed after implantation of CGCCA; 4 to 6 wk static later, all animals were sacrificed by CO_2 asphyxia. The xenograft was dissected, and the histopathology of the xenograft was evaluated as described[12]. The xenografted tumors were compared with the original cell line for morphology changes.

FDG autoradiography

FDG positron emission tomography (PET) is an important imaging technique for the evaluation CCA in humans[17]. To evaluate the different levels of fluorodeoxyglucose uptake of the CGCCA cell line xenograft of the nude mice, FDG autoradiography was performed 4-6 wk after tumor implantation. Animals were food-deprived for 8 h, and 37 MBq of FDG was given intravenously. The animals were sacrificed by decapitation after deep anesthesia with isoflurane 45 min after radiotracer injection. The details of the quantitative autoradiography procedures have been described by the authors[18]. In brief, the target tissues, including liver, tumor, and thigh muscle, were quickly removed and placed on dry ice for fixation. The frozen samples were cut to a 10-μm thickness and mounted on glass slides. The slides were exposed to a phosphor image plate (IP) for 2 h and digitized using FLA5100 scanner (Fuji; Japan, Tokyo). The radioactivities of the adjacent tissue sections (assumed to possess the same radiotracer distribution) were measured by γ counter and decay corrected to the time of injection. The correlations between the radioactivities and IP signal intensities were established. All IP signal intensities were converted to radioactivities by using the following calibration curve. Regions of interest (ROI) were manually drawn around the edge of the tumor xenograft activity by visual inspection. The mean activities were recorded from the entire ROI. The percentage injected dose per gram (%ID/g) was calculated as follows: %ID/g = activity in a gram of tissue (*Ci*)/injected dose × 100%. The slices were stained with hematoxylin-eosin (HE) for histologic examination.

Statistics analysis

All data are presented as mean ± SD. Group comparisons of FDG uptake among tissues were determined using analysis of variance (ANOVA). All statistical analysis was performed using SPSS computer software (Chicago, IL) and a *P* value of < 0.05 was considered statistically significant.

RESULTS

Estimating growth kinetics of cells in vitro

To establish a TAA-induced rat cell line, 25 wk of orally administered TAA rat liver tissues were harvested for culturing. CGCCA rat cells showed a typical growth curve that included lag, logarithmic, and stationary phases (as shown in Figure 1). The doubling time of the CGCCA cell line was calculated to compare the growth of 10^3 cells. Under the series surveillance, a cell population doubling time of 32 h was determined (6 points at day 4, 5, 6, 7, 8, and 10). When the CGCCA cell line underwent the 26th *in vitro* passage, we harvested cells to perform the cytogenetic or IHC experiments in the current study. The cell line has been maintained in culture for approximately a year so far. Therefore, viable CGCCA cells have been cryopreserved at almost every *in vitro* passage time, from which new cultures may be established.

Figure 1 MTT assay. Twenty-five weeks orally administrated TAA rat liver tissues cells have been harvested and successfully cultured. The cells followed a typical growth curve; lag, logarithmic, and stationary phases during culturing were estimated. Under series surveillance, a cell population doubling time of 32 h was determined (6 points at day 4, 5, 6, 7, 8, and 10).

Tumorigenicity study of CCA in transplanted mice

To examine whether the CGCCA cell line contained the tumorigenicity of CCA, the cells were transplanted into the thigh area of seven recipient nude mice and given a 100% incidence of CCA. In addition, their morphological features were essentially identical to those of the parental tumor from which the tumorigenic CCA cells were originally isolated. Tumors formed at the cell transplantation site had a latency period of 4-6 wk, as represented by the photomicrographs shown in Figure 2.

Autoradiography

All seven mice developed a large tumor 4-6 wk after tumor cell implantation. Necropsy and histology confirmed the presence of TAA-induced CCA in 7 mice (Figure 2). Central necrosis could be observed in all large tumors suggesting the fast growth of this malignant tumor. Of note, all tumor cells, excluding necrosis tissue, possessed high FDG uptake. The quantitative uptake value of fluorodeoxyglucose in muscle, liver, and tumor were 0.67 ± 0.17, 2.23 ± 0.85, and 5.00 ± 2.15 %ID/g, respectively (Figure 3A). The tumor to liver and tumor to muscle ratios of FDG uptake were 2.25 ± 0.43 and 7.48 ± 1.78, respectively (Figure 3B). These data are highly consistent with our previous *in vivo* findings, indicating that FDG metabolic activity is significantly higher in the CGCCA xenograft in the nude mice.

The rat CGCCA cell line and heterotransplantation of nude mice tissues were evaluated by immunohistochemistry (IHC) stainings.

To demonstrate the phenotype characteristics and histopathology of CGCCA cells, IHC staining was performed on either the cell line or mouse xenograft tissues. The CGCCA cells revealed prominent cytoplasmic expression of CK19 (biliary cytokeratin 19), as well as c-erb-B2, c-Met, COX-II, EGFR, and MUC4 (Figure 4C-H). However, the CGCCA cells revealed a negative expression of K-ras (Figure 4A and B). All of the data from the neoplastic glandular epithelia of the TAA-induced rat CGCCA cell line were highly consistent with previous *in vivo* findings, indicating that these proto-oncogenes are concordantly overexpressed. The tumor tissues from the heterotransplanted nude mice retained the characteristic traits of their *in vitro* cell counterparts. Phenotypically, xenograft highly expressed cytoplasmic immunostaining of CK19, mucin-producing tubular adenocarcinomas closely resembling in their histological and phenotypic features those of the parent tumor; besides, COX-II, MET, and MUC4 revealed strong and diffuse cytoplasmic immunostaining as well (Figure 4I-L).

Cytogenetic study of the CGCCA cell line

Spectral karyotyping (SKY) and G-banded analyses were performed to determine the genetic alterations in the CGCCA cell line using the 26th week's TAA-induced rat CGCCA cell line. The cytogenetics study revealed a number of chromosomes ranging between 50 to 56 diploidy (2n) karyotype with complicated genetic abnormalities of marker chromosomes. Obviously, at least two clones were identified in this cell line. In the clones, the loss of whole chromosome 8 and 20 was observed in all analyzed cells; multiple translocated chromosomes formed at the site of chromosome 2q10, such as t(2;3), t(2;5), t(2;3;10); similarly, at the site of chromosome 4q10, commonly formed t(4;13) and t(4;11;4) fusion chromosomes were observed as well. Further, i(6)(q10) was frequently observed in most of the clones. Notably, two major similar contents of ring and giant rod marker chromosomes were involved in these clones; they either simultaneously appeared in a cell or only one type of marker chromosome appeared as a pair to be observed (Figure 5).

DISCUSSION

CCA is the second most common primary hepatic tumor after hepatocellular carcinoma, which is also known as a slowly progressing bile-duct cancer. CCA usually originates in the liver or the intrahepatic bile ducts, and it is characterized by a poor prognosis. Incidence rates account for between 5% and 30% of primary liver cancers and vary geographically[19]. For instance, peripheral CCA represented 3.58% of all primary liver cancers reported by the Japan Liver Cancer Society[1]. According to the report of Bartlett[20], the mortality of intrahepatic CCA has increased 15-fold, and it is currently a more common cause of mortality than hepatocellular carcinoma. New insights into the pathogenesis of this disease, either by using a panel of systematic *in vitro* cell lines for revealing the obscure mechanisms of CCA, or animal models for development of novel therapeutic strategies, are urgently required for clinical-therapeutic purposes.

To our knowledge, there are two published human CCA cell lines available for the purpose of study; however, both have limited availability due to their long-term passage *in vitro*, and they have been shown to be markedly aneuploid. With respect to experimental animal CCA culture models, two published reports have described

Figure 2 The tumors formed at the cell transplantation site of the CCA xenograft with central necrosis in all large tumors suggesting the fast growth of this malignant tumor at the thigh of the nude mice had a latency period of 4-6 wk and, as represented by (A) gross picture, (B) the photomicrographs of the necropsy, (C) histology, and (D) autoradiography (D). Of note, all tumor cells excluding necrosis tissue possessed high 2-Deoxy-2-(^{18}F)fluoro-D-glucose uptake.

Figure 3 The mean quantitative uptake values of fluorodeoxyglucose in the muscle, liver, and tumor represented by injected dose per gram of tissue (%ID/g) were (A) 0.67 ± 0.17, 2.23 ± 0.85, and 5.00 ± 2.15, respectively. The tumor to liver and tumor to muscle ratios of FDG uptake were (B) 2.25 ± 0.43 and 7.48 ± 1.78, respectively.

the process of establishment; one was developed from liver fluke-associated CCA induced in a hamster model[21]; the other was developed from furan-fed rat CCA culture model[22]. We have been working for several years and have succeeded in establishing a TAA-induced rat intestinal-type CCA model. This model provides a unique and useful study tool for CCA investigation. The important aspects of the cellular and molecular pathogenesis of CCA that are potentially relevant to the human disease have been addressed in previous reports as well[12,23]. In the current study, we further aim to establish a CCA cell

line from a TAA rat CCA model and report its identical karyotype as well as immunohistochemical characteristics. This systematic *in vitro* cell line panel will be used as a valuable study tool for revealing the obscure mechanisms of CCA, and searching for the potential biomarkers for CCA tumorigenesis.

Regarding the growth kinetics of the CGCCA cell, CGCCA cells exhibit a 32-h doubling time. This is longer than C611B cells derived from a furan rat model, which exhibited a cell doubling time of approximately 24 h and were aneuploid[13]; but comparable with the hamster liver

Figure 4 Immunohistochemical staining (× 400) analysis of Chang Gung CCA cells (upper two panels, A-H) and xenograft tissues of CCA mouse models (lower panel, I-L). A: Negative control; B: Negative expression of K-ras; C: EGFR weakly expressed in a cytoplasmic distribution; D-G: Her-Ⅱ, Biliary cytokeratin (CK19), COX-Ⅱ, and Met diffusely expressed in a cytoplasmic distribution; H: MUC-4 strongly and diffusely expressed in a cytoplasmic and membranous distribution; I-L: The results revealed that CK-19, COX-Ⅱ, Met, and MUC4 are diffusely expressed in a cytoplasmic distribution in the rat CCA xenograft.

Figure 5 Examples of the karyotype spectral karyotyping analysis revealed by the 26th passage cell culture; the analysis established that, from the 25th week, TAA-induced CCA rat cells presented either (A) a ring chromosome (short arrows) or (B) giant rod chromosome (long arrow); complicated chromosomal alterations could be observed in most of the chromosomes and are illustrated at the bottom.

fluke-associated CCA cells[21]. While skeptics question whether human population doubling times can be slower than animal cell lines, after comparing the population doubling times with some human CCA cell lines cultured

under similar conditions, the human cell lines presented range from 50 to 180 h[24-27].

Regarding phenotype, the strong and diffuse expression of biliary cytokeratin (CK19) confirms the bile ductular ontogeny of the CGCCA cells and xenograft. The molecular alterations involved in CGCCA cells are similar to TAA rat models previously described[12,22,28,29]; the receptor tyrosine kinases c-Met, c-erb-B2 (also known as HER-2/neu), and EGFR and their interact elements, COX-II, MUC4, were over-expressed in the current neoplastic cells, either in CGCCA cells or xenograft tissues. It is well known that receptor tyrosine kinases have become important therapeutic targets for anti-tumor molecularly targeted therapies. There is increasing evidence to suggest that, when the HGF/SF interacts with the receptor tyrosine kinases c-Met, the activation could lead to a plethora of biological and biochemical effects in the cell[30] and may play an important role in the development and/or progression of human CCA[31-34]. Other molecular alterations include the overexpression of COX-2[5,35,36] and MUC4, which acts as a ligand for c-erb-B2 and was also confirmed to be overexpressed in the CGCCA cells in our current study. Furthermore, we recently demonstrated that MUC4 could be an independent risk factor of poor prognosis in clinical patients with the mass-forming type of intrahepatic CCA who underwent hepatectomy[37].

Notably, negative K-ras expression was observed in the current CGCCA cells. It is known that very high frequency multiple K-ras gene mutations at codon 12 are commonly detected in CCA (15/15 showed one mutation, and 9/15 showed more than two mutations)[38]. Evidence has further indicated that the mutation status of the K-ras gene affects the response of cetuximab, an epidermal growth factor receptor (EGFR) inhibitor[39]. Therefore, K-ras is considered to be one of the important factors involved in the stepwise progression of neoplastic cells to full malignancy. It is also proven to be related to the higher incidence of bile duct cancers that arise distally in the common bile duct[40,41]. Therefore, the current CGCCA cell line could offer a valuable suitable model that could avoid the influence from K-ras expression.

Nevertheless, evidence of the overexpression of these typical oncoproteins in the CGCCA cell line provides strong resemblances with the human CCA disease, as well as an avenue for future pathogenetic or pharmacologic studies.

In addition, there is evidence that FDG PET imaging may be useful in the diagnosis and management of both hilar and peripheral cholangiocarcinomas in humans[17]. We have previously shown that the FDG uptake pattern in TAA-induced rat CCA was similar to that observed in other human studies[18]. In the present study, our CGCCA xenograft closely mimicked the TAA-induced rat CCA with regard to fluorodeoxyglucose uptake as evaluated by FDG autoradiography. The xenograft had a high tumor to liver and tumor to muscle FDG uptake ratio, which makes *in vivo* tumor detection possible by FDG microP-

ET. The data of the animal PET with regard to the TAA mice models were highly consistent with our previously published *in vivo* findings, indicating that FDG metabolic activity is significantly higher in the CGCCA xenograft in the nude mice[18].

The results of cytogenetic analysis with regard to CGCCA cells revealed complicated chromosomal alterations, and the hyperdiploid karyotype has been characterized in the CGCCA cell line. Basically, the hyperdiploid karyotype is thought to arise from the maintenance of heterozygosity. According to the marker chromosomes observed in the CGCCA cell line, at least three clones could be identified in current cell line, suggesting that the hyperdiploidy does not arise from a near haploid precursor. In addition, although hyperdiploid clones have been identified, all the clones tend to show a pattern of chromosome loss with all copies of chromosomes 8 and 20; further, the gains are more often tetrasomic than trisomic for the chromosomes 2, 3, 4, 11, 12, 16, and 17 (Figure 5). Notably, the marker rings and/or giant rod chromosomes could be observed in every cell as well; the materials contained in the marker chromosomes of the ring or rod shapes varied from cell to cell; however, the major materials mostly came from chromosome 4 as was demonstrated by SKY (Figure 5). To our knowledge, rings are rare in benign tumors, whereas they are common in certain invasive tumors. In addition, the ring chromosomes are even common in certain tumors, especially in subgroups of sarcomas where they may be used as diagnostic indicators for these lesions as described by Gisselsson *et al*[42]. The other additional anomalies, such as translocations and other structural chromosome abnormalities, were present in approximately half of the cells; apparently, the presence of non-random alterations in every clone is most likely the primary change event; in addition, the duplication of chromosome 4 fragments are the most common additional change; deletion of chromosomes 8 and 20, and other random structural abnormalities, such as der(2)t(2;3)(q10;q2), der(2)t(3;10;2), der(2)t(2;5)(q10;q1), der(4)t(4;13)(q10;q?) × 2, der(4)t(4;11;4), are probably a secondary event (Figure 5).

However, although the presence of non-random translocations, such as der(3)t(3;7)(q10;q13), der(3)t(3;7)(q10;q13), der(5)t(5;8)(q10;q1), der(7)t(7;10) (q10;q1), der(11)t(11;1)(q10;?), der(11)t(11;14)(q10;?), der(11)t(11;14)(q10;?), der(17)t(17;Y), der(18)t(18;6) (p10;q1), der(19)t(19;1)(q21;qter), indicates the occurrence of translocation and hyperdiploidy, none of them are known have clinical prognostic implications so far. Therefore, to improve the classification of the disease according to translocation rather than diploidy group in order to assign the correct prognostic implications, further cytogenetic studies to compare the disease stages combined with a series of clinical data for the evaluation of cases are necessary.

Accordingly, our findings suggest that the genes involved in the ring marker chromosomes could play a role in the early stage of tumor development. The correlation

between the conjecture of the cytogenetic changes and tumor progression was also consistent with our previous PET findings. We detected that a 100% initial visual yield of invasive CCA was observed by the 22nd week in rats; however, a 50% yield rate of invasive CCA was observed by the 16th week, and the occurrence of biliary dysplasia and invasive CCA precedes the development of hepatic fibrosis by 4 wk[12].

In conclusion, the current CGCCA cell line was well established and characterized in order to obtain information regarding diagnostically useful tumor markers, which could shed light on a dark area of CCA tumorigenesis for a future understanding of human clinical therapeutics.

COMMENTS

Background

Cholangiocarcinoma is characterized by a great diversity of symptoms commonly occurring in the late course of the disease, and therefore making treatment puzzling. In addition, neither radiation therapy nor chemotherapy significantly improves long-term survival rates. However, many data have shown that the incidence and mortality rates of CCA have been rising worldwide over the past several decades, particularly the intrahepatic CCA. Therefore, the goal is to identify potential possible diagnostic biomarkers as the investigation of the molecular pathophysiology associated with this disease becomes more and more important and necessary. Herein, the authors developed the rat CCA tumor cells as a cell line designated as Chang Gung CCA (CGCCA).

Research frontiers

Positive immunostaining of CK19, c-Met, COX-II, and MUC4 determined the phenotype of the cell line. The genotype was examined by cytogenetic studies, and the 2-Deoxy-2-(^{18}F)fluoro-D-glucose-avid character of the CGCCA xenograft of the nude mice was demonstrated by animal PET. All of the evidence proved that the CGCCA cell line rat was derived from the original primary tumor formed by the TAA carcinogen.

Innovations and breakthroughs

The current work supports the view that the systematic cell cultures may provide a relevant CCA model to study the complex mechanisms involved in CCA by revealing the potential pathogenesis of this disease. In addition, the authors may be able to determine the possible diagnostic markers for the early detection and diagnosis of this disease.

Applications

The current CGCCA cell line was well established and characterized in order to obtain information regarding diagnostically useful tumor markers, which could shed light on a dark area of CCA tumorigenesis for a future understanding of human clinical therapeutics.

Peer review

The authors describe the characterization of a new cholangiocarcinoma cell line model and report its successful implantation into nude mice. The paper is well-written, clear and concise.

Abstract

AIM: To investigate the role of α-fetoprotein (AFP), a cancer-associated fetal glycoprotein, in glucocorticoid-induced precocious maturation in rat colon.

METHODS: Colons from suckling Sprague-Dawley rats were used in this study. Corticosterone acetate at a dose of 100 μg/g body weight was given to normal pups on days 7, 9 and 11 after birth to induce hypercorticoidism. Control animals were injected with identical volumes of normal saline. Some rats receiving corticosterone 7 d after birth were also treated with mifepristone (RU38486), a glucocorticoid cytoplasm receptor antagonist to investigate the effects of glucocorticoids (GCs). The morphological changes of the crypt depth and villous height of the villous zone in colon were observed as indices of colon maturation. Expression levels of AFP in colons were detected by reverse transcriptase polymerase chain reaction and Western blotting. To identify the cellular localization of AFP in developing rat colons, double-immunofluorescent staining was performed using antibodies to specific mesenchymal cell marker and AFP.

RESULTS: Corticosterone increased the crypt depth and villous height in the colon of 8- and 10-d-old rats with hypercorticoidism compared with that in the control animals (120% in 8-d-old rats and 118% in 10-d-old rats in villous height, $P = 0.021$; 145% in 8-d-old rats and 124% in 10-d-old rats in crypt depth, $P = 0.017$). These increases were accompanied by an increase of AFP expression in both mRNA and protein (2.5-folds in 8-d-old and 2.5-folds in 10-d-old rats higher than in control animals, $P = 0.035$; 1.8-folds in 8-d-old and 1.3-folds in 10-d-old rats higher than in control animals, $P = 0.023$). Increased crypt depth and villous height and increased expression of AFP in the colon of rats with hypercorticoidism were blocked by mifepristone. Both had positive staining for AFP or vimentin, and overlapped in mesenchymal cells at each tested colon.

CONCLUSION: GCs promote the development of rat colon. AFP appears to be involved, in part, in mediating the effects of GCs in the developmental colon.

INTRODUCTION

Glucocorticoids (GCs) have been routinely used in clinical practice to prevent diseases of prematurity such as respiratory distress syndrome. GCs treatment may reduce the incidence of necrotizing enterocolitis[1-3], in which a typical immaturity of the intestine[4-6] indicated that GCs may enhance intestinal maturation. Although this regulation seems to be mediated by the GCs receptor pathway, the precise regulatory mechanisms have not yet been documented.

The effect of GCs may require interactions with another tissue or cell type, such as mesenchyme[7]. During late embryogenesis, the mouse colon develops from a pseudostratified, undifferentiated endoderm to a single-layered columnar epithelium accompanying with mesenchymal maturation. Mammalian α-fetoprotein (AFP) is a single-chain glycoprotein with a molecular mass ranging from 66 to 72 kDa and 3%-5% carbohydrate (glycan) content. Recent reports showed that the AFP was expressed and produced in mesenchymal cells and was considered as an important growth factor with a specific function in gastrointestinal development, including pancreas and colon[8-10]. In contrast, AFP enhancer segment contains a sequence resembling the steroid hormone response element and the enhancer activity was mediated by dexamethasone in a dose-dependent manner[11]. Thus, AFP seems to play a role in GCs-induced precocious gastrointestinal maturation.

Numerous investigators have reported the ability of GCs to stimulate intestinal maturation in postnatal rodents[12-14]. However, little is known about the involvement of GCs in rat colon during development.

MATERIALS AND METHODS

Chemicals

Corticosterone acetate (CA), gel mount aqueous mounting medium (G0918), and mifepristone were purchased from Sigma Chemical (St. Louis, USA). TRIZOL reagent was purchased from Invitrogen Life Technologies (Burlington, Ontario, Canada). Takara RNA polymerase chain reaction (PCR) 3.0 Kit was from Takara (Dalian, China). Rabbit anti-goat IgG conjugates and goat polyclonal anti-AFP were from Santa Cruz Biotech (USA). Monoclonal antibody of anti-vimentin was from Chemicon International (Temecula, CA, USA). Protease inhibitor cocktail was from Roche (Mannheim, Germany). Nitrocellulose membranes were from Bio-Rad (Hercules, CA, USA), BCA Protein Assay Kit and enhanced chemiluminescence reagents were from Pierce (Rockford, IL, USA) and CBL202 from Chemicon International, Inc. Temecula (CA, USA).

Animals

Pregnant female Sprague-Dawley rats in late gestation were purchased from Nanjing Medical University Animal Centre. After arrival, cages were checked twice daily for pups. The day of birth was designated as day 0, and experiments were conducted at various ages thereafter. Litter size was restricted to 12 pups per dam that was performed at day 2 postpartum. All animals were kept in a temperature-controlled room (22 ± 1℃) and maintained on a 12-h light-dark cycle. To prevent the stress of removing one animal from a cage on sequential days, all the animals in a cage were killed on a single day. Young rats were never separated from their mothers except during the period of fasting. During this period, the pups were placed in cages artificially warmed by electric light bulbs. Before studies, all rats were fasted for various times. To prevent mortality from prolonged fasting, the 8- and 10-d-old rats were fasted for 18 h, and 14-d-old rats were fasted for 24 h. Experiments were designed using littermate controls disregarding the sex of the pups. All animals were killed between 8 and 10 am[15]. CA was given at a dose of 100 μg/g body weight by intraperitoneal injection to normal pups on days 7, 9, and 11 to induce hypercorticoidism. Control animals were given identical volumes of normal saline[16]. To observe the effect of GCs on suckling rats, another experiment was designed as follows: 100 μg/g body weight of CA was given once to pairs of 7-d-old pups (HC group) by intraperitoneal injection. Control pups (C group) were injected with identical volumes of normal saline at the same day. Pups were treated with 50 μg/g body weight mifepristone (17β-hydroxy-11β-4-dimethyl-aminophenyl-17α-propynylestra-4,9-diene-3-one, RU38486), a glucocorticoid cytoplasm receptor antagonist alone (M group), or 100 μg/g hydrocortisone plus 50 μg/g mifepristone (H+M group)[17].

Colons from control and hypercorticoidism rats at 8, 10 and 14 d of age were used in this study and five rats were used in each age stage. Samples were fixed in 4% paraformaldehyde overnight at 4℃ followed by a standard protocol of dehydration and paraffin embedding. Five-micrometer sections were prepared for morphological and fluorescence immunohistochemical studies. Total RNA and lysate were extracted from tissues at each time point for the reverse transcriptase PCR (RT-PCR) and Western blotting analysis. The study protocol was approved by the Nanjing Medical University Animal Care and Use Committee.

Morphology

Routine hematoxylin and eosin-stained sections for light microscopic (LM) evaluation were used to study the hormonal effects in the morphological development of colon. Slides were viewed under an Olympus BX51 microscope (Olympus Optical, Tokyo, Japan). Morphologic measurement made by the same technician was blinded to the different treatment groups. Under LM, the crypt depth and villous height of the villous zone were mea-

sured using an image analysis system (NYD100). The group means were obtained based on 10 villi and 20 crypts per slide, with a minimum of five animals in each group.

Serial levels of AFP

Blood samples of rats were centrifuged at 2000 × *g* for 20 min, and sera were stored at -20℃ until analyzed. AFP levels in the rat serum were measured by the routine standard radioactive method used in the Nanjing Clinical Nuclear Medicine Center (Nanjing, China).

RNA expression of AFP

Total RNA was isolated from tissues by Trizol according to the protocol supplied by the manufacturers. cDNA was synthesized using Takara RNA PCR 3.0 Kit in a total volume of 10 μL, containing 0.5 μL avian myeloblastosis virus RT, 0.5 μL random 9 primer, 2 μL 25 mmol/L MgCL$_2$, 1 μL 10 × RT buffer, 1 μL dNTP mixture (each 10 mmol/L), 0.25 μL RNase inhibitor, 1 μL RNA, and 3.75 μL dH$_2$O. Conditions for RT were: 30℃ for 10 min, 42℃ for 25 min, 99℃ for 5 min, and 5℃ for 5 min. PCR was performed in 50 μL reactions containing 2.5 ng cDNA, 1 μL each primer pair, and 25 μL Premix *Taq* in the Takara RNA PCR kit. PCR was carried out in a T-gradient Biometra PCR thermal cycler (Montreal Biotech Inc., Kirkland, Quebec, Canada) to determine the annealing temperature for each paired primers. The following AFP primer pairs were used: 5'-GCTGAACCCAGAG-TACTGCAC-3' (forward), and 5'-GACACGTCGTAG-ATGAACGTG-3' (reverse). Amplification reactions were carried out for 30 cycles at 94℃ for 30 s, 58.4℃ for 30 s, and at 72℃ for 1 min.

The amplified products were 443 bp and analyzed on 1% agarose gels and visualized by ethidium bromide staining. Omitting RT, cDNA or DNA polymerase were adopted in the controls, and showed no reaction bands. The data were normalized by actin.

Protein expression of AFP

The tissues were homogenized in a sample buffer containing 50 mmol/L Tris-HCl (pH 7.5), 150 mmol/L NaCl, 5 mmol/L EDTA, 10 mmol/L NaF, 1 mmol/L sodium orthovanadate, 1% Triton X-100, 0.5% sodium deoxycholate, 1 mmol/L phenylmethylsulfonyl fluoride and protease inhibitor cocktail. An equal amount of protein samples were separated by 12.5% SDS-polyacrylamide gel electrophoresis (SDS-PAGE). After transferred to nitrocellulose membranes and blocked with 5% fat-free milk in Tris-buffered saline plus 0.05% Tween 20 overnight at 4℃, polyclonal antibody for AFP and the corresponding secondary antibody were applied. Blots were visualized with enhanced chemiluminescence reagents and exposed to X-Omat BT film. Signal intensity was quantified using a Bio-Rad image analysis system and the results were normalized to band intensities at e18.5. The β-actin was used as an internal control and the primary antibody was omitted for negative controls.

Regional and cellular localization of AFP

Double-immunofluorescent staining of AFP and vimentin, a specific marker of mesenchymal cell, were used to determine the regional and cellular localization of AFP in rat colons. Staining was performed according to the standard procedures. Briefly, the sections were deparaffinized in xylene, cleared with graded ethanol in phosphate buffered saline (PBS), and then placed in 10 mmol/L citrate buffer (pH 6.0) for 15 min at 100℃ for antigen retrieval. The sections were applied to goat anti-AFP polyclonal antibody overnight at 4℃ and then linked with FITC-labeled rabbit anti goat-IgG. After washing by Tris buffered saline (TBS), mouse anti-vimentin monoclonal antibody and rhodamine-labeled anti-mouse IgG were applied. Sections were placed in Gel Mount aqueous mounting medium with a cover glass and were examined under an Olympus BX51 microscope. Controls were treated by omitting the primary or secondary antibodies. No staining was observed under the negative control conditions. Images were taken at a magnification of × 200. An image analysis system (NYD100) was used for quantitative analysis of cell density (cell number/view field) of the AFP-positive cells in the rat colon. Four sections from four rats in each group were used. AFP-positive cells were counted in five randomly selected view fields per section at a magnification of × 400. At least 20 fields in each group were analyzed.

Statistical analysis

All experiments were done in triplicate. The experimental data was analyzed using PDQuest 7.0 software (Bio-Rad Laboratories, Hercules, CA, USA) and one-way analysis of variance and paired *t* test were used. Data were presented as mean ± SD. *P* < 0.05 was considered statistically significant.

RESULTS

Morphology

Injecting corticosterone into the suckling animals for 1, 2, and 3 d showed no effect on the animal's intestinal and body weights (data not shown). The crypt depth and villous height after corticosterone treatment were higher in the colon of 8- and 10-d-old rats with hypercorticoidism than in the control animals and did not influence those in the 14-d-old rats with hypercorticoidism (Table 1).

Expression of AFP

The serum AFP levels in the rats were near 18 μmol/L in all measured rats and had no difference between hypercorticoidism and control animals (data not shown). In this study, we analyzed the effect of corticosterone on the level of AFP mRNA by RT-PCR. The AFP mRNA concentration increased significantly after corticosterone treatment, by 2.5-folds in the 8-d-old and 2.5-folds in the 10-d-old rats compared with those in the control animals (Figure 1). The transcriptional regulation of AFP expres-

Figure 1 Expression of α-fetoprotein mRNA by reverse transcriptase polymerase chain reaction analysis in colons of suckling rats treated with or without hydrocortisone. Molecular weight markers are indicated on the left. A: The α-fetoprotein (AFP) mRNA levels in colons of hydrocortisone-treated animals were higher than in controls of 8- and 10-d-old rats; B: Results are indicated in percentage above the β-actin value and are representative of three independent experiments. [a]$P < 0.05$ *vs* controls; C: Pups received saline; HC: Pups received hydrocortisone.

sion of corticosterone was confirmed by the Western blotting analysis (Figure 2).

Regional and cellular localization of AFP

The AFP positive cells were scattered on the epithelium in either corticosterone treated or untreated rats. The cell density of AFP-positive cells was higher in 8- and 10-d-old corticosterone-treated rats than in control animals (Table 2). Double-immunofluorescent staining for the vimentin and AFP showed that there was complete overlap between the AFP-positive cells and the antibody staining for vimentin in all the tested animals (Figure 3).

Figure 2 Expression of α-fetoprotein protein by Western blotting analysis in colons of suckling rats treated with or without hydrocortisone as indicated in lanes, respectively. Western blotting analysis using α-fetoprotein (AFP) (C-19), revealed a 72 kDa isoform. A: AFP levels in colons of hydrocortisone-treated animals were higher than in controls of 8- and 10-d-old rats; B: Results are indicated in percentage above the β-actin value and are representative of three independent experiments. [a]$P < 0.05$ *vs* controls; C: Pups received saline; HC: Pups received hydrocortisone.

Effect of mifepristone

The effect of increased crypt depth and villous height in the colon of 8-d-old rats with hypercorticoidism was blocked by mifepristone (Figure 4). The increased expression of AFP was also inhibited in the rats treated with mifepristone (Figure 5).

DISCUSSION

Although rodent colon may differ from human colon in the breadth of its responses to GCs, it is nevertheless a useful model to address issues related to morphological maturation, since the development of gastrointestinal functions is similar in all mammals. The aim of this study was to assess the role of exogenous GCs in the maturation of the colon. Accordingly, we used the rats in the first postnatal week whose circulating concentrations of natural GCs were very low (< 0.5 μg/mL)[18].

Exogenous administration of GCs causes precocious maturation of the intestine. In this study, GCs did result in an increase in villous height and crypt depth of the colon (Table 1) in 8- and 10-d-old rats compared with the age-matched controls. This effect was completely blocked

Figure 3 Immunofluorescence localization of α-fetoprotein and vimentin in the suckling rats treated with or without hydrocortisone. Labeling by the α-fetoprotein (AFP) antibody was detected with a fluorescein isothiocyanate (green) labeled secondary antibody. Labeling of vimentin was detected with a rhodamine-(red)-labeled secondary antibody on the same section. The overlap of AFP (green) and vimentin (red) labeling displayed orange color. Double-staining revealed complete colocalization of AFP and vimentin in the same cells of rat colons treated with or without hydrocortisone. All of the primary magnifications are × 200.

Figure 4 Morphological changes in colons of suckling rats treated with or without hydrocortisone, hydrocortisone + mifepristone and mifepristone alone. Villous height (A) and crypt depth (B) were determined. Each data point (± SD; bars) is the mean of four independent trials. C: Pups received saline; HC: Pups received hydrocortisone; HC+M: Pups treated with both hydrocortisone and mifepristone; M: Pups treated with mifepristone only. [a]$P < 0.05$ *vs* control animals; [d]$P < 0.01$ *vs* hydrocortisone-treated animals.

Figure 5 α-fetoprotein expressions in 8-d-old rat colons treated with or without hydrocortisone, hydrocortisone + mifepristone and mifepristone alone. α-fetoprotein (AFP) expression was determined by the Western blotting using AFP polyclonal antibody (A), and results indicated are in percentage above the β-actin value and are representative of three independent experiments (B). Each data point (± SD; bars) is the mean of four independent trials. C: Pups received saline; HC: Pups received hydrocortisone; HC+M: Pups treated with both hydrocortisone and mifepristone; M: Pups treated with mifepristone only. [a]$P < 0.05$ *vs* control animals; [d]$P < 0.01$ *vs* hydrocortisone-treated animals.

by the mifepristone, a glucocorticoid cytoplasm receptor antagonist (Figure 4). It is possible that GCs had a precocious effect on the development of rat colon in the first postnatal week, and in the rat small intestine as well[19,20].

In contrast, the GCs had no effect on the colon in 14-d-old rats. It has been suggested that immature gastrointestinal tract seems to have more sensitive responsiveness to the regulation of GCs[21]. It is possible that prepartum cellular differentiation progresses until day 10 in rats after birth[22]. On the other hand, cytoplasm receptors of GCs are activated after the binding of GCs that allows their translocation to the nucleus. Of note is the pattern of ontogeny changes in the concentration of GCs receptors in the small intestine as cytoplasm GCs receptors are present in the intestine at all ages, but at higher concentrations during the two postnatal weeks than in older rats[23]. Moreover, GCs receptors themselves have been shown to downregulate by GCs through GCs enhanced expression of a factor (repressor), which binds the regulatory sequence in the GCs receptor gene promoter[24]. This might serve as a negative feedback control in the GCs response systems under developmental conditions. In 14-d-old rats, the plasma corticosterone of GCs was raised to 5 μg/mL[18], and a loss of responsiveness to GCs for colon development might occur in these rats. No effect of exogenous GCs administration could be also explained by a fall in GCs re-

ceptors in 14-d-old rats with a natural rise in corticosterone level, although this was not tested in this study.

AFP is known to be associated with the successful completion of term pregnancies in mammals and even minute amounts of AFP may still be necessary during human pregnancy[25]. The capability of both up and down modulation of growth and differentiation as a dose-dependent function of AFP has been demonstrated in a multitude of cell types, including placental, ovarian, uterine, and lymphoid, epidermal, endothelial, testicular, breast, and liver[26-30]. In our previous studies, we indicated that AFP was expressed and produced in mesenchymal cells, which might act as a potent paracrine regulator of colonic cell proliferation and organ maturation[10]. In this study, exogenous administration of GCs demonstrated an increased expression of AFP, this effect was also inhibited by mifepristone (Figures 2 and 3). Double-immunofluorescent staining for the vimentin, a mesenchymal cell marker, and AFP showed that the AFP was localized in the mesenchymal cells both in GCs-treated and control colons, similar to our previous study[10].

In present study, the AFP levels in the rat serum were near 18 μmol/L in all measured rats and had no difference between hypercorticoidism and control animals (data not shown). High cortisone concentration in serum prompts the acceleration of colonic ontogenesis, and is not accompanied by an increased level of serial AFP. In the current study, we did observe an increased expression of AFP in both RNA and protein levels in the GCs-treated premature colon of rats. Therefore, mesenchymal cell-derived AFP acted as a potent paracrine regulator in rat developmental colon.

The effect of GCs may require interactions with another tissue or cell type, such as mesenchyme[7]. The epithelial-mesenchymal interactions play an essential role in the control of gastrointestinal epithelial growth and differentiation not only in fetal stages, but also in adults[31,32]. There is no report that GCs could regulate the growth colonic mucosa directly. Our *in vitro* study also showed a negative result for GCs stimulating the proliferation of colonic epidermis (data not shown). The exogenous GCs were blocked, and the effect of accelerating maturation and the increased expression of AFP were also inhibited. Therefore, mesenchymal cell-derived AFP appears to be responsible, in part, in mediating the effects of GCs on developmental colon. Our present study may help us discern whether the epithelial-mesenchymal interactions and the effect of GCs enhance intestinal maturation in the gastrointestinal tract.

The involvement of GCs in AFP expression in the gut still remains an open question. Studies are now in progress in our laboratory using animal and tissue culture models to test it.

In summary, our present study for the first time demonstrated that GCs promote the development of rat colon. AFP appears to be responsible, in part, in mediating the effects of GCs on developmental colon. The exact function of AFP in rat colon development remains to be determined.

COMMENTS

Background
Glucocorticoids (GCs) are considered to play an important role in the maturation of the gastrointestinal (GI) tract. However, the mechanism of GCs on GI system development has not been fully elucidated.

Research frontiers
Although rodent colon may differ from human colon in the breadth of its responses to GCs, it is nevertheless a useful model to address issues related to morphological maturation, since the development of gastrointestinal functions is similar in all mammals. This study assessed the role of exogenous GCs in the maturation of the colon in rats.

Innovations and breakthroughs
This study for the first time demonstrated that GCs promote the development of rat colon. α-fetoprotein (AFP) appears to be responsible, in part, in mediating the effects of GCs on developmental colon. The exact function of AFP in rat colon development remains to be determined.

Applications
This animal model is a useful tool for the study of mechanism of gastrointestinal mucosal proliferation and differentiation *in vivo*.

Terminology
Corticosterone acetate is a chemical compound of GCs. Mammalian AFP is a single-chain glycoprotein with a molecular mass ranging from 66 to 72 kDa and 3%-5% carbohydrate (glycan) content.

Peer review
This is an excellent study.

Abstract

AIM: To investigate whether this might be related to the presence of hyperhomocysteinemia.

METHODS: From January 1998 to December 2008, we evaluated the presence of hyperhomocysteinemia in a series of 165 adult celiac disease (CD) patients (138 females and 27 males, mean age 43 years).

RESULTS: Hyperhomocysteinemia was evident in 32 patients (19.3%), although most of them had moderate levels (mean value 25 mcg/ml; range 15-30). Only one patient had a history of myocardial infarction (heterozygosis for N5-N10-metil tetrahydrofolate reductase mutation).

CONCLUSION: The systematic assessment of hyperhomocysteinemia seems, at present, unjustified in CD patients.

Key words: Celiac disease; Endoscopy; Histology; Hyperhomocysteinemia

INTRODUCTION

Hyperhomocysteinemia, considered as an important risk factor in venous thrombosis[1-3], has a prevalence in the general population of 5%-7%[4], and causes damage of the vascular endothelium by disrupting the release of nitric oxide, an important vasodilator factor[5], followed by

platelet activation and thrombus formation[4].

Celiac disease (CD) is a gluten-sensitive enteropathy due to intolerance to dietary wheat gliadin and related proteins in genetically predisposed individuals[6]. The malabsorption of folates and vitamins (the deficiency of which may be a cause of hyperhomocysteinemia) is frequent in CD patients, either in the classic or oligosymptomatic type[7], and several cases of thrombosis have been reported in patients with CD before establishing a diagnosis of gluten-related duodenal mucosal damage[8,9]. Thus, we investigated the presence of hyperhomocysteinemia in a series of patients with CD, to see whether it might be increased and represent a marker of increased venous thrombosis in these patients.

MATERIALS AND METHODS

Patients
In the period January 1998-December 2008, 165 patients with CD (27 men, 138 women, mean age 43 years) were studied. Inclusion criteria were: positivity for anti-endomysial IgA and anti-transglutaminase IgA antibodies (Eurospital, Trieste, Italy) and duodenal histology suggestive for CD.

Histological assessment
Four samples were obtained by endoscopy forceps from the proximal and distal parts of the duodenum. The biopsies, correctly oriented on acetate cellulose filters (Bio-Optica, Milano, Italy), were fixed in 10% buffered formalin, processed and included in paraffin. After obtaining 5 μm thick sections, these were stained with Hematoxylin-Eosin; some sections were also processed for immunohistochemistry and stained with an anti-CD3 monoclonal antibody (Dako, Denmark) to identify intra-epithelial lymphocytes (IEL). IEL density was expressed as the number of IEL/100 epithelial cells, with a density value of > 25 cells considered as pathological. Histological classification was based on the Marsh-Oberhuber criteria[10] and a new, recently proposed simpler classification[11,12] (Table 1).

Laboratory assessment
Serum homocysteinemia, vitamin B12 and folic acid levels were measured in all patients. In case of hyperhomocysteinemia, mutations in N5-N10-metil tetrahydrofolate reductase (MTHFR), cystathionine beta synthetase (CBS) and the prothrombin gene were searched for. DNA was extracted from whole blood collected in tubes containing K3-EDTA using a commercial kit (Genomic DNA Isolation kit, Puregene -Gentra System). DNA analysis for MTHFR gene mutation (C677T) was performed by a PCR-RFLP method, as previously described[13]. A fragment of 232 base pairs was then amplified by polymerase chain reaction. The fragment was digested by *Hin*f I restriction enzyme, and subsequent electrophoresis on ethidium bromide stained 3% agarose gel was performed.

The concentration of total homocysteine in plasma (K3-EDTA tubes) was determined by high performance

Table 1 The Marsh-Oberhuber classification of duodenal histological lesions in celiac disease, compared to the "simplified classification"[11,12]

Histologic type	IEL	Glandular crypts	Villi	Simplified
0	Normal (< 25/100 epithelial cells)	Normal	Normal	Normal
1	Increased	Normal	Normal	Grade A
2	Increased	Hyperplastic	Normal	Grade A
3a	Increased	Hyperplastic	Mild atrophy	Grade B1
3b	Increased	Hyperplastic	Moderate atrophy	Grade B1
3c	Increased	Hyperplastic	Severe (total) atrophy	Grade B2

IEL: Intra-epithelial lymphocytes.

liquid chromatography, as previously described[14]. Basal hyperhomocysteinemia (normal value 5-15 μmol/L) was classified as moderate (16-30 μmol/L), intermediate (31-100 μmol/L) and severe (> 100 μmol/L) according to Hankey *et al*[15]. In all patients, the presence of any thrombotic episode was also evaluated.

The study was approved by the Institutional Review Board of the Desio Hospital.

RESULTS

Histological findings
Most CD patients (24/32, 75.0%) showed mild to severe villous atrophy, with the latter being present in 41.0% of patients (Table 2).

Laboratory findings
Overall, hyperhomocysteinemia was detected in 32 (19.4%) CD patients (24 women, 8 men); average symptoms' onset was 7 (range 1-40) years. Table 3 shows the serologic findings of these patients. Most patients (29/32, 91.0%) had moderate hyperhomocysteinemia, two (6.0%) intermediate and one (3.0%) severe increase of this value. Mutation of MTHFR was found in 13 (41.0%) patients, 7 homozygotes and 6 heterozygotes; one patient displayed heterozygotic mutation of the prothrombin gene. No CBS mutations were found.

Serum B12 vitamin levels were low in 5 (15.6%) patients and serum folate levels were low in 6 (19.0%) patients. No correlation (Spearman's test) was found between serum homocysteine and age ($r = 0.10$, $P = 0.58$), gender ($r = 0.66$, $P = 0.07$), onset of symptoms ($r = -0.06$, $P = 0.75$), vitamin B12 ($r = -026$, $P = 0.14$), folic acid ($r = 0.05$, $P = 0.75$), and histological grading ($r = -0.01$, $P = 0.9$). Moreover, no correlation was also found between histological grading, vitamin B12 ($r = -0.10$, $P = 0.56$) and folic acid ($r = -0.2$, $P = 0.3$) values.

Clinical findings
Concerning vascular pathology, one patient with heterozygosis for MTHFR mutation and moderate hyperhomocysteinemia had myocardial infarction, whereas the single

patient with severe hyperhomocysteinemia underwent coronary angiography for atypical chest pain, but no evidence of vessel pathology was found. No patient in this series had episodes of venous or arterial thrombosis, or any stroke episodes.

DISCUSSION

Our findings show that hyperhomocysteinemia is relatively frequent in patients with CD, being present in about 20% of the patients in our series. Hyperhomocysteinemia might represent a link between undiagnosed gluten-sensitive enteropathy and some of its complications[16]. Interestingly, these results were similar to those obtained in an overlapping geographic area, which showed the presence of hyperhomocysteinemia in about 20% of newly diagnosed CD patients compared to about 6% of controls[17].

Hyperhomocysteinemia may be due to genetic factors, with CBS deficiency being considered the most common genetic cause[5,17], or from acquired folate and vitamin B12 deficiencies[18,19]. A homozygous deficiency of MTHFR, the vitamin B12 dependent enzyme for the

remethylation of homocysteine to methionine, may cause hyperhomocysteinemia and it has a worse prognosis than CBS deficiency for the absence of an effective therapy[20]. Moreover, treatment with a gluten-free diet and folic acid in CD patients with MTHFR variants does not consistently improve hyperhomocysteinemia[21].

Thus, CD (in which malabsorption of folate and vitamin B12 is common[22]) might lead to increased cardiovascular risks due to an increase of secondary (acquired) hyperhomocysteinemia, further aggravated by the possible presence of genetic abnormalities responsible for hyperhomocysteinemia. However, notwithstanding the relative frequency of hyperhomocysteinemia in our CD patients, this was almost always of moderate entity, with only one patient displaying high levels. Interestingly, the only patient to have a cardiovascular event (myocardial infarction) had relatively low levels of hyperhomocysteinemia and presented heterozygous mutations of MTHFR. No CBS mutations were found in our series. Only one mutation of the prothrombin gene was found, and this is in line with the paucity of reports of such mutations in CD patients[23].

In conclusion, at present it seems unnecessary to systematically investigate CD for the presence of hyperhomocysteinemia; conversely, a serological screening for CD in patients with hyperhomocysteinemia, cardiovascular events and vitamin deficiency could be considered, especially because adult CD patients may display only a few to no intestinal symptoms[24,25], and the onset of the disease may rarely be due to a thrombotic event[26-28].

COMMENTS

Background
Venous thrombosis has been reported in patients with celiac disease (CD). Since this might be related to hyperhomocysteinemia, a risk factor for vascular disease, we investigated the prevalence of hyperhomocysteinemia in a series of adult celiac patients.

Research frontiers
An increased prevalence of hyperhomocysteinemia in CD might lead to increased cardiovascular risk.

Innovations and breakthroughs
To date, most data on this topic originates from single reports, and only one other study investigated systematically celiac patients.

Applications
It appears that, given the low prevalence of hyperhomocysteinemia in celiac patients, it is unnecessary to screen systematically patients; this is useful information in terms of sanitary expenses.

Peer review
The authors evaluated in a cohort of 165 CD patients the presence of hyperhomocysteinemia during a period of time of 10 years. They showed that seems unnecessary to investigate systematically CD for the presence of hyperhomocysteinemia. Their work could contribute to the epidemiologic information of the CD in the Italian population.

Abstract

AIM: To analyze the association between the emergence of tyrosine-methionine-asparatate-asparatate (YMDD) mutants (reverse transcription; rtM204I/V) and deterioration of liver function during long-term lamivudine treatment of Japanese patients with chronic hepatitis B virus (HBV) infection.

METHODS: The data of 61 consecutive Japanese patients with chronic hepatitis B who underwent continuous lamivudine treatment for more than 24 mo and had a virological response were analyzed. Analysis of YMDD mutants was done by real-time polymerase chain reaction with LightCycler probe hybridization assay for up to 90 mo (mean, 50.8 mo; range, 24-90 mo).

RESULTS: A mixed mutant-type (YMDD + tyrosine-iso-leucine-asparatate-asparatate: YIDD or tyrosine-valine-asparatate-asparatate: YVDD) or a mutant-type (YIDD or YVDD) were found in 57.4% of 61 patients at 1 year, 78.7% of 61 patients at 2 years, 79.6% of 49 patients at 3 years, 70.5% of 34 patients at 4 years, 68.4% of 19 patients at 5 years, 57.1% of 14 patients at 6 years, and 33.3% of 6 patients at 7 years. Of the 61 patients, 56 (92%) had mixed mutant- or a mutant-type. Only 5 (8%) had no mutants at each observation point. Virological breakthrough was found in 26 (46.4%) of 56 patients with YMDD mutants, 20 of whom had a hepatitis flare-up: the remaining 30 (53.6%) had neither a virological breakthrough nor a flare-up. All 20 patients who developed a hepatitis flare-up had a biochemical and virological response after adefovir was added to the lamivudine treatment.

CONCLUSION: Our results suggest that it is possible to continue lamivudine treatment, even after the emergence of YMDD mutants, up to the time that the patients develop a hepatitis flare-up.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection affects more than 350 million people worldwide, with 75% living in the Asia-Pacific region[1,2]. Although Japan was historically endemic for HBV infection, our previous studies have shown that the prevalence of hepatitis B surface antigen (HBsAg) carriage in Okinawa, Japan markedly decreased from 12.4% in 1970 to 4.2% in 1996[3,4]. However, chronic HBV infection continues to be a major health problem because it leads to the development of liver cirrhosis, hepatocellular carcinoma (HCC), and raises the risk of hepatic disease-related death. Because HBV replication is associated with liver injury, therapy for patients with chronic HBV infection aims to stop or reduce disease progression and to prevent the development of hepatic decompensation through the sustained suppression of HBV replication[5]. For this purpose, interferon or oral antiviral nucleos(t)ide analogues, such as lamivudine, adefovir, entecavir, telbivudine and tenofovir have been approved for the treatment of patients with chronic HBV infection. Previous studies have shown that HBV genotype influences liver disease progression[6,7], and our epidemiological study of the Japanese HBV genotype distribution showed that most patients were infected with genotype C[8]. Because genotype C has been reported to be associated with severe liver damage and to be resistant to non-pegylated interferon[8-10], Japanese patients with chronic hepatitis B are often given nucleos(t)ide analog treatment. Nucleos(t)ide analogs have fast and potent inhibitory effects on HBV polymerase and reverse transcriptase activity, are safe and easy to use, and can induce HBV DNA suppression, alanine aminotransferase (ALT) normalization and improvement of liver histology[11-14].

Lamivudine is the first oral nucleoside analogue to be approved for the treatment of chronic hepatitis B patients, and it has been shown to suppress HBV replication by interfering with HBV DNA polymerase and disease activity, to reduce the incidence of HCC, and to improve survival[15,16]. A study that included a large number of Japanese chronic hepatitis B patients showed lamivudine to have good virological and biochemical efficacy in long-term treatment[17].

Although there is much evidence supporting the effectiveness of lamivudine for chronic hepatitis B patients, the clinical benefit of lamivudine treatment has been eroded, in the case of long-term treatment, by the emergence of lamivudine-resistant HBV mutants with mutation of the reverse transcriptase domain of the polymerase gene. The emergence of lamivudine-resistant mutants is mainly based on point mutation from methionine to valine/isoleucine at rt204 (rt204V/I) in the tyrosine-methionine-asparatate-asparatate (YMDD) motif[18]. The emergence of lamivudine-resistant HBV has been linked to virological breakthrough, sometimes followed by biochemical breakthrough, and to flare-ups of hepatitis[19].

The detection of YMDD mutants has mainly been done by methods such as direct DNA sequencing or hybridization[20,21], but these methods are labor-intensive and time-consuming. Fluorometric real-time polymerase chain reaction (PCR) with the LightCycler probe hybridization assay is reported to be an easy, rapid and accurate method for the detection of YMDD mutants[22,23]. Few studies have sequentially assessed the emergence of YMDD mutants during long-term lamivudine treatment in Japan. The aim of the present study was to analyze the association between the emergence of YMDD mutants and deterioration of liver function during long-term lamivudine treatment of Japanese chronic hepatitis B patients by use of the LightCycler probe hybridization assay.

MATERIALS AND METHODS

Patients

The study included 61 consecutive Japanese patients with chronic hepatitis B who underwent continuous lamivudine treatment for more than 24 mo, and had a virological response (defined as a decline of more than 4.0 log copies/mL in HBV DNA level during treatment). The patients started lamivudine treatment between February 2001 and May 2007 at the Department of General Internal Medicine, Kyushu-University Hospital in Fukuoka, Japan. Before the start of lamivudine treatment, all patients had HBsAg and detectable levels of HBV DNA by PCR assay. The diagnosis of chronic hepatitis and cirrhosis was based on a liver biopsy for most patients, but if unavailable it was based on clinical laboratory and ultrasonography data. None of the patients tested positive for antibody to hepatitis C virus or human immunodeficiency virus type 1, nor was there evidence of other forms of liver diseases, such as alcoholic liver disease, drug-induced liver disease, or autoimmune hepatitis.

All patients received lamivudine (Zeffix, Glaxo Smith Kline, UK) in a single oral daily dose of 100 mg. Observation was for up to 90 mo (mean, 50.8 mo; range, 24-90 mo) after the start of lamivudine administration, and the emergence of YMDD mutants during treatment was identified using the LightCycler probe hybridization assay. Serum ALT, hepatitis B e antigen (HBeAg), anti-HBe, and HBV DNA were measured every 1-2 mo. Sera were tested for mutation of the HBV polymerase gene every 6-12 mo during treatment.

Definitions of "virological breakthrough" and "flare-up" of hepatitis

Virological breakthrough was defined as an increase in serum HBV DNA of more than 1 log copies/mL from the nadir of the initial response[19]. A flare-up of hepatitis was defined as an increase in ALT level to more than 3 times the upper limit of normal.

Routine laboratory tests and viral markers

Biochemical tests were performed using standard procedures before and at least once monthly during treatment. HBsAg, HBeAg and anti-HBe were determined by a chemiluminescence enzyme immunoassay (Abbott Japan Co., Tokyo, Japan). HBV genotype analysis was performed by

a previously reported method[24]. Serum HBV DNA level was measured by a PCR-based method (Roche Amplicor HBV Monitor; Roche Diagnostics, Mannheim, Germany). The detection range of the assay was between 2.6 (corresponding to 400 copies/mL) and 8.7 log copies/mL.

Serum samples and extraction of HBV DNA

Serum samples were obtained from all patients before and during lamivudine treatment and stored at -20℃ until use. HBV DNA was extracted from serum using the QIAamp DNA mini kit (Qiagen Ltd., Crawley, United Kingdom) according to the manufacturer's instructions.

Monitoring the emergence of lamivudine-resistant mutants by the LightCycler probe hybridization assay

Lamivudine-resistant mutation was detected by rapid PCR amplification across the YMDD-encoding gene locus and analysis of the hybridization kinetics of an integrated probe to infer its sequence was done using the LightCycler (Roche Diagnostics) according to the method reported by Whalley *et al*[22].

Briefly, HBV DNA was extracted from serum, and a 399 bp region of the polymerase gene was amplified by hemi-nested PCR assay. The amplified PCR product was denatured and hybridized to the Bi-probe system, which uses Cy5-labeled probes in conjunction with SYBR Green I (Bio/Gene, Kimbolton, United Kingdom). The LightCycler was used for amplification of PCR clones and to determine the melting characteristics of the probe-amplification hybrid. A melting curve analysis of the data was performed using the LightCycler analysis software v3.5 (Roche Diagnostics). Melting curves were converted to melting peaks by plotting the negative derivative of fluorescence with respect to temperature (-dF/dT). This analysis gave the melting temperature (*Tm*) at which 50% of the hybridizing probe was annealed to the PCR product. Because the presence of a single-base mismatch results in a shift in the melting temperature to a temperature lower than that for the probe-specific sequence, analysis of the probe melting curves allows differentiation of the wild-type YMDD from the YMDD mutants including YIDD, YVDD, and the YMDD/YIDD and YMDD/YVDD mixed types. The detection limit of this assay was about 10%-20% of the total virus pool (data not shown).

Statistical analysis

The distribution of continuous variables was analyzed by the Mann-Whitney *U* test. Differences in proportions were tested by Fisher's exact test. A two-tailed *P* value of less than 0.05 was considered statistically significant. Statistical analysis was performed with the SPSS statistical package (version 11.0, SPSS, Inc., Chicago, IL, USA).

RESULTS

Baseline characteristics

Of the 61 patients, 45 were male with a median age of

Figure 1 Melting curve analysis using the LightCycler probe hybridization assay. The melting curves were converted to melting peaks by plotting the negative derivative of fluorescence with respect to temperature [-d(F3)/dT]. The melting temperature (*Tm*) for each of the YMDD mutants is indicated with a vertical line. A: Representative results for differentiating HBV YMDD mutants. YMDD, YVDD and YIDD mutants showed distinct *Tm* values; B: The shoulder curve indicated the mixed mutant-type. Representative results show YMDD + YIDD mutants.

50 years (range, 28-65 years) and 16 female with a median age of 49 years (range, 38-69 years). All patients were infected with genotype C, 36 (59%) were negative for HBeAg, 15 (25%) were cirrhotic, and the median HBV DNA level was 6.5 log copies/mL (range, 2.7-8.7 log copies/mL).

Melting curve analysis for the detection of HBV YMDD mutants

YMDD mutants were analyzed by melting curve analysis. The melting peaks of the wild-type and mutant HBV strains were typically observed at different temperatures, as shown in Figure 1A. The melting temperatures of the YIDD and YVDD mutants were approximately 9℃ and 2.5℃ lower than that of the wild-type, respectively. Because the melting curve showed a double peak in the case of YIDD or YVDD mutant mixed with the wild-type YMDD, as shown in Figure 1B, this type of melting curve was considered to be the mixed mutant-type.

Seven-year change in the wild, mixed mutant and mutant-types

The mixed mutant- or mutant-type was found in 57.4% of 61 patients at 1 year, 78.7% of 61 patients at 2 years,

Table 1 Comparison of patients with and without the emergence of YMDD mutants during treatment, median (range)

Characteristics	Mutant- or mixed mutant-type (*n* = 56)	Not detected or wild-type (*n* = 5)	*P*-value

Figure 2 Change in the proportion of YMDD wild, mixed mutant, and mutant-types during lamivudine treatment.

79.6% of 49 patients at 3 years, 70.5% of 34 patients at 4 years, 68.4% of 19 patients at 5 years, 57.1% of 14 patients at 6 years, 33.3% of 6 patients at 7 years, as shown in Figure 2.

Comparison of patients with and without the emergence of YMDD mutants during treatment

Of the 61 patients, 56 (92%) had the mixed mutant- or mutant-type: Only 5 (8%) had none of the tested mutations during the observation period. Virological breakthrough or a flare-up of hepatitis was observed in 26 (46.4%) and 20 (35.7%), respectively, of the 56 patients with YMDD mutants. None of the 5 patients without YMDD mutants had virological breakthrough or a flare-up of hepatitis. Virological breakthrough or a flare-up of hepatitis was experienced significantly more often by patients with than without YMDD mutants (*P* < 0.0001).

No significant differences in sex, age, pretreatment ALT level, serum albumin, platelet count, frequency of

HBeAg positivity, pretreatment HBV DNA level, presence of cirrhosis, or history of HCC were observed between these groups. Of the 56 patients with YMDD mutants, 30 (53.6%) had no virological breakthrough. However, no significant differences in sex, age, pretreatment ALT level, serum albumin, platelet count, frequency of HBeAg positivity, pretreatment HBV DNA level, presence of cirrhosis, or history of HCC were observed for the patients with mutants, with or without virological breakthrough (data not shown) (Table 1).

Of the 61 patients, 36 (59%) were HBeAg negative. Although about 90% of patients with or without HBeAg had YMDD mutants, HBeAg negative patients had a tendency to have a lower frequency of virological breakthrough and hepatitis flare-ups than HBeAg positive patients. However, no significant between group differences were found in sex, age, number of patients with YMDD mutants, the frequency of virological breakthrough and hepatitis flare-ups; only pretreatment HBV DNA level showed a significant difference (Table 2).

Characteristics of the patients with hepatitis flare-up

Of the 61 patients, a flare-up of hepatitis was experienced by 20 (32.8%), 15 (75%) males, 5 (25%) females, median age 56 years (range, 44-65 years), 11 (55%) with cirrhosis, and 14 (70%) with HBeAg. All patients who developed flare-ups of hepatitis following an increase in the HBV DNA level had YMDD mutation. The peak HBV DNA level (median 6.7 log copies/mL; range, 5.7-8.0 log copies/mL) at the time of a flare-up was significantly lower than at pretreatment (median 7.6 log copies/mL; range, 6.0-8.7 log copies/mL) (*P* < 0.05) (Table 3).

Clinical course of patients with hepatitis flare-up

All 20 patients who had a flare-up were prescribed 10 mg of adefovir dipivoxil daily, in addition to lamivudine treatment, and all had a biochemical and virological response.

DISCUSSION

Early detection and monitoring of HBV genotypic resis-

HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen.

tance in patients with chronic hepatitis B using nucleoside analogues allows clinicians to avoid virological breakthroughs followed by flare-ups of hepatitis. In this retrospective study, we found that the LightCycler probe hybridization assay was useful for monitoring the emergence of YMDD mutants. Furthermore, our results provide important data on the YMDD mutation of Japanese chronic hepatitis B patients undergoing long-term lamivudine treatment.

Continuous lamivudine treatment is associated with an increased percentage of patients with YMDD mutants. Lamivudine-genotypic resistance was reported in 24% of patients after 1 year of treatment, 41% after 2 years, 53% after 3 years and 70% after 4 years by PCR using a restriction fragment-length polymorphism assay (PCR-RFLP)[25]. Similarly, the present study showed an increased percentage of patients with YMDD mutants within 3 years of treatment, although the percentage was higher than that of the previous report, probably a reflection of different sensitivities of the assay used for the detection of YMDD mutants. Direct DNA sequencing, PCR-RFLP, and reverse hybridization line probe assay are common methods of detecting lamivudine-genotypic resistance[20]. The detection limits of these assays are about 20%, 5%, and down to 10% of the total viral pool, respectively[21]. These methods are labor-intensive, time-consuming, and have the risk of contamination because they require s separate set of endonuclease reactions for each of the mutants, or a specific probe for each mutant. The LightCycler probe hybridization assay can detect YMDD mutants within 1 h and the risk of carryover contamination is minimal because PCR is performed in a closed glass capillary. The detection limit of this assay is about 10%-20% of the to-

tal virus pool, and minor subpopulations can be detected (those constituting about 20% of the total population). Our results may more accurately reflect the actual rates of YMDD mutants than were found in previous reports. Because of the quasi-species nature of HBV, YMDD mutants have been detected in patients with chronic hepatitis B who never received lamivudine treatment using a more sensitive method than our method[26-28]. Unfortunately, the present study could not determine if preexisting mutants prevailed after the initiation of lamivudine treatment because this assay could not detect YMDD mutants before treatment.

The present study showed that virological breakthrough and flare-ups of hepatitis occurred after the emergence of YMDD mutants, as reported previously[29]. Therefore, monitoring ALT and HBV DNA levels after the emergence of YMDD mutants is clinically important for the management of patients treated with lamivudine. It has been reported that a short latency to the emergence of YMDD mutants, mixed type YMDD mutant (YIDD + YVDD type), and a low ALT level in patients with YMDD mutants were associated with virological breakthrough or flare-up of hepatitis[30]. In the present study, 20 (35.4%) of 56 patients with YMDD mutants developed flare-ups after virological breakthrough during the treatment. As reported in previous studies[17,31], our results also showed that a flare-up of hepatitis was frequently observed in patients with cirrhosis, or HBeAg positive patients, which may be related to the more active liver disease of HBeAg positive patients. However, our results showed no virological breakthrough by about half of our patients with YMDD mutants during long-term lamivudine treatment. It is important to consider the prognosis

of the patients who continued lamivudine treatment after the emergence of YMDD mutants. It has been reported that there was no benefit for patients who continued lamivudine treatment after the emergence of YMDD mutants compared with patients who discontinued treatment, based on a comparison of the rates of flare-ups of hepatitis, hepatic decompensation, and HBe seroconversion over a 12-mo period[32]. Another report, however, showed a benefit of long-term lamivudine treatment, for 8 years, in Asian patients with YMDD mutants without advanced disease, who had a lower risk of development of cirrhosis and HCC, a greater reduction of HBV DNA level, and a similar rate of flare-ups of hepatitis compared with untreated patients[33]. Our data from the present study suggests that it is possible to continue lamivudine treatment even after the emergence of YMDD mutants if clinicians note the above risk factors associated with virological breakthrough or flare-ups of hepatitis.

The present study showed that about half of patients with YMDD mutants did not encounter virological breakthrough during long-term lamivudine treatment. It has previously been shown that YMDD mutants (rtM204V or rtM204I) have preexisting polymorphisms in HBV-infected patients because of the quasi-species nature of HBV in infected individuals, and that these mutants appeared randomly in viral populations, which had a replication disadvantage to the YMDD wild-type in the absence of lamivudine[34]. A previous study showed that HBV mutants with mutations in the YMDD motif in patients before treatment would not be selected by lamivudine or induce breakthrough hepatitis[27]. Furthermore, the rtM204V mutant in domain C frequently accompanies rtL180M mutants in domain B[26]. *In vitro* studies showed that rtM204I alone had lower replication competency than rtL180M/rtM204V[35]. These data suggest that the gain of replication capacity of YMDD mutants during lamivudine treatment may be associated with multiple factors, including intrinsic replicative advantages potentially conferred by mutations accumulating outside domain C, the fluctuating environment in which these mutants replicate, and the host immune response.

In the present study, 5 (8%) of 61 patients had no emergence of YMDD mutation during the treatment. Hashimoto *et al*[30] reported that factors associated with YMDD mutants not appearing during 5-year lamivudine therapy for patients with chronic HBV infection are HBeAg negativity, lack of cirrhosis, and high γ GTP level. We were not able to confirm their results because there were too few patients free of YMDD mutants to draw a significant conclusion.

Adding adefovir dipivoxil, which is without cross-resistance to lamivudine, is effective for achieving a virological and biochemical response in patients with lamivudine-resistance[36,37]. The American Association for the study of Liver Disease guidelines on HBV recommend the addiction of a second drug in the event of lamivudine resistance[38,39]. It has been reported for patients with lamivudine resistance that the virological and biochemical re-

sponse rates were similar between a group being switched to adefovir monotherapy and a group for which adefovir was added to lamivudine treatment, but adefovir resistance more frequently occurred in the patients who had combined adefovir and lamivudine treatment[37,40]. Therefore, the add-on treatment is thought to be superior to switching treatment with regard to the prevention of subsequent multi-drug resistance. The above data supported our result of a biochemical and virological response by all patients who had adefovir added to lamivudine treatment after a flare-up of hepatitis.

In conclusion, no virological breakthrough was observed in about half of the patients with YMDD mutants during long-term lamivudine treatment. Patients who developed flare-ups of hepatitis were successful in achieving a virological and biochemical response by addition of adefovir to lamivudine treatment. These data suggest that it is possible to continue lamivudine treatment even after emergence of YMDD mutants, at least until the patients develop a flare-up of hepatitis.

COMMENTS

Background
Although there is much evidence of the effectiveness of lamivudine in chronic hepatitis B patients, the number of patients with tyrosine-methionine-aspartate-asparatate (YMDD) motif mutation, which is linked to virological breakthrough, sometimes followed by a flare-up of hepatitis, is higher with prolonged lamivudine treatment. There is little information about the association between YMDD mutants and deterioration of liver function during long-term lamivudine treatment.

Research frontiers
The detection of YMDD mutants has mainly been by methods such as direct DNA sequencing, polymerase chain reaction (PCR)-restriction fragment length polymorphism, or reverse hybridization line probe assay, but these methods are labor-intensive, time-consuming, and have the risk of contamination. In this study, the authors demonstrated that fluorometric real-time PCR with the Light-Cycler probe hybridization assay was an easy, rapid and accurate method for the detection of YMDD mutants.

Innovations and breakthroughs
Regardless of hepatitis B e antigen positivity, the present study showed, by use of the LightCycler probe hybridization assay, that about half of the patients with YMDD mutants did not encounter virological breakthrough during long-term lamivudine treatment. Furthermore, all patients who developed flare-ups of hepatitis had a biochemical and virological response after adefovir was added to the lamivudine treatment.

Applications
The results suggest that it is possible to continue lamivudine treatment, even after the emergence of YMDD mutants, up to the time that the patients develop flare-ups of hepatitis.

Peer review
In this study, Murata *et al* retrospectively analyzed 61 HBV patients for up to 90 mo to find out the association between lamivudine resistance from its emergence with the hepatic deterioration. The positive finding of this study is the indication of continuation of lamivudine therapy in patients of genotype C having YMDD mutation until the stage of hepatic flare-up. The potential of Light Cycler probe hybridization for detection and monitoring of such mutants has also been elucidated. This is an important issue because lamivudine resistance is associated with progressive liver disease.

Abstract

AIM: To study the safety and feasibility of total embolization of the main splenic artery as a supplemental treatment modality for hypersplenism with thrombocytopenia or leukocytopenia accompanying liver cirrhosis.

METHODS: Fifteen consecutive patients with hypersplenism due to cirrhosis were enrolled in this study from January 2006 to June 2010. All patients underwent total embolization of the main splenic artery. Clinical symptoms, white blood cell (WBC) and platelet (PLT) counts, splenic volume, and complications of the patients were recorded. The patients were followed up for 1 and 6 mo, and 1, 2, 3 years, respectively, after operation.

RESULTS: Total embolization of the main splenic artery was technically successful in all patients. Minor complications occurred in 13 patients after the procedure, but no major complications were found. The WBC and PLT counts were significantly higher and the residual splenic volume was significantly lower 1 and 6 mo, and 1, 2, 3 years after the procedure than before the procedure ($P < 0.01$). Moreover, the residual splenic volume increased very slowly with the time after embolization. All patients were alive during the follow-up period.

CONCLUSION: Total embolization of the main splenic artery is a safe and feasible procedure and may serve as a supplemental treatment modality for hypersplenism with thrombocytopenia or leukocytopenia accompanying liver cirrhosis.

INTRODUCTION

Partial splenic embolization (PSE) is a non-surgical procedure for hypersplenism resulting from hepatic disease and can thus avoid the disadvantages of splenectomy[1]. It has been shown that PSE can increase peripheral blood cell counts[2-5]. However, PSE often results in a number of complications, including daily intermittent fever, abdominal pain, nausea, vomiting, postemboliza-

tion syndrome, splenic abscess and rupture, pneumonia, refractory ascites, pleural effusion, and gastrointestinal bleeding[2-8].

Total embolization of the splenic artery is a safe and effective procedure for splenic artery aneurysms[9-13]. Moreover, stainless steel spring coils are used to embolize the main branch of splenic artery to increase the platelet (PLT) count before splenectomy[14]. To date, no report is available on the treatment of hypersplenism with total embolization of the main splenic artery. The present study was to study the safety and feasibility of total embolization of the main splenic artery for hypersplenism with thrombocytopenia or leukocytopenia accompanying liver cirrhosis.

MATERIALS AND METHODS

Patients
Fifteen consecutive patients (10 males and 5 females with a mean age of 50.07 ± 8.98 years, ranging 38-60 years) with hypersplenism due to cirrhosis were enrolled in this study from January 2006 to June 2010 and subsequently underwent computed tomography (CT) follow-up at our hospital. The causes of cirrhosis were hepatitis B virus (HBV) infection in 13 patients and hepatitis C virus (HCV) infection in 2 patients. The patients were diagnosed as hypersplenism based on their history, clinical laboratory tests, ultrasonography and CT. The protocol was approved by The Ethics Committee of Fudan University and the patients provided their written informed consent.

The inclusion criteria were those with hypersplenism, HBV/HCV-related active cirrhosis, neutropenia (neutrophil count $\leqslant 2.0 \times 10^9$ cells/L), thrombocytopenia (PLT count $\leqslant 50 \times 10^9$ cells/L) or both, and follow-up time > 2 years. Those with severe jaundice [serum total bilirubin (TB) level $\geqslant 81.4$ μmol/L] or spontaneous bacterial peritonitis were excluded from the study.

Hypersplenism was classified as Child-Pugh class A in 10 patients, class B in 3 patients, and class C in 2 patients. The demographics of these patients are summarized in Table 1.

Endovascular techniques
Metallic coils and gelfoam were used as embolization materials, either alone or in combination. In general, the embolization coils used in this series were standard 0.089-cm (0.035-in.) fibered coils, microcoils (Tornado; Cook Inc., Bloomington, IN, USA).

Embolization was performed in all patients *via* the femoral artery. Selective angiography of the celiac trunk, splenic artery, and superior mesenteric artery was performed *via* the right femoral artery with a 5-Fr diagnostic catheter (Cook). Patency of the collateral arteries connected to the hilar splenic artery from the left gastric artery or from the gastroepiploic artery on a celiac arteriogram was monitored to avoid total splenic infarction.

Total embolization of the main splenic artery was performed after confirmation of these connections.

All embolization procedures were performed by 2 experienced interventional radiologists. Details of the coiling procedures have been described previously[9,11,15]. Selective splenic artery, celiac, and superior mesenteric artery angiograms were performed to confirm occlusion of the main splenic artery and patency of the collateral arteries after embolization. Preoperative antibiotic prophylaxis was used routinely for 3 d. Following embolization, patients were monitored and antibiotics were continued after the procedure for several days to avoid infectious complications.

Follow-up protocol and postoperative outcome evaluation
All patients were followed up at our outpatient clinic. Peripheral blood cell parameters, including white blood cell (WBC), PLT, and red blood cell counts, were monitored at different time points prior to the procedure and on days 3, 14, and 30 after the procedure, then at 6-mo intervals during the 3-year follow-up period. To determine the effect of embolization on liver function, serum levels of aspartate aminotransferase, alanine aminotransferase, TB, and albumin were measured and prothrombin time was calculated at the same follow-up time points as above before and after the procedure. The procedure-related frequency and type of complications were recorded.

Abdominal CT scans were routinely performed before and 2 wk after the procedure, and then every 6 mo during the follow-up. Based on enhanced CT images, the pretreatment splenic volume and the post-embolization residual splenic volume were measured and compared on a workstation (Siemens Syngo MMWP VEZIA) using the volumetric analysis software. The infracted splenic volume (mL) was measured by subtracting the noninfarcted splenic volume from the pretreatment splenic volume. The splenic infarction rate was calculated by dividing the infarcted splenic volume by the pretreatment splenic volume ($\times$ 100%).

The procedure-related complications were divided into major and minor ones. Major complications associated with the procedure, including splenic abscess, splenic rupture, pneumonia, refractory ascites or pleural effusion, gastrointestinal bleeding, rupture of varices, and hepatic failure, were defined as complicated disease requiring surgical intervention or prolonged postoperative hospital stay time of more than 30 d. Minor complications, including abdominal pain, fever, vomiting, abdominal fullness, and appetite loss, were defined as those that lead to no consequential events and can be tolerated by the patients.

Statistical analysis
All data were expressed as mean $\pm$ SD. Changes in WBC and PLT counts after PSE were evaluated by paired *t* test. The variables between the 2 groups were compared by Mann-Whitney test, χ^2-test or Fisher's exact test when ap-

Pre-EM: Pre-embolization; AP: Abdominal pain; F: Fever; V: Vomiting; WBC: White blood cell.

propriate. All statistical analyses were performed using the SPSS package, version 13.0 (SPSS, Chicago, Illinois, USA).

RESULTS

Primary procedure results

Total embolization of the main splenic artery was technically successful in all patients, with no procedure-related complications. The mean postoperative hospital stay time was 8.40 ± 2.53 d (range, 5-15 d) after the procedure and the 30 d mortality rate was zero.

Minor complications occurred in 13 patients with no major complications found after the procedure. The most frequent side effects were abdominal pain, fever, and nausea. Prolonged fever, lasting over 15 d after the procedure, developed in 1 case. These side effects were controlled after conservative therapy.

Changes in peripheral blood cell counts after embolization

The outcomes of total embolization of the main splenic artery in 15 patients are shown in Table 1. All patients were assessed 1 and 6 mo, and 1, 2, 3 years after the procedure. The patients were followed up for 38.0 ± 8.32 mo (range, 24-52 mo). The mean WBC count increased from 1.4 (0.3) × 10⁹/L before the procedure to 8.1 (1.1) × 10⁹/L, 6.0 (1.2) × 10⁹/L, 5.6 (1.0) × 10⁹/L, 5.1 (0.9) × 10⁹/L, and 4.8 (0.9) × 10⁹/L, respectively, 1 and 6 mo, and 1, 2, 3 years after the procedure ($P < 0.01$).

The mean PLT count increased from 36.5 (8.3) × 10⁹/L before the procedure to 172 (34.1) × 10⁹/L, 152 (38.7) × 10⁹/L, 148 (11.6) × 10⁹/L, 140 (11.1) × 10⁹/L, and 134 (8.6) × 10⁹/L, respectively, 1 and 6 mo, and 1, 2, 3 years after the procedure ($P < 0.01$).

Changes in splenic volume after embolization

The mean splenic volume decreased from 769.87 (60.51) cm³ before the procedure to 314.60 (44.52) cm³, 304.0 (36.10) cm³, 300.80 (35.20) cm³, 301.73 (35.17) cm³, and 306.00 (32.02) cm³, respectively, 1 and 6 mo, and 1, 2, 3 years after the procedure ($P < 0.05$). During the follow-up, the residual splenic volume in these patients increased a very slowly. The mean infarction rate of the spleen was 60% (range, 59%-61%) 3 years after the procedure. No death occurred during the follow-up.

DISCUSSION

The results of his study show that total embolization of the main splenic artery with coils is a safe and feasible procedure for hypersplenism due to liver cirrhosis. The peripheral blood cell parameters including WBC and PLT counts increased significantly during the follow-up and the residual splenic volume increased very slowly after embolization.

Hypersplenism is a well-known complication of portal hypertension due to cirrhosis, which can result in thrombocytopenia and/or leukocytopenia. Splenectomy can eliminate hypersplenism-induced blood cell destruction, but the incidence of severe complications after splenectomy is 9.6%-26.6% whether laparoscopy or open splenectomy is performed[16-18]. In addition, splenectomy is often associated with an increased long-term risk of septic events[16-18].

Although PSE is an effective alternative to splenectomy to increase the peripheral blood cell counts[1-5], severe complications of PSE, such as splenic abscess, splenic rupture, pneumonia, refractory ascites or pleural effusion, and gastrointestinal bleeding[6-8], greatly limit its use. Furthermore, the complications of PSE are correlated with the infracted splenic volume. In addition, when 50% or less than 50% of the spleen is embolized, hypersplenism would relapse shortly after PSE[2,8]. Therefore, to ensure a sustained increase in PLT and leukocyte counts,

the splenic infarction rate should be greater than 50%[8], which, however, inevitably results in severe complications. To increase the PLT and leukocyte counts and reduce the rate of severe complications, total embolization of the main splenic artery was performed for hypersplenism due to liver cirrhosis in the present study.

The key procedure for reducing the severe complications and ensuring the sustained increase in PLT and leukocyte counts is to confirm the patency of collateral arteries connected to the hilar splenic artery from the left gastric artery or from the gastroepiploic artery. If these connections are absent or incomplete, total embolization of the main splenic artery should not be performed because the procedure may result in more severe complications.

When the main splenic artery is completely embolized, the main blood flow supplying the spleen is stopped, but the collateral arteries connected to the hilar splenic artery from the left gastric artery or from the gastroepiploic artery may provide a small amount of blood for the spleen to avoid complete infarction of the spleen. Thus, most of the spleen should be embolized with reservation of a partial normal spleen. Thus, the PLT and leukocyte counts increase after the procedure, and the occurrence of severe complications can be circumvented. In this study, the safety and feasibility of total embolization for hypersplenism of the main splenic artery were studied.

As compared with PSE, total embolization of the main splenic artery has the following advantages, including a low risk of procedure-related complications, persistent maintenance of normal WBC and PLT counts, and a very slow increase in residual splenic volume.

Although these results are encouraging, this study had the following limitations. First, it was not a comparative study and the number of patients was small with no control group. Future randomized multicenter trials comparing PSE with total embolization are needed to determine their long-term clinical efficacy and risk of complications. Second, total embolization could not be performed in patients with no or incomplete collateral arteries.

In conclusion, total embolization of the main splenic artery is a safe and feasible procedure for hypersplenism with thrombocytopenia or leukocytopenia accompanying liver cirrhosis and may serve as a supplemental treatment modality for it. Further clinical trials and expanded follow-up studies are needed to confirm its safety.

COMMENTS

Background
Partial splenic embolization (PSE) is a non-surgical procedure for hypersplenism resulting from hepatic disease, thus avoiding the disadvantages of splenectomy. However, after PSE, patients often experience complications, including daily intermittent fever, abdominal pain, nausea, vomiting, and postembolization syndrome.

Research frontiers
Total embolization of the splenic artery has been widely used in treatment of splenic artery aneurysms, but no report is available on treatment of hypersplenism with it. In this study, total embolization of the main splenic artery for hyper-splenism with thrombocytopenia or leukocytopenia accompanying liver cirrhosis was studied.

Innovations and breakthroughs
Total embolization of the main splenic artery was devised for the treatment of hypersplenism with thrombocytopenia or leukocytopenia accompanying liver cirrhosis. All procedures were performed under fluoroscopic control. This is the first study reporting the treatment of hypersplenism with total embolization of the main splenic artery.

Applications
Total embolization of the main splenic artery is a safe and feasible procedure and may serve as a supplemental treatment modality for hypersplenism with thrombocytopenia or leukocytopenia accompanying liver cirrhosis with a low complication rate and a good mid-term clinical efficacy.

Terminology
Hypersplenism is a well-known complication of portal hypertension due to cirrhosis, which can result in thrombocytopenia and leukocytopenia.

Peer review
The finding in this study is interesting. Further study is needed confirm its safety in a much larger series of patients.

Abstract

AIM: To evaluate bacterial cytosine deaminase (bCD) mutant D314A and 5-fluorocytosine (5-FC) for treatment of colon cancer in a mouse model.

METHODS: Recombinant lentivirus vectors that contained wild-type bCD gene (bCDwt), and bCD mutant D314A gene (bCD-D314A) with green fluorescence protein gene were constructed and used to infect human colon carcinoma LoVo cells, to generate stable transfected cells, LoVo/null, LoVo/bCDwt or LoVo/bCD-D314A. These were injected subcutaneously into Balb/c nude mice to establish xenograft models. Two weeks post-LoVo cell inoculation, PBS or 5-FC (500 mg/kg) was administered by intraperitoneal (i.p.) injection once daily for 14 d. On the day after LoVo cell injection, mice were monitored daily for tumor volume and survival.

RESULTS: Sequence analyses confirmed the construction of recombinant lentiviral plasmids that contained bCDwt or bCD-D314A. The lentiviral vector had high efficacy for gene delivery, and RT-PCR showed that bCDwt or bCD-D314A gene was transferred to LoVo cells. Among these treatment groups, gene delivery or 5-FC administration alone had no effect on tumor growth. However, bCDwt/5-FC or bCD-D314A/5-FC treatment inhibited tumor growth and prolonged survival of mice significantly ($P < 0.05$). Importantly, the tumor volume in the bCD-D314A/5-FC-treated group was lower than that in the bCDwt/5-FC group ($P < 0.05$), and bCD-D314A plus 5-FC significantly prolonged survival of mice in comparison with bCDwt plus 5-FC ($P < 0.05$).

CONCLUSION: The bCD mutant D314A enhanced significantly antitumor activity in human colon cancer xenograft models, which provides a promising approach for human colon carcinoma therapy.

INTRODUCTION

Colorectal cancer has one of the highest mortalities worldwide[1]. Conventional therapies consist of surgery, chemotherapy, radiotherapy, and biotherapy. Despite advances in the treatment of colorectal cancer, the prognosis for locally advanced or metastatic disease remains relatively

poor[2]. Therefore, it is crucial to develop novel therapeutic strategies, not only to completely cure cancer, but also to prevent its recurrence. Among these approaches, gene-directed enzyme-prodrug therapy (GDEPT) has received considerable attention[3,4].

Suicide gene therapy for cancer is an appealing alternative to standard methods of chemotherapy because most chemotherapeutic agents lack tumor specificity. Classic chemotherapeutic agents are often unable to distinguish tumor cells from normal dividing cells, which results in indiscriminate toxic effects. In contrast, suicide gene therapy allows for specific targeting of the tumor while preventing damage to normal cells. This is accomplished by introducing a gene that encodes a prodrug-activating enzyme into cancer cells. Although delivery systems have not been fully optimized, delivery of the gene is typically done using either a viral vector (retrovirus or adenovirus) or by other non-viral means[5-7]. Once the gene is delivered into the cancer cell, a non-toxic prodrug is administered. The enzyme converts the non-toxic prodrug into its active and lethal form that results in cancer cell death. *Escherichia coli* or bacterial cytosine deaminase (bCD) is responsible for the activation of the non-toxic prodrug 5-fluorocytosine (5-FC) to its toxic form, 5-fluorouracil (5-FU)[8]. The absence of an endogenous cytosine deaminase in mammalian cells provides for deamination of 5-FC only in cells that express bCD. This is followed by the conversion of 5-FU into its deoxyribonucleoside, fluorodeoxyuridine (FUdR) by thymidine phosphorylase. Upon phosphorylation of FUdR by endogenous thymidine kinase, thymidylate synthase is irreversibly inhibited by the product, 5FdUMP, thereby preventing dTTP formation and ultimately leading to inhibition of DNA synthesis.

One of the key advantages of the bCD/5-FC enzyme/prodrug system is the phenomenon known as the "bystander effect", which is defined as the killing of untransfected cells neighboring those cells transfected with the suicide gene[8]. This type of killing has been described extensively with regard to the herpes simplex virus-1 thymidine kinase and ganciclovir enzyme/prodrug system, and occurs primarily by the transfer of toxic antimetabolites through gap junctions[9,10]. Unlike phosphorylated ganciclovir, 5-FU is a small, uncharged molecule that can pass freely in and out of the cell by diffusion. Consequently, cell-cell contact is not required for the bystander effect with bCD/5-FC; an advantage for those cell types with limited gap junctions[11]. bCD has been used successfully in gene therapy for a variety of animal tumor models and is currently under investigation for the treatment of human cancers[12-15].

The limiting factors for successful suicide GDEPT are transfection efficiency and the ability of the enzyme to turn over the prodrug, which is an analog of its natural substrate. From a kinetic perspective, 5-FC is a poor substrate for bCD (Km = 3.3 mmol/L) compared with its native substrate, cytosine (Km = 0.2 mmol/L)[16]. Thus, high doses of this prodrug must be administered to achieve cell killing. The plasma levels of 5-FC required to obtain a significant amount of active metabolites may lead to adverse effects. This is observed with 5-FC, whereas deamination by CD of bacterial intestinal microflora into 5-FU is responsible for side effects[17]. Other studies have suggested that the CD from *Saccharomyces cerevisiae* (yCD) displays a kinetic advantage towards 5-FC over bCD[18]. However, yCD is considerably less thermostable than bCD; a characteristic that may make the bacterial enzyme a preferable catalytic system for gene therapy.

Fortunately, Mahan *et al*[16,19] have used random mutagenesis to create novel bCDs that demonstrate an increased preference for 5-FC over cytosine. Among these mutants isolated, the mutant D314A [substitution of an alanine (A) for the aspartic acid (D) at position 314 of bCD] enzyme demonstrates a dramatic decrease in cytosine activity (17-fold), as well as a slight increase in activity toward 5-FC (twofold), which indicates that mutant D314A prefers the prodrug over cytosine by almost 20-fold. Despite the thermolability of yCD, others have suggested that yCD is superior to bCD in gene therapy settings because of a 23-fold relative substrate preference for 5-FC that is displayed by yCD[18]. However, given the thermostability of bCD and the 19-fold relative substrate preference that the bCD mutant D314A displays towards 5-FC, bCD D314A may be a superior suicide gene to yCD. These results indicate that bCD mutant D314A is a superior candidate for suicide gene therapy. Recently, this mutant D314A has been demonstrated to enhance cytotoxicity of human glioma and pancreatic cancer cells, and to increase therapeutic efficacy against human glioma and human pancreatic tumor xenografts, especially combined with radiotherapy[20,21]. However, there have been only a few studies of bCD mutants in colorectal cancer.

Previously, we have used the bCD gene to treat colon cancer, and have found that the efficacy of wild-type bCD is not sufficient to abolish cancer cells *in vitro* or *in vivo*, therefore, combination therapy with other genes, such as interleukin-2 or interferon-γ, is needed to improve the cytotoxicity of bCD[7,22,23]. Recently, we have constructed bCD-D314A using site-directed mutagenesis[19], and have demonstrated that it has significantly increased cytotoxicity in human colon cancer cell line LoVo, compared with wild-type bCD (bCDwt) *in vitro*[24].

The aim of the present study was to investigate whether bCD-D314A suicide gene and 5-FC prodrug therapy produce increased therapeutic efficacy *in vivo* for human colon cancer in nude mice using lentiviral vectors. The results presented here indicated that mutant bCD-D314A was able to significantly enhance antitumor efficacy in human colon cancer xenograft models *in vivo* compared with bCDwt.

MATERIALS AND METHODS

Cells and cell culture

Human colon cancer cell line LoVo (CCL-229; ATCC, Manassas, VA, USA) was cultured in RPMI-1640 medium (Gibco, Invitrogen, Carlsbad, CA, USA) supplemented with 10% fetal bovine serum (FBS; Gibco). HEK 293T (human embryonic kidney 293T cell line containing SV40 large T antigen) (CRL-11268; ATCC) was cultured in Dulbecco's Modified Eagle's Medium (Gibco) supplemented with 10% cosmic calf serum (Hy-

clone, Logan, UT, USA), 2 mmol/L L-glutamine (Sigma, St. Louis, MO, USA), 100 U/mL penicillin (Sigma) and 0.1 mg/mL streptomycin (Sigma). LoVo and HEK 293T cells were in a 5% CO₂-humidified atmosphere at 37℃.

Reagents, animals, plasmids and vectors

5-FC was obtained from Sigma. Restriction enzymes *Hin*d Ⅲ, *Kpn* Ⅰ, *Nhe* Ⅰ, *Eco*R Ⅰ and *Dpn* Ⅰ, T4 DNA ligase, pfu DNA polymerase, DNA marker DL2000 and PCR reagents were obtained from Takara (Otsu, Shiga, Japan). Primers were chemically synthesized by Shanghai Generay Co. Ltd. (Shanghai, China). The plasmid DNA extraction (Mini) kit was provided by Qiagen (Crawley, West Sussex, UK). TRIzol and Lipofectamine 2000™ transfection reagent were obtained from Invitrogen.

Female athymic Balb/c (nu/nu) nude mice were purchased from Shanghai SLAC Laboratory Animal Co. Ltd. (Shanghai, China) and were housed under aseptic conditions in micro-isolator cages, which were approved by the local Institutional Animal Care and Use Committee.

The plasmid pcDNA3.1/bCDwt that contained whole-length wild-type bCD gene, and pcDNA3.1/bCD-D314A that contained the mutant *D314A* gene, were prepared and stored in our department. The pLJM1-GFP lentivirus vector with green fluorescence protein (GFP) gene was a generous gift from Prof. J Li (Nanjing Medical University).

Recombinant bCDwt or bCD-D314A plasmids construction and identification

The pcDNA3.1-bCDwt and pcDNA3.1-bCD-D314A plasmids were all double digested with *Hin*dⅢ and *Kpn* Ⅰ. The products of enzyme digestion were connected to the lentiviral vector pLJM1-GFP, which was double digested with *Nhe* Ⅰ and *Eco*R Ⅰ, to produce pLJM1-bCDwt-GFP and pLJM1-bCD-D314A-GFP. These plasmids were then transformed into *E. coli* XL1-Blue. The colonies were selected for PCR identification. The sense sequence of bCD primers was 5'-CGCAAATGGGCGGTAGGCGTG-3', whereas the antisense sequence was 5'AATTCTCAAC-GTTTGTAATCGATGG-3'. These recombinant plasmids were extracted and sent to BGI Sequencing Company (Shanghai, China) for sequencing.

Recombinant lentivirus construction, cell infection and stable cell line generation

To produce recombinant lentiviruses that encoded bCD-wt, bCD-D314A or GFP gene, three types of plasmids (pLJM1-bCDwt-GFP, pLJM1-bCD-D314A-GFP and pLJM1-GFP) were transfected to 293T cells according to the instructions for Lipofectamine 2000™ (Invitrogen). The virus-containing supernatant was collected 48 h after transfection, concentrated by centrifugation (4000 r/mim, 4℃ for 5 min), and filtered with a 0.45-μm membrane filter. The virus titers were determined in 293T cells.

For LoVo cell infection, there were three groups: bCDwt-GFP, bCD-D314A-GFP, and GFP (null). LoVo cells were seeded at a density of 1×10^5 cells in a 60-mm plate and infected with different lentiviral vectors in the presence of 10 μg/mL polybrene (Millipore, Billerica,

MA, USA). At 10-12 h post-infection, the growth medium was replaced. Forty-eight hours later, the GFP expression of transduced cells was observed under fluorescence microscopy. LoVo cells were infected twice in the same way. At 3 d after transfection, the FACSCalibur flow cytometer (BD, Franklin Lakes, NJ, USA) was used for fluorescence-activated cell sorting and then stable transfected cells, LoVo/null, LoVo/bCDwt and LoVo/bCD-D314A were cultured in a 5% CO₂-humidified incubator at 37℃.

Detection of bCD gene in transfected LoVo cells with RT-PCR

Total RNA was extracted from transfected LoVo cells harvested from the different groups with TRIzol reagent. First-strand cDNA was synthesized by reverse transcription according to the instructions for M2MLV (Promega, Madison, WI, USA). The sense sequence of bCD primers used in RT-PCR was 5'TTATGTCGAATAACGCTT-TACAAAC-3', whereas the antisense sequence was 5'TACCTCCACGTTTGTAATCGATGGC-3'. PCR was performed for 35 cycles (94℃ for 1 min, 60℃ for 1.5 min, 72℃ for 1.5 min) in an automated DNA Thermal Cycler (Perkin-Elmer Cetus, Norwalk, CT, USA).

Xenograft tumor model study

To compare antitumor effects of bCDwt- and bCD-D314A-mediated molecular chemotherapy *in vivo*, combination of 5-FC, pools of LoVo, LoVo/null, LoVo/bCDwt or LoVo/bCD-D314A cells [5×10^6 cells in 100 μL PBS (pH 7.3)] were injected subcutaneously (s.c.) into the right flanks of 5-6-wk-old female Balb/c nude mice ($n = 20$, respectively). Two weeks post-LoVo cell inoculation, PBS or 5-FC (500 mg/kg) was administered by i.p. injection once daily for 14 d. Starting at day 1, the tumor volume was monitored daily using caliper measurement, calculated using the formula: $\pi/6 \times$ (width $\times$ length^2). On the day after LoVo cell injection, mice were monitored daily for survival.

Statistical analysis

The treatment groups were compared with respect to tumor size. To test for significant differences in tumor volume among treatment groups, one-way ANOVA was conducted. When ANOVA indicated that a significant difference existed ($P < 0.05$), multiple comparison procedures were used to determine where the differences lay. Kaplan-Meier survival curves were analyzed by the log-rank test, and specific pairwise multiple comparisons were made using the Holm-Sidak method. All comparisons were made using the 0.05 level of significance.

RESULTS

Identification of recombinant lentiviral plasmids

Sequencing results of recombinant lentiviral plasmids showed that pLJM1-bCDwt-GFP contained the wild-type bCD gene, and pLJM1-bCD-D314A-GFP contained the mutant D314A (Figure 1), which indicated that the two recombinant lentiviral plasmids were constructed successfully.

Figure 1 Sequencing results of recombinant plasmid pLJM1-bCDwt and pLJM1-bCD-D314A. The codon 985 of bCDwt, A, was mutated to C in bCD-D314A, which was the mutant D314A of bCD.

Figure 2 LoVo cell with fluorescence after transfection with lentiviral vector containing bCDwt-GFP gene (× 100). A: Green fluorescence field; B: Visible light field.

Efficacy of gene delivery by lentiviral vectors

Lentiviral vectors have improved efficiency to deliver genes. In this study, GFP was used as a reporter gene. Figure 2 shows that the efficacy of gene delivery by lentiviral vectors was satisfactory.

Identification of bCD gene in LoVo cells transfected with lentiviral vectors

LoVo cells transfected with different lentiviral vectors, LoVo/null, LoVo/bCDwt and LoVo/bCD-D314A, were subjected to RT-PCR to identify bCD gene expression. As shown in Figure 3, LoVo/bCDwt and LoVo/bCD-D314A cells had bCD gene expression, while bCD gene was not detected in LoVo/null cells.

Figure 3 Identification of bCD gene in LoVo cells transfected with different lentiviral vectors. M: Marker; 1: Positive control (pcDNA3.1/bCDwt); 2: LoVo/bCDwt; 3: LoVo bCD-D314A; 4: LoVo/null; 5: Negative control (LoVo).

Antitumor effects of bCDwt and bCD-D314A in combination with 5-FC in human colon carcinoma xenograft model

To evaluate the potential of bCD-D314A gene therapy with 5-FC *in vivo*, LoVo cells with different stably gene delivery were injected s.c. into the right flank of athymic nude mice. Two weeks after cell inoculation, before treatment, the tumors in each group were palpable and the mean volumes in each group did not differ significantly among the treatment groups ($P > 0.05$), and within treatment variances (PBS *vs* 5-FC) were not significantly different ($P > 0.05$). The baseline mean tumor volume at 14 d after tumor cell injection was 412.63 ± 36.79 mm^3.

PBS or 5-FC (500 mg/kg) was administered i.p. once daily for 2 wk. Starting at day 1, mice were monitored for tumor volume and survival. Inhibition of tumor growth was initially noted in mice treated with LoVo/bCDwt or LoVo/bCD-D314A in combination with 5-FC compared with the other groups on day 20 ($P < 0.05$) (Figure 4). There were no significant differences in tumor growth between the other groups ($P > 0.05$), which indicated that gene delivery or 5-FC administration alone had no influence on tumor growth. From day 20 onwards, tumors in the mice treated with LoVo/bCD-D314A and 5-FC shrunk daily, whereas the tumors in mice treated with LoVo/bCDwt and 5-FC increased gradually. The difference in tumor volume between these two groups became increasingly marked ($P < 0.05$). At the same time, the tumors in the other groups kept growing (Figure 4).

As to the influence of bCD-D314A and bCDwt on survival, we showed that bCD-D314A/5-FC or bCDwt/5-FC treatment significantly prolonged survival of mice in comparison with the other groups. As shown in Figure 5, the median survival time of other groups was about 35 d and there was no difference among them ($P > 0.05$), whereas it was prolonged to 62 or 94 d in the bCDwt/5-FC or bCD-D314A/5-FC group, respectively ($P < 0.05$). Furthermore, bCD-D314A plus 5-FC significantly prolonged survival of mice in comparison with bCDwt plus 5-FC ($P < 0.05$).

DISCUSSION

Worldwide, more than one million individuals will develop colorectal cancer annually, and the disease-specific mortal-

Figure 4 Growth of LoVo, LoVo/null, LoVo/bCDwt, and LoVo/bCD-D314A xenografts treated with PBS or 5-fluorocytosine. Treatment was started on 14 d after tumor cell inoculation. PBS or 5-fluorocytosine (5-FC) (500 mg/kg) was injected intraperitoneal once a day for 14 d. Data points represent the mean tumor volume of each group of animals. bCD: Bacterial cytosine deaminase; bCDwt: Wild-type bCD; bCD-D314A: bCD mutant D314A; LoVo/null: LoVo cell transfected with pLJM1-GFP; LoVo/bCDwt: LoVo cell transfected with pLJM1-bCDwt-GFP; LoVo/bCD-D314A: LoVo cell transfected with pLJM1-bCD-D314A-GFP.

ity rate is nearly 33% in the developed world[1]. Substantial progress has been made in understanding the molecular pathogenesis, diagnosis (hereditary and sporadic), and treatment of colorectal cancer during recent decades. Despite the use of 5-FU-based combination chemotherapy and active targeted drugs for treatment of metastatic colorectal cancer in the past decade, and improvement in overall survival for non-resectable disease, cure rates remain low[25]. There is a need for the development of new alternative therapeutic strategies. Gene therapy is a novel approach that might lead to improved treatments for colorectal cancer. Among these approaches, GDEPT using the bCD/5-FC system has been developed. The gene that encodes the CD that converts the prodrug 5-FC to 5-FU is delivered to the target tumor cells, which results in their death.

The most important characteristic of suicide gene therapy is its bystander effect. Although the viral or non-viral gene delivery systems currently available have poor efficacy for *in vivo* gene transfer, complete eradication of tumors has been seen in some experimental animal models, which is thought to depend on the bystander killing effect. In the bCD/5-FC system, the bystander effect is caused by the passive diffusion of 5-FU into the extracellular milieu and its diffusion into the adjacent cells, which requires no gap junctions[11]. The immune-related response also contributes to the bystander effect[26], which has been confirmed by our experimental results from the immunocompetent and immunodeficient mice[27]. Although this approach has been in development for several decades, new combinations with cancer therapies, such as selective conventional chemotherapy[28] and radiotherapy[29], are being tested.

Unlike conventional chemotherapy, suicide gene therapy renders specific killing of the tumor cells that express the suicide gene, but it may lead to systemic toxicity if these genes are delivered to normal cells. Thus, target specificity is of great importance to suicide gene therapy. The rationale

Figure 5 Efficacy of wild-type bCD gene or bCD mutant D314A gene suicide gene therapy in human colon carcinoma xenografts. LoVo human colon carcinoma cells with different gene transfection (5×10^6 cells/mouse) were injected into the right flank of athymic nude mice (10 mice/group). Two weeks after tumor cell injection, PBS or 5-fluorocytosine (5-FC) (500 mg/kg) was injected intraperitoneal once a day for 14 d. On the day after LoVo cell injection, mice were monitored daily for survival. bCD: Bacterial cytosine deaminase; bCDwt: wild-type bCD; bCD-D314A: bCD mutant D314A; LoVo/null: LoVo cell transfected with pLJM1-GFP; LoVo/bCDwt: LoVo cell transfected with pLJM1-bCDwt-GFP; LoVo/bCD-D314A: LoVo cell transfected with pLJM1-bCD-D314A-GFP.

behind suicide gene therapy is that, after targeted transfer of these genes into tumor cells, only tumor and neighboring cells will be rendered sensitive to their cytotoxic action. Specifically, targeted expression of the prodrug-activating enzyme avoids systemic toxicity, and results in high drug concentrations in the tumor mass and an improved therapeutic index compared with non-targeted gene delivery. To kill carcinoembryonic antigen (CEA)-positive colorectal carcinoma cells specifically using the bCD/5-FC system, we have constructed a new replication-deficient recombinant adenoviral vector that contains the bCD gene controlled by the CEA promoter, AdCEACD, and have evaluated its *in vitro* cytotoxic effects. We have shown that this vector can transfer bCD to CEA-positive tumor cells specifically by comparing the vector with cytomegalovirus (CMV) promoter, AdCMVCD[7]. However, the cytotoxic effects of bCD/5-FC decreased to some extent[22,23]. Although this loss of activity may be due to differences in transcriptional activation between the CEA and CMV promoters, the low affinity displayed by wild-type bCD towards 5-FC in comparison with cytosine is thought to be the principal factor that leads to the relatively poor turnover of 5-FC of wild-type bCD and limits the overall therapeutic response.

It has been shown previously that the bCD mutant, D314A, decreased efficiency for endogenous cytosine, which can compete with the prodrug for the active enzyme site, in combination with increased efficiency for 5-FC that resulted in a 19-fold relative substrate preference for 5-FC in comparison with bCDwt[16,19]. The bCD mutant D314A has been demonstrated to be an excellent candidate for

subsequent preclinical comparisons with wild-type bCD and yCD.

Recently, we have constructed the bCD mutant D314A using site-directed mutagenesis. The *in vitro* results have indicated that its killing and bystander effects on human colon cancer LoVo cells are enhanced significantly as compared with wild-type bCD[24]. Thus, the rationale for using the mutant bCD gene for colon carcinoma *in vivo* is that the bCD mutant D314A can more effectively convert 5-FC to 5-FU, and increase the antitumor activity and prolong survival.

In the present study, we investigated mutant bCD gene transfer with lentiviral vector for treatment of human colon cancer in xenograft models. Lentivirus-based vectors (lentivectors) have been developed with improved efficiency, specificity, and safety, and are being increasingly used in basic and applied research. Clinical trials of human gene therapy are currently underway using lentivectors in a wide range of human diseases[30]. In the present study, lentiviral vector was used to transfer suicide genes. These preliminary results confirmed the efficacy of lentiviral vector for suicide gene delivery.

After the LoVo cells stably transfected with bCDwt gene or mutant bCD-D314A gene were established, they were inoculated into athymic nude mice to produce xenograft tumor models. Afterwards, 5-FC was administered. As expected, a more potent cytotoxicity effect for colon cancer was obtained using bCD-D314A/5-FC treatment in comparison with bCDwt/5-FC. During 5-FC administration, the tumors treated with bCDwt/5-FC or bCD-D314A/5-FC grew slower than those in other treatment groups, which indicated that 5-FC or suicide gene transfer alone had no effect on colon cancer. The comparative study of bCD-D314A/5-FC and bCDwt/5-FC showed an increased antitumor effect, and decreased tumor growth was observed following bCD-D314A/5-FC gene therapy. Furthermore, survival analysis showed that bCD-D314A/5-FC therapy prolonged life significantly, which confirmed the enhanced antitumor activity of bCD mutant D314A.

Although the intratumoral or blood 5-FU concentration was not estimated after 5-FC administration in this study, the enhanced antitumor effect of bCD mutant D314A in combination with 5-FC was thought to be due to its ability to convert 5-FC to 5-FU more effectively, which is consistent with recently published data in other tumor models[20,21]. The blood and tumor levels of 5-FC and 5-FU are a subject for future studies that will enable a rational dosing strategy.

In summary, our studies provide preliminary evidence that treatment using bCD mutant D314A for suicide gene/5-FC prodrug therapy is a promising approach for treatment of human colon carcinoma. Further studies on delivery systems, doses and protocols would be worthwhile to optimize this approach.

ACKNOWLEDGMENTS

COMMENTS

Background
Suicide gene therapy is an appealing alternative to conventional therapies for colorectal cancer. Bacterial cytosine deaminase (bCD) can convert the non-toxic prodrug 5-fluorocytosine (5-FC) to its toxic form, 5-fluorouracil (5-FU). However, 5-FC is a poor substrate for bCD compared with its native substrate, cytosine, and its antitumor effect is limited.

Research frontiers
The bCD mutant, D314A, has been shown to prefer 5-FC over cytosine by nearly 20-fold, and has been demonstrated to enhance therapeutic efficacy against human glioma and human pancreatic tumors. However, there have been only a few studies of bCD mutants in colorectal cancer.

Innovations and breakthroughs
Recently, the authors have constructed the bCD mutant, D314A, using site-directed mutagenesis, and have demonstrated that D314A has significantly increased cytotoxicity on human colon cancer cell line LoVo compared with wild-type bCD (bCDwt). The present study indicated that mutant D314A was able to significantly enhance antitumor efficacy in human colon cancer xenograft models compared with bCDwt.

Applications
Collectively, these studies provide preliminary evidence that treatment using bCD mutant D314A for suicide gene/5-FC prodrug therapy provides a promising approach for human colon carcinoma.

Terminology
Suicide gene therapy is a form of gene-directed enzyme-prodrug therapy. When the suicide gene is delivered to cancer cells and a non-toxic prodrug is administered, the enzyme converts the non-toxic prodrug into its active and lethal form, which results in cancer cell death.

Peer review
The authors investigated whether bCD mutant D314A suicide gene and 5-FC prodrug therapy increased therapeutic efficacy in a nude mouse model of human colon cancer, using lentiviral vectors. It revealed for the first time that D314A significantly enhanced antitumor activity in human colon cancer xenograft models. The results are useful and may provide a new strategy to treat colorectal cancer.

Abstract

AIM: To identify cancer stem cells (CSCs) in human gallbladder carcinomas (GBCs).

METHODS: Primary GBC cells were cultured under serum-free conditions to produce floating spheres. The stem-cell properties of the sphere-forming cells, including self-renewal, differentiation potential, chemoresistance and tumorigenicity, were determined *in vitro* or *in vivo*. Cell surface expression of CD133 was investigated in primary tumors and in spheroid cells using flow cytometry. The sphere-colony-formation ability and tumorigenicity of CD133+ cells were assayed.

RESULTS: *In vitro* culture experiments revealed that floating spheroids were generated from primary GBC cells, and these sphere-forming cells could generate new progeny spheroids in serum-free media. Spheroid cells were differentiated under serum-containing conditions with downregulation of the stem cell markers Oct-4, Nanog, and nestin ($P < 0.05$). The differentiated cells showed lower spheroid-colony-formation ability than the original spheroid cells ($P < 0.05$). Spheroid cells were more resistant to chemotherapeutic reagents than the congenetic adherent cells ($P < 0.05$). Flow cytometry showed enriched CD133+ population in sphere-forming cells ($P < 0.05$). CD133+ cells possessed high colony-formation ability than the CD133- population ($P < 0.01$). CD133+ cells injected into nude mice revealed higher tumorigenicity than their antigen-negative counterparts ($P < 0.05$).

CONCLUSION: CD133 may be a cell surface marker for CSCs in GBC.

INTRODUCTION

Gallbladder carcinoma (GBC) is the most common

malignant neoplasm of the biliary tract and the seventh most common gastrointestinal cancer[1]. Its clinical presentation is nonspecific and may include abdominal pain, weight loss, fever, and jaundice. Current evidence suggests that radical surgery is the only curative treatment for GBC. However, despite development in surgery, the 5-year survival rate in patients with advanced stage GBC is still only around 10%[2,3]. Pooling of carcinogens under conditions causing biliary stasis, or malignant degeneration of metaplastic changes after chronic inflammation have been suggested as possible factors, but the precise pathogenetic mechanisms of GBC remain unclear[1]. The biology of GBC therefore needs further investigation.

Emerging evidence has shown that the abilities for tumor growth and propagation reside in a small population of tumor cells, termed cancer stem cells (CSCs) or tumor-initiating cells. These cells possess properties of self-renewal, differentiation potential, resistance to chemotherapy, and high tumorigenicity[4-8]. Based on this hypothesis, CSCs were initially isolated from human acute myeloid leukemia[9]. Regarding solid tumors, the existence of CSCs in breast cancer was reported in 2003, when as few as 200 CD44[+]CD24[-/low] ESA[+] breast cancer cells were shown to be adequate to produce new tumors in nonobese diabetic/severe combined immunodeficient mice, whereas a significantly higher number of other cell populations failed to form tumor xenografts[10]. Tumor-initiating cells with distinct cell surface markers have recently been identified in various solid tumors, such as brain[11], prostate[12], pancreatic[13], and ovarian cancer[14], and in Ewing's sarcoma[15]. It is generally considered that the identification of the CSCs could have a significant impact on the understanding of tumor biology and therapy.

Several different methods have previously been used to identify CSCs[16,17], including the culture of cancer cells under non-adherent conditions in serum-free media containing epidermal growth factor (EGF) and basic fibroblast growth factor (bFGF). The growth of spherical colonies is considered to reflect the self-renewal ability and phenotype of CSCs. In the present study, we cultured primary GBC cells to generate spherical colonies and estimated their differentiation potential in the serum medium. We compared the chemoresistance of spheroid cells and differentiated cells *in vitro*. We also examined the expression of the CSC surface marker CD133, and investigated its use as a candidate marker to further identify the CSC phenotype in GBC, including comparing the *in vitro* spheroid-colony-formation and *in vivo* tumorigenicity of CD133[+] and CD133[-] cells. The results of this study may clarify the phenotype of CSCs in GBC, thus contributing to the development of more effective therapeutic approaches.

MATERIALS AND METHODS

Preparation of single cancer cells

Two samples of human GBC were obtained after surgical excision in accordance with Institutional Review Board-approved guidelines. Tumor tissue specimens were dissociated using scissors and scalpels, mixed with collagenase IV (Invitrogen, USA) in medium199 (collagenase 200 U/mL, Invitrogen), and incubated at 37℃ for 2.5-3 h. At the end of the incubation, cells were filtered through a 40-μm nylon mesh and washed twice with phosphate-buffered saline (PBS)/10% fetal bovine serum (FBS, Gibco, USA).

Tumor cell cultures

The single tumor cells were suspended in serum-free DMEM/F12 (1:1 volume, Gibco) consisting of 20 ng/mL human recombinant EGF (PeproTech, USA), 20 ng/mL bFGF (PeproTech), 5 μg/mL insulin (Sigma, USA), and cultured in 24-well culture plates at a density of 1×10^4/well. Fresh serum-free DMEM/F12 (described above) was added into the wells at 0.05 mL/well every day. Spheroids were collected and dissociated 2 wk after primary culture. The resulting single cells were placed into stem cell culture medium to generate progeny spheres. Images of the spheroid colonies were recorded using an inverted microscope (Nikon, Type 108) equipped with a Nikon 2000-S Inverted Photomicroscope and Nikon NIS-Elements F2.30 software.

Differentiation assay

To assess their differentiation potential, spheres were collected and placed into DMEM/F12 supplemented with 10% FBS without growth factors, as described previously, and cell morphology was observed. After 14 d of culture in differentiating medium, tumor cells were collected and suspended in serum-free DMEM/F12 (described above), and cultured in 96-well culture plates at a density of 10 cells per well. Fresh serum-free DMEM/F12 was added into the wells at 0.025 mL per well every day. After 2 wk, each well was examined under light microscope and the total number of spheroid colonies in the 96-well plates was counted.

Real-time quantitative reverse transcription-polymerase chain reaction

Total RNA was extracted from spheroid cells or adherent cells using RNeasy Mini kit (Qiagen), and was reverse transcribed into cDNA using M-MLV reverse transcriptase enzyme (Sigma). Real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR) was performed using an ABI PRISM 7900HT sequence detection system (Applied Biosystems), according to the manufacturer's instructions. The relative mRNA expression levels of the tested genes were normalized to the level of endogenous control gene, glyceraldehyde-3-phosphate dehydrogenase.

Chemoresistance experiments

Cells were seeded in 96-well plates at 3000 cells per well. Each well was supplied with DMEM medium containing 10% FBS, together with either gemcitabine (1 μg/mL, Sigma) or 5-fluorouracil (0.1 μg/mL, Sigma), or no drug as control. The culture medium was changed 3 d after

Figure 1 Culture of floating spheres. Single primary gallbladder carcinoma cells were cultured in serum-free medium containing human epidermal growth factor (20 ng/mL) and basic fibroblast growth factor (10 ng/mL). A: After culture for 1 wk, non-adherent spheres were observable (original magnification × 200); B: The spheres were dissociated and were plated into the same stem-cell-selective medium; similar progeny spheres emerged after 2 wk (original magnification × 200); C: The second progeny spheres were derived from the first progeny sphere-forming cells (original magnification × 200).

initial treatment and the number of viable cells was determined using the 3-(4,5-dimethylthiazol-2)-2,5-diphenyltetrazolium bromide (MTT) method. Briefly, 20 μL of MTT (5 mg/mL in PBS, Sigma) was added to the medium for 4 h. Medium and MTT were removed, dimethylsulfoxide (Sigma) was added, and the absorbance was measured at 490 nm using a plate reader Multiskan EX (Thermo Fisher Scientific Inc., Waltham, MA).

Detection of CD133 expression using flow cytometry

Cells derived from primary tumors or spheres were separately resuspended in PBS with 2% FBS at a concentration of 10^6/100 μL. Anti-CD133/1-phycoerythrin (eBioscience, USA) was added to the samples, and incubated on ice for 30 min. After incubation, the samples were washed twice with 2% FBS/PBS and resuspended in 2% FBS/PBS. Flow cytometric analysis was performed using a FACSAria (BD Immunocytometry Systems, Franklin Lakes, NJ, USA).

Spheroid-colony-formation assay of CD133+ GBC cells

CD133+ and CD133- populations were sorted from sphere-forming cells using fluorescence-activated cell sorting (FACS). For FACS, cells were collected and stained, and sorted using a FACSAria. The sorted tumor cells were suspended in serum-free DMEM/F12, and cultured in 96-well culture plates at a density of 10/well. After 2 wk, the total number of spheroid colonies in the 96-well plate was counted, as described above.

Tumorigenicity of CD133+ GBC cells in vivo

Female nude mice (BALB/C), 4-6 wk old, were purchased from Hunan Slack King of Laboratory Animal Co., Ltd. (Changsha, China). CD133+ and CD133- populations were sorted from two primary tumors (tumor 3 and tumor 4), and from sphere-forming cells using FACS. Cells were routinely sorted twice, and reanalyzed for a purity, which was typically > 90%. Sorted cells were resuspended in PBS/Matrigel mixture (1:1 volume). The mice were anesthetized using ethyl ether and 10 000 tumor cells were

injected subcutaneously into the abdominal region, using a gauge needle. The mice were maintained under standard conditions according to the institutional guidelines for animal care. Tumor appearance was inspected weekly by visual observation and palpation. Animal experiments were terminated 3 mo after cell injection.

Hematoxylin and eosin staining and immunohistochemistry

Primary tumor tissues and mouse xenografts were fixed in 10% formalin and embedded in paraffin. Sections were cut and stained with hematoxylin and eosin (HE) to assess tumor type. The sections were incubated with anti-human CA19-9 antibody (Abcam, UK) and secondary antibodies using an ImmunoPure ABC Staining kit (Santa Cruz, USA), according to standard immunohistochemical procedures. Negative controls containing no primary antibody were prepared. All microscopic images were captured as above.

Statistical analysis

Data were expressed as mean ± SD and Student's *t* test was used to compare the differences between groups. Values of $P < 0.05$ were considered significant.

RESULTS

Spheroid formation

Previous studies indicated that CSCs could produce floating three-dimensional tumor spheroids under stem-cell-selective conditions[18-21]. Based on these studies, we cultured primary human GBC cells in serum-free DMEM/F12 in an attempt to expand human GBC CSCs. Non-adherent spheres derived from human GBCs were observable after *in vitro* culture for 1 wk (Figure 1A), and these continued to expand for 2-3 wk in serum-free media. The spheres were dissociated and the resulting single cells were plated in the same stem-cell-selective medium; similar progeny spheres emerged after 2 wk (Figure 1B and C). This demonstrated that tumor sphere cells had self-renewing characteristics.

A

B

C

Figure 2 Differentiation of spheroid cells. Non-adherent spheres were collected and placed into DMEM/F12 supplemented with 10% fetal bovine serum. A: After 6 h, cells migrated from the spheres and became adherent and the sphere volume was significantly reduced (original magnification × 200); B: The spheroid-colony-forming ability of spheroid cells decreased under differentiating conditions. [a]$P < 0.05$ *vs* spheroid cells under stem-cell-selective conditions; C: The expression levels of Oct-4, Nanog and nestin were examined using real-time quantitative reverse transcription-polymerase chain reaction. The stem cell markers were downregulated in the adherent cells. [a]$P < 0.05$ *vs* spheroid cells under stem-cell-selective conditions.

Sphere-forming cells displayed differentiation potential

Spheres were cultivated under differentiating conditions to determine the differentiation potential of the tumor sphere cells. After 6 h of culture, the floating tumor spheres attached to the bottom of the culture plates and cells migrated from the spheres and became adherent (Figure 2A). After 14 d of culture in differentiating conditions, the sphere-formation ability of the adherent cells was assayed. The spheroid-colony-forming ability decreased, compared with that of the original sphere-forming cells ($P < 0.05$, Figure 2B). The expression of stem cell markers, including Oct-4, Nanog and nestin, were examined using real-time RT-PCR. These markers indicate an undifferentiated stem cell phenotype[22,23]. Spheroid cells showed higher expression of these markers than adherent cells ($P < 0.05$, Figure 2C), strongly supporting the idea that spheroid cells were differentiated in serum-containing medium.

Sphere-forming cells displayed high chemoresistance in vitro

Previous studies suggested that CSCs in several solid tumors possessed higher chemoresistance than non-CSCs[24-26]. To examine if our spheroid cells also possessed a CSC chemoresistant phenotype, the chemosensitivities of these cells were assessed under stem-cell-selective *vs* differentiating conditions. Spheroid cells under stem-cell-selective conditions displayed a greater resistance to gem-

Figure 3 Chemoresistance assays of spheroid cells. Sphere-forming cells and differentiated cells were seeded in 96-well plates at 3000 cells/well. Chemotherapeutic reagents gemcitabine (1 μg/mL) and 5-fluorouracil (0.1 μg/mL) were added and cell survival was estimated by 3-(4,5-dimethylthiazol-2)-2,5-diphenyltetrazolium bromide assay. [a]$P < 0.05$ *vs* differentiated cells.

citabine and 5-fluorouracil than those under differentiating conditions ($P < 0.05$, Figure 3).

CD133[+] cells were enriched in tumor spheres

The expression pattern of a possible candidate cell surface marker for CSCs was examined in primary human GBC and in sphere-forming cells, using flow cytometry. CD133 was selected as a potential marker, based on the results of previous studies of CSCs in solid tumors. Flow cytometric analysis revealed that CD133[+] cells were pres-

Figure 4 CD133 expression in gallbladder carcinoma spheroid cells. The single cells dissociated from primary tumors or spheres were incubated with anti-CD133/1-phycoerythrin and flow cytometric analysis was performed. The percentage of CD133[+] cells was higher in the spheroid cells. *P* < 0.05 *vs* primary gallbladder carcinoma cells.

Figure 5 Spheroid-colony-formation assay of CD133[+] cells. Sphere-forming cells were isolated by fluorescence-activated cell sorting for marker CD133 and cultured in 96-well plates in serum-free medium (10 cells per well) containing human epidermal growth factor (20 ng/mL) and basic fibroblast growth factor (10 ng/mL). After 2 wk, the total number of spheroid colonies containing more than 20 cells was counted. CD133[+] cells generated more spheroid colonies. [b]*P* < 0.01.

Table 1 Tumorigenicity of CD133[+] and CD133[-] cells sorted from primary gallbladder carcinomas or spheroids				
Cell type	Fraction	1st mo	2nd mo	3rd mo[a]
Spheroid cells	CD133[+]	1/6	3/6	6/6
	CD133[-]	0/6	0/6	1/6
Tumor 3	CD133[+]	0/3	1/3	3/3
	CD133[-]	0/3	0/3	1/3
Tumor 4	CD133[+]	1/3	2/3	3/3
	CD133[-]	0/3	0/3	0/3

Freshly-sorted cells were injected subcutaneously into the abdominal regions of nude mice at a dose of 10 000 cells. [a]*P* < 0.05.

ent at relatively low percentages in samples from both primary tumors (3.79% in tumor 1 and 3.15% in tumor 2). The CD133[+] populations, however, were significantly increased to 18.65% (tumor 1) and 21.54% (tumor 2) in the tumor spheres (*P* < 0.05, Figure 4). These results suggest that CD133 could be a candidate cellular surface marker for GBC progenitors.
CD133[+] GBC cells showed higher spheroid-colony-forming ability in vitro

The growth of spherical colonies is considered to reflect the self-renewal ability and phenotype of CSCs[16]. CD133[+] cells were isolated from spheres and placed into stem-cell-selective conditions. After *in vitro* culture for 2 wk, the total number of spheroid colonies containing more than 20 cells was counted, and CD133[+] cells generated more spheroid colonies than the CD133[-] fractions (*P* < 0.01, Figure 5). These results suggest that the CD133[+] subset plays a dominant role in the spheroids.

CD133[+] GBC cells showed higher tumorigenicity in vivo

To authenticate the *in vitro* findings, sorted GBC cells were transplanted into nude mice. An apparent difference in tumorigenicity was observed between the cell populations (*P* < 0.05, Table 1, Figure 6A). It was found that 10[4] CD133[+] GBC cells were able to generate tumors in six

out of six or three out of three nude mice after 9-12 wk, while the same number of CD133[-] cells induced tumors in only one out of six or one out of three nude mice, with smaller mass and longer latency. HE staining and immunohistochemistry demonstrated that the xenografts in the immunodeficient mice were generated from the injected human GBC cells. The xenograft tumors revealed similar histologic characteristics and expression of CA19-9 to those of the primary GBC (Figure 6B). Taken together, these results indicate that CD133[+] GBC cells exhibited cancer stem-cell-like characteristics, strongly supporting the existence of tumor-initiating cells in this population.

DISCUSSION

A number of studies have demonstrated the presence of CSCs in solid tumors. These cells possess the abilities of self-renewal and differentiation, high tumorigenicity, and resistance to current treatments[10-15]. In this study, we described the characterization of CSCs in human GBC. Previous studies showed that tumor spheres could be generated from tumor cells in serum-free medium and that the constituent cells exhibited the properties of CSCs, including self-renewal, differentiation potential, chemotherapy resistance, and high tumorigenicity[11,14].

Figure 6 Xenograft formation of CD133[+] gallbladder carcinoma cells. Sorted cells were injected subcutaneously into the abdominal regions of nude mice at a dose of 10 000 cells. A: CD133[+] cells produced palpable xenograft tumors at the injection site, whereas CD133[-] cells generated no tumors; B: Hematoxylin and eosin staining of xenograft and expression of CA19-9 (original magnification × 200).

In our experiments, primary GBC cells formed tumor spheres when cultivated under stem-cell-selective conditions similar to those reported previously. The self-renewal and differentiation potentials, proliferation ability and chemosensitivity of the sphere-forming cells were assessed. These cells displayed CSC properties by regenerating new tumor spheres in serum-free medium, over-expressing stem cell markers and showing a higher resistance to chemotherapeutic reagents, while these features were diminished under differentiating conditions. These results indicate that CSCs were enriched in these floating GBC spheres.

Cell surface markers of CSCs can help distinguish, isolate and purify these tumor-initiating cells for further biological investigation. The protein CD133 is cell surface marker for CSCs in brain tumor[11], Ewing's sarcoma[15] and liver cancers[26]. The development and differentiation of human bile ducts and liver are closely related; both start from hepatic endodermal cells and hepatoblasts just after liver primordium formation. We therefore selected CD133 as a potential CSC marker in the current study, and detected its expression in primary GBC and in sphere-forming cells. CD133[+] cells comprised a small fraction of the total tumor population in all three samples studied, but represented an increased percentage of the sphere-forming cells. This suggests that CD133 could act as a cell surface marker for CSCs in GBC. We also investigated the use of this cell surface protein as a candidate marker to further identify the CSC phenotype in GBC. The self-renewal ability of CD133[+] cells was tested using spheroid-forming assays in serum-free medium. CD133[+] cells possessed higher clonogenicity than their antigen-negative counterparts. Subsequent *in vivo* tumorigenesis experiments demonstrated that CD133[+] cells possessed higher tumorigenicity than the CD133[-] subpopulation. Furthermore, the tumors generated in nude mice displayed the same phenotype as the primary GBC tissue. Taken together, these results firmly suggest that CD133[+] cells possess the potentials for self-renewal and high tumorigenicity, exhibiting cancer stem-cell-like characteristics in human GBC.

The internal relationship between the expression of CD133 and the characteristics of CSCs remains unclear. Previous studies suggested that CD133 expression was associated with cell motility in melanoma[27] and colorectal cancer cells[28], and a high level of CD133 was also associated with increased resistance to staurosporine-inducing apoptosis[28]. These associations may be due to the interaction between CD133 and the canonical Wnt pathway[27]. However, the role of CD133 in these biological activities remains to be further clarified.

In summary, the results of this study demonstrate that CSCs are enriched in non-adherent spheres derived from GBC cells, and that CD133 protein may represent a cell surface marker for this cell population.

COMMENTS

Background
Gallbladder carcinoma (GBC) is the most common malignant neoplasm of the biliary tract and the seventh most common gastrointestinal cancer. Emerging evidence has shown that the abilities for tumor growth and propagation reside in a small population of tumor cells, termed cancer stem cells (CSCs) or tumor-initiating cells.

Research frontiers
Tumor-initiating cells with distinct cell surface markers have recently been identified in various solid tumors. In this study, the authors demonstrate that primary human GBC cells also contain tumor-initiating cells and that CD133 protein may be a cell surface marker for this cell population.

Innovations and breakthroughs
Previous studies have suggested that CD133 expression is associated with cell motility and is a cell surface marker for tumor-initiating cells in some tumors. This is the first study to report upregulation of CD133 in spheroids derived from primary human GBC cells. Furthermore, the *in vitro* and *in vivo* studies suggest that CD133 protein may represent a cell surface marker for CSCs in GBC.

Applications
This study may provide a novel approach to the diagnosis and treatment of GBC.

Peer review
The presented manuscript deals with extremely thrilling issue of cancer development. It should be of great interest for the readers reflecting progress in our comprehension of carcinogenesis.

Abstract

Chronic intestinal pseudo-obstruction (CIPO) is a rare disease due to a severe gastrointestinal motility disorder which may mimic, on both clinical and radiological grounds, mechanical obstruction. We report a case of a 26-year-old woman who presented to our institution for plain abdominal radiography for referred long-lasting constipation with recurrent episodes of abdominal pain and distension. At X-ray, performed both in the upright and supine position, an isolated air-fluid level was depicted in the left flank, together with a number of radiological signs suggestive of pneumoperitoneum. First, subphrenic radiolucency could be observed in the upright film. Second, the intestinal wall of some jejunal loops appeared to be outlined in the right flank. Third, the inferior cardiac border was clearly depicted in the upright film. The patient however had no evidence of peritoneal signs but only hypoactive bowel movements. Unenhanced multi-detector computed tomography (MDCT) of the abdomen and pelvis was therefore performed. MDCT revealed abnormal air-driven distension of the small and large bowel, without evidence of extraluminal air. All radiological signs of pneumoperitoneum turned out to be false-positive results. The patient was submitted to pan-colonoscopy and to anorectal manometry to rule out Hirshprung's disease, and was finally discharged with a diagnosis of CIPO.

Pseudopneumoperitoneum in chronic intestinal pseudo-obstruction: A case report. *World J Gastroenterol* 2011; 17(24): 2972-2975 Available from: URL: http://www.wjgnet.com/1007-9327/full/v17/i24/2972.htm DOI: http://dx.doi.org/10.3748/wjg.v17.i24.2972

INTRODUCTION

Chronic intestinal pseudo-obstruction (CIPO) is a rare motility disorder of the gastrointestinal (GI) tract that is usually observed in a number of different neuropathies, mesenchymopathies or myopathies, but it can also be idiopathic[1]. It is characterized by failure of the GI tract to propel its content and may result in a clinical picture mimicking mechanical obstruction, with patients complaining of recurrent episodes of abdominal distension,

with or without abdominal pain, nausea and vomiting[2].

The diagnosis of CIPO is mainly clinical and is usually postulated after exclusion of any organic lesion occluding the gut lumen at endoscopy, while it can be supported by radiographic documentation of dilated small and/or large bowel loops, without evidence of a definite transition zone. This, in adults, is now best accomplished by multi-detector computed tomography (MDCT), which can obviate the need for unnecessary laparotomy[3]. However, plain abdominal films are one of the most important examinations in the diagnosis of CIPO in which abnormal air-driven distension of both small and large bowel is usually depicted[4].

Here, we report a case of a 26-year-old woman who presented to our institution for plain abdominal radiography as part of clinical and radiological work-up for referred long-lasting constipation with recurrent episodes of abdominal pain and distension. At X-ray, an isolated air-fluid level could be observed in the left flank region, together with a number of radiological signs suggestive of pneumoperitoneum. These could be appreciated both in the upright and supine films, but turned out to be false-positive results, as an unenhanced MDCT scan failed to show evidence of extra-luminal air in the peritoneal cavity.

CASE REPORT

A 26-year-old woman with a history of recurrent episodes of abdominal pain and distension came to our institution to undergo plain abdominal radiography. Abdominal plain films were obtained both in the upright (Figure 1A) and supine (Figure 1B) position. The upright film showed an isolated air-fluid level in the left flank region, consistent with an obstruction of the descending colon, together with a number of X-ray findings suggestive of pneumoperitoneum. First, subphrenic radiolucencies were clearly depicted on both sides in the upright film. Second, the inferior cardiac border could be observed from the cardiac apex to the inferior vena cava. Third, the intestinal wall of some jejunal loops appeared to be outlined in the right flank (Figure 1A). This latter finding was also evident in the supine film, configuring the so-called bas-relief or Rigler's sign together with the lack of normal hepatic shadow in the right subphrenic space, the so-called hyperlucent liver sign (Figure 1B). Based on these X-ray findings, the on-call radiologist immediately contacted the referring physician to communicate a diagnosis of pneumoperitoneum.

At physical examination, however, only a large abdominal distension with hypoactive bowel could be observed, but no peritoneal signs. It was therefore agreed upon to perform MDCT (Aquilion 4; Toshiba, Japan). This was performed with a detector configuration of 4 × 5 mm, table speed 30 mm/s, rotation time = 0.5 s, beam pitch = 0.75, 120 kVp, 250 mA. Only unenhanced acquisition was performed. The MDCT scan showed marked dilation of the large bowel, with both hepatic and splenic

Figure 1 Upright (A) and supine (B) films in a female patient complaining of long-lasting constipation, with recurrent episodes of abdominal pain and distension. A: An isolated air-fluid level is depicted in the left flank, suggesting mechanical obstruction at the level of the descending colon. Subphrenic radiolucency is evident on both sides, together with the outlining of the intestinal wall of some small bowel loops in the right flank (arrowheads) and that of the inferior cardiac border (arrows); B: Outline of the intestinal wall of small bowel loops appears to be depicted in the right flank (arrowheads), configuring the so-called bas-relief or Rigler's sign. In addition, hyperlucency is depicted in the right subphrenic space in place of the normal hepatic shadow, configuring the bright or hyperlucent liver sign (*).

flexures displaced underneath the diaphragm (Figure 2A). Air-driven distension involved both small (Figure 2B) and large bowel (Figure 2C) loops. There was no evidence of any obstructive lesion and both the sigmoid colon and rectum were normally filled with feces (Figure 2D). No evidence of free air in the peritoneal cavity was found, therefore, a diagnosis of pneumoperitoneum could not be confirmed.

Further clinical, biochemical and instrumental investigation involving pan-colonoscopy and anorectal manometry revealed no underlying causes, and the patient was finally discharged with a diagnosis of CIPO.

DISCUSSION

Pneumoperitoneum is usually referred to as the presence of free air within the peritoneal cavity. Its radiological diagnosis usually relies on the evidence of typical subphrenic radiolucency in the posterior-anterior projection taken in the upright position[5]. As a result, the term pseudopneumoperitoneum is used when the subphrenic radiolucency does not correspond to free intraperitoneal air[6], but can be traced to either subphrenic fat pad[7] or basal lung atelectasis[8]. In these cases, the clarifying role of CT has been acknowledged[9].

To the best of our knowledge, whereas the possible occurrence of pneumoperitoneum in CIPO has been described[10], the occurrence of pseudopneumoperitoneum in CIPO has not been reported to date. In our case, subphrenic radiolucency depicted in the upright film (Figure 1A) was due to hepatic and splenic colonic flexures abnormally dilated and displaced below the diaphragmatic shadows, as shown by CT (Figure 2A).

In the emergency setting, prompt recognition of radiological signs of pneumoperitoneum in the anterior-

Figure 2 Unenhanced four-row MDCT. Images are displayed with lung (A-C) and soft tissue (D) windows. A: Hepatic (h) and splenic (s) flexures, air-filled and abnormally dilated, are displaced under the diaphragm, accounting for the subphrenic radiolucency depicted in the upright film; B: Intraluminal air in the large bowel (c) appears to outline the intestinal wall (arrowheads) of a jejunal loop (j) that is also mildly dilated and air-filled, accounting for the Rigler's sign depicted on the upright and supine films; C: Abnormally dilated colonic segment situated between the liver (l) and anterior abdominal wall, simulating the hyperlucent (bright) liver sign depicted in the supine film; st: Stomach; sp: Spleen; D: Rectum is normally filled with feces. u: Uterus.

posterior projection taken in the supine position may be of diagnostic value because it allows a confident diagnosis of pneumoperitoneum whenever an L-L projection is not available or cannot be performed[11].

These radiological signs, which can be mostly traced to either the intestinal wall[12] or various peritoneal folds[13-15], outlined by the presence of free air within the peritoneal cavity, have been recently revised and classified into four major categories as bowel-related signs, right upper quadrant signs, peritoneal ligament signs, and other signs[16].

For at least one of these signs, namely the Rigler's sign, the possible occurrence of false-positive cases is well acknowledged. Rigler's sign can be simulated by two contiguous, moderately dilated and air-filled loops of bowel, whereby intraluminal air in one loop of bowel may appear to outline the wall of the adjacent loop[17]. These false-positives cases, however, have only been reported in the supine film where the sign itself was originally described[12]. To the best of our knowledge, the occurrence of a false-positive Rigler's sign in the upright position has never been described. As shown by MDCT, the intestinal wall of some jejunal loops was in our case outlined by intraluminal air in the large bowel, which was abnormally dilated (Figure 2B). The anomalous dislocation of jejunal loops in the right flank was not further investigated, although it was likely due to concomitant malrotation.

Possible occurrence of false-positive results for the

inferior cardiac border sign were also postulated in the original description. The inferior border of the heart becomes visible on supine radiography whenever it is outlined by air; either free air in the peritoneal cavity, such as in pneumoperitoneum, or air within the pleural and/or pericardial sac. Occasionally, gas-filled loops collected beneath the left hemi-diaphragm may simulate this sign[18]. As with Rigler's sign, these false-positive signs are also expected to occur in the supine position and not in the upright. In our case, however, the sign could not be detected in the supine film because of suboptimal technical positioning (Figure 1B).

Finally, the hyperlucent liver sign which could be observed on the supine film (Figure 1B) also turned out to be a false-positive result because it was clearly due to the interposition of dilated, air-filled large bowel loops between the liver and the anterior abdominal wall, as shown by MDCT (Figure 2C). To the best of our knowledge, false-positive cases of hyperlucent liver sign have never been reported.

In the present case, MDCT not only ruled out the radiological diagnosis of pneumoperitoneum but it also excluded mechanical obstruction, and showed that the sigmoid colon and rectum were normally filled with feces, without evidence of a transition zone (Figure 2D). As this latter CT finding is rather atypical in patients with Hirschsprung's disease[19], this was also excluded by anorectal manometry, which revealed a normal inhibitory

rectoanal reflex[20]. The patient was therefore discharged with a diagnosis of CIPO.
We have described a case of pseudopneumoperitoneum in a patient with CIPO. All radiological findings of pneumoperitoneum that were clearly depicted in the upright and supine films turned out to be false-positive results, as shown by MDCT. To the best of our knowledge, such a case has not been reported to date.

Abstract

Worldwide, the burden of the non viral causes of hepatocellular carcinoma (HCC) is usually underestimated. Clearly industrial goods, tobacco, alcohol and processed foods are the agents of new epidemics in modern times which far outscore the burden of infectious agents on morbidity and mortality. Smoking, a dose-related contributing factor for HCC, receives too little attention in clinical practice. In France, tobacco, hepatitis B and C virus and alcohol are the main risk factors for HCC mortality (33%, 31% and 26%, respectively). In developing countries, where tobacco consumption is dramatically increasing, this epidemic may soon surpass hepatitis B. Obesity and diabetes are the contributing factors too. The role of industrial processed foods in the increase of the prevalence of obesity and diabetes cannot be ignored.

Key words: Hepatocellular carcinoma; Tobacco; Alcohol; Processed foods; Industrial epidemics

Peer reviewer: Dr. Ajith TA, Associate Professor, Department of Biochemistry, Amala Institute of Medical Sciences, Amala Nagar, Thrisssur, Kerala-680 555, Pakistan

TO THE EDITOR

Worldwide, hepatocellular carcinoma (HCC) is the fifth most common cancer and the third most common cause of cancer-related death. The Journal must be acknowledged for the publication of Blonski *et al*[1] review who wisely underlined the burden of non viral causes of HCC which are usually underestimated.

Blonski *et al*[1] rightly stressed the role of smoking, a dose related contributing factor for HCC, and this is important because some are still ignoring it[2]. In France, tobacco, hepatitis B and C virus and alcohol are the main risk factors for HCC mortality (33%, 31% and 26%, respectively)[3,4].

Blonski *et al*[1] also listed obesity and diabetes as contributing factors for HCC. The role of industrial processed foods in the increase of the prevalence of obesity and diabetes cannot be ignored.

Clearly industrial goods, tobacco, alcohol and processed foods are the agents of new epidemics in modern times which far outscore the burden of infectious agents on morbidity and mortality.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statisical review is performed after peer review. We invite an expert in Biomedical Statistics from to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission

System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…"; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present P values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be

used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables
Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. [a]$P < 0.05$, [b]$P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, [c]$P < 0.05$ and [d]$P < 0.01$ are used. A third series of P values can be expressed as [e]$P < 0.05$ and [f]$P < 0.01$. Other notes in tables or under illustrations should be expressed as [1]F, [2]F, [3]F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES
Coding system
The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI
Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references
Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated

first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634   DOI: 10.3748/wjg.13.5396].

Style for book references
Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data
Write as mean ± SD or mean ± SE.

Statistical expression
Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as υ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units
Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, ρ (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc*. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations
Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics
Quantities: t time or temperature, c concentration, A area, l length, m mass, V volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS
Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.
